ORNL ISOTOPIC POWER FUELS QUARTERLY REPORT
FOR PERIOD ENDING JUNE 30, 1972

Eugene Lamb and R. G. Donnelly

SUMMARY

Preparation for cutting samples from the tungsten fuel block of the Kilowatt Heat Source for metallographic examination are underway. Installation of test facilities for studies of helium release and identification of other volatile species released from vented fuel forms in a high-temperature, high-vacuum environment container is 50% completed.

A large batch of Gd_2O_3 microparticles was prepared for use in making an experimental Ir-Gd $_2O_3$ cermet. Tests to determine the effect of alpha damage on the helium permeation of metals were initiated. Curium oxide powder was placed in contact with an aluminum foil thinner than the range of alpha particles in the aluminum. No detectable amount of helium permeation was observed after 4 weeks of alpha irradiation. The x-ray diffraction study of the fuel sample from the Curium Source Test showed that the fuel was $^{244}Cm_2O_3$, but due to high radiation levels from the ^{244}Cm no conclusion as to impurities or concentration could be made. The preliminary design of a process for separating curium from fission products has been completed. The process consists mainly of removing the lanthanide-actinide fraction by solvent extraction in a differential extraction system.

The laser beam velocity measurement system has been installed and tested with the impact gun. Repeatability of the impact gun is excellent. The impact gun has been calibrated so that specimens can be impacted at any desired velocity.

Variable mechanical properties obtained on Pt-Rh-W sheet were traced to tungsten segregation and/or surface defects. Inspection and processing changes have been instituted to overcome these problems. Annealing temperatures have been determined for optimum formability, and mechanical properties are shown to be nondirectional in finished sheet. Property improvement is indicated in material with the rhodium content increased from 26 to 30% while the tungsten content is maintained at 8%.

The mechanical properties of iridium sheet were determined as a function of temperature. No sharp ductile-to-brittle

transition temperature was observed. The effects of a simulated reentry heat pulse on the mechanical properties of iridium were also determined.

TZM was found to be incompatible with low-pressure oxygen at 1000°C. Reduced ductility is also observed in TZM exposed to CO at 1000°C. Compatibility testing of a wide variety of nonfuel materials couples has been completed and examined in support of the DART program.

CURIUM-244 FUEL DEVELOPMENT

(Division of Space Nuclear Systems Program 04 30 05 03)

Curium-244 Oxide Fuel Development and Properties

Heat Capacity of $^{244}\text{Cm}_2\text{O}_3$

Various tools necessary to handle the $^{244}\text{Cm}_2\text{O}_3$ heat capacity sample were made, and a trial run for loading the sample into the experimental apparatus was successfully carried out.

Kilowatt Heat Source Examination

Preparation for the metallurgical examination of samples cut from the tungsten fuel block was begun. The first step, involving the opening of the container in which the fuel block was stored, was initiated. The second step will be the removal of the major quantity of $^{244}\text{Cm}_2\text{O}_3$ from the fuel channels. The third step will include sectioning of the fuel block and metallographic inspection of selected specimens in HRLEL.

Vented Capsule Fuel Form Study

Installation of a high-temperature, high-vacuum furnace for testing fuel forms in vented capsules is 50% completed. The test is to simulate and study the effects of space-like conditions on the fuel form of a prototype vented capsule. The helium release characteristics of the fuel form will be determined, and the residual atmosphere in the furnace and the possible vapor species from the fuel form will be measured. Following the exposures at temperature, the specimens will be sectioned and examined for compatibility effects. The test facility enclosed in a shielded alpha glove-manipulator cell consists of a Brew-type furnace, a turbomolecular pump, and a quadrupole mass spectrometer for analyses of gaseous and vapor species.

Preparation of Sized $^{244}\text{Cm}_2\text{O}_3$ Particles

A large batch of Gd_2O_3 microparticles was prepared for use in making an experimental Ir- Gd_2O_3 cermet. The preparation of this material used the available resin. More of the same brand and type was obtained; however,

it behaves differently and leads to the frequent fracturing of particles. The two resins which had been previously used successfully were Rexyn 102H and IRC-72. In a recently purchased batch of Rexyn 102H the particles differed appreciably from the old resin in physical form and in ion-exchange capacity. Tests with the resin were abandoned. A new batch of IRC-72 was the same in appearance and in nominal capacity; however, many of the beads were observed to break in both the loading and the carbonization steps. This difficulty had not been encountered in earlier tests with certain exceptions. The beads of a batch of very highly bonded material had been badly broken and beads which had been initially in the NH_4^+ form tended to break during carbonization. It also had been found that the presence of oxygen during carbonization caused all types of beads to break.

The breaking of beads during loading was eliminated by a change in procedure to eliminate agitation during loading. A loading apparatus was developed which operates on the principle of the coffee percolator in which the solution percolates through a bed of the resin.

Work continued on the adaptation of the resin process to hot-cell operation by defining the heating cycle required to minimize particle breakage and optimize sintering. Equipment for hot-cell preparation of $^{244}\text{Cm}_2\text{O}_3$ particles has been fabricated.

Helium Release from Cermets

Tests to determine the effect of alpha damage on the helium permeation of metals were initiated.¹ Curium oxide powder was placed in contact with an aluminum foil of thickness less than the range of alpha particles in the aluminum. A pressure of helium of 17 lb/in.² was put on the aluminum foil while the opposite side of the foil was connected to a mass spectrometer to determine helium permeation of the foil. After four weeks of alpha irradiation, no detectable amount of helium permeation was observed. An annealed platinum foil, 8.3 μm thick, is being tested, but no results are available.

Cermet Test Program

Strength deterioration and reduced helium permeability of $^{244}\text{Cm}_2\text{O}_3$ -bearing cermets upon aging are of particular concern to the development of an isotopic power fuel form. We are investigating these effects in Mo-ThO₂ compacts.¹

Aging of Mo-ThO₂ specimens for 1000 hr at 1200 and 1500°C and $<10^{-5}$ torr was completed. All aged specimens appeared to be in excellent condition. Specimens hot-pressed at 1200°C showed a slight increase in density from a corresponding reduction in physical dimensions. The aging treatments produce little, if any, significant change in specimens hot-pressed at 1450 and 1700°C. Due to a change in programmatic priorities no further evaluation of these specimens is planned.

Metallography of Curium Source Test Fuel

The x-ray diffraction study of the fuel sample from the Curium Source Test was terminated. The study showed that the fuel was $^{244}\text{Cm}_2\text{O}_3$. Due to high radiation levels from the ^{244}Cm no conclusion as to impurities or concentration could be made.

Recovery of Curium-244 from Fuel Reprocessing Waste

The preliminary design of a process for separating curium from fission products has been completed. The process consists essentially of the removal of a lanthanide-actinide fraction from the mixed fission products by solvent extraction using the differential extraction process. This is followed by the separation of the curium from the lanthanides and other actinides by a chromatographic ion-exchange process. The process was designed to minimize capital costs and to avoid any appreciable increase in the volume of solid wastes.

Curium Source Neutron Dose Measurement

The water shielding tank to be used in the curium neutron dose measurement experiment was completed.

Impact Testing of Heat Source Materials

Velocity Measurement System

The laser beam velocity measurement system was installed and tested with the impact gun. Some minor problems were experienced with the system being too sensitive to shock waves generated by the impact of the sabot on the wall of the catcher box. The eye of the photosensor was so small that, if the laser beam deviated only a small amount due to vibrations, the system would generate enough of a pulse to start the electronic timer. The original photosensors were replaced with ones having a larger eye which would allow the laser beam to vibrate on the eye and trigger the timer only upon total eclipse of the beam. This change eliminated the premature triggering of the timer.

Impact Gun Testing

The toggle brackets for the sabot heater electrical connections were installed in the impact gun gas chamber. Tests of the heater system indicated that 1000°C can be attained.

The impact gun sabot gripper was energized with the heater at the maximum temperature to test the system at temperature. Gas could be heard escaping around the sabot during the test, and only 150-psig gas pressure could be maintained on the system with the gas regulator wide open. The gun was disassembled, and the gripper was dimensionally inspected. A

0.006-in. permanent distortion was found in the center of the gripper indicating that the gripper and gun had expanded more than had been anticipated. A new sabot heater and gripper were designed to provide proper clearances for impact testing of pellets at 700°C. The gripper was energized with the heater at 750°C and the pressure was adjusted to 250 psig with no apparent leakage of gas.

To test the repeatability of the impact gun, five aluminum sabots were test fired. The projectile used in this test was a 1-in.-diam steel ball. Table 1 shows the excellent repeatability of the impact gun.

In order to impact specimens at any desired velocity within the range of the gun, a calibration of the gun relating firing pressure, mass, and velocity is being made. Table 2 lists the data collected to date on the firing of the impact gun using unheated sabots.

Figure 1 shows a plot of firing pressure versus kinetic energy $\times 32 \times 10^{-3}$. (To calculate kinetic energy in ft-lb, "M" must be in slugs, but direct substitution of the weight of the sabot and specimen is more convenient; thus the term kinetic energy $\times 32$.) By assuming that the equation of the straight line shown in Fig. 1 has the form:

$$P = S(MV^2/2) + b \quad (1)$$

where

- P = firing pressure, psig
- M = sabot and specimen weight, lb
- V = specimen velocity, ft/sec
- S = slope of line, (lb of force sec²)/(lb of mass ft² in.²)
- b = intercept of line, psig

then by the classical slope-intercept method, the equation of the impact testing gun was found to be

$$P = (1.464 \times 10^{-3})MV^2 \quad (2)$$

Equation (2) has been found to be very reliable in setting the firing pressure for a desired velocity, given the weight of the sabot and specimen. A nomograph (Fig. 2) was constructed using Eq. (2) written in the form

$$\text{Log } P = \text{Log } M + 2 \text{ Log } V - 2.83446 \quad (3)$$

The data used to derive Eq. (2) were from tests in which the impacted specimen and sabot were not heated. Further tests will be made to determine if the equation holds true for impacts with heated specimens.

A 3/4-in.-diam gadolinium sesquioxide (Gd₂O₃) sphere was heated to 750°C and impacted on a granite block. The sabot and specimen weight was 532.8 g, and the sabot was fired at 125 psig. A high-speed movie was

CLADDING MATERIALS PROGRAM

(Division of Space Nuclear Systems Program 04 30 05 04)

Characterization of Pt-Rh-W Alloys

J. H. Erwin and H. Inouye
Metals and Ceramics Division

Previously we reported that the 0.030 × 8-1/2 × 11-in. sheet prepared from a 4-lb ingot (Heat Pt-1D, nominal composition Pt-26% Rh-8% W) was shown by eddy current inspection to contain isolated areas of tungsten segregation.¹ Metallographic examination of the cross section of an area indicating maximum segregation showed up as a 0.0005-in.-wide tungsten stringer extending the length of the specimen. To further evaluate the nondestructive results, tensile specimens were blanked from the sheet so that the indicated areas of segregation were in the gage section. Table 3 shows that the strength and ductility of specimens showing segregation were generally lower than the homogeneous specimens. The lack of a better correlation is attributed to missing the segregated areas which were as small as 1/16 in. in diameter. We conclude from these results that the eddy current method is a reliable quality-control technique for detecting tungsten segregation.

The effect of annealing temperature and the directional properties of the homogeneous portions of sheet Pt-1D are shown in Table 4. The specimens show the characteristic decrease in strength and increase in ductility with increasing annealing temperature. No significant directional properties are evident. This may be due to the cross rolling during warm reduction at 1000°C.

Table 3. Correlation Between Nondestructive Testing Inspection and Room-Temperature Tensile Properties^a of Pt-26% Rh-8% W (Heat Pt-1D)

Annealed 1 hr at 1300°C	81,200	45,200	9.4

^aStrain rate is 0.05 in./in./min.

Using hydrogen-annealed powder instead of arc-melted and crushed tungsten and a modified melting procedure,¹ an additional 4-lb ingot of Pt-26% Rh-8% W (Heat Pt-1ER) was cast and successfully rolled to 0.030-in.-thick sheet using the same fabrication procedures previously used. Eddy current inspection of this sheet showed no indication of tungsten segregation. To date the formability of this sheet, as determined by a modified Olsen cup test, is shown in Table 5. The results are compared with blanks taken from the homogeneous areas of Heat Pt-1D. The cup height as a function of the heat treatment shows no appreciable difference between the two heats and a peak in the formability of specimens annealed between 990 and 1000°C. According to our previous studies, a 1-hr anneal at this temperature is just at or below the recrystallization temperature.

Table 5. Results of Annealing 1 Hr at Various Temperatures on the Cup Height Obtained on 0.030-in.-thick Pt-26% Rh-8% W Alloy Sheet in a Modified Olsen Cup Test

Heat Treatment Temperature (°C)	Cup Height (in.)	
	Pt-1D ^a	Pt-1ER ^b
900	0.305	0.287
950	0.307	0.309
990	Not tested	0.467
1000	0.464	0.427
1050	0.278	0.257
1100	0.270	0.387
1200	0.241	0.257
1300	0.264	0.261

^aSheet contained segregated areas of tungsten, but not in areas of sample blanks.

^bSheet showed no segregation.

Bend test results of similarly heat-treated samples from the two sheets are summarized in Table 6. The bend test is the standard 2T test described in *Evaluation Test Methods for Refractory Metal Sheet Specimens*, MAB-176M (1961). In this respect, these data verify the 1000 to 1100°C temperature range indicated by the tensile and cup tests as optimum heat treatment for the 21% cold-rolled alloy. The calculated elongation and bend strength are 25 to 50% higher than the values obtained from tensile tests. This is perhaps due to differences in sample geometry and calculation methods. Duplicate samples for a given heat treatment showed occasional wide differences in the bend angle to failure. Examination of the fractures reveal grain boundary separation in the less ductile samples. We associated the grain boundary fracture with tungsten segregation from previous experience with the Pt-1D sheet; however, examination of samples by metallography has not revealed any differences in grain boundaries of the samples.

The tensile properties of Pt-26% Rh-8% W (heat Pt-1ER) specimens taken from an 0.030 × 12 × 12-in. sheet are shown in Table 7. These data show consistent and nondirectional properties for a given heat treatment. The ductility increases uniformly with temperature from approximately 11% at room temperature to approximately 50% at 1316°C. On the other hand, the reduction in area is seen to increase abruptly from approximately 6% at room temperature to 100% at and above 760°C. Table 8 shows that the calculated impact capabilities at 1316°C of the alloy [defined as 0.5(UTS + YS) × fracture strain] increase somewhat with the strain rate by virtue

of corresponding increases in the ultimate tensile and yield strength. The impact values for T-111 and iridium are 11,000 and 7,400 in.-lb/in.³, respectively. The superior impact values of the platinum alloy arise from the fact that the yield strength is about 86% of the ultimate strength and that the fracture ductilities are also higher than T-111 or iridium.

To determine the effect of the rhodium content in Pt-Rh-W alloys, we increased the rhodium content from the previous 26% to 30% at the 8% W level. One small ingot (heat Pt-4A) was fabricated into sheet in a manner similar to previous procedure with excellent results. An Olsen cup test

on a blank heat treated for 1 hr at 990°C in vacuum produced a full 7/8-in.-diam hemisphere with only two small surface cracks. This is in contrast with failure of the Pt-26% Rh-8% W alloy (Pt-1ER) blank at a cup height of only 0.467 in. Results of the bend tests on this alloy are also given in Table 6. Samples heat treated at both 990 and 1100°C withstood a 90° 2T bend test.

The tensile properties of heat Pt-4A are shown in Table 9. At room temperature this alloy is stronger and more ductile than Pt-26% Rh-8% W; however, at 1093 and 1316°C a significant amount of scatter was observed. Because the specimens showing poor tensile properties were taken from the same side of the rolled sheet, it is suspected that contamination or segregation has occurred.

^aSpecimens annealed 1 hr at 1200°C, tested at 0.05 in./in./min.

^bSpecimens showed numerous cracks in gage length after testing.

To assess the effect of observed subsurface voids on erratic mechanical properties, the surfaces of six adjacent bend test specimens from a 0.030-in.-thick Pt-30% Rh-8% W alloy sheet (Pt-4B) were ground, heat treated, and given a 2T bend. The results are given in Table 10. No appreciable difference appears between the as-rolled samples and those polished to remove about 0.0005 in. from the surface. However, both samples that were ground to remove 0.003 in. followed by polishing the surface withstood the 2T bend test without failure. To further verify the effect of the voids, three sets of three samples each were taken from a Pt-26% Rh-8% W alloy sheet (Pt-1ER) that had previously shown inconsistent bend test results. The samples were filed and polished to remove about 0.0045 in. from the surface followed by heat treatment in air at 1000°C and in vacuum at 1000 and 1100°C. Data from these samples (Table 11) show no difference in the ductility of the vacuum heat-treated

samples. However, samples oxidized 4 hr in air at 1000°C (approximates the final hot-rolling temperature and heating time) failed at a 50° bend angle and an elongation of 10.5%.

An examination indicates that the depth of the voids reaches a maximum after a short exposure at a given temperature and that their size and perhaps number also increase with time. Pt-30% Rh-8% W (Pt-4B) and Pt-26% Rh-8% W (Pt-1ER) alloy samples oxidized 4 and 8 hr contain voids with a maximum depth of about 1 mil and an average depth of 1/4 to 1/2 mil. Pt-30% Rh-8% W (Pt-4B) samples oxidized 19 hr at 1200°C contain voids with a maximum depth of about 3 mils and an average depth of 1 mil.

To assess the weldability of 0.030-in.-thick sheet, test specimens containing transverse electron-beam welds were filed to reduce the weld bead to the thickness of the original sheet and were given a 2T bend test. Data shown in Table 12 indicate bend angle at failure, elongation, and bend strength about 75% of that expected for similar unwelded samples. Failure usually occurred in the welds.

Characterization of Iridium

C. T. Liu
Metals and Ceramics Division

Recent thermal analysis at General Electric indicates that the minimum impact temperature for the MHW heat source is about 593°C.² Since this temperature is close to the ductile-to-brittle transition temperature (DBTT) of iridium which was reported to be ~500°C,³ it is important to determine the DBTT of iridium and how it varies with thermal treatments such as might be experienced during fabrication, operation, or reentry.

For this purpose, iridium sheet specimens recrystallized 1 hr at 1500°C were tested at various temperatures. The tensile data are listed in Table 13 and show:

1. The room-temperature yield strength of recrystallized iridium is only 25,000 psi. This low value may create difficulty in handling iridium hardware with a thickness of <30 mil.
2. The elongation of iridium increases almost linearly with temperature up to 1093°C. This result suggests that, in terms of tensile elongation, there is no well-defined DBTT for iridium. The elongation remains at a constant value of ~40% above 1093°C.
3. In contrast, the reduction in area, which has a low value at low temperatures, increases significantly at temperatures above 500°C. This result is quite consistent with that reported by Douglass *et al.*³
4. The fracture surface shows a transition of fracture mode in iridium. Iridium fractured in a brittle manner (probably grain boundary separation) at and below 500°C and in a ductile manner at and above 760°C. Thus, there is a correlation between reduction in area and the fracture mode.

Table 13. Tensile Properties of Commercial Iridium
 Recrystallized 1 Hr at 1500°C^a

Testing Temperature (°C)	Tensile Strength (psi)	Yield Strength (psi)	Elongation (%)	Reduction in Area (%)	Fracture Mode

1093	35,000	16,000	39.6	>60	Ductile
1316	26,000	13,000	38	>60	Ductile

^a0.020-in. sheet, strain rate 0.05 in./in./min.

In order to produce polycrystalline iridium from zone-refined stock, a bar specimen was strained 20% at 800°C, followed by annealing at 1600°C. Preliminary results show that fine-grained iridium cannot be produced by repetition of this strain-annealing process.

To show the effect of a heat pulse as during re-entry of the MHW heat source on the tensile properties of iridium, sheet specimens were heated 5 min in vacuum after recrystallization for 1 hr at 1500°C. The tensile results obtained to date at various temperatures are presented in Table 14. Except for the one test which gives a low elongation of 6.4% at 1093°C, the data in the table indicate that both tensile strength and ductility are insensitive to the heat-pulse treatment, although the yield strength is considerably lower than the as-recrystallized data shown in Table 13. A plot of elongation as a function of temperature shows no well-defined ductile-to-brittle transition temperature in iridium.

PHYSICAL METALLURGY OF REFRACTORY ALLOYS

(Division of Reactor Development and Technology Program 04 40 02 05 1)

C. T. Liu
Metals and Ceramics Division

Effect of Oxygen Contamination on the Mechanical Properties of Molybdenum-Base Alloys

Previous work indicates that TZM is compatible with low-pressure oxygen and CO at 825°C (Pioneer operation temperature). In order to further evaluate TZM for space isotopic heat sources at higher temperatures, a series of sheet specimens was doped with oxygen at 1×10^{-5} torr oxygen pressure and at 1000°C for different periods of time. Table 15 summarizes the tensile results obtained at room and elevated temperatures. TZM shows

a sharp increase of yield strength with doping time. The yield strength at 825°C increases by a factor of 3 after 207 hr of exposure. Comparatively, the tensile strength is less sensitive to the oxygen contamination. The ductility decreases sharply with doping time, and TZM is completely brittle at all temperatures within a 200-hr exposure. Like oxygen-contaminated T-111, an increase in the testing temperature does not significantly improve the ductility. Note that TZM, like T-111, is also less sensitive to the oxygen contamination when tested at 825°C. Based on the data in the table, we conclude that TZM is not compatible with low-pressure oxygen at 1000°C.

Effect of Carbon Monoxide Contamination on the Mechanical Properties of Molybdenum-Base Alloys

TZM specimens were exposed to 1×10^{-5} torr CO at 1000°C for different periods of time to determine in simulation its compatibility with gases outgassed from graphite and Min-K 1301. The results of tensile tests are presented in Table 16. The tensile strength shows a general increase

with doping time. The ductility at room temperature drops sharply between 240- and 500-hr exposures at 1000°C but remains constant at a value of approximately 30% at 1316°C. As shown in Table 16, the ductility after 1000 hr of exposure is a maximum at 825°C. TZM doped with CO behaves quite differently from that doped in oxygen. Complete characterization requires more data.

MATERIALS COMPATIBILITY TESTING FOR THE LASL-DART PROJECT

*J. R. DiStefano and A. C. Schaffhauser
Metals and Ceramics Division*

Compatibility couples involving several non-fuel materials being considered in constructing the DART were examined after 500 hr at 1300, 1400, and 1500°C, and the data are summarized in Tables 17-19. Only the couples tested at 1400°C were examined in detail.

From the data it would appear that graphite is very compatible with BeO, W, Re, and Pt-Rh-W up to 1500°C. In cases where tungsten and rhenium cracked, it did not appear to be the result of interaction with the graphite and probably occurred during cutting and/or mounting.

All three oxides, ZrO₂, HfO₂, and BeO, showed good compatibility with the metals they were tested against. Visual observation indicated some discoloration of both ZrO₂ and HfO₂, and relatively large weight losses were noted in both those oxides. Beryllium oxide showed little tendency to interact even in the 1500°C tests that were examined. However, a rather serious mass transfer effect was found in the closed tungsten capsule that contained BeO. The tungsten showed rather large weight losses and had an etched appearance indicative of dissolution. Since this was not observed in the couple that was tested in dynamic vacuum, it seems likely that oxygen was involved in the process. One possible type of reaction is

The source of oxygen is the BeO, and for vapor transport to occur, the reverse reaction must take place somewhere in the system. The driving force for the reverse reaction is difficult to postulate. An activity gradient could occur from a temperature gradient, pressure change, or energy change as a result of geometrical considerations. For a closed system of the type we have, it is hard to identify the reason for such an energy gradient to occur. However, we previously found the same type of thing when we exposed tungsten to Cm₂O₃.⁴
