Abstract

The challenge of chemistry in the 21st century is to achieve 100% selectivity of the desired product molecule in multi-path reactions (green chemistry) and develop renewable energy based processes. Surface chemistry and catalysis play key roles in this enterprise. Development of in-situ surface techniques such as high pressure scanning tunneling microscopy (STM), sum frequency generation (SFG) vibrational spectroscopy, time-resolved Fourier Transform Infrared (FT-IR) methods and ambient pressure X-ray photoelectron spectroscopy (AP-XPS) enabled the rapid advancing of three fields; nanocatalysts, biointerfaces, and renewable energy conversion chemistry. In materials nanoscience, synthetic methods have been developed to produce monodisperse metal and oxide nanoparticles (NP) in the 0.8 –10 nm range with controlled shape, oxidation states, and composition, which can be used as selective catalysts since chemical selectivity appears to be dependent on all of these experimental parameters. New spectroscopic and microscopic techniques have been developed that operate under reaction conditions and reveal the dynamic change of molecular structure of catalysts and adsorbed molecules as the reactions proceed with changes in reaction intermediates, catalyst composition, and oxidation states. SFG vibrational spectroscopy detects amino acids, peptides and proteins adsorbed at hydrophobic and hydrophilic interfaces and monitors the change of surface structure and interactions with coadsorbed water. Exothermic reactions and photons generate hot electrons in metal nanoparticles that may be utilized in chemical energy conversion. The photo-splitting of water and carbon dioxide that are important research directions in renewable energy conversion is discussed.

I. Introduction

Surface chemistry had a glorious 40 years during which it became an atomic scale and molecular level science. Using model surfaces, single crystals at first, the evolution of electron, ion and molecular scattering techniques provided atomic and molecular structures, composition and oxidation states and energy transfer information upon adsorption, desorption and scattering of molecules from surfaces¹⁻⁴. Figure 1 shows the timeline of this development and evolution of surface science. Since these surface instruments required high vacuum and clean surfaces, surface chemistry at low pressures developed first. Then molecular surface chemistry developed by application of new experimental and theoretical techniques that permitted molecular level studies of all the other interfaces; solid-gas, solid-liquid, solid-solid, and liquid-liquid⁵⁻⁹. An up-to-date list of the surface techniques that lead to the evolution of surface science is shown in Figure 2. Since life on this planet does not operate in high vacuum the techniques that probe the buried interfaces opened up molecular level investigations of many applications of interfaces. Many of the surface chemists trained in our laboratories and elsewhere pursue research in these fields. For us, we were always fascinated by catalysis by surfaces such as transition metals and in the human body (which may be viewed as a polymer-water interface with a layer of adsorbed proteins). Fortunately both of these interface science applications are developing exponentially in recent years due to two entirely different reasons. The rise of nanosciences permitted the synthesis and characterization of nanoparticles and most catalysts, heterogeneous, homogenous and enzyme are nanoparticles. Heterogeneous transition metal catalysts are nanoparticles (NPs) with sizes in the 1 – 10 nm range and we could synthesize them with uniform size (monodispersed) and shape¹⁰. Figure 3a shows the plot of the size of Pt nanocrystals as a function of [Pt(IV) to Pt(IV) + Pt(II)] in the initial solution¹¹. Figure 3b and shows the shape control of Pt nanoparticles by adding Ag ions¹². It was found that these Ag ions can be removed using nitric acid while the shape and size of nanoparticles remain the same. Figure 3c shows the shape control of Pt/Pd bimetallic nanoparticles by adding oxygen gas.

Nanoparticles with controlled size and shape became our model catalysts after using metal single crystals for decades. As we find that selectivity depends on both NP

size and shape, we can directly probe these as well as other molecular factors that make them nature's choice and the choice of chemical technologies as catalysts.

Biointerfaces are vital components of body implant chemistry as we are dramatically improving our life expectancy by replacing a failed organ or body part by an artificial one ¹³. Figure 4 shows several frequently used replacement parts that are inserted daily in every hospital such as contact lenses, stents and prosthesis. The ability of the human body to accept these replacement parts (biocompatibility) is a major challenge and the driver of molecular level research in the field of biointerfaces.

The energy crisis drives the rapid developments in the interface chemistry of nanocatalysts. Production of one desired molecule that may be used as a fuel or chemical out of several thermodynamically possible molecules that would be waste byproducts is called catalytic selectivity and it is the foundation of "green chemistry" ^{14,15}. In catalytic studies using model single crystal surfaces of metals we learned a great deal about the molecular mechanism of one-product molecule reactions such as ammonia synthesis, ethylene hydrogenation to ethane and carbon monoxide oxidation. However, selectivity in multi-path reactions are much more difficult to decipher. Figure 5 shows schematically a small shift in the relative heights of two potential energy barriers, of about 2 kcal/mol, dramatically changing the product distribution ¹⁶. Selectivity is the key component of energy efficiency in chemical energy conversion. By studying the selectivity in multi-path hydrocarbon conversion reactions we find that it depends on both the size and the shape of the metal nanoparticles ^{11,17} as well as other molecular factors that will be reviewed in this Perspective. One major challenge in our quest of renewable energy conversion is the use of sunlight to dissociate water and carbon dioxide. The state of research in these seminal fields of photochemistry utilizing nanoparticles is discussed.

II. Nanocatalysts

Studies that Focus on Model Catalytic Surfaces – Metal Single Crystals and Monodispersed Nanoparticles of Size 1-10 nm and Controlled Shape

Single crystals have been used as model surfaces for both experimental and theoretical studies of metal catalysis. Ammonia synthesis^{18,19}, CO oxidation^{20,21}, H₂/D₂ exchange^{22,23} and ethylene hydrogenation^{24,25} were some of the important reactions that were studied on single crystal surfaces. Advances in nanoscience has made it possible to fabricate metal nanoparticle(NP)s in the 1-10 nm regime, which is the identical size range of the metal catalysts used as industrial catalysts²⁶. As a result, model studies could be extended from single crystal metal surfaces to nanoparticles of controlled shape and size. Single crystalline metals used for modeling industrial catalysts inherently lack the complexity needed to uncover many of the factors important for catalytic turnover and selectivity. The most versatile way of fabricating nanoparticle catalysts uses colloid chemistry. By using a metal salt in solution such as hexachloroplatinic acid or rhodium acetyl acetonate as a precursor monomer²⁷, it is possible to produce monodisperse metal nanoparticles, each coated with surfactant or a polymer layer that prevents their aggregation in solution. Under optimized reduction conditions it was possible to control the size and shape of the platinum and rhodium nanoparticles or bimetallic systems when these were fabricated²⁸⁻³⁰. Figure 6 illustrates the one-step synthesis of monodispersed Rh/Pt bimetallic nanoparticles. By changing the stoichiometry of rhodium(III) acetylacetonate and platinum acetylacetonate, tuning of the composition of the bimetallic nanoparticles with 9 nm size was achieved³⁰.

These monodisperse NPs with uniform size and shape can be deposited as a two-dimensional film by using the Langmuir-Blodgett technique (Figure 7)³¹. The nanoparticles can also be deposited in a mesoporous three-dimensional oxide framework at much higher surface concentrations^{32,33} (Figure 8). Studies of these different NP arrangements show that they yield model surfaces that approximate the size and morphology of NPs currently used in chemical technology. Recently dendrimer encapsulated metal nanoclusters have been explored for catalysis^{34,35}. The structure and

chemical properties of dendrimers can be controlled by changing the core structure of these hyper-branched polymers, the number and type of the duplicating units and the terminal functional groups. Single metallic and bimetallic nanoparticles having dimensions less than 3 nm have been prepared within the cavities of these dendrimers. The many methods of characterization for studying two- or three-dimensional nanoparticles are listed in Figure 2.

The Molecular Factors that Control Selectivity in Nanocatalysts

Product selectivity is essential in developing processes that yield the desired molecules in multi-path reactions with complete selectivity. 100% selectivity, often called green chemistry, towards just one desired product molecule out of many thermodynamically stable molecules is the major challenge of the 21st Century^{15,36}. For multi-path reactions, instead of a single potential energy barrier that reflects the activation energy for the formation of a product there are several possible reaction products which have different potential energy barriers with small energy differences. The corresponding potential energy plot for the competitive formation of two products is depicted in Figure 5. The relative energy differences between the activation energy barriers determine the reaction selectivity. These differences can be induced by coadsorbates, small structural changes, or the addition of electron donors or acceptors, which change the binding energies of reaction intermediates. A small change in charge states of the metal catalysts (oxidation states) can also induce major changes in product selectivity.

It was found that catalytic selectivity during multi-path reactions on nanoparticle arrays depends on the size and shape of nanoparticles. Figure 9a shows the product selectivities during furan hydrogenation as a function of catalyst size and structure at 363K. The results reveal the higher selectivity of ring-opening for the larger the nanoparticle, and the exposure of more <100> facets. Over the 10 nm Pt cubic nanoparticles butanol is formed only at lower temperatures, and vanishes at higher temperatures, while over the 1.0 nm Pt nanoparticles it is not seen at all. This is consistent with SFG-VS data on Pt(111) under furan hydrogenation conditions which

shows that the planar furan ring lies parallel to the metal surface. Butanol is bound to the surface through the O atom, adsorbed in a parallel orientation. The surface concentration of butanol increases with increasing temperature over Pt(111), and THF is bound to the surface in an upright binding geometry. Over Pt(100) the SFG-VS spectra also indicate a parallel furan adsorption under hydrogenation conditions³⁷. Both butanol and THF are seen bound to the Pt(100) surface in upright geometries. A similar trend was observed for pyrrole hydrogenation and ring-opening over Pt nanoparticles³⁸. The smaller the nanoparticle, the higher the production of the partially saturated ring. These results are summarized in Figure 9b which depicts dependence of the selectivity of the hydrogenation of pyrrole (4 Torr pyrrole, 400 Torr H₂, 413 K) on the size of the platinum nanoparticles encapsulated in a dendrimer or PVP³⁸.

The dependence of the selectivity of benzene hydrogenation on the shape of the platinum nanoparticles of the same size and single crystal surfaces with different surface structure was studied by Bratlie et al.¹⁷. Benzene hydrogenation turns out to produce two molecules: cyclohexane and cyclohexene on the platinum (111) surface while only one molecule (cyclohexene) on the (100) face. Similar trend was observed on nanoparticles arrays of different shapes (cubic and cuboctahedral). While cuboctahedra give rise to two products just like (111) single crystal surfaces, Pt cubes give rise to one product like the (100) single crystal surface. This result is summarized in Figure 10.

We have so far identified seven molecular factors that affect selectivity¹⁵; 1) surface structure, 2) adsorbate-induced restructuring, 3) adsorbate-mobility, 4) reaction intermediates, 5) surface composition, 6) charge transfer during catalysis, and 7) oxidation state of the catalyst. The understanding of the roles of these factors were enabled by development of new in-situ surface sensitive techniques, which we will describe next.

Surface Techniques that Operate Under Reaction Conditions

Since the 1980's researchers have worked to develop techniques that uncovers the structure composition and dynamics of surfaces at high pressure. The four techniques that we examine here in detail are ambient pressure X-ray photoelectron spectroscopy

(AP-XPS)^{39,40}, high pressure scanning tunneling microscopy (STM)^{41,42}, sum frequency generation (SFG) vibrational spectroscopy^{43,44}, and time-resolved Fourier Transform Infrared method (FT-IR)³⁹.

Surface Composition and Oxidation States under Reaction Conditions revealed by AP- XPS

Surface composition is the key factor influencing the catalytic activity and selectivity of materials composed of two or more metals. The use of bimetallic nanoparticles allows the role of surface composition to be studied on the nanometer scale. The schematic representation of the APXPS experiment is shown in Figure 11^{39,45}. It illustrates the differentially pumped electrostatic lens system that refocuses the scattered electrons into the object plane of a standard electron energy analyzer in the high-vacuum region. The kinetic energy of the detected electrons can be varied by tuning the photon energy of the X-ray source. This method permits the surface-specific XPS signal to be examined and the surface composition of the bimetallic nanoparticles to be determined.

Figure 12(a) and (b) show that the XPS results on rhodium/palladium and palladium/platinum 50/50% bimetallic nanoparticles as a function of the kinetic energy of the X-rays, and shows the moderate surface segregation of rhodium and palladium, respectively in ultrahigh vacuum⁴⁰. Figure 12(c) and (d) shows AP-XPS data for rhodium/palladium and palladium/platinum 50/50% bimetallic nanoparticles under oxidizing (NO), reducing (CO) and reaction (NO/CO) conditions, which directly shows the change of the surface composition as the reaction conditions are varied. The results suggest that rhodium atoms are pulled to the surface during the oxidizing conditions of the reaction. Under reducing conditions rhodium and the palladium surface compositions are roughly equal. These results indicate that the reaction conditions dramatically change the surface composition of bimetallic NPs. Because of their small size they undergo rapid random walk diffusion that will change the surface composition as the reaction conditions are varied. Thus the bimetallic system adjusts its surface composition to the type of reaction it catalyzes.

Surface structure, adsorbate-induced metal restructuring and adsorbate-mobility detected by HP-STM

The adsorbate mobility during catalytic turnover has been observed by high pressure scanning tunneling microscopy^{41,46-48} (Figure 13a). No distinctive feature of the surface can be observed when scanning the surface at the rate of 100 Å per millisecond during the hydrogenation/dehydrogenation of cyclohexene or hydrogenation of ethylene. All the adsorbed molecules on the surface, reaction intermediates and products, are more mobile under these conditions than the scanning speed of the tunneling tip. However, if the surface is poisoned using, for example, carbon monoxide the catalytic reaction stops and there are ordered structures formed on the surface as shown in Fig. 13b. The poisoning of the catalyst also minimizes the mobility of the adsorbate. In many cases, adsorbate mobility is required for the catalytic process to occur as the adsorbed reactants must find an active site, and that requires mobility on the surface. Thus the catalytically active surface is dynamic. High-pressure STM measurements show that adsorption of a gas such as oxygen, hydrogen or carbon monoxide, changes the structure of single crystal surfaces (Fig. 13c). During the chemisorption there is an increased coverage of the different chemisorbed molecules under pressure, which results in the number of chemical bonds between the adsorbate and substrate becoming greater. The reversibility of adsorbate-induced restructuring was readily observed by hydrogen adsorption/desorption or other chemisorbed gas adsorption and subsequent desorption⁴⁹. After evacuating the chamber the original structure is once again obtained. Both the metal and the adsorbates restructure under the conditions of the catalytic reaction.

Reaction intermediates detected by SFG vibrational spectroscopy

SFG, a surface specific technique is based on similar principles as second harmonic generation^{50,51 52 ,53}. Figure 14a shows a schematic representation of the experimental set-up for analyzing the catalytic reaction by high pressure SFG vibrational spectroscopy^{50,54,55}. In SFG two laser beams in the IR or visible region are spatially and

temporally overlapping. Scanning the frequency of the IR laser enables the sum frequency signal and thus a vibrational spectra in the visible region to be obtained. Such a transition is symmetry forbidden for a centrosymmetric medium such as the bulk phase of a face centered cubic crystal or an isotropic high-pressure gas, or a liquid. However, at the surface the second order susceptibility is non-zero allowing the measurement of a vibrational spectrum that is sensitive to the monolayer. Such a spectrum can also give us vibrational frequencies of adsorbed molecules across a pressure range of 10-12 orders of magnitude.

The use of sum frequency generation vibrational spectroscopy enables reaction intermediates on the surface to be identified during catalytic turnover. By measuring the turnover rate as well as the SFG signals the kinetics of the reactions can be related to reaction intermediates. For example, in the case of the hydrogenation of ethylene some of the surface-bound species such ethynidyne and di- σ -bonded ethylene are spectators and they do not participate in the hydrogenation of ethylene⁵⁶. Weakly bound π -bonded ethylene, which will be converted into ethane, is present at only concentrations of 4% in the monolayer. Figure 14b shows the species that we see in the hydrogenation and dehydrogenation of cyclohexene. During this reaction, three reaction intermediates; 1,3-cyclohexadiene, 1,4-cyclohexadiene and π -allyl molecule, are observed, all of which participate at different concentrations depending on the surface structure in the formation of the product, cyclohexene or benzene⁵⁷. High pressure SFG can also be used to study reaction intermediates on nanoparticle surfaces. For SFG measurements on nanoparticles, two dimensional nanoparticle arrays are deposited on a prism which allows for total internal reflection to increase the detection sensitivity^{58,59}. Our recent SFG studies indicate that during hydrogenation of pyridine, pyridinium ions are the reaction intermediates and the formation of piperidine as the product of complete hydrogenation in the gas phase⁴⁸. SFGVS of ethylene hydrogenation on the clean platinum nanoparticles after UV-ozone cleaning showed existence of ethynidyne and di- σ -bonded species, indicating the similarity between single-crystal and nanoparticle systems⁵⁸.

Transient Reaction Intermediates revealed by Time-Resolved FTIR Spectroscopy

A structure sensitive spectroscopy with temporal resolution ranging from nanoseconds to seconds for monitoring of heterogeneous catalysis over metal nanoparticles under practical reaction conditions is offered by the Fourier Transform Infrared method (FT-IR). To achieve such time resolution, initiation of the catalysis by a short reactant pulse synchronized with interferometric signal acquisition is required. This can readily be done for light-initiated reactions, and time-resolved FT-IR spectroscopy in heterogeneous environments using the step-scan method (nano and microseconds) was initially developed for photochemical systems^{60,61}. For temporal resolution in the millisecond regime, the rapid scan method gives the best results. The technical challenge of applying time-resolved FT-IR techniques to catalysis is the delivery of a reactant pulse to the nanoparticle catalyst surface on a time scale that is short compared to reactive events of interest. Figure 15 shows the schematic of a reactor for time-resolved FT-IR monitoring of gas phase catalysis over supported metal nanoparticle catalysts at 1 atm and temperatures ranging from 295 to 700 K.

For the search for transient surface intermediates of ethylene hydrogenation over alumina supported Pt nanoparticles, a gas pulse of ethylene was released from a fast mechanical valve that merged with a continuous flow of H₂ diluted by nitrogen (1 atm total pressure, 4.5 L min⁻¹ flow rate, H₂/N₂ = 0.05, 323 K) in close proximity of the catalyst surface^{62,63}. As shown in Figure 15, time resolved infrared spectra revealed instant growth of surface ethyl species (CH₃CH₂Pt, 1200 cm⁻¹ CH₂ wagging mode, 2870 cm⁻¹ CH stretch) that decayed with a time constant of 122 milliseconds. The kinetics of surface ethyl decrease coincided with the rise of the gas phase ethane product (CH stretch band, Figure 15). The link between the temporal behavior of the two species established direct kinetic evidence for surface ethyl as the relevant reaction intermediate. This confirms that the barrier to surface ethyl hydrogenation is substantially higher than the preceding surface ethylene to ethyl hydrogenation step under reaction conditions.

For catalysis with metal nanoparticle catalysts supported on mesoporous silica, the time resolved FT-IR method allows the study of the diffusion and fate of reactants or

products inside the nanoscale channels. When hydrogenating propylene over Pt nanoparticles (1.7 nm) supported on SBA-15 silica material, propane emerged inside the silica pores within 100 milliseconds (383 K)⁶⁴. The CH stretching absorptions of propane inside the channels were distinct from the gas phase spectrum of C₃H₈, as shown in Figure 16. Spectral analysis allowed us to monitor the escape of the alkane product from the silica pores into the surrounding gas phase in real time, the first direct spectroscopic observation of emerging products of heterogeneous catalysis on a nanoporous support. Desorption of propane from the 8 nm wide, approx. one micrometer long channels was found to occur within 300 millisecond (1 atm, 383 K).

III. Biointerfaces

The rapid evolution of the use of implants in the human body to replace or repair organs or body parts gave rise to research in biocompatibility to learn the body's response to accept or reject the implant. Figure 4 shows several implants commonly utilized in the medical practice. When a biomaterial is introduced into the body, one of the first events to occur is the adsorption of proteins from the surrounding fluid onto the surface of the implant. Because of the structural complexity of proteins, the use of model systems is now seen as essential to understanding these phenomena.

The surface modifications as they influence the interactions with proteins, peptides and amino acids in buffered water solutions were studied by SFG^{13,65,66}. The amount of adsorbates on hydrophobic or hydrophilic surfaces were monitored by quartz crystal microbalance (QCM), that is an ultra-sensitive (ng cm⁻²) in situ mass sensor^{5,66}. A QCM consists of a layer of piezoelectric quartz sandwiched between two conductive pieces of gold. Any material (such as silica or polystyrene) may be applied to the gold, providing a surface for molecular adsorption. An AC-field is applied across the quartz, causing it to oscillate at a characteristic frequency. As molecules adsorb from the surrounding medium to the crystal, the frequency changes. The Sauerbrey equation⁶⁷ relates this change in frequency to a proportional change in the adsorbed mass, making a

QCM one of widely used tool in the study of the adsorption of biomolecules. Another complimentary technique that is frequently used in biointerfacial studies is atomic force microscopy (AFM) which permits the study of surface topography and the measurement of surface mechanical properties, such as friction, adhesion, stiffness, and plastic deformation of the biomaterials. For example, protein adsorption on surfaces can also be characterized and measured with AFM⁶⁸.

Figure 17 shows the surface vibrational spectra of poly-HEMA, a hydrogel commonly used as a contact lens material, when in contact with water and air⁶⁹. Figure 17 (a), (b) and (c) shows SFG spectra of poly(HEMA) surfaces (a) at the water/polymer interface, (b) in hydrated state, and (c) dehydrated state. Figure 17 (d) depicts the change of molecular structure of poly(HEMA) during dehydration detected by SFG at the water/poly(HEMA) interface. The carboxyl groups segregate to the surface in water while the methyl groups segregate in air controlled by the hydrophilic and hydrophobic interactions, respectively. Thus, the surface composition changes with humidity.

Infection due to implanted biomaterials is a serious complication initiated by bacterial adhesion to the surface of the implant. To control the bacterial contamination, the polymer surface must be modified to reduce the bacterial adhesion^{70,71}. The surface composition of polyurethane frequently used as an implant material can be altered using hydrophilic end-groups (OH groups for example) or hydrophobic end groups (-OCH₃ groups) so-called surface modifying end groups (SMEs). Self-assembling monolayer end-groups (SAMEs) that are covalently bonded to the polymer during synthesis can also be used to modify the surface composition (Figure 18). By binding a molecule to the end of the alkyl chain that imparts antimicrobial activity to the SAME modified surface, the membrane of the bacterium compromised and the bacterium dies⁷². Surface modifying coatings can also enhance the thrombo-resistance or biostability of the polymer employing fluorocarbon SMEs.

A model short-chain peptide has been used to demonstrate the effects of the properties of biomolecule and surface on the adsorption orientation^{13,66}. The model peptide, LK14, is an amphiphilic 14-amino acid peptide composed of hydrophobic Leucine (L) and hydrophilic Lysine (K) residues of sequence LKKLLKLLKLLKL as shown in Figure 19(a). The LK14 peptide assumes an α -helical structure in a pH 7.4

phosphate-buffered saline (PBS) solution with most of the hydrophobic residues pointing to one side of the molecule and hydrophilic residues to the other side. When the peptides are adsorbed to a hydrophobic deuterated polystyrene (d₈-PS) surface and a hydrophilic SiO₂ surface from the PBS solution, SFG spectra show a marked difference (Figure 19(b)). The SFG spectrum at the PBS/ d₈-PS interface is dominated by the C-H stretch bands from the CH₂ and CH₃ groups, while, at the PBS/SiO₂ interface, only the N-H stretch band is observed. The SFG results suggest that the hydrophobic interaction drives the hydrophobic methyl groups at one side of the peptide in contact with the hydrophobic surface to form an ordered layer of methyl groups, and that the disordered hydrophilic residues on the other side of the peptide form hydrogen bonds with water molecules. At the PBS/SiO₂ interface, the positively charged hydrophilic residues on one side of the peptide interact with the negatively charged SiO₂ surface, and the NH end groups also form hydrogen bonds with the surface, which renders the N-H stretch band visible in the SFG spectrum. AFM and QCM were used to characterize the adsorption of a model peptide LK14 to both silica and polystyrene surfaces^{13,66}. It was observed that at short times, the peptide adsorbs in small clusters, and the lateral dimensions of these clusters increase with time.

SFG vibrational spectra exhibit three different types of water structures (Figure 20) at the water-solid interfaces⁷³. Since water is a coadsorbate with the peptide and protein molecules at biointerfaces one can monitor the role and nature of bonding of water molecules and how this influences the adsorbed biomolecule structure and orientation. Surface electrochemistry studies using SFG and FTIR indicate that adsorbed molecules change their orientation as the electrode potential is altered⁷⁴. It is likely that the bonding of amino acids, peptides and proteins at the interface will be altered in the presence of changing surface charge. The fundamental surface chemistry of biomolecules influences increasingly the studies of biocompatibility of implant materials.

IV. Renewable Energy Conversion Chemistry

Development of reliable and renewable energy sources from abundant resources is one of challenges in the 21st Century. The principal renewable energy sources are biomass from plants, geothermal power from heat stored in Earth, wind energy, and solar energy from the Sun. Out of these, solar energy is one of the most significant and promising renewable energy sources^{75,76}. Solar energy is converted to electricity by solar cells (also known as photovoltaic cells) or stored chemical energy via photo-splitting processes⁷⁷⁻⁷⁹. In this section, we describe the recent progress and challenges in energy conversion chemistry using nanomaterials with an emphasis of conversion of exothermic reaction or photon adsorption to hot electron flow using a nanodiode, and photo splitting of water and carbon dioxide.

IV.a. Conversion of Exothermic Reactions and photons to Electron Flow at Metal Surfaces – Detection of Hot electron Flow with Metal-Semiconductor Nanodiode

Fundamental mechanisms of energy dissipation and conversion at the surface and interfaces have been key issues in the surface science community. Energy dissipation at metal surfaces and interfaces is mediated by excitation of phonons and electron-hole pairs once the external energy is deposited to the surface during the exothermic chemical processes. Electron excitation in exothermic catalytic reactions or the incidence of photons at metal surfaces results in the flow of high energy electrons with energy of 1-3 eV, assuming that most of the chemical or photon energy is converted to electron flow on a short, femtosecond time scale before atomic vibration dissipate energy adiabatically (in picoseconds)⁸⁰⁻⁸⁶. These energetic electrons that are not in thermal equilibrium with the metal atoms are called “hot electrons”. These hot electrons move into the bulk of the metal catalyst, and eventually dissipate energy and turn into low energy electrons through lattice atom relaxation within the length scale of the electron mean free path, which is in the 5-10 nm range and within the lifetime of 10 femtoseconds. Recent experimental and theoretical studies have demonstrated electronic excitations created during atomic or

molecular processes at surfaces. Theoretical models assuming that the nonadiabatic energy transfer during a surface chemical process is dominated by electron-hole pair excitations has been suggested⁸⁷⁻⁹⁰. Pump-probe experiments carried out on femtosecond time scales detect the presence of hot electrons in the metal^{91,92}. When vibrationally excited molecules strike another surface they are rapidly de-excited because of hot electron formation. If the metal thickness or size is of the order of the electron mean free path, hot electrons can be collected during ballistic transport across the metal⁹³.

Hot electron generation from exothermic reaction and its detection with catalytic nanodiodes

To detect this flow of hot electrons, we fabricated metal-semiconductor Schottky diodes. If the metal particle or film is of the diameter or thickness of the electron mean free path (~10 nm) hot electrons can be collected as they are transported across the metal without collision as shown in figure 21(a) and 21(b). For an n-type Schottky diode, hot electrons are detected as a chemicurrent if their excess energy $E_{ex} = |E - E_F|$ is larger than the effective Schottky barrier, which is the difference between the conduction band minimum and the Fermi energy, E_F , at the interface^{83,85}. Once hot electrons arrive at the oxide, they dissipate energy and thus cannot go back to the metal. Therefore, the Schottky energy barrier leads to irreversible one-way charge transfer of hot electrons from the metal to semiconductor. After hot electrons move from metal to semiconductor, they are replaced by low energy electrons supplied by the external leads connected to the Pt and semiconductor, resulting in the continuous flow of hot electrons generated by the catalytic reaction.

Schematics of the Pt/TiO₂ and Pt/GaN nanodiode configurations that use surface catalyzed reactions to generate steady state current are shown in Figs. 22a and 22b, respectively⁹⁴. In the first case, the bottom electrode, including a 50 nm adhesion layer of Cr or Ti and a 150 nm Au layer, was deposited through the first mask onto an oxidized p-type Si (100) wafer under 1×10^{-6} Torr pressure by an electron beam evaporator. Then, 50 nm of Ti was then deposited on the top of the bottom electrode to form the Ohmic contact

between the bottom electrode and TiO₂ film. Next, a 150 nm TiO₂ film was deposited by sputtering through a third mask. A strip of 150 nm thick silicon nitride was then deposited through a fourth mask by plasma enhanced chemical vapor deposition (PECVD) at room temperature. Platinum of 2 mm in diameter with a thickness between 1 and 15 nm was then e-beam evaporated through a fifth mask onto the TiO₂. Finally, the front gold electrode was e-beam deposited through the sixth mask onto the silicon nitride and the platinum to complete the diode circuit. Pt/GaN Schottky diode was fabricated through a standard microfabrication method. Platinum with a thickness of several nanometers was deposited through the mask on n-type GaN epitaxial layer grown on a sapphire substrate. A Schottky barrier is formed at the interface of Pt/GaN. Ti/Al layers were deposited on GaN to make the Ohmic contact between the GaN layer and the Schottky electrode. A quartz thickness monitor was used to monitor the film thickness during the deposition. The thickness of platinum films has been calibrated with profilometry and atomic force microscopy (AFM).

Figure 23 shows the TOF and chemicurrent detected on Pt/TiO₂ nanodiodes under CO oxidation conditions. The measurement of continuous chemicurrent indicated that chemical energy of exothermic catalytic reaction was directly converted into hot electron flux in the catalytic nanodiodes⁸⁵. The chemicurrent was well correlated with the turnover rate of CO oxidation separately measured by gas chromatography.

Hot electron generation from photon absorption on metallic film collected with metal-semiconductor Schottky diode

The concept of photon energy conversion to hot electron flow was suggested by McFarland and Tang⁹⁵. In this scheme, photons are harvested by dye molecules adsorbed on a Schottky diode composed of a thin gold layer on titanium dioxide (TiO₂). When light falls on the dye layer, electrons are released from the dye molecules and injected into the conduction band of the metal layer. The disadvantage of this scheme is the ineffectiveness of the adsorbed dye molecules in producing photocurrents. One reason for this is that electrons injected by the dye layer into the metal can be immediately

recaptured through reverse charge transfer from filled electronic states of the metal into the dye, resulting in no net current flow.

By using metal-semiconductor Schottky diode, steady-state current from the continuous flow of ballistic charge carriers was measured that is generated by absorption of photons. The scheme and the energy band diagram of the photovoltaic device are also described in Figure 21a and 21b, respectively. To generate electric current through the device, these electrons need enough energy to travel over the Schottky barrier and into the TiO₂ conduction band.

The short-circuit photocurrent was measured as a function of the wavelength of light on the metal-semiconductor Schottky diodes. Figure 24 shows the plot of the short-circuit photocurrent as a function of photon energy measured on a Pt/TiO₂ diode with metal film thickness of 5 nm. Photocurrent increases with increasing photon energy. In order to verify the relation between the hot electron flux and the photon energy, we fit the photocurrent to Fowler's law^{96,97}. According to Fowler's law, the photoelectric current I is

$$I = c (h\nu - \phi)^n$$

where c is a constant, ϕ is the work function of the sample, and $h\nu$ is the photon energy. For most metals, $n = 2$; other exponents apply to semiconductors. Figure 24 also shows the fit of photocurrent to Fowler's law with the fitting parameter of $n=2$ and ϕ (in our case, E_{SB} , the Schottky barrier height) of 1.2 eV. The fitting result shows that the measured photocurrent is in good agreement with Fowler's law. This result confirms that the measured photocurrent is mainly attributed to the hot electron flow, assuming that the contribution by defect states localized in the bandgap of TiO₂ is ignorable. At high photon energy (> 3.2 eV), the photocurrent increases significantly, showing a departure from the Fowler's law fit, indicating the additional contribution of electron-hole pair excitation in titanium oxide. This result indicates that the steady-state flow of hot electrons generated from photon absorption can be directly probed with metal-semiconductor Schottky diodes.

IV.b. Heterogeneous Photocatalysts for the Splitting of Carbon Dioxide and Water

All-inorganic heterogeneous photocatalysts for the synthesis of methanol or other low alcohols from carbon dioxide and water as starting materials is an attractive approach for making a renewable liquid fuel by sunlight. The principal advantage of inorganic materials, especially oxides is robustness, a critical factor for developing viable solar fuel generators. In fact, early demonstration of UV light-induced splitting of water to H₂ and O₂^{98,99} involved stable oxides, such as TiO₂ or SrTiO₃. Very efficient and robust photocatalysts for overall water splitting by UV light based on metal oxides have been developed in recent years^{100,101}. These include a La substituted tantalate with a NiO co-catalyst exhibiting a quantum yield of 56%¹⁰². By contrast, visible light-driven overall water splitting with inorganic semiconductor materials remains a challenge. A successful photocatalytic material is GaN:ZnO solid solution, but efficiencies remain low¹⁰³. GaInP₂ material serves as H₂ evolution photocatalyst of an integrated photovoltaic-photoelectrochemical cell for overall water splitting that operates at high efficiency, but the materials lack chemical stability¹⁰⁴.

For CO₂ reduction by H₂O, early work with stable large bandgap oxides including TiO₂ and SrTiO₃ showed conversion to formic acid, carbon monoxide, methanol or methane under UV irradiation^{105,106}. Reduction of CO₂ is initiated by transfer of photogenerated conduction band electrons to surface-adsorbed CO₂ or carbonate, while valence band holes drive oxidation of H₂O. Although product yields were low and the materials lack the visible absorption properties needed for use of sunlight, the work showed that activation of CO₂ and H₂O by bandgap excitation is feasible. Over the ensuing decades, efforts by the heterogeneous photocatalysis community focused on exploring smaller bandgap semiconductors for carbon dioxide activation by visible light. Particles or colloids with better donor ligands such as CdS or ZnSe afford CO₂ reduction under visible light but are chemically unstable, requiring sacrificial reductants to suppress irreversible oxidation of the material¹⁰⁷⁻¹⁰⁹. The need for sacrificial reagents prevents the use of these materials for artificial photosynthesis.

Binuclear Photocatalysts on Nanoporous Silica Supports for CO₂ Splitting

With the emergence of nanoporous silica in 1990^{110,111}, materials became available for developing well-defined photocatalytic sites for CO₂ and H₂O activation on nanostructured high surface area supports by functionalizing pore walls with single metal centers, heterobinuclear sites or well defined polynuclear clusters. For example, substantially improved conversion efficiencies were reported upon UV excitation of single tetrahedral Ti centers in mesoporous silica material type MCM-41 for CO₂ reduction by H₂O to methanol or methane, when compared with dense phase TiO₂ particles¹¹² (MCM-41 has a 1-dimensional system of channels of 3 nm diameter¹¹⁰). In-situ FT-IR and mass spectrometric monitoring of the photochemistry in the silica pores revealed CO and O₂ as initial products and confirmed that H₂O acts as electron donor¹¹³. Binuclear units consisting of metals with appropriate redox potentials for driving CO₂ reduction or H₂O oxidation catalysis assembled on silica nanopore surfaces open up opportunities to use visible instead of UV light for activating these molecules. In such a unit, e.g. TiOCu(I), visible light activates the metal centers by electron transfer from the donor center (Cu(I)) to the acceptor (Ti(IV)). As shown in Fig. 25, the Ti(IV)OCu(I) → Ti(III)OCu(II) metal-to-metal charge-transfer (MMCT) chromophore gives rise to a broad absorption band extending across the visible spectrum to 600 nm¹¹⁴. Infrared spectroscopy reveals bond modes of the covalently anchored binuclear site, and X-ray absorption measurements give insight into the coordination geometry of the metal centers (Fig. 25).

When exciting the Zr(IV)OCu(I) → Zr(III)OCu(II) MMCT chromophore of the related ZrOCu(I) site in mesoporous silica MCM-41 loaded with 1 atm of gaseous carbon dioxide, splitting of CO₂ to CO (2148 cm⁻¹) and H₂O as coproduct (1600 cm⁻¹) was observed at room temperature, as shown in Fig. 26¹¹⁵. Simultaneous depletion of the Cu(I)O infrared mode of the ZrOCu group at 643 cm⁻¹ and growth of a Cu(II)O band at 540 cm⁻¹ confirmed stoichiometric oxidation of the Cu donor center in this half reaction. Isotope labeling of the carbon dioxide molecule confirmed that CO and H₂O are formed

by splitting of the carbon dioxide molecule upon capture of an electron from transient Zr(III). This is the first observation of CO₂ photoreduction at an all-inorganic binuclear redox site. Light-driven generation of CO from CO₂ is the most critical step of the 6-electron reduction to a low alcohol product.

Polynuclear Photocatalysts for Water Oxidation with Visible Light

Reduction of CO₂ or oxidation of H₂O molecules are multi-electron transfer processes. A general approach (and one used by Nature) for accomplishing visible light-driven multi-electron transfer catalysis is coupling of a single photon, single electron pump to a multi-electron catalyst for sequential extraction (donation) of electrons to/from the catalyst. Nanoporous silica supports provide a synthetically flexible environment for assembling robust all-inorganic photocatalysts consisting of a heterobinuclear MMCT chromophore coupled to a metal oxide nanocluster catalyst. An example is a water oxidation photocatalyst consisting of a TiOCr(III) MMCT chromophore coupled to an IrO₂ nanocluster, shown in Fig. 27^{116,117}. The unit was synthesized on silica nanopore surfaces by sequential redox coupling steps, each highly selective¹¹⁶. Optical and EXAFS (extended X-ray fine structure) measurements shown in Figure 27 confirm the broad visible absorption and the oxo-bridged structure of the chromophore. The IrO₂ catalyst clusters were directly observed inside the MCM-41 channels by high resolution Z-contrast TEM imaging coupled with energy dispersive X-ray spot analysis (Fig. 27). Ir oxide was selected as oxygen-evolving catalyst because of its high efficiency established previously by use as anode coating in electrochemical cells, and from chemical oxidation experiments with IrO₂ colloids^{118,119}.

When shining visible light on an aqueous suspension of MCM-41 particles containing TiOCr-IrO₂ photocatalyst units (pH 5.7, 295 K), O₂ evolution was readily detected by an oxygen-selective Clark electrode, and a quantum efficiency of 13% (lower limit) was derived from the measurements¹¹⁶ (Figure 28(a)). At the same time, in situ FT-Raman and EPR spectroscopy revealed the formation of superoxide species in the solution, and use of H₂¹⁸O directly confirmed that water was the source of the O₂ product

(Fig. 28(b) and (c)). While performing the half reaction required the use of an electron acceptor (persulfate, which re-oxidizes transient Ti(III) to Ti(IV)), irradiation of the photocatalyst in the absence of persulfate showed accumulation of Ti(III) based on EPR spectroscopic measurements (Fig. 28(d)). This observation implies that electron transfer from the IrO₂ nanocluster catalyst to the transient Cr(IV) donor center is competitive with back electron transfer from Ti(III) even in the absence of an electron acceptor. The result indicates efficient electronic coupling of the catalyst with the binuclear chromophore, which is responsible for the good reaction quantum efficiency.

Co Oxide Clusters as Efficient Water Oxidation Catalysts

In addition to being efficient, an important property of the all-inorganic TiOCr-IrO₂ unit is its chemical stability. Yet, the photocatalyst would not be viable for large scale application because iridium is not an earth-abundant element. By contrast, oxides of metals like Co and Mn are known to exhibit catalytic activity for water oxidation when used as anode coatings in electrochemical cells¹¹⁹, or in particulate form when driven by a chemical oxidant generated either photochemically or directly added to the solution^{118,120}. The previous works suggest that these abundant metal oxides might form robust, efficient nanometer sized catalysts for water oxidation if very large surface area nanostructured forms with highly active surface metal sites can be developed.

Using wet impregnation (Co(NO₃)₂ in ethanol, 4wt% loading) followed by controlled calcination, we prepared 35 nm size Co₃O₄ clusters consisting of parallel bundles of nanorods (8 nm diameter) interconnected by short bridges inside the pores of SBA-15 silica support, shown in Fig. 29(a)-(c)³³. Close inspection of the TEM images of the clusters inside the silica scaffold and in bare form (after removal of the silica scaffold by etching) show that the nanorod bundles are perfect replica of the SBA-15 mesopore structure. XRD and EXAFS spectra confirmed the spinel structure of the Co oxide catalysts (Fig. 29(d)). Suspension of the SBA-15 particles containing Co₃O₄ clusters in aqueous solution (pH 5.8, room temperature) and driving the catalysts by visible light-generated Ru⁺³(bpy)₃ species (a standard technique for comparing efficiencies of various water oxidation catalysts) resulted in rapid evolution of O₂ in the headspace of the

aqueous solution as monitored by mass spectroscopy. As can be seen from Figure 29 (e) and (f), oxygen generation leveled off due to consumption of the persulfate acceptor, but resumed at the initial rate after adding fresh $\text{S}_2\text{O}_8^{2-}$ acceptor. From these measurements, a turnover frequency (TOF) of 1140 s^{-1} per cluster was calculated (pH 6, overpotential 350 mV, 295 K). Taking into account the geometrical projection of the 35 nm diameter cluster onto a plane, the TOF corresponds to $1 \text{ O}_2 \text{ molecule s}^{-1}\text{nm}^{-2}$. The high rate, mild catalytic conditions, low overpotential, robustness and abundance of the material make this a promising catalyst for water oxidation in solar fuel generating systems.

Comparison of the rates of O_2 production of nanostructured catalyst clusters and micron-sized Co_3O_4 particles (Fig. 29(f)), normalized to equal weight, furnishes insight into the factors responsible for the high efficiency. The nanoclusters are 1550 times more efficient than the micron-sized particles³³. Two factors contribute to the 3 orders of magnitude higher rate of the nanoclusters: A factor of 96 is due to the much larger surface area of the nanostructured cluster, with the additional factor of 16 attributed to the higher activity of Co sites on the steeply curved nanorod surface.

While we focus here on multi-electron catalysts in the form of Co oxide nanoclusters, there are other interesting recent developments in the field of all-inorganic water oxidation catalysts: Electrodeposits on anodes generated from Co phosphate solution were discovered to form a durable oxygen-evolving electrocatalyst that operates under mild conditions¹²¹. Polyoxometallates are emerging as another form of robust, all-inorganic catalyst for water oxidation^{122,123}.

Closing the Photocatalytic Cycle

A crucial property of photocatalytic units made of a binuclear charge-transfer chromophore coupled to a multi-electron catalyst is the flexibility in selecting donor and acceptor metal center and oxidation state. The synthetic techniques for assembling the oxo-bridged units afford selection from a variety of abundant first row metals such as Cr(III), Mn(II), Co(II), Ce(III)^{114,124,125}, which allows us to match the redox potential of the donor centers with the potential of catalysts driving water oxidation. This is essential for maximizing the fraction of the photon energy converted to chemical energy of the

products, a persistent challenge in the development of efficient photocatalysts for artificial photosynthesis. The ability to carefully select the redox potential of donor and acceptor center of an MMCT chromophore is equally important for closing the photocatalytic cycle by driving the CO₂ reduction with electrons generated by the water oxidation reaction. In order to accomplish directional electron transport from the water oxidation site to the CO₂ reduction photocatalyst with minimum loss of energy, the redox potentials of the two photocatalytic sites need again to be carefully matched. The selective methods for assembling binuclear chromophores and metal oxide nanocluster catalysts in silica nanopores offer a new approach for addressing this long standing challenge.

V. Conclusion and future perspective

The development of techniques that use photons and electrons that are uniquely surface sensitive enabled researchers to determine surface composition, atomic and molecular structures, electronic structures, charge states, and reaction dynamics at surfaces in vacuum and buried interfaces, solid-gas, solid-liquid, solid-solid, and liquid-liquid interfaces.

The rapid evolution of nanosciences made possible the synthesis of monodispersed nanoparticles with controlled size, shape and composition. Catalysts are nanoparticles in the 1-10 nm size range and reaction selectivity could be achieved by synthetic control of the molecular factors that influence reaction dynamics. This provides the foundation of green chemistry, the production of one desired molecule as fuel or chemical while suppressing the formation of other thermodynamically possible molecules that would be waste byproducts.

Biointerfaces that form when implants inserted in the human body must be biocompatible to function properly and this requirement guides the rapid advancements in the understanding of adsorption processes in this application of surface science. Renewable energy conversion is the challenge of the 21st century. Nanomaterials provide means to convert heat liberated in exothermic reactions or by absorption of light to

electron flow. The photo-splitting of water to H₂ and O₂ and photosplitting of CO₂ to CO and O₂ are important directions of research. CO₂ reduction with electrons generated by water oxidation would close the photocatalytic cycle and research is focused on using chemically stable inorganic catalysts.

As the techniques of molecular surface science become increasingly diverse and available, many other applications of surfaces and interfaces can be explored on the atomic and molecular scale. In addition to nanocatalysts, biointerfaces and renewable energy conversion that are the focus of this Perspective, electrochemistry, corrosion, tribology and colloids come to mind. As the surface techniques achieve improved time resolution, spatial resolution and energy resolution, new surface phenomena will be discovered. There are exciting opportunities to develop new science at surfaces and interfaces.

Figure 1.

Surface Science Techniques for Molecular-Level Studies
Surface Composition: Auger electron spectroscopy, X-ray photoelectron spectroscopy, Secondary ion mass spectrometry, Ion scattering spectroscopy
Surface structure: Low-energy electron diffraction, Transmission electron microscopy, Atom diffraction, Atomic force microscopy, Scanning tunneling microscopy, Surface X-ray diffraction, X-ray absorption fine structure
Surface electronic structure: Second harmonic generation, Ultraviolet photoelectron spectroscopy, X-ray emission spectroscopy, Scanning tunneling spectroscopy
Surface vibration and reaction dynamics: Electron energy loss spectroscopy, Helium atom scattering, IR spectroscopy, Raman spectroscopy, Sum-frequency generation spectroscopy, Molecular beam surface scattering
Surface thermodynamics: Microcalorimetry, adsorption/desorption

Figure 2.

Figure 3.

(a) Soft Contact Lens

Soft contact lens:
crosslinked pHEMA

$$\left[\begin{array}{c} \text{CH}_3 \\ | \\ \text{CH}_2 - \text{C} \\ | \\ \text{C=O} \\ | \\ \text{O} \\ | \\ \text{C}_2\text{H}_4\text{OH} \end{array} \right]_n$$

In water, it swells and forms a hydrogel.

pHEMA = poly(2-hydroxyethyl methacrylate)

(b)

(c) Polyurethane Under Reversible Loading (Fatigue Test)

3.2 billion heart valve loading cycles in ~80 years of normal heart function.
