Production of Positive Mesons by Photons on Hydrogen

A. S. Bishop, J. Steinberger, and Leslie J. Cook

Radiation Laboratory, Department of Physics
University of California, Berkeley, California

June 26, 1950

A short time ago we reported some features of the production of mesons on carbon and hydrogen by photons.⁽¹⁾ The hydrogen cross sections had been obtained by a paraffin-carbon subtraction. The experiment has been repeated, using the same counting technique, but liquid hydrogen as a target. The new data have better energy resolution and statistical accuracy.

The reaction is $\gamma + p \rightarrow \pi^+ + n$. The photons are produced in the Berkeley synchrotron with a bremsstrahlung spectrum of 330 Mev maximum energy. In the experiment, both meson range and angle of production with respect to the beam are measured. The energy of the meson is computed by means of the range energy relation, and that of the responsible photon by the conservation laws. It is possible, therefore, to measure cross sections as a function of photon energy, despite the continuous character of the x-ray spectrum.

Fig. 1 shows the energy spectrum of mesons produced at 90° to the beam direction, as well as the number of photons as a function of the energy of the mesons which they produce. The x-ray spectrum is the theoretical bremsstrahlung spectrum⁽²⁾ corrected for:

(a) thickness of target producing the x-rays,

(1) J. Steinberger and A. S. Bishop, Phys. Rev. 78, 494 (1950)

(2) This spectrum has been checked and shown to be correct within the accuracy of their experiment by Walter Hartsough, Milton Hill, and Wilson M. Powell; Phys. Rev. (in press)

(b) variation of electron energy due to variations in the magnetic field of the synchrotron during the 2×10^{-3} sec. period of x-ray emission,

(c) angular resolution of the meson production angle. (3)

Dividing the meson spectrum by the photon spectrum, one obtains the cross section for meson production at 90° in the laboratory system as a function of photon energy (Fig. 2). One source of error is the nuclear absorption of the mesons, which discriminates against the higher energy mesons. It is improbable that the nuclear absorption proceeds with larger cross section than nuclear area. To show the upper limit of this effect, we include in Fig. 2 the excitation function, revised on the basis that the nuclear absorption cross section is equal to the nuclear area. (4)

The angular distribution of mesons produced by 250 Mev photons is shown in Fig. 3 together with the older results. (1) Since no attempt has yet been made to obtain an accurate absolute cross section, the results from the two experiments were normalized in absolute magnitude to give the best fit. As has already been pointed out, the angular distribution shows clearly that photo-meson production is not a dipole photo effect, as predicted by scalar meson theory, but that the interaction of the nuclear spin with the photon must play an important role.

A full account of these experiments, together with a discussion of their theoretical significance, is being prepared.

(3) Since the meson production angle enters into the correspondence between photon and meson energies, any lack of angular resolution will result in a dispersion in the photon energy in this analysis.

(4) The cross section for producing nuclear events at high meson energies is approximately equal to the nuclear area, according to the experiments of U. Camerini, P. H. Fowler, W. O. Lock, and H. Muirhead, Phil. Mag. 41, 413 (1950)

We are indebted to Dr. V. Z. Peterson for the use of his hydrogen target in the angular distribution measurements, and to Professor E. M. McMillan for stimulating discussions about this work. The bombardments were carried out by the synchrotron crew under the direction of W. Gibbins and G. McFarland.

This work was performed under the auspices of the Atomic Energy Commission.
