Abstract:

Synchrotron-based X-ray photoemission electron microscopy (X-PEEM) was used to characterize the near surface composition of polyethylene oxide (PEO) combined with 1.5, 5, and 10 wt-% pentaerythritol triacrylate (PETA) cross-linker. It was found that as the concentration of PETA increased, it became the dominant component in the top 10 nm of the film surface. The same surfaces were also exposed to human serum albumin (HSA) and the distributions of the protein relative to PEO and PETA were measured with X-PEEM. A positive correlation was found between levels of PETA and HSA at the surface. Above PETA concentrations of 5 wt-%, HSA adsorption was significant, which suggests high levels of PETA (often used to immobilize PEO by cross-linking) can significantly reduce the non-fouling properties of PEO.

Keywords: photoemission electron microscopy, X-PEEM, NEXAFS, mapping, protein adsorption, HSA, pentaerythritol triacrylate (PETA) crosslinker, polyethylene oxide (PEO), topography.

1. Introduction

Polyethylene oxide (PEO) is a hydrophilic polymer commonly used in biomedical applications to reduce protein adsorption [1] or improve biocompatibility [2]. The exact mechanism of protein resistance is not known, however PEO density, chain length, conformation, lack of charge, and its interactions with water are all known to affect protein resistance [3-6].

Since PEO is soluble in water, several techniques such as γ [4], UV [5,6] and electron irradiation [7], have been employed to crosslink the PEO chains to prevent mass loss upon protein exposure. UV-initiated crosslinking of PEO with pentaerythritol triacrylate (PETA) or other radical crosslinkers [8] is becoming increasingly popular since PEO can be crosslinked in both solution and solid state [9,10]. The inclusion of PETA to form crosslinked PEO has been used in biomedical applications such as hydrogels [11,12] and micelles [13] for drug delivery, or to form chemically patterned surfaces for cell studies [14]. However, to our knowledge, the effect of PETA crosslinker on the biocompatibility of PEO-based materials has not been systematically investigated.

In this study, we use synchrotron-based X-ray photoemission electron microscopy (X-PEEM) for surface characterization of thin PEO films containing variable levels of PETA crosslinker. We then investigate the effect of the PETA on the adsorption of human serum albumin (HSA) to these surfaces. Previously, we used X-PEEM to study HSA adsorption to phase segregated polystyrene (PS)-poly(methyl methacrylate) (PMMA) [15-19] or PS-poly(lactide) (PLA) [16] thin films. This study is part of an on-going effort to use X-PEEM and other techniques to obtain detailed information on the interfacial interactions of proteins by measuring the spatial distribution of specific proteins over a well-characterized, chemically segregated surface at high resolution.

Experimental

2.1 Materials and Protein Exposure

PEO (MW=600K) and PETA were purchased from Sigma Aldrich and used as received. Human serum albumin (HSA) was purchased from Behringwerke AG, Marburg, Germany, and found to be homogeneous as judged by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE).

To examine the effect of PETA crosslinker, PEO (50 mg) and PETA (0%, 1%, 5% and 10% by weight) were dissolved in dichloromethane (5 g) and spun cast (4000 rpm, 40s) onto a clean native oxide silicon wafer. Then the substrates were exposed to a 365 nm UV lamp under flowing nitrogen for 40 min to crosslink the PEO. Next, the thin films were immersed in 5 mL of 0.005 mg/mL HSA for 20 min, washed vigorously and air dried. For the PEO sample with 0% PETA, the PEO dissolved upon exposure to protein solution.

2.2 X-ray spectromicroscopy

High quality near-edge X-ray absorption fine structure (NEXAFS) reference spectra of PEO, PETA and HSA (Figure 1) were collected with a scanning transmission X-ray microscope (STXM) on beamline 5.3.2 at the Advanced Light Source (ALS) in Berkeley, CA [17,18]. While the STXM presents slightly better energy resolution (0.1-0.2 eV) compared to X-PEEM (0.4-0.5 eV), similar spectral lines shapes are obtained from both techniques. Samples were solvent-cast onto an X-ray transparent silicon nitride window and micrometer sized areas were probed using image sequences [19]. The intensity scale of each reference spectrum was normalized to the signal expected from 1 nm of the polymer or protein at its bulk density.

X-PEEM data collection was performed at the ALS on beamline 7.3.1 with the PEEM-2 microscope. Briefly, photoelectrons and secondary electrons are ejected upon absorption of 70-80% left circularly polarized monochromatic X-rays and enter the electrostatic imaging column where the spatial distribution is detected with a CCD camera [20]. X-PEEM is a total electron yield technique and is highly surface sensitive (probes the top 10 nm of the sample) with a sampling depth of (1/e) of 4 nm for polymers [21]. To eliminate second-order light, a 100 nm thick titanium filter was used and a shutter with 0.1 second response time blocked the X-ray beam except during image acquisition.

2.3 X-PEEM Data Analysis

All data analyses were performed with the aXis2000 software package [22]. C1s image sequences were aligned and then normalized to the ring current with the I_0 spectrum obtained from a clean HF-etched Si chip. The I_0 spectrum was corrected for the absorption of underlying silicon and the X-PEEM bolometric response, which is a linear energy term. External calibration was used by calibrating the C 1s $\rightarrow \pi^*_{C=C}$ transition of a clean polystyrene sample to 285.15 eV.

Singular value decomposition was used to fit each pixel of a C1s image sequence with the PEO, PETA and HSA reference spectra via least squares refinement [23,24]. The fit coefficients obtained from the SVD fitting result in component maps which show the spatial distribution of each reference component. Skewed illumination correction was adjusted by dividing each component map with a heavily smoothed image of the sum of all components. Furthermore the intensity of each image was divided by a scale factor which results in a total average thickness (sum of all components) of 10 nm, the sampling depth of X-PEEM [21].

PEO-rich and PETA-rich areas were examined quantitatively by applying a threshold mask to the stack to obtain pixels specific to PEO or PETA (Figure 2). Only pixels above a defined value were included and the average NEXAFS spectrum from each masked region was further altered by setting the pre-edge intensity to zero. Each PEO-rich or PETA-rich average NEXAFS spectrum was then fit with the PEO, PETA and HSA reference spectra. Several stacks were quantitatively examined and the results were averaged to determine the uncertainty or standard deviation.

3. Results and Discussion

The C 1s reference spectra for PEO, PETA and HSA are plotted in Figure 1. At the C 1s edge, the three species can be easily distinguished. The PEO spectrum is dominated by C 1s $\rightarrow$ $\sigma^*_{\text{C-H}}$ and C 1s $\rightarrow$ $\sigma^*_{\text{C-O}}$ transitions at 289.0 and 289.8 eV [25]. PETA is characterized by two main transitions at 284.45 and 288.6 eV corresponding to C 1s $\rightarrow$ $\pi^*_{\text{C=C}}$ and C 1s $\rightarrow$ $\pi^*_{\text{C=O}}$ transitions. The C=C π^* transition at 284.45 eV is 0.7 eV lower than the transition obtained for polystyrene which reflects conjugation of double bonds in the PETA structure. HSA shows a strong C 1s $\rightarrow$ $\pi^*_{\text{C=O}}$ transition at 288.20 eV, which is 0.4 eV lower than the C=O π^* transition of PETA due to the less electronegative environment of the amide-group in proteins.

The color coded maps of the PEO films with 1.5, 5 and 10 wt-% PETA crosslinker obtained from X-PEEM are shown in Figure 3. The same data are presented in two different ways. The rescaled maps are shown such that the intensity of each component is mapped separately to the full range (0-255) of its color, resulting in greater sensitivity for the localization of each component. The absolute maps are displayed on a common scale (0-10 nm), which preserves the thickness information.

The rescaled color coded image (Figure 3d) for the 1.5 wt-% PETA sample reveals an inhomogeneous surface with small PETA domains (~ 50 nm) scattered within a PEO matrix, with PEO, PETA and HSA color coded as red, green and blue, respectively. These small PETA domains are hard to resolve and may be beyond the resolution limits of the X-PEEM used for these studies. As the concentration of crosslinker increases, the surface evolves from slightly structured to having large circular domains of green crosslinked PETA. With increasing crosslinker concentration, the images become pinker and teal, indicative of HSA adsorption to the entire surface. At the highest PETA concentration studied (10 wt-%), there is a marked correlation between the green dots of PETA and intensely blue HSA (Figure 3n).

The absolute color coded images show the surface changing from bright red (Figure 3e) to bright green (Figure 3o) as the concentration of PETA increases from 1.5% to 10%, suggesting that surface enrichment of PETA occurs at the substrate-air interface. In these images, the blue color representing HSA is faint indicating that although PETA segregates to the surface, the PEO still retains some protein resistance.

Figure 4 compares the average spectra extracted from the 1.5, 5 and 10 wt-% PETA samples compared to pure PEO and pure PETA. As the concentration of PETA increases the main NEXAFS peak shifts to lower energy and the spectral line shape transitions from mainly PEO (1.5% wt- PETA sample) to mainly PETA (10 wt-% PETA sample).

Doytcheva et al. suggested that under UV irradiation, PETA (singlet) undergoes an intersystem crossing to form an excited triplet state which is capable of cleaving a proton from PEO to form a PEO radical and a PETA radical [10]. Our experiments verify that PETA acts as both an initiator and a crosslinker since UV irradiation of PEO alone does not form crosslinked PEO. Also, our NEXAFS spectra show almost no C=C π^* transition at 284.45 eV, which should be evident if the double bonds of PETA are present. This clearly indicates that the crosslinking mechanism occurs by PEO and PETA radical attack of the PETA double bond. FTIR analysis of PEO crosslinked with PETA for micelle formation also observed the absence of C=C double bonds as evidence for complete radical polymerization [26].

The quantitative results extracted from PEO-rich and PETA-rich areas are summarized in Table 1. For the 1.5 wt-% PETA sample, a small amount of PETA (0.7 nm) is detected in the PEO-rich area. At this low crosslinker concentration, PEO still retains its non-fouling properties with no detectable HSA adsorption. The PETA-rich area shows an increase of 6 % PETA

revealing that PEO remains the dominating component ($\sim 90\%$) across the top 10nm of the surface. Even in the PETA-rich areas, no HSA is detected.

However, as the concentration of PETA increases to 5 wt-%, a detectable amount of HSA adsorbs to the surface. At 5 wt-% PETA, the crosslinker thickness in the PEO-rich areas increases from 0.7 nm to 3.7 nm, while in the PETA-rich area, it increases by almost four-fold to 4.9 nm. At this relatively low PETA concentration (5 wt-%), the top 10 nm of the surface shows a mixture of $\sim 50:50$ PEO:PETA with about 0.3-0.7 nm of HSA. These results show that PETA is strongly surface segregated. Typically, in polymer systems, the component with the lower surface free energy segregates to the surface [27]. Since PETA is more hydrophobic than PEO [26], PETA should have lower surface free energy and would be expected to segregate to the surface [28,29]. Furthermore, the molecular weight difference between PETA and PEO should also affect the surface composition with the lower molecular weight PETA segregating to the surface [30].

At 10 wt-% PETA, the crosslinker becomes the dominant component (65-70%) at the surface for both the PEO and PETA-rich regions. Here, the thickness of adsorbed protein doubles to 1.3-1.4 nm across the entire surface with only a small amount of PEO (15-20%) detectable. These quantitative results show that at a crosslinker concentration > 5 wt-%, the PEO surface begins to lose its non-fouling properties and begins to adsorb protein. As the concentration of PETA increases, the amount of adsorbed HSA also increases, suggesting that HSA binds preferentially to the crosslinker.

Recently, fluorescence microscopy treated by integral geometry analysis was used to quantify the adsorption of labeled lentil lectin (LcH) or concavalin A (ConA) to several polymeric surfaces including PEO crosslinked with PETA [31]. While this technique can spatially resolve and quantify lectin adsorption to the surface, it provides no information on the polymeric substrate. This fluorescence study suggested that lectin adsorption may be influenced to some extent by the presence of PETA; however, since the spun-cast PEO film studied was prepared using 15% PETA, the crosslinker is undoubtedly the dominant component of the film surface.

The inclusion of PETA and other UV-initiated radical crosslinkers [32] to form PEO-based biomaterials such as hydrogels [6,12] or micelles [13] for drug delivery is becoming increasingly common. In the formation of micelles, PETA is used to stabilize the hydrophobic

core [26] and is likely not present at the air-substrate interface. However, for hydrogel or micro-array applications, it is likely that the highly surface active PETA crosslinker is present as a major component at the interface, and as such may compromise the antifouling properties of PEO.

4. Conclusions

PEO containing 1.5, 5 and 10 wt-% PETA was crosslinked by UV exposure, exposed to 0.005 mg/mL HSA and examined with X-PEEM. As the concentration of PETA increased, it became the dominant component in the top 10 nm of the surface. Upon exposure to HSA, increased protein adsorption was seen with increasing PETA concentration. It is concluded that at PETA concentrations above 5 wt-%, PEO begins to lose its non-fouling properties.
