The “Jobless Recovery” From the 2001 Recession: A Comparison to Earlier Recoveries and Possible Explanations

Summary

The Business Cycle Dating Committee determined that the tenth recession in the post-World War II era ended in November 2001 based upon its assessment that most of the relevant economic variables had since shown sustained improvement. Labor market data are the aberration. From November 2001 to July 2003, private nonfarm sector employment has declined by 1.2 million. The labor market was also slow to rebound after the recession of the early 1990s, and the term “jobless recovery” was coined. Since this has occurred twice in a row and is perceived to contrast with the historic pattern following other recessions, there is concern that the two recoveries might indicate a trend rather than an anomaly.

The labor market is indeed rebounding more slowly than usual coming out of the 2001 recession. For example, during just two of the previous nine recoveries, the unemployment rate worsened for more than a year (14 and 16 months). At 20 months through July 2003, the rise in the unemployment rate has persisted for unusually long. The weakness of employment is even more unusual. Employment has declined by 1% since the recession ended, and is still declining 20 months into the recovery. The second largest decline in the post-war period was a 0.6% decline that lasted 11 months into the recovery from the 1990-1991 recession. Typically, employment rebounds within 3 months after a recession has ended.

The most compelling explanation for the jobless recovery is the weakness of aggregate spending during the recovery. Growth at this stage of the recovery typically exceeds 5%; in this recovery it has averaged 2.6%, below the sustainable growth rate. The nation has undergone a number of shocks since 2001 that could have depressed spending, including oil shocks, the stock market crash, the corporate scandals, September 11, and the Iraqi War. Some claim that strong productivity growth is reducing employment; but productivity growth would not depress demand as long as the recipients of the income generated by productivity growth, a firm’s workers or investors, quickly spend it on consumption or capital investment.

It is also possible that the rise in the unemployment rate is caused by a rise in the nation’s long-run “natural rate” of unemployment, determined by the nation’s labor market characteristics and policies. The natural rate of unemployment is unemployment that is unrelated to temporary changes in the business cycle. It is unusual for the natural rate to significantly change in a couple of years. If the natural rate is playing a role today, it is more likely because unemployment was further below the natural rate than previously suspected in the late 1990s, and is now returning to the natural rate.

Looking to the future, there are two possibilities. Either the recovery will strengthen and employment will rebound, or the current weakness in the labor market will lead to a “double dip” recession. Forecasters are predicting that the former scenario will prevail, but slowly. This report will be updated as events warrant.

The “Jobless Recovery” From the 2001 Recession: A Comparison to Earlier Recoveries and Possible Explanations

The Business Cycle Dating Committee of the National Bureau of Economic Research (NBER) determined that the tenth recession in the post-World War II era ended in November 2001, a scant 8 months from its inception in March. The more than 9 million people who remain unemployed and the more than 4 million people who want full-time jobs but remain in part-time positions more than one-and-a-half years since the recession’s end are unlikely to agree with its assessment. Nonetheless, the committee concluded that – aside from data on labor market conditions – the economic variables it takes into account to determine the turning points in the business cycle (e.g., real personal income) have shown sufficient, sustained improvement to declare November 2001 the beginning of a recovery period.¹

After the not-quite-as-brief and not-quite-as-mild recession of the early 1990s, the labor market was similarly slow to rebound. The 1990-1991 recession became widely known as having been followed by a jobless recovery, the same appellation being applied to the current situation.² The fact that this has occurred twice in a row and seemingly contrasts with the historic pattern following other recessions has prompted concern that these two recoveries might be a trend rather than an anomaly. It has also prompted concern that the jobless recovery could presage a coming double-dip recession – another period of economic contraction in the near future.

This report begins by examining the current labor market situation compared to the 2001 peak and trough in the business cycle. It then compares the behavior of selected labor market indicators during the recovery with their behavior during earlier post-World War II recoveries and explores explanations that have been offered for any differences. The report concludes by discussing the near-term prospects for the economy.

¹ Jon E. Hilsenrath, “Despite Job Losses, the Recession Is Finally Declared Officially Over,” The Wall Street Journal, July 18, 2003. Note: The article reports that the anomalous behavior of employment was the major point of contention within the committee on choosing a date.

² Although the 1991 recovery is frequently referred to as the first jobless recovery, there was one earlier recession that followed a similar pattern: after the 1969-1970 recession, unemployment rose for 14 months.
The Current Situation in the Labor Market

One way to assess the labor market’s response to the ongoing economic rebound is to compare the current situation with the trough (November 2001) and the preceding peak (March 2001) in the business cycle. In this manner, we can determine whether the labor market has advanced from the recession’s bottom and to what extent it has recaptured recession-induced losses.

Unemployment

As measured by all the unemployment and employment variables shown in Table 1, workers on average have not yet begun to experience any improvement. There are about 1 million more persons currently unemployed than at the bottom of the business cycle (9.1 million and 8.1 million, respectively). The unemployment rate is higher (6.2% in July 2003) than it was at the end of the recession (5.6%) and is 2 percentage points above its level at the pre-recession peak (4.2%). At 20 months into the current recovery, the unemployment rate is above the level it reached at a comparable point during five of the eight preceding recoveries. (The recovery from the 1980 recession is excluded from the total number of postwar recessions in this instance because another recession began a year after its end.)

The jobless rate fluctuated in a narrow range (5.6%-6.0%) for more than a year after November 2001. Not until some 900,000 people searching for work joined the labor force between the first and second quarters of 2003 did the unemployment rate rise above 6.0%. The growth of the labor force (i.e., the number of people employed and the unemployed) had been so small up until then that it exerted limited upward pressure on the unemployment rate despite substantial job losses. In fact, the rise in the unemployment rate would have been larger if it were not for the decline in the proportion of the population that is in the labor force, a decline that actually began before the recession. Other recessions, in contrast, saw little or no decline in the labor force participation rate.

Another indicator of conditions in the labor market is how quickly people are able to find jobs. At present, according to the data in Table 1, the average time a worker spends unemployed is 19.3 weeks. In contrast, jobseekers were able to become employed 4.8 weeks faster, on average, at the trough of the business cycle. The average duration of unemployment thus has lengthened more during the recovery

---

3 The unemployment rate 20 months into the recovery from the 1990-1991 recession was 7.4%; from the 1981-1982 recession, 7.5%; the 1973-1975 recession, 7.8%; the 1969-1970 recession, 5.6%; the 1960-1961 recession, 5.4%; the 1957-1958 recession, 5.3%; the 1953-1954 recession, 4.0%; and from the 1948-1949 recession, 3.2%.

4 The unemployment rate is defined as the number of people in the civilian noninstitutional population age 16 or older who do not have jobs and who are actively seeking employment, divided by the number of people age 16 or older in the civilian labor force.

(4.8 weeks) than it did during the recession (1.7 weeks). Similarly, the share of unemployed workers who have not held a job in at least 27 weeks (21.7% in July 2003) continues to exceed levels recorded in March 2001 (11.2%) and November 2001 (14.3%).

**Discouraged Workers**

It often has been noted that the unemployment rate does not fully reflect the state of the labor market because it measures only the extent of joblessness among those in the labor force. In light of the marked decrease in the fraction of the population that either has a job or has actively sought a job in the 4 weeks before the monthly administration of the Current Population Survey (CPS), this is a very salient point at the present time: between November 2001 and July 2003, the proportion of the civilian noninstitutional population age 16 or older that was in the labor force (i.e., the labor force participation rate) fell by 0.6 percentage point to 66.2%. As previously mentioned, it was not until people surged into the labor force in second quarter 2003 that the unemployment rate rose above 6.0%.

People who are able and willing to work may not recently have sought a job for a variety of reasons, in which case they would not be officially classified as unemployed. Some may not have searched for reasons unrelated to economic conditions (e.g., child care or transportation problems). For others – who perhaps have themselves experienced a lengthy spell of unemployment or who have repeatedly heard of major corporations announcing layoffs involving thousands of workers – the reason could be discouragement over their employment prospects (e.g., because they think no work is available or because they lack education or training).

Almost 500,000 people currently are not seeking jobs because they believe looking is futile. This marks the second-highest level of worker discouragement for the month of July since the CPS underwent substantial revisions in 1994, the first year for which comparable data are available. There were significantly more discouraged workers in July 2003 (470,000) than in July 2002 (405,000), and in July 2002 than mid-way through the 2001 recession (310,000).

---

8 For information of mass layoff activity see CRS Report RL30799, Corporate Downsizing and Other Mass Layoffs, by Linda Levine.

9 The BLS data (July 2003) refer to individuals who looked for a job during the prior 12 months and were available to take a job during the reference week of the CPS, i.e., those who show some attachment to the labor force.

10 Unlike the other variables included in this report, monthly data on discouraged workers are not adjusted for seasonal factors. Therefore, comparisons across different months are (continued...

Source: U.S. Bureau of Labor Statistics (BLS). All but the last three variables in the table are derived from the Current Population Survey, a survey of households. The last three variables come from BLS’ establishment survey, which queries employers rather than the population.

a This reflects the number of jobs at establishments in the private nonfarm sector rather than the number of people employed throughout the economy (e.g., a person may have a job at more than one firm and some individuals are self-employed).

b Hours relate to production and nonsupervisory workers, who represent the majority of all jobholders.
Employment

Switching to the employment side of the equation does not reveal a more sanguine picture. (See Table 1.) Fewer members of the population have jobs today (62.1% in July 2003) compared to the fraction either at the outset of the recession (64.3%) or at its end (63.0%). (As mentioned above, the unemployment rate is affected by changes in the size of the labor force, which does not affect the employment-to-population ratio.)

Employment, as measured by the number of employees on nonfarm payrolls in the private (non-government) sector, has continued to contract during the recovery. There are almost 1.2 million fewer jobs today than there were at the recession’s end. The economy would need to add almost 3.2 million jobs to July 2003’s total to equal the number that existed at the outset of the recession.

Manufacturers have been laying off employees since July 2000, well before the recession began; and the recovery has not reversed the job cutbacks. Manufacturers have shed 1.2 million jobs thus far during the recovery, according to BLS data. The continuing difficulties of one segment of the “information technology (IT) industry” can be seen at firms that manufacture computer and electronic products, where 238,000 jobs have disappeared since the recession’s end. On the software side of the IT industry, another 102,000 jobs have been lost at firms in the service-producing sector that provide computer system design and related services. The continuing impact of the burst dot-com or internet bubble can be seen in the sector’s information services component, which employs many workers with IT skills: between November 2001 and July 2003, telecommunications providers have let go 143,000 workers; internet service providers, search portals, and data processing firms have terminated 36,000 employees; and internet publishers and broadcasters have separated almost 5,000 workers from their payrolls – for a total of 184,000 fewer jobs. These losses and those in other segments of the service-producing sector (e.g., retail trade and transportation) have offset job growth elsewhere in the sector (e.g., health services and temporary help services). As a result, the private service-producing sector as a whole has thus far eked out a 63,000 job gain during the recovery.11

Underemployment and Hours Worked

As with the unemployment rate, it is thought that changes in employment do not fully reflect the conditions faced by workers. Some individuals are underemployed, that is, they accept part-time jobs (i.e., 1-34 hours a week) despite their preference for full-time positions. In July 2003, as shown in Table 1, some 4.6 million part-timers wanted full-time jobs, which is about 1.3 million more underemployed persons than in March 2001 and 336,000 more than in November 2001.12

12 For information on the long-run increase in involuntary part-time employment see CRS Report 98-695, Part-Time Job Growth and the Labor Effects of Policy Responses: An (continued...
Employers have not only continued to cut employees from their payrolls since the recession’s end, but they also have not generally lengthened employees’ workweeks.\textsuperscript{13} After expanding by 12 minutes from 33.8 hours in November 2001 to a peak of 34.0 hours in June 2002, the average workweek held at about 33.8 hours through March 2003. Since then it has contracted, and in July 2003, dipped to 33.6 hours on average, or 12 minutes shorter than at the outset of the recovery.

For much of 2002, manufacturers were having their employees work 24-36 minutes longer a week, on average, rather than recalling laid off workers.\textsuperscript{14} But, in July 2003, the average workweek in manufacturing fell back to 40.1 hour weeks—the same as it had been in November 2001. The overtime hours of factory workers (which are included in the workweek total) have followed a similar path, that is, elevated during 2002 but then falling during the last several months of 2003.\textsuperscript{15} Nonetheless, factory workers are still putting in slightly more overtime than they had at the start of the recovery (a total of 4.0 hours per week as compared to 3.8 hours, respectively).

### Comparison of the Current Recovery to Past Recoveries

As can be seen in Table 2, there has always been some lag time before the unemployment rate showed sustained improvement coming out of a recession. In all but two of the previous nine recoveries, the unemployment rate began to decline within 6 months of the recession’s end. The exceptions are the recoveries that followed the 1969-1970 and 1990-1991 recessions, during which the unemployment rate continued to climb for 14 months and 16 months, respectively. At 20 months through July 2003, then, the current lag in the unemployment rate showing steady progress is unusually long. The three recessions that were followed by a jobless recovery, based on this criterion, are three of the four mildest recessions in post-war history. The fourth was the short recession of 1980. (The relationship between the strength of recessions and recoveries is discussed in Explanations for the Jobless Recovery, which appears later in the report.)

\textsuperscript{12}(...continued)

\textit{Overview}, by Linda Levine.

\textsuperscript{13}For information on the long-run decrease in the length of the workweek see Katie Kirkland, “On the Decline in Average Weekly Hours Worked,” \textit{Monthly Labor Review}, July 2000.

\textsuperscript{14}For information on manufacturers’ increased use of overtime during the past decade compared to earlier periods see CRS Report 97-884, \textit{Longer Overtime Hours: the Effect of the Rise in Benefit Costs}, by Linda Levine.

\textsuperscript{15}Overtime has been identified as a leading indicator for changes in employment. If this relationship holds, it would suggest some decline in manufacturing employment in the months ahead. See Stephen Stanley, “Manufacturing Employment and Overtime,” \textit{Cross Sections}, Federal Reserve Bank of Richmond, v. 9, no. 2, Summer 1992.
Policymakers are interested not only in changes in the unemployment rate, but also in the proportion of persons who experience long periods without work. The federal-state unemployment compensation system provides income for varying lengths of time to those displaced workers who meet differing state eligibility criteria. In response to some past recessions and the 2001 recession, Congress provided additional funds to workers who had been jobless for so long that they exhausted their regular unemployment benefits. It appears that during the latest recovery the fraction of workers unemployed for at least 27 weeks may have peaked in February 2003, 15 months since the trough of the recession. (See Table 3.) Only the recoveries from the 1969-1970 and 1990-1991 recession were more delayed: it took 17 months and 19 months, respectively, from the start of the two recoveries for the share of workers unemployed longer than 6 months to peak. Nonetheless, it took

longer for the share to peak during the current recovery than it did during the other seven recoveries, even though many of the recessions they followed were deeper.

Rather than utilizing unemployment data to determine whether a recovery is jobless, one could analyze how employment has fared in the post-war recessions and recoveries. Employment (measured in the establishment survey as the number of jobs) and unemployment (measured in the CPS, which counts individuals) need not move together since the latter is affected by changes in the size of the labor force. Looking at employment data, the difference between the last two recoveries and the other post-war recoveries is even more pronounced. Historically, employment has been more of a coincident indicator of economic activity, and less of a lagging indicator, than the unemployment rate. Employment typically began to increase in the month the recovery began, and at most 3 months after the recession had ended. The last two recoveries have been quite a different story. As shown in Table 4, employment did not reach a trough until 11 months after the 1990-1991 recession had ended. Currently, employment has still not reached its trough 20 months after the end of the 2001 recession.17

*Percent decline and number of months through July 2003.

**less than 0.1%.

Another measure of employment recovery is the date in which post-recession employment surpasses its previous peak. By this measure, the last two recoveries stand out as unusually sluggish. Not until May 1993 did employment surpass its previous peak in March 1990, 26 months after the 1990-1991 recession had ended. (See Table 4.) Currently, 20 months after the 2001 recession ended, employment is still more than 3 million below its February 2001 peak. After every other post-war recession, employment surpassed its previous peak 10-15 months after the recession had ended.

Another important difference in the past two recoveries is that a significant portion of the decline in employment occurred after the recession had ended. As measured by the change in employment during the recession itself, the 2001 recession ranks as the third mildest recessions in the post-war period, with less than a 2% decline. Yet, the post-recession decline in employment through July 2003 is by far the largest of the post-war period (1.0%).
Explanations for the Jobless Recovery

Inadequate Aggregate Demand

In the short run, the unemployment rate is very sensitive to changes in economic growth. Although the recession ended in November 2001, the recovery has been unusually weak. Growth has been below its sustainable rate for the last 3 quarters, during which time it averaged 1.7%. Growth has been below its sustainable rate for 5 of the 7 quarters of this recovery. At the least, one would not expect unemployment to fall when growth is weak, and it is not surprising to see it rise.

The current recovery has not followed the pattern of most post-war recoveries, which featured post-recession booms. Part of the reason the recovery has been unusually mild is that the recession was so mild. In the first 3 quarters of 2001, output contracted by a cumulative 0.6% of gross domestic product (GDP), making it the mildest recession of the post-war period. After a deep recession, output can be rapidly increased because there are many existing unemployed labor and capital resources that can be brought back into production when aggregate spending recovers. Because the contraction in output was negligible in 2001, following this recession, there are far fewer idle resources to be put back into use. A look at the historical record confirms this hypothesis (see Table 5). There were only two other post-war recoveries besides the current one in which average growth was 3.1% or below at a similar stage in the recovery (first 7 quarters): the recoveries beginning in 1970 and 1991. Altogether, the mild recoveries followed three of the five mild post-war recessions, in which output declined by less than 2%.

---

18 The sustainable rate of growth is the rate at which additions to the labor force, capital stock, and technical efficiency can increase output in the long run when the economy is at full employment. Most economists today put the sustainable growth rate for the United States at 3%-3.5%.

19 Capacity utilization data tell a different story. The fall in capacity utilization in this recession was much larger than the fall in output, and this suggests there are potentially more idle resources to be brought back into use in the recovery. Annually, capacity utilization fell from 82.7% in 2000 to 74.8% in 2003 (through July). This is larger than the decline during the 1990-1991 recession and similar to the decline during the 1981-1982 recession. The capacity utilization data cover only the industrial sector, however, which was harder hit than the service sector in the 2001 recession. If similar data were available for the service sector, it would presumably show a much smaller decline.

20 The unusual behavior of growth in the 1949 recession and subsequent recovery is attributable to the demobilization of the wartime economy. The 1980 recession is omitted from this discussion because the subsequent recovery lasted less than 7 quarters.
These results are consistent with an economic rule of thumb known as Okun’s Law, which roughly relates changes in economic growth to changes in the unemployment rate. In one version of Okun’s Law, the unemployment rate will rise if economic growth is not rapid enough to accommodate growth in productivity and the labor force. If the potential growth rate of productivity is 2.5% and the labor force grows at 1% a year, then unemployment will rise when economic growth is below 3.5%. As can be seen in Table 5, Okun’s law correctly predicts all three of the post-war jobless recoveries (1970, 1991, 2001). See CRS Report RS21139, Unemployment and Economic Growth, by Brian Cashell.

Source: U.S. Bureau of Economic Analysis.
Note: For the purposes of this table, the recession is dated as beginning in the first quarter of negative growth and the recovery is dated as the first quarter of positive economic growth. Data for the 1980-1981 recovery are omitted because the 1981-1982 recession began less than 7 quarters after the 1980 recession ended.

The correlation between mild recessions and mild recoveries also holds when measured by employment. There were only four post-war recessions in which employment decreased by less than 2%: 1969-1970, 1980, 1990-1991, and 2001 (see Table 4) Unsurprisingly, all three of the recoveries in which the unemployment rate continued to rise for 6 months or more are included in this group (see Table 2), with only the 1980 recovery leading to a quick decline in unemployment (followed shortly thereafter by another recession).

What is holding the current recovery back? The economy has faced a number of unusual shocks since 2001. Before the recession began, oil prices more than doubled on an annual basis. Since then they have fluctuated between $20 and $30 a barrel – higher than the pre-spike price – increasing again in the months heading up to the war in Iraq. Oil spikes temporarily reduce aggregate production by

21 These results are consistent with an economic rule of thumb known as Okun’s Law, which roughly relates changes in economic growth to changes in the unemployment rate. In one version of Okun’s Law, the unemployment rate will rise if economic growth is not rapid enough to accommodate growth in productivity and the labor force. If the potential growth rate of productivity is 2.5% and the labor force grows at 1% a year, then unemployment will rise when economic growth is below 3.5%. As can be seen in Table 5, Okun’s law correctly predicts all three of the post-war jobless recoveries (1970, 1991, 2001). See CRS Report RS21139, Unemployment and Economic Growth, by Brian Cashell.
increasing the price of an important input in the production process and reduce aggregate spending if the shift in income to foreign oil producers is not quickly spent on American goods and services. The recession also coincided with a large decline in equity prices (e.g., the Standard and Poor’s 500 Index fell 45% from peak to trough), which began to recover only in early 2003. This reduced the willingness or ability of firms to borrow to finance new investment spending and reduced personal consumption through a negative wealth effect. Toward the end of the recession, September 11 occurred. This may have weakened consumer and investor demand by creating uncertainty and reducing confidence. It also caused large sectoral shifts on the production side of the economy, with long lasting effects on certain industries such as the airlines, tourism, and insurance, and certain regions, such as New York City. The recovery was also buffeted by the corporate governance and accounting scandals set off by the Enron bankruptcy, which undoubtedly reduced investment spending and equity prices further. Finally, the lead-up to military action in Iraq was thought to harm the economy both through the oil price channel outlined above and by further reducing consumer and investor confidence.

It is difficult to quantify many of these effects since they were each unique and of a qualitative nature. Some of them may have been relatively insignificant in relation to overall economic activity. Nevertheless, added up, it is impressive how many negative events harmed the economy in 2001-2002, compared to how few positive events there were to offset them. To the extent that these events heightened uncertainty, they may have made employers less willing to quickly expand their workforces than they otherwise would have been. Still, it is somewhat surprising that the economy has not reacted more quickly to the large stimulus provided by monetary and fiscal policy over the past 2 years. During that time, the federal funds rate was reduced from 6.5% to 1% and the budget moved from a surplus of 1.3% of GDP in 2001 to a projected deficit of 4.2% of GDP in 2003.

During recessions, firms engage in what economists call “labor hoarding.” Rather than laying off enough workers so that the remaining workforce is fully employed in a downturn, firms prefer to keep more workers than output requires because it is less costly than hiring and training new workers when the economy recovers. It is possible that more labor hoarding occurs in shallow recessions, and firms are forced to make larger layoffs in deep and prolonged recessions. If so, that implies that firms will initially need to make fewer hires following a mild recession since the initial increase in output can be met by the previously underutilized

---

One measure that seems to confirm this theory is the ratio of job losers to total unemployed. If firms are hoarding labor, then there should be a smaller increase in the ratio of job losers to total unemployed. There was a much larger increase in this ratio in the deep recessions of 1973-1975 and 1981-1982 than in the mild recessions of 1969-1970, 1990-1991, and 2001.

This argument is made, for example, in “A Jobless Recovery?,” Time Magazine, July 15, 2002, p. Y9. For more information on the performance of productivity in the recession, see CRS Report RS21527, The Performance of Productivity During the Recent Slowdown, by Marc Labonte.

It is interesting to note that in the late 1990s, many economists were arguing that faster productivity growth was temporarily reducing the unemployment rate. They argued that workers, who had not anticipated the increase in productivity growth, were raising their wage demands too slowly. This made labor relatively inexpensive and led firms to hire more workers. For example, see Laurence Ball and Gregory Mankiw, “The NAIRU in Theory and Practice,” Journal of Economic Perspectives, vol. 16, n. 4, Fall 2002.

This assumes that the Federal Reserve Board will allow monetary policy to accommodate the increase in supply. With the federal funds rate at its lowest point in decades, it is difficult to argue that such an accommodation has not occurred at the present.
capital investment or efficiency gains). From the mid-1970s to the mid-1990s, when productivity was growing at about 1.5% a year, the economy could grow at 2.5% without an increase in the unemployment rate. Now that the productivity growth rate seems to have increased, a 2.5% economic growth rate is no longer sufficient to keep the unemployment rate stable, and no longer indicates that demand is growing quickly enough to keep production at full employment.

A Change in the Natural Rate of Unemployment

The other possible explanation for why the unemployment rate has risen for so long during this recovery is that the economy’s natural rate of unemployment is rising, independent of the effects of changes in aggregate spending.

In the long run, the economy always adjusts so that aggregate spending (demand) matches aggregate production (supply). The unemployment rate that would prevail in this situation is called the natural rate of unemployment. When unemployment is at the natural rate, none of the unemployment is caused by weak economic growth. Rather, workers are unemployed because they are either in the process of moving from one job to another or their skills are incompatible with the jobs available in the local area. In other words, the natural rate of unemployment is caused by the supply side of the labor market. The natural rate can change over time as the characteristics of the labor market change. For example, since older workers have a lower unemployment rate than younger workers, as the population ages, the natural rate of unemployment would automatically decline. The natural rate can also change if labor market policies alter the characteristics of the labor market. For example, most economists believe that the natural rate in the United States is about half the rate in many Western European countries because the U.S. labor market is more flexible. In the United States, it is easier for a firm to alter the size of its workforce, there is a less generous social safety net, and there is more regional labor mobility.30

Because the natural rate is a long-run concept, it is difficult to believe the natural rate could have changed significantly over the past two-and-a-half years. There has not been any major change in labor market policy during that time, and demographic changes are incremental. If the natural rate has changed, it would be part of a longer trend that will not be identifiable in the near term.

There is another reason why the unemployment rate might have continued to rise for so long related to the natural rate concept. Even if the natural rate had not changed over the past two-and-a-half years, it is possible that when unemployment reached 3.9% in December 2000, it was further below the natural rate than suspected. Just as the unemployment rate can temporarily rise above its natural rate when growth is too slow, unemployment can temporarily fall below the natural rate when growth is unsustainably fast. In these circumstances, one would expect to see a rising inflation rate as wages are pushed above productivity because too many jobs are chasing too few workers. Few economists believed the natural rate had reached as

low as 3.9% in 2000, but many assumed that 3.9% was not too far from the natural rate since there was no significant upward pressure on inflation at that time. In hindsight, if the natural rate has been higher than suspected in recent years, say 6.0% versus 5.0%, then the prolonged increase in the unemployment rate could partly be attributable to the long-term adjustment back toward the natural rate from an unsustainably low level. In this case, one would expect the unemployment rate to fall once the recovery becomes more robust, but it will fall less than expected. Those who argue that the natural rate was underestimated in the late 1990s point to the fact that the natural rate averaged 6%-6.5% in the 1970s and 1980s. To put that figure in perspective, consider that today’s unemployment rate would have been considered to be full employment, only attainable near the peak of the business cycle, 20 years ago.

Since the natural rate is a long-run concept, it is too soon to determine which portion, if any, of the recent increase in the unemployment rate is supply-side driven, and which portion is demand-driven. But the inflation rate is one piece of evidence to determine whether inadequate demand or a change in the natural rate is currently driving the rise in unemployment. If the economy is suffering from insufficient demand, the inflation rate should be falling; if the unemployment rate is being driven by changes in the labor market, inflation should be unaffected. The core inflation rate, which strips out volatile food and energy prices, has fallen from 2.6% in 2001 to 2.4% in 2002 to 1.6% in 2003. This indicates that insufficient demand is likely at least part of the story behind the rise in the unemployment rate.

**Looking to the Future**

Economist Herbert Stein once said “If something cannot go on forever, it will stop,” and this is undoubtedly true of the jobless recovery. Rising employment is an essential characteristic of every economic expansion, and it is certain to be a characteristic of the current expansion once the economy picks up steam, even if employment has continued to fall for an unusually long time thus far. The relevant question is how long it will take the economy to return to full employment. If the natural rate of unemployment is 4.5%-5.5%, as economists were suggesting in the late 1990s, then the economy would need to grow fairly rapidly, at a rate above its long-term sustainable rate, to return to full employment quickly.

Economic forecasters are not predicting rapid enough growth in the next year-and-a-half to bring the economy back to full employment in that time period. For example, the Blue Chip forecast of 50 private forecasters is predicting growth to increase to 3.75% in the second half of the year and 2004. This would be an improvement over the economy’s performance to date, and indicates that forecasters believe the recovery has taken root. But forecasted growth would not be strong enough to bring the unemployment rate down to the natural rate by the end of the forecast period: the forecasters are predicting an unemployment rate of 6.2% in the
second half of the year and 5.9% in 2004. These results are uncertain, as the margin of error on forecasts is great.

There is an alternative course the economy could follow. While much of the recent economic data give one reason to feel relatively upbeat about future prospects, the failure of the labor market to recover does raise the question of whether the United States is heading for a “double dip” recession. In the early 1980s, the economy shrank for 6 months in 1980, grew for 1 year from 1980 to 1981, and then shrank for 16 months from 1981 to 1982. It is possible that the labor market is signaling that the economy will follow a similar pattern today.

Perhaps the best reason to think that the double dip scenario is too pessimistic is that many of the factors that were recently holding the recovery back have passed. The uncertainty that war, and to an extent terrorism, placed on the economy has lifted. The stock market seems to be staging a recovery, and discoveries of fresh corporate scandals seem to be waning. Oil prices are more likely to fall than rise in the future, and even if they stay constant, the economy should soon have fully adjusted to the earlier shock. With these shocks dissipated, most economists believe the highly stimulative stance of fiscal and monetary policy should soon take hold.

Will future recoveries follow the pattern of the past two jobless recoveries? No generalization can be made since every recession and recovery is unique. One can say, however, that most macroeconomists believe that policymakers have improved their ability to make recessions milder in recent decades through the more effective use of monetary policy. If the past two recoveries are any guide, this suggests that an unintended and unwanted side effect of milder recessions could be a more sluggish recovery of the labor market.
