MASS SPECTROMETRIC INVESTIGATION OF LASER-INDUCED
VAPORIZATION OF BINARY SOLID COMPOUNDS

Robert Allan Olstad

University of California, Berkeley, California

ABSTRACT

The laser-induced vaporization of iron and of a binary solid compound, zirconium hydride, was studied using a quadrupole mass spectrometer. A Q-switch ruby laser with pulse width of 80 nanoseconds was used to heat zirconium hydride samples under high vacuum to temperatures up to 2500°C. The mass spectrometer ionizer was located in a line-of-sight path 40 cm from the target. By an analysis of the measured mass spectrometer signals, the rate of vaporization of hydrogen during the rapid temperature transient could be determined.

Application of an equilibrium model to the vaporization process predicts that predominantly H_2 (rather than H-atoms) should be emitted. The vaporized H_2 should have a Maxwellian velocity distribution characteristic of the instantaneous surface temperature, and the rate of vaporization should be related to the H_2 vapor pressure by the Langmuir equation. Since the H_2 vapor pressure is a function of both surface temperature and surface hydrogen concentration, it was necessary to solve simultaneously the time-dependent heat conduction and hydrogen diffusion equations in the heated zirconium hydride in order to predict the vaporization rates.

It was found that H-atom and H_2 molecules were emitted at thermal equilibrium with the surface. At low laser power density, the magnitude of the H_2 signals agreed with the equilibrium model. At high laser

power density, the magnitude of the H_2 signals was less than predicted, possibly because of a diffusion barrier at the surface. The H-atom signals were much larger than predicted, indicating that they were produced by a non-equilibrium surface process.

Conventional mode laser pulses (1 msec duration) were used to vaporize iron samples. The measured mass spectrometer signals were in agreement with equilibrium calculations if the flow of molten iron was taken into account.

I. HISTORY OF LASER SOLID INTERACTIONS

A. Introduction

Since the development of the laser in the early 1960's, there has been much experimental and theoretical effort to understand the interaction of laser radiation with matter. The interaction of lasers with many elements and compounds, including metals, semiconductors, insulators, and gases, have all been investigated. In discussing lasers and laser-material interactions, there are several laser parameters useful in characterizing the process:

- 1) Laser energy is the total energy contained in a laser pulse.
Laser power is the instantaneous rate of energy emitted by the laser.
- 2) Energy density and power density are the laser energy and power per unit target area respectively. Whereas energy and power are characteristic of a particular laser, the energy density and power density also depend on the spot size to which the laser is focused. Lasers can deliver high power densities to a target because the emitted radiation is coherent as well as intense. The coherence property causes the laser energy to be emitted in a slightly diverging beam which can be focused by a lens to a small spot.
- 3) Absorbed energy density and power density are the fraction of the incident energy density and power density, respectively, that are absorbed at the surface of reflectivity R , and are equal to $(1-R)$ times the incident values.

Many materials can exhibit lasing action under suitable optical pumping, but only several are of use in high power laser interactions. The solid state lasers, ruby (0.6943 micron wavelength) and neodymium-glass (1.06 micron wavelength) can obtain peak powers of $10^8 - 10^9$ watts when operated in the Q-switch mode with pulse duration 10 - 100 nanoseconds. When operated in the conventional mode, the peak powers are 10^4 to 10^5 watts for pulses of 10^{-4} to 10^{-3} sec duration. When mode-locked operation is used, pulses of picosecond duration are produced with peak power greater than 10^{12} watts.

The effects observed when laser radiation is absorbed at a metal surface, in order of increasing power density, are: (a) increase in target temperature, melting, and vaporization of neutral thermal-energy species, (b) emission of electrons and thermal ions, (c) emission of high energy ions and neutrals, and (d) formation of a highly ionized plasma in front of the target surface. The experimental results of studying these effects are reported by such quantities as total yield (number of atoms removed from the target), depth of craters produced, energy and species of the emitted particles, and apparent surface and plasma temperatures.

Among the reasons for studying these effects are: (a) desire to understand the physical principles involved in the interaction, (b) determination of material behavior under rapid thermal transients and at higher temperatures than can be maintained at steady state, (c) practical applications such as laser cutting and welding, (d) eventual possibility of obtaining plasma temperatures high enough for controlled thermonuclear fusion, and (e) possible use of lasers as weapons.

The literature on the interaction of laser radiation with matter has been extensively reviewed in two recent publications.^{1,2} The literature data generally exhibit a large amount of scatter because experimental results are very sensitive to the particular experimental conditions. Comparisons of results obtained by different investigators are often difficult to make because of uncertainties in the laser energy and power densities used.

B. Experimental Observations

1. Melting and Vaporization

The most apparent effect observed when a high power laser is focused onto a metal surface is the formation of a crater at the focal spot. The laser radiation absorbed at the metal surface can heat it to several thousand degrees Kelvin. A crater is formed because of vaporization and the removal of molten metal from the center of the interaction area by the pressure exerted by the recoiling molecules. The depth of the craters produced by conventional and Q-switch pulses on different metals was determined experimentally by Ready.³ The measured depths generally agreed with the depths calculated assuming that the surface temperature was given by the solution to the conduction equation with constant material properties. Ready's calculations^{1,3} show that for a particular energy density a high power density heats a small amount of material to high temperatures while a low power density heats a large amount of material to lower temperatures. Therefore, conventional mode pulses can melt a substantial amount of a metal target and form deep craters while Q-switch pulses form shallow craters by

vaporizing atoms from the surface at very high temperatures. Ready³ has proposed that at very high power densities, the pressure of the recoiling atoms is sufficient to prevent significant vaporization until the critical temperature is reached. Calculations and yield measurements by Varsi⁴ using focused Q-switch pulses on metals indicate that vaporization occurs at temperatures below the critical temperature and that in fact the critical temperature is seldom reached.

As discussed in Ref. 1, several studies have examined the morphology of the craters produced by lasers on metal and semiconductor surfaces. Typically, a crater produced by a conventional pulse has a raised rim because of the flow of liquid metal. Damage areas produced by Q-switch pulses show microcraters surrounding a central melt zone. An electron microscope observation of the damage area produced by low intensity laser radiation on germanium showed a structure of hillocks and etch pits.⁵

2. Electron Emission

Historically, electron emission was the first aspect of particle production from laser heated surfaces to be studied. The electrons emitted by a target under vacuum typically are drawn to a nearby collector which is at a positive potential relative to the target. An early experiment⁶ using a conventional mode pulse on carbon and tungsten showed that the electron emission coincided with the individual laser spikes. Calculations of the transient surface temperature showed that the electron currents could be attributed to thermionic emission according to the Richardson equation. In another study,⁷ it was shown that the emission of electrons from tungsten and platinum targets heated by Q-switch pulses was thermionic in origin.

As discussed in Ref. 1, several investigators have measured the emission of electrons because of a multiphoton photoelectric effect. The energies of laser photons (1.78 eV for ruby, 1.17 eV for Nd-glass) are lower than the typical work functions of metals and semiconductors (2-5 eV). If two or three laser photons are simultaneously absorbed by an electron, it can have sufficient energy to overcome the work function barrier and be emitted. This effect is small and can be observed only when the surface temperature is low enough to prevent masking the effect by thermionic emission.

3. Positive Ion Emission

The positive ions produced in a laser-surface interaction are most easily detected by the method of charge collection. In this method, the ions produced are drawn to a nearby collector which is at a negative potential relative to the target. The current pulse measured across a load resistance contains information on the total ion current produced as well as the time of flight of the ions from target to collector. If the ion mass is known, the energy of the ions can be determined from an analysis of the ion current pulse shape.^{1,6}

Mass spectrometry has often been used to detect the ions and neutrals emitted in laser-surface interactions. As discussed in Ref. 9, the types of mass spectrometers used include magnetic, time of flight (TOF), and quadrupole mass spectrometers. In order to be detected, neutrals must first be ionized, usually by an electron beam. Magnetic mass filters use a magnetic field to spatially separate ions of different mass. TOF mass spectrometers separate ions of different mass in time rather than space because of the different velocities given

the ions by an accelerating potential. Special modifications of TOF spectrometers have been made to study laser surface interactions.^{10,11} Quadrupole mass spectrometers detect ions of a selected mass which have a stable orbit in a combined RF and DC field applied to a quadrupole structure. Ions are most often detected by an electron multiplier located after the mass filter, but ion sensitive plates have also been used.

Thermionic emission of ions from laser heated metals has been observed in several studies using charge collection techniques.^{1,12} The measured ion currents are consistent with the values expected for thermionic emission of ions according to the Richardson-Smith equation. These thermionic ions were observable at sufficiently low laser power densities that no cratering of the surface occurred ($\sim 1 \times 10^5$ watts/cm² for conventional mode, $\sim 8 \times 10^7$ watts/cm² for Q-switch mode).

Several studies have used the charge collection technique to determine the energy of the ions emitted under high laser intensities. Linlor¹³ measured ions with energy as large as 1000 eV emitted from various materials irradiated by Q-switch pulses with power density $\sim 5 \times 10^9$ watts/cm². Using an electron multiplier to detect the ions emitted from a magnesium target, Isenor¹⁴ found that ion energies increased with increasing power density. Ion energies varied from 10-400 eV for power densities $\sim 10^9$ watts/cm². At very high power densities ($\sim 10^{11}$ watts/cm²) Gregg¹⁵ measured ions with energy as high as 2000 eV emitted from various materials.

A TOF spectrometer was used to study the masses and energies of ions desorbed from a tungsten surface.¹⁶ Even though relatively low Q-switch power densities were used ($2-8 \times 10^7$ watts/cm²), some ions with energy greater than 170 eV were detected. The ions observed were primarily Na⁺ and K⁺, but C⁺, H₂O⁺, CO⁺, CO₂⁺ and W⁺ were also detected. It was estimated that the total number of particles, including neutrals, was orders of magnitude greater than the number of ions emitted.

4. Neutral Molecule Emission

A quadrupole mass spectrometer was used to determine the species of neutral molecules desorbed from a tungsten surface.¹⁷ A Q-switch laser pulse delivering 2×10^7 watts/cm² was used. The species detected were CO, CO₂, H₂, H₂O and hydrocarbons. Calculations showed that the desorption was a thermal process in that the observed desorption rates were consistent with calculated surface temperatures.

In another study, a quadrupole spectrometer was used to observe high energy neutrals produced by a Q-switch laser on W, Ni, Ti, C and Na targets.¹⁸ Power densities were from 5×10^7 to 10^8 watts/cm². The spectrometer was tuned opaque and the ionization chamber was turned off so that no ions or low energy molecules were detected. High energy neutrals were detected directly by the electron multiplier, which was in a line-of-sight path with the target. The energies of the neutral molecules were determined to be up to 100 eV. The species of molecules detected depended on which target material was used, but H₂, CO, and CO₂ were most commonly observed.

In an early study, a magnetic mass spectrometer was used to measure the composition of the neutral molecules emitted from laser heated graphite.¹⁹ A conventional mode laser was used to obtain carbon vapor temperatures of approximately 4000°K. The results showed that carbon molecules from C_1 to C_{11} were emitted with an odd-even variation in intensities as a function of the number of atoms per molecule.

In a recent study,²⁰ a TOF spectrometer was used to detect the molecules emitted from graphite heated by a Q-switch laser. Temperatures were estimated to be at the carbon triple point (4100 to 4600°K). The intensities of the C_2 to C_5 peaks relative to the C_1 peak were approximately 30% of the intensities expected for an equilibrium process. This indicates that the formation of the complex molecules was limited by the kinetics of association and subsequent vaporization of the molecules.

The vaporization of selenium by a conventional mode laser was investigated with a TOF spectrometer.²¹ The most predominant ionic species produced was Se^+ , but all molecular ions from Se_2^+ to Se_9^+ were detected. Excited neutral species from Se_2^* to Se_8^* were detected.

5. Plasma Production

At laser power densities greater than about 10^9 watts/cm², the blowoff material in front of the target surface is highly ionized and can be considered a plasma. The nature of the plasma has been examined experimentally using photography, interferometry, spectroscopy, mass spectrometry and charge collection. Photographic measurements of the ionized plume have shown that the velocity of the plasma luminous front increases rapidly after the material has been emitted from the

target, indicating that laser energy is absorbed by the blowoff material itself. Results of plasma studies show that plasma temperatures up to hundreds of electron volts can be obtained for laser power density up to 10^{13} watts/cm².¹

In one study,²² lithium hydride particles were heated by a Q-switch laser with power density 3×10^{11} watts/cm². The measured and calculated plasma temperatures were on the order of 100 eV. After the plasma is heated the thermal energy is converted to a directed motion of expansion which gives ion kinetic energies up to 1300 eV.

C. Qualitative Model of Laser Interaction at High Power Densities

Laser radiation incident on a metal surface is partially reflected and partially absorbed by electrons beneath the surface. When an electron absorbs the photon energy, it is raised to a higher energy level in the conduction band. The electron collides with lattice phonons and other electrons, thereby converting the photon energy to thermal energy of the lattice. As the lattice heats up, thermionic electrons and ions are emitted as well as neutrals. As laser power density increases, the degree of ionization of the emitted vapor increases. The electrons in the vapor can absorb laser photons by the inverse Bremsstrahlung process.¹ In order for momentum to be conserved, the process must occur within the field of an ion. The plasma becomes heated by collisions between the energetic electrons and the ions. The plasma is heated by the laser photons to temperatures of the order of tens or hundreds of electron volts until the plasma expands and becomes transparent. When highly ionized, the dense plasma shields the surface from the laser so that most vaporization occurs early in

a high power density pulse. As analyzed in Ref. 22, the plasma expansion is driven by pressure gradients within the plasma. After the plasma is heated, the total plasma energy goes into a directed energy of expansion away from the target. The kinetic energies of ions of the expanded plasma are typically an order of magnitude larger than the thermal energy of the plasma. This model therefore explains the large ion kinetic energies that have been measured in various experiments.

II. EXPERIMENTAL

A. Purpose

The purpose of this research is to examine the behavior of a binary solid compound under the rapid transient heating by a pulsed laser. In contrast, most previous studies have examined the interaction of laser radiation with elemental solids, especially metals. The binary compound zirconium hydride was chosen for several reasons: (a) the large partial pressure of hydrogen in equilibrium with zirconium hydride at elevated temperatures should allow easy detection of the emitted particles; (b) the material properties of zirconium hydride have been studied extensively; and (c) the behavior of zirconium hydride under transient heating conditions is of interest because of its nuclear applications.

TRIGA research reactors and SNAP (Systems for Nuclear Auxiliary Power) reactors use a uranium-zirconium hydride alloy for the fuel and moderator. The uranium exists as a fine dispersion of metallic uranium in the zirconium hydride matrix, so the material properties of the mixture are approximately the same as those of pure zirconium hydride. The hydrogen atoms in the zirconium hydride are an effective moderator because of their low mass number and high concentration. The behavior of the uranium-zirconium hydride fuel under rapid transient heating is of interest for the safety analysis of the fuel under accident conditions.

In the present experiment, a quadrupole mass spectrometer is used to detect the molecules emitted from a zirconium hydride sample heated by a Q-switch laser. By analyzing the mass spectrometer signals, the following information was sought: (a) whether the hydrogen is emitted as H_2 molecules, as expected from equilibrium considerations, or whether it is emitted as H atoms; (b) whether the velocity distribution of the

emitted particles is that expected for thermal equilibrium at the surface; (c) whether the amount of emitted particles is that expected for an equilibrium process; and (d) whether the temperature transient at the surface is satisfactorily described by the solution to the transient heat conduction equation with a heat source equal to the absorbed laser power.

Although the time scale of the temperature transient is on the order of 10^{-9} seconds, heat and mass transport in the solid will be analyzed by application of the usual conservation equations. The latter are usually applied to situations in which local thermodynamic equilibrium is approached. The justification for considering an equilibrium model of transport within the solid is that the time scale of the laser pulse (10^{-9} sec) is much larger than the electron collision and lattice vibration times (10^{-13} sec). Since the photons are absorbed by the electrons of the material, the photon energy should be converted to heat instantaneously. Since heat is transported by lattice vibrations and electrons, the concept of thermal conductivity should be valid. However, the vaporization processes occurring at the surface may not be well approximated by equilibrium considerations usually applied to steady state or slow transient situations. It is the surface vaporization phenomena rather than the solid heat and mass transport processes to which the present investigation is directed. However, because of the close coupling of surface and bulk processes during the transient initiated by a laser pulse, the surface phenomena can be evaluated only if the transport processes in the solid are assumed to be adequately described by conventional theory.

The qualitative model proposed for the transient behavior of zirconium hydride is as follows: (a) the laser radiation is absorbed at the surface and causes a temperature transient according to the time-dependent heat conduction equation; (b) H_2 molecules (and perhaps H atoms) are emitted from the heated surface at a rate which depends on surface temperature and hydrogen content of the solid; and (c) the depletion of hydrogen near the surface because of the H_2 flux is described by the time-dependent diffusion equation. The major question is whether step (b) is adequately described by a model based upon equilibrium thermodynamics and detailed balancing (i.e., Langmuir type vaporization, see Ref. 23)).

The behavior of zirconium hydride at moderate maximum surface temperatures (less than $\approx 2500^\circ K$) was of interest in this study. The vaporization of the zirconium lattice and production of an ionized plume of vapor at high laser power densities were not of direct interest.

In addition to studying the behavior of zirconium hydride heated by a Q-switch laser, the laser-induced vaporization of iron was also investigated. This was done because the vaporization of a monatomic substance is a much simpler phenomenon than the vaporization of a binary compound. When calculations and experiments on iron are compared, the validity of certain aspects of the equilibrium model and experimental technique may be established.

B. Experimental Apparatus

1. Introduction

The experimental apparatus shown in Figs. 1 and 2 consists of three main components: (a) the laser and equipment for measurement of laser power and energy, (b) vacuum system containing the target and the

XBL 7211-7231

Fig. 1 Schematic of experimental setup: The three regions separated by the dashed lines are (a) laser equipment for measuring laser power and energy; (b) vacuum system containing the target and mass spectrometer; (c) the mass spectrometer signal processing equipment.

Fig. 2b Experimental apparatus. From left to right are the laser, mass spectrometer chamber, and target chamber. Below the mass spectrometer chamber are the ion pump and ion gauge controllers.

mass spectrometer, and (c) the signal processing equipment. The laser pulse is focused onto the solid target under vacuum at an angle of 45° from the normal. As a result of heating by the laser, the target emits molecules or ions. A small fraction of the emitted particles pass through the collimating aperture between the target and mass spectrometer chambers and pass through the mass spectrometer ionizer. A small percentage of the molecules passing through the ionizer are ionized by electron impact and those of a particular mass pass through the mass filter are detected by an electron multiplier. The current produced at the electron multiplier output is displayed on an oscilloscope. This measured signal contains information on the amount of a particular species emitted as well as the time of flight (hence velocity or energy) of the emitted species.

2. Laser Apparatus

The laser used is a Korad KQ-1 system. A 4 in. $\times$ 9/16 in. ruby rod of standard doping ($0.5\% \text{Cr}^{3+}$) is pumped by a helical xenon flashlamp. The laser can operate in either the conventional or Q-switch mode. In the conventional mode the rear reflector is 100% reflecting at the laser wavelength $6943\text{\AA}$, and the output reflector used is a 13% transmitting sapphire etalon. The output is a series of vertically polarized spikes with a total duration of about 1.0 msec and total energy of up to 10 joules. In the Q-switch mode, lasing is suppressed by a passive cell at the rear reflector until the light intensity is sufficient to bleach the cryptocyanine dye in the cell. When the dye is bleached, the rear reflector becomes 100% reflecting, allowing stimulated emission of the highly inverted

population of the Cr^{3+} energy levels. In this case the laser output is a single "giant pulse" lasting about 50 nanoseconds and containing energy of about 1 joule.

The optical elements following the laser output reflector are a beam splitter, a cell containing a solution of CuSO_4 in water, a focusing lens, and a pyrex window in the vacuum chamber.

The transmissivity of the CuSO_4 cell is calibrated as a function of CuSO_4 concentration. Therefore the laser energy incident on the target can be varied by varying the CuSO_4 concentration. The focusing lens serves three purposes: a) it determines the spot size at the focal plane and hence determines the energy density at the target, b) it produces the far-field pattern at the focal plane which has a simpler spatial characterization than the near field pattern, and c) it permits easy alignment of the laser on the target by vertical or horizontal adjustment of the lens position.

A glass laboratory slide is used for a beam splitter, which reflects several per cent of the incident laser radiation to an MgO diffuser. Since the MgO block is a diffuse reflector, only a small amount of the laser radiation incident on it is detected by the Korad KD1 photodiode. For each laser pulse, the Korad photodiode produces a signal proportional to the laser power and a signal proportional to the laser energy (that is, the time integral of the power signal). The power signal is fed into a Textronics Type 519 scope which has a risetime of less than 1 nanosecond. Since a 519 scope does not have any gain control, the distance between the photodiode and the MgO block must be adjusted so the power signal gives almost full scale

deflection on the scope. The power trace is triggered internally by use of an internal delay line. The energy signal is measured on a Tektronics Type 585A dual trace scope which is triggered by a pulse at the time the flashlamp is fired. There is a delay of approximately 0.5 millisecond between the time the flashlamp is fired and the onset of lasing. When the laser is operated in the conventional mode, the power signal on the 519 scope is too small to measure, but the power can be determined by differentiating the total energy signal.

The energy contained in a laser pulse is determined by using a factory-calibrated Korad KJ-2 calorimeter. The calorimeter is aligned to detect the full unfocused laser beam (a focused laser beam can damage the window of the calorimeter absorbing cell). The calorimeter output is fed into a Keithley Model 150A microvoltmeter, which is connected to a strip chart recorder. The laser is fired into the calorimeter, the photodiode energy trace is photographed, and the calorimeter signal is measured. Knowing the calorimeter calibration factor (i.e., microvolts output per joule input), the energy trace can be calibrated. The transmissivity of the CuSO_4 cell as a function of concentration is determined in a similar manner by measuring the transmitted energy with the calorimeter placed behind the cell.

The laser is aligned on the target by use of a He-Ne continuous gas laser. The gas laser is aligned so that it is coaxial with the ruby laser. This is done by firing the ruby laser at a polaroid print placed in front of the vacuum chamber window. The gas laser is aligned so that it passes through the center of the ruby and hits the center of the damage area on the print.

A partially successful attempt was made to measure the laser energy reflected from the target. A United Detector Technology PIN8/LCA silicon photodiode with a 1 cm^2 active area was mounted in the vacuum chamber to detect the specularly reflected laser beam. In order to reduce the laser intensity sufficiently for detection, a sealed cell of concentrated CuSO_4 solution and a red and green glass filter were placed in front of the diode. The glass filters blocked out the white light from the flashlamp during the photodiode calibration with the direct laser beam. The photodiode was in a circuit similar to that of the Korad photodiode. The energy detected by the photodiode is proportional to the voltage drop across a capacitor partially discharged during the laser pulse. This voltage drop is measured simultaneously with the Korad energy trace on the dual trace 585A scope. See Section D for a discussion of these results.

3. Vacuum System

The Target is mounted on a linear feed-through, so that the target could be displaced slightly after each shot, thereby providing fresh areas of the target for successive laser pulses. The target chamber is pumped to 10^{-7} torr by a 500 liter/sec, 6-inch oil diffusion pump with liquid nitrogen cooled baffle. A 1/8 in. diameter collimating aperture is located between the target and mass spectrometer chambers at a distance of 8 in. from the target.

The mass spectrometer chamber is pumped by a 200 liter/sec ion pump and a titanium sublimation pump. A gate valve is located between the two chambers so that the mass spectrometer is kept under high vacuum when changing the target. With the gate valve closed, the pressure can be maintained in the 10^{-10} torr range. During experimental runs

with the gate valve open, the pressure in the mass spectrometer chamber is about 8×10^{-9} torr.

The mass spectrometer ionizer is located 8 in. from the collimating aperture. A beam flag mounted on a linear feed-through can be positioned between the orifice and the ionizer in order to block the molecules emitted by the target. The alignment of the laser spot on the target, collimator, and ionizer is made by sighting through a window in the mass spectrometer chamber down the molecular beam axis.

4. Mass Spectrometer

The detector used is an EAI Quad 250 quadrupole mass spectrometer with its ionizer modified to permit a molecular beam to pass through unobstructed. Some of the molecules passing through the ionizer are ionized by electrons emitted from a heated tungsten filament. Some of these ionized molecules are drawn into the quadrupole region by the fringe field reaching into the ionizer from an electrostatic focusing lens at a potential of 115 volts relative to the ionizer (see Fig. 13). For detecting ions emitted from the target, the ionizing electrons are removed by not heating the tungsten filament. The ions are deflected by 90° to enter the quadrupole structure by the fringe field of the 115 volt potential. Only ions with initial energy greater than 15 eV can be detected because the ionizer is at a potential of 15 volts relative to the target and ground. The quadrupole structure has an applied RF and DC field which determines whether an ion of a particular charge-to-mass ratio has a stable orbit down the structure or not. If the voltages are such that the ion has a stable orbit, the ion is detected by an electron multiplier mounted at the end of the analyzer.

The current produced at the electron multiplier output is measured on a Tektronics Type 532 oscilloscope, and the trace is photographed. For the laser in the Q-switch mode, the scope is triggered by the gate pulse from the 519 scope at the beginning of the giant pulse. For the laser in the conventional mode, it was found more reliable to trigger the mass spectrometer trace by the trigger pulse produced at the time the flashlamp is fired.

The time dependence of the mass spectrometer signal measured when the target is bombarded by a giant pulse contains direct information on the energy of the detected molecule or ion. This is because the duration of the laser pulse is much shorter than the time of flight of the ions or molecules from the target to the ionizer. However, the magnitude of the measured signal should be much less than the signal from steady state vaporization because the molecular velocity distribution causes the signal to spread out in time.

In the conventional mode, the time of flight and the spread in time due to the velocity distribution are on the same order as the duration of the laser pulse. Therefore, in this case, the mass spectrometer signal is primarily a measure of the amount rather than the energy of the vaporized material.

C. Laser Parameter Measurement

1. Energy Incident on the Target

The energy incident on the target is given by:

$$e_{inc} = e_o \tau_{CuSO_4} \tau_{lens} \tau_{window} \quad (2.1)$$

where e_o = laser energy determined by the energy calibration

$$= V_{K.E.} \times \left(\frac{\mu V}{V_{K.E.}} \right) / \left(\frac{\mu V}{\text{joule}} \right)$$

$\left(\frac{\mu V}{\text{joule}} \right)$ = Korad-supplied calorimeter calibration factor

$\left(\frac{\mu V}{V_{K.E.}} \right)$ = experimentally determined ratio of calorimeter signal to the voltage of the Korad energy trace.

τ_{CuSO_4} = experimentally determined transmissivity of the $CuSO_4$ cell

$\tau_{lens} \tau_{window}$ = transmissivity of the lens and vacuum chamber window

The transmissivity of the $CuSO_4$ cell as a function of saturated $CuSO_4$ concentration is shown in Fig. 3. As expected, the transmissivity decreases exponentially with concentration.

The reflectivity of a plane electromagnetic wave normal to a dielectric with index of refraction n is given by ²⁴

$$\frac{I_{reflect}}{I_{incident}} = \left(\frac{n-1}{n+1} \right)^2 \quad (2.2)$$

Assuming the index of refraction for the lens and window is 1.5 and considering that the laser is reflected at each of the four surfaces gives

$$\tau_{lens} \tau_{window} = \left[1 - \left(\frac{1.5 - 1}{1.5 + 1} \right)^2 \right]^4 = 0.85 \quad (2.3)$$

XBL7211-7249

Fig. 3 Calibration curve of the transmissivity of the CuSO_4 cell.

2. Laser Power

The shape in time of the giant pulse power trace measured on the 519 scope varies somewhat from shot to shot. For the laser cavity configuration used, the shape is approximately triangular with the peak at approximately 40 nanoseconds and the end of the pulse at 80 nanoseconds. The time corresponding to the peak and the width of individual pulses may vary from this by ± 15 nanoseconds. The shape is very sensitive to the alignment of the laser reflectors relative to the ruby. A characteristic giant pulse power trace is shown in Fig. 4.

The power of a conventional mode pulse is actually a series of spikes, as shown in Fig. 5. By measuring the individual spikes of a conventional mode pulse it is found that each spike has a duration of from 0.3 to 1 microsecond with 0.5 μsec being representative. The time spacing between spikes is approximately $1.5 \pm 1 \mu\text{sec}$. The average power as a function of time can be found by differentiating the Korad energy trace with respect to time. As shown in Fig. 6, the shape of the average power curve for a conventional mode pulse is approximately triangular, with the peak at time $\tau_1 = 0.15 \text{ msec}$ and the end of the pulse at time $\tau_2 = 1.0 \text{ msec}$.

3. Spot Size and Incident and Absorbed Energy Density

An unfocused laser beam has a very nonuniform spatial energy density. This is because some regions of the ruby lase more efficiently than others and the optical pumping is not perfectly uniform. The particularly active regions are called filaments or hot spots and have a diameter much less than the ruby diameter. In addition, lasing can occur in off-axis modes.

Fig. 4 Typical O-switch laser power signal. Horizontal scale is 20 nsec per division.

XBB 7210-5371

Fig. 5 Typical conventional mode laser power output. Horizontal scale is 0.1 msec per division.

XBL 7210-5781

Fig. 6 Typical conventional mode total energy signal and its time derivative. + = energy signal, x = derivative of the energy signal, which is proportional to laser power.

If it is assumed that the primary mode is the TEM_{00} mode, the intensity variation in the beam as a function of angle θ from the axis has a Gaussian shape:²⁵

$$E_{inc}(\theta) = \frac{e_{inc}}{\pi\delta^2} \exp(-\theta^2/\delta^2) \quad (2.4)$$

where $E_{inc}(\theta)$ = incident energy/solid angle at angle θ

e_{inc} = total incident energy

δ = mean angular radius of the Gaussian beam

By using geometrical optics, it can be shown that a ray at angle θ to the axis incident on a simple lens of focal length f is a distance $f\theta$ from the axis at the focal plane. In other words, a cone of light with half-angle θ is focused by a lens to a spot size of radius $f\theta$ at the focal plane. Therefore, the incident energy density of a Gaussian beam at the focal plane is found using Eq. (2.4):

$$E_{inc}(r)dA = E_{inc}(\theta)d\Omega \quad (2.5a)$$

where $dA = r dr d\phi = r f d\theta d\phi$

$$d\Omega = \sin\theta d\theta d\phi \cong \theta d\theta d\phi = \frac{r}{f} d\theta d\phi$$

So, the incident energy density as a function of radius at the focal plane is:

$$E_{inc}(r) = \frac{e_{inc}}{\pi(\sigma)^2} \exp\left(-\frac{r^2}{\sigma^2}\right) \quad (2.5b)$$

where $\sigma = \delta f$

Korad Corporation made measurements of the laser angular divergence on the ruby used in the present experiment. Based on their data, a value for δ was calculated to be 2.56 milliradians. Therefore, the radius σ at which the power density is $1/e$ times the peak power density is

$$\begin{aligned}\sigma &= 0.0512 \text{ cm for } f = 20 \text{ cm} \\ \sigma &= 0.256 \text{ cm for } f = 100 \text{ cm}\end{aligned}\quad (2.6)$$

Equation (2.5b) is actually only an approximation to the actual case. The beam divergence is larger if modes other than TEM_{00} are present, as happens if there is slight misalignment of the laser reflectors. Also, diffraction effects of the lens limit the ultimate spot size to the order of a wavelength. Experimentally observed damage areas agree with the general behavior of Eq. (2.5b) since damage is more pronounced in the center than at the edges. However, two observations show that the form of Eq. (2.5b) is only approximate: a) for the giant pulse power at the threshold for visible damage to the zirconium hydride target, a diffraction pattern is visible (Fig. 7), and b) a conventional pulse on an etched iron sample shows damage areas due to individual off-axis spikes (Fig. 8).

Finally, since the laser is incident on the target at an angle of 45° , the energy density at the target is reduced by $\cos 45^\circ$ and has an elliptical shape. The actual incident energy density at the target is then:

$$E_{inc}(r', \phi') = \frac{\cos 45^\circ e_{inc}}{\pi \sigma^2} \exp\left(\frac{r'^2(1 - \sin^2 45^\circ \cos^2 \phi')}{\sigma^2}\right) \quad (2.7)$$

where r' = radial position on the target

ϕ' = azimuthal angle at the target measured from horizontal

To compare the calculated results with the experimental results, it is necessary to relate the absorbed energy density $E_{abs}(r', \phi')$ to the incident energy density $E_{inc}(r', \phi')$. Assuming the surface of the target has a constant reflectivity R ,

Fig. 7 Diffraction pattern produced by Q-switch laser on zirconium hydride. Dark bands are the damaged area. Incident energy density = 0.27 cal/cm^2 . (50 $\times$ magnification)

XBB 7210-5372

Fig. 8 Conventional mode laser damage to etched iron surface. Spots are damaged areas due to individual spikes around the periphery of the central damage zone. Incident energy density at center of damaged zone = 77 cal/cm^2 . (200 $\times$ magnification)

$$E_{\text{abs}}(r', \phi') = (1 - R) E_{\text{inc}}(r', \phi') \quad (2.8)$$

As shown in Section G and H, the energy density over the face of the zirconium hydride samples is approximately constant, but the energy density over the interaction area of the iron samples is a function of r' and ϕ' according to Eq. (2.7). Since the numerical calculations are made assuming a uniform energy density at the surface, an effective laser spot size on the iron samples is defined as follows: Consider a differential area of the target at position r', ϕ' . The total energy absorbed by this surface region during the laser pulse is $E_{\text{abs}}(r', \phi') dA$. The vaporization rate from dA due to this energy input depends on the temporal shape of the laser pulse, the thermal properties of the solid, and the vapor pressure of the solid. Given these quantities, the transient vaporization rate for the differential area dA can be computed. In general, the rate of vaporization at first increases, passes through a maximum, and then decreases. The maximum vaporization rate depends upon the energy density at the location of region dA , and may be denoted by $\phi_{\text{max}}[E_{\text{abs}}(r', \phi')] dA$. The maximum vaporization rate due to the entire target area is the integral of this expression over all r' and ϕ' . Define an effective target area A_{eff} as that area of the target which would give the same maximum vaporization rate as that of the entire target if the centerline absorbed energy density were constant over A_{eff} . Thus, the effective target area is defined by:

$$\phi_{\text{max}}[E_{\text{abs}}(r' = 0)] A_{\text{eff}} = \int_0^{\infty} \int_0^{2\pi} \phi_{\text{max}}[E_{\text{abs}}(r', \phi')] r' dr' d\phi' \quad (2.9)$$

Change the variables r' and ϕ' to the radial position r in the focal plane, where $r = r'(1 - \sin^2 45^\circ \cos^2 \phi')^{1/2}$. Since $E_{\text{abs}}(r', \phi') = E_{\text{abs}}(r) = E_{\text{abs}}(0) \exp(-r^2/\sigma^2)$, the right-hand side of Eq. (2.9) becomes

$$\int_0^\infty \int_0^{2\pi} \phi_{\text{max}}(E_{\text{abs}}(r)) r' dr' d\phi' = \int_0^\infty \int_0^{2\pi} \phi_{\text{max}}(E_{\text{abs}}(r)) \frac{r dr d\phi'}{(1 - \sin^2 45^\circ \cos^2 \phi')} \quad (2.9)$$

The integral over ϕ' equals $2\pi/\cos 45^\circ$, so the effective target area is

$$A_{\text{eff}} = \frac{2\pi}{\cos 45^\circ \phi_{\text{max}}[E_{\text{abs}}(0)]} \int_{r=0}^\infty \phi_{\text{max}} \left[E_{\text{abs}}(0) \exp \left(-\frac{r^2}{\sigma^2} \right) \right] r dr \quad (2.10)$$

where $E_{\text{abs}}(0)$ = absorbed energy density at the center of the target area

The above integral is calculated numerically using the results of the numerical calculations for ϕ_{max} as a function of absorbed energy density (see Section VI-A-1). For the 20 cm focal length lens, $\sigma = 0.0512$ cm, which gives calculated values of A_{eff} from $0.4 \times 10^{-3} \text{ cm}^2$ for $E_{\text{abs}}(0) = 13 \text{ cal/cm}^2$ to $5.0 \times 10^{-3} \text{ cm}^2$ for $E_{\text{abs}}(0) = 60 \text{ cal/cm}^2$. This corresponds to effective spot diameters of 0.023 cm and 0.080 cm, respectively.

D. Surface Reflectivity Measurement

1. Iron Reflectivity

The reflected energy diode was used to measure the average reflectivity of polished iron during a conventional pulse. For energy densities of 20 to 100 cal/cm^2 , the measured reflectivity varied from 0.3 to 0.7 with a large amount of scatter. While these values are reasonable they are not considered reliable because

- a) At high energy densities, values of reflectivity greater than unity were measured, indicating either faulty calibration or possibly the detection of other radiations produced during the interaction.
- b) When the surface melts, the reflected laser radiation is not reliably intercepted by the 1 cm^2 active area photodiode.
- c) During calibration it was difficult to ascertain that all the incident laser energy was detected by the photodiode.

It was therefore considered more reliable to assume the iron reflectivity was given by the literature value during the pulse.

2. Zirconium Hydride Reflectivity

The zirconium hydride samples were found not to scatter specularly but rather in a broad band in the specular direction. Rather than attempt to measure the reflectivity during a laser pulse, a room temperature value was measured. A He-Ne continuous gas laser beam was attenuated and directed at a zirconium hydride sample. A photomultiplier tube was used to measure the reflected band as well as the incident intensity. The reflectivity was determined to be 0.45 ± 0.05 at the He-Ne laser wavelength $6328\text{\AA}$. Assuming that the zirconium hydride reflectivity is a slowly varying function of wavelength, the measured reflectivity is approximately that at the ruby laser wavelength $6943\text{\AA}$.

E. Mass Spectrometer Calibration

1. Calibration on Iron

To calibrate the mass spectrometer, an iron molecular beam was generated by electron beam heating an iron disk at the target position. The iron temperature was measured by an optical pyrometer, and the mass spectrometer signal was recorded on a strip chart recorder. Figure 9 shows the electron beam heater configuration.

The disks were high purity polycrystalline iron polished with 6 micron diamond paste. They were 0.46 in diameter $\times$ 0.11 in thick. A 1/32 in diameter black body hole with depth to diameter ratio of about three was drilled below the center of the disk at an angle of 45 degrees. The disk was held in a tantalum crucible with a tantalum cover ring. The face of the iron was covered by a circular tungsten foil with a 1/16 in. or 3/16 in diameter hole in the center plus an opening to expose the black body hole. A tantalum shield prevented molecules vaporized from the black body hole from reaching the mass spectrometer.

The tantalum holder was heated from the rear by electrons accelerated from a heated tungsten filament. The holder was held in place by two molybdenum screws and a tungsten spring to allow for thermal expansion. The iron temperature was quite uniform because of the few contact points between the holder and the electron beam heater.

The iron temperature was measured by viewing the black body hole through a 90° prism and the vacuum chamber window. Except during actual temperature measurements, the window was shielded to prevent the deposition of an iron coat. The shield could be moved away from the window by a magnet.

XBL 7211-7227

Fig. 9 Schematic of electron beam heater and iron molecular beam source.

If it is assumed that the surfaces of the black body hole have an emissivity of 0.5, numerical calculations show that the apparent emissivity of the hole is 0.98 for a depth to diameter ratio of three.²⁶ This apparent emissivity is sufficiently close to unity that the hole is considered to be an ideal black body.

The apparent temperature as measured by the optical pyrometer has to be corrected for the transmissivity of the prism and window. The optical pyrometer determines temperature by comparing radiation intensities at wavelength $\lambda_p = 0.65$ microns. The observed intensity at this wavelength is less than that from an ideal black body because the transmissivity is less than unity. The relation between true and apparent temperature is:²⁷

$$\frac{1}{T_{\text{true}}} - \frac{1}{T_{\text{app}}} = \frac{k}{hc} \lambda_p \ln \tau \quad (2.11a)$$

For $\tau = \tau_{\text{prism}} \tau_{\text{window}}$ close to unity:

$$T_{\text{true}} - T_{\text{app}} \cong -T_{\text{app}}^2 \frac{k\lambda_p}{hc} [\ln \tau_{\text{prism}} + \ln \tau_{\text{window}}] \quad (2.11b)$$

The constants k , h and c are Boltzmann's constant, Planck's constant, and speed of light respectively. Rather than measure τ_{window} and τ_{prism} , correction terms supplied by the pyrometer manufacturer were used. Equation (2.11b) shows that the total correction term is the sum of the correction terms for the window and prism as a function of T_{app} .

The mass spectrometer calibration was made for iron temperatures from 1135°C to 1385°C. The mass 56 signal was measured continuously

with the 532 scope in parallel with a strip chart recorder. The load resistance was 1 M for all measurements. For each data point, the iron signal above background was determined by taking the difference between the mass 56 signal with and without the beam flag in front of the ionizer.

The mass spectrometer settings used for the calibration and all other experiments were:

$V_{\text{electron}} = 90 \text{ volts} = \text{electron potential}$

$V_{\text{ion}} = 15 \text{ volts} = \text{ion potential relative to the ionizer at the entry to the quadrupole structure}$

$V_{\text{focus}} = 100 \text{ volts} = \text{ion focusing potential}$

$V_{\text{extractor}} = 40 \text{ volts} = \text{electron extraction potential}$

$V_{\text{multiplier}} = -3000 \text{ volts} = \text{potential across the electron multiplier dynodes}$

$I_{\text{emiss}} = 1.0 \text{ milliamp} = \text{emitted electron current}$

$I_{\text{extractor}} = 0.92 \text{ ma} = \text{collected electron current}$

The mass spectrometer resolution setting at mass 56 was adjusted so that the valley between adjacent mass peaks just touched the base line. This resolution is called unit resolution. On measurements of hydrogen from the zirconium hydride, the resolution control was set for unit resolution at mass 18 rather than mass 56.

Two calibration runs were made--one with a 1/16 in. and one with a 3/16 in. diameter source aperture. As derived in Section III-B, the steady state current should be proportional to P_{eq}/T . According to the Clausius-Clapeyron equation, the vapor pressure of a condensed phase is given by

$$P_{eq} = P_o \exp(-\Delta H_{vap}/RT) \quad (2.12)$$

where ΔH_{vap} = heat of vaporization per mole, approximately constant

R = gas constant

T = absolute temperature

Therefore, a plot of $\log(IT)$ vs $1/T$ should have slope $-\Delta H_{vap}/R \ln 10$, where I is the measured current in amps. The product IT is plotted against $1/T$ in Fig. 10 for the two calibration runs. Least squares fits of these data give the results:

for 1/16 in. aperture:

$$\log(IT) = 7.101 - 20.10 (10^3/T) \quad (2.13a)$$

which gives $\Delta H_{vap} = 92.0 \pm 2$ kcal/mole

for 3/16 in. aperture:

$$\log(IT) = 8.184 - 20.681 (10^3/T) \quad (2.13b)$$

which gives $\Delta H_{vap} = 94.6 \pm 1.4$ kcal/mole

The 3/16 in. aperture data is more reliable than the 1/16 in. aperture data because the signals were larger and covered a wider range of temperature.

The heat of vaporization given by the JANAF tables²⁸ for iron varies from 95.6 to 94.5 kcal/mole over the temperature range of the calibration. Since the measured value of heat of vaporization is in excellent agreement with the literature value, the calibration technique is considered reliable.

2. Calibration on Molecular Hydrogen

A rough calibration of the mass spectrometer was made on molecular hydrogen. An accurate calibration would require the construction of a molecular hydrogen beam of known source strength located at the

XBL 7211-7247

Fig. 10 Mass spectrometer calibration curve for atomic iron.

target position. By chopping the beam with a mechanical chopper and measuring the modulated H_2 signal, the calibration could be determined. Instead of doing this, however, the calibration was made by measuring the H_2 signal due to a large background H_2 pressure in the mass spectrometer chamber. Hydrogen was introduced into the target chamber through a variable leak. The H_2 pressure in the mass spectrometer chamber increased because of the flow of hydrogen through the 1/8 in. diameter aperture between the two chambers.

The pressure in the mass spectrometer chamber was measured with an ionization gauge. The H_2 signal was measured with the same mass spectrometer settings as for the iron calibration except that the resolution control was set for unit resolution at mass 18 rather than mass 56. The H_2 and H_1 signals measured across a 1 M load at different mass spectrometer chamber pressures where:

P_{ms} (torr)	V_{H_2} (volts)	V_{H_1} (volts)
5×10^{-8}	0.33	0.04 (variable leak off)
1×10^{-7}	4.3	0.14
2×10^{-7}	14.0	0.4

The mass spectrometer signals on the other background gases were approximately constant, so the increase in pressure was attributed entirely to hydrogen. The true pressure of hydrogen is 1.8 times the pressure measured by an ionization gauge.²⁹ The calibration on H_2 expressed in amps/torr is therefore given by:

$$\frac{\text{amps}}{\text{torr}} = \frac{10^{-6} (V_{H_2} - V_{H_2}^0)}{1.8 (P_{ms} - P_{ms}^0)}$$

where $V_{H_2}^{\circ}$ and P_{ms}° are the H_2 voltage and mass spectrometer chamber pressure respectively when the variable leak is off. The mass spectrometer calibration on H_2 calculated from the above equation is 48 amps/torr.

The H_1 signal is due to ions with charge to mass ratio of unity. These can be either H_1^+ ions produced by cracking of H_2 molecules or H_2^{++} ions produced by double ionization of the molecules. The ratio of H_1 to H_2 signal due to cracking and double ionization is equal to $V_{H_1}/V_{H_2} \approx 3\%$.

3. Mass Spectrometer Time Constant

The time constant of the mass spectrometer signal measurement circuit was measured. The RC time constant is due to the cable, connectors, and oscilloscope capacitances. Individual mass spectrometer pulses were photographed on a high gain Hewlett-Packard 130 C oscilloscope. The measurements were made with a scope load of 1M in parallel with a 0.3M resistor. The time constant of the traces was calculated to be 29 μ sec. Therefore, the total capacitance is 126 picofarads. The Textronics 532 scope has a capacitance 2 pf larger than the HP 130C. Therefore, when using the 532 scope, the time constant is

$$\begin{aligned}\tau &= 30 \mu\text{sec for load } 0.3 \text{ M in parallel with } 1 \text{ M} \\ \tau &= 12 \mu\text{sec for load } 0.1 \text{ M in parallel with } 1 \text{ M}\end{aligned}\tag{2.14}$$

F. Fabrication of Zirconium Hydride Samples

Since bulk samples of zirconium hydride are not readily available commercially, zirconium hydride samples were fabricated for the experiment. The method used to hydride zirconium rod was similar to that described in Ref. 30. The experimental setup used is shown in Fig. 11. The hydrogen

-42-

XBL721F-7230

Fig. 11 Schematic of experimental setup for production of zirconium hydride.

flow system consisted of a tank of high purity hydrogen (99.999+), a copper catalyst to remove oxygen, a liquid-nitrogen-cooled cold trap to condense out water produced in catalyzing the oxygen, a bellows valve, the reaction chamber, a Wallace-Tiernan vacuum gauge, a needle valve, and a forepump. The copper catalyst, designated as BTS, is described in Ref. 31. It consists of 30% copper in a very finely dispersed form stabilized on an inert alumina-based carrier, and getters oxygen very effectively when maintained at 200°C.

Each zirconium hydride sample was made from high purity (99.995% pure) 1/8 in. diameter zirconium rod. Before hydriding, the sample was mechanically polished and etched in a solution of 5 parts H₂O, 5 parts HCl, and 1 part HF to remove the surface oxide.

The sample was put in a molybdenum crucible and suspended in a quartz tube reaction chamber. The crucible was heated by an induction coil around the quartz tube. The temperature was measured by an iron-constantan thermocouple that penetrated a hole in the crucible. The crucible acted like a black body in uniformly heating the sample. Hydrogen pressure and flow rate were controlled by adjusting the bellows and needle valves.

It was decided to make delta phase zirconium hydride because it does not undergo a phase change at the eutectoid temperature 550°C and has a high hydrogen content. See Section V-B-1 (especially Fig. 15) for a discussion of the zirconium-hydrogen phase system. The desired composition was ZrH_{1.63}. The vapor pressure at this composition as a function of temperature is given by Libowitz.³² The actual composition produced was determined by the weight gain from hydriding. Knowing the initial weight W_i and final weight W_f , the H/Zr atom ratio y is:

$$y = \frac{M_{\text{Zr}}}{M_{\text{H}}} \frac{W_f - W_i}{W_i} = \frac{91.22}{1.008} \frac{W_f - W_i}{W_i} \quad (2.15)$$

Before performing the hydriding operation, the heated copper catalyst was cleaned by pumping on the system with the diffusion pump for about six hours. Next the sample was inserted into the reaction chamber, which was then pumped down to the 10^{-7} torr range. Hydrogen was flushed through the system for over an hour, the hydrogen inlet valve to the reaction chamber was closed, and the chamber was again pumped with the diffusion pump for several hours. The zirconium was slowly heated to 700°C and held for 30 minutes to outgas the chamber walls. The diffusion pump was then closed and a hydrogen flow established at 10-12 mm Hg pressure. The sample was held at 700°C at this pressure for over an hour to bring the composition to $\text{ZrH}_{0.9}$ at the $\beta - (\beta + \delta)$ phase boundary. The final stage of hydriding was done by increasing the hydrogen pressure to 106 mm Hg, the equilibrium vapor pressure of $\text{ZrH}_{1.63}$ at 700°C . This pressure and temperature were maintained for 1 1/2 hours to ensure complete hydriding of the sample. The sample was then slowly cooled to room temperature while maintaining the corresponding equilibrium vapor pressure.

Three crack-free samples were made by this procedure. After hydriding, each sample had a faint golden color, indicating the formation of a nitride layer at the surface. The initial weight, final weight, and H/Zr atom ratio calculated by Eq. (2.15) for the samples are:

Sample #	W_i (gms)	W_f (gms)	y
1	0.6493	0.6609	1.62
2	0.6399	0.6515	1.64
3	0.5575	0.5676	1.64

The close agreement between the calculated values of H/Zr atom ratio and the desired value of 1.63 indicates that the samples were fully hydrided.

G. Laser Shots on Iron

The iron samples for the laser vaporization experiments were machined from the same high purity polycrystalline stock as used for the iron calibration measurements. The samples were 3/16 in. diameter by 1/2 in. long rods. The ends of the rods were machined flat and brought to a final polish with 6 micron diamond paste. Two rods were mounted on the end of the linear feed-through in the target vacuum chamber. Each rod could be positioned so that the normal to the end face was coaxial with the collimating aperture and mass spectrometer ionizer.

The mass spectrometer signal from iron atoms vaporized by a Q-switch laser pulse could not be detected above the background signal at the same mass number. The signal produced is much smaller than in steady state because iron atoms are emitted over a very short time compared to the expected width of the signal. As calculated in Section IV-B-6, the spread of velocities of the iron atoms emitted from a surface at 2000°K leads to an expected width of the signal of approximately 400 μ sec. If the atoms are emitted over the duration of

40 nanoseconds, the resulting signal has amplitude approximately $0.04/400 = 10^{-4}$ times the steady state signal. At high Q-switch laser energy densities, iron ions with energy of approximately 30 eV were produced which could be detected by the mass spectrometer. The sensitivity of the mass spectrometer to ions is much greater than to neutrals because the efficiency of ionizing neutrals by electron bombardment is low. The production of iron ions was attributed to the formation of an ionized plume of vapor in front of the iron surface. This phenomenon was not of interest in this investigations.

Measurable mass spectrometer signals were obtained, however, when conventional mode laser pulses were fired on the iron surface. In this case the iron atoms are vaporized from the surface for approximately 100 μ sec. For the same peak temperature, the amplitude of the signal is therefore on the order of 10^3 times that when the iron is heated by a Q-switch pulse. In order to get a large enough energy density for measurable vaporization, the laser was focused with a 20 cm focal length lens. The resulting spot size was approximately 1 mm diameter, so several laser shots could be made on each end face of the iron rods. Measurements were made for incident energy densities from 50 to 140 cal/cm² by varying the concentration of the CuSO₄ cell. The results of these measurements are discussed and analyzed in Section VI-A. All mass spectrometer measurements were made with a 0.3 M resistor in parallel with the 1 M load of the oscilloscope to minimize the effect of the time constant on the shape of the measured signal.

In principle, the temperature of the iron surface during a conventional mode pulse could be measured with an infrared pyrometer with response time much less than the duration of the laser pulse. An indium antimonide photodetector with response time of less than 10 microseconds was available for the purpose. The characteristics and calibration of this pyrometer were reported in Ref. 33. The pyrometer was not used, however, because an accurate calibration could be made only if it viewed an isothermal surface of at least 1/8 in. diameter. Since this is considerably larger than the laser spot size, the infrared pyrometer could not be used. Even if the laser spot size were large enough, the pyrometer would have to be calibrated on an iron surface of known temperature in order to account for the emissivity of the iron in the 2 to 6 micron wavelength region. Also a filter would have to be used to assure that the infrared pyrometer did not detect any of the reflected laser radiation.

H. Laser Shots on Zirconium Hydride

The ends of the three zirconium hydride rods were polished with 6 micron diamond paste and mounted on the end of the linear feed-through in the target chamber. After one laser shot on the end of each rod, the rods were removed and repolished before firing on them again. This was done so that the initial surface H/Zr atom ratio was known and equal to 1.63.

Measurable H_2 and H_1 signals were obtained when the zirconium hydride rods were heated with Q-switch laser pulses. The laser was focused with a 100 cm focal length lens. The calculated laser spot size of approximately 0.5 cm diameter is larger than the 0.32 cm diameter of the rods, so the energy density over the face of the rods was approximately constant. Measurements were made for incident energy densities from 0.02 to 0.15 cal/cm². For energy densities greater than about 0.2 cal/cm², atomic hydrogen ions and zirconium ions were detected. The signals were known to be due to ions because they were obtained even when the ionizer electron current was set to zero. The results obtained on zirconium hydride are discussed and analyzed in Section VI-E.

For a particular current produced by the mass spectrometer, the time constant and the measured voltage are proportional to the resistive load. Since the currents produced were small, it was desirable to have a large load. On the other hand, it was desirable to have a small load in order to minimize the effect of the time constant on the shape of the measured signal. An acceptable compromise between these two effects was made by choosing the load to be either a 0.1 M or 0.3 M resistor in parallel with the 1 M load of the oscilloscope.

III. THEORY--PREDICTED MASS SPECTROMETER SIGNAL

A. Equilibrium Model for Vaporization from the Surface

An equilibrium model is used to describe the vaporization of the molecules from the surface. According to the principle of detailed balance,³⁴ for a system in equilibrium, all processes which maintain the equilibrium occur at the same rate in a forward and backward direction. As applied to a condensed phase in equilibrium with its vapor, the rate of condensation of vapor molecules of a given velocity is exactly equal to the rate of vaporization of molecules of the same velocity.

Assume that the vapor in thermal equilibrium with the condensed phase has a Maxwell velocity distribution. This is true for ideal gases, for which the potential energy of interaction between molecules is negligible. The Maxwell velocity distribution is given by:³⁵

$$F(v)dv d\Omega = \frac{P_{eq}}{kT} \left(\frac{m}{2\pi kT} \right)^{3/2} v^2 \exp \left(\frac{-mv^2}{2kT} \right) dv d\Omega \quad (3.1)$$

where $F(v)dv d\Omega$ = number of molecules of speed $v \rightarrow v + dv$ in solid angle $d\Omega$ per unit volume

P_{eq} = equilibrium vapor pressure

m = molecular mass

k = Boltzmann constant

T = absolute temperature

The number of vapor molecules with speed $v \rightarrow v + dv$ in $d\Omega$ that strike a unit surface area per unit time is equal to:

$$v \cos\theta F(v)dv d\Omega \quad (3.2)$$

where θ is the angle between the surface normal and the direction of the incident molecule.

The rate at which molecules actually condense on the surface may be less than the rate at which they strike the surface. This difference can be accounted for by a temperature dependent condensation coefficient $\alpha(T)$, which is defined³⁶ as the fraction of gaseous molecules striking a surface which condense. Assuming that this fraction is independent of the velocity and direction of the molecules and using the principle of detailed balance to equate the condensation rate to the vaporization rate for molecules of all velocities at equilibrium, the number of molecules vaporized from a unit area of the surface in speed $v \rightarrow v + dv$ into solid angle $d\Omega$ per unit area per unit time is equal to:

$$\alpha(T) \frac{P_{eq}(T)}{kT} \left(\frac{m}{2\pi kT} \right)^{3/2} v^3 \exp\left(\frac{-mv^2}{2kT}\right) \cos\theta \, dv d\Omega \quad (3.3)$$

If it assumed that the process of vaporization is independent of the presence of the vapor phase in equilibrium with the condensed phase, the vaporization rate in vacuo is equal to the vaporization rate at equilibrium. Therefore under this assumption, the vaporization rate in vacuum is given by Eq. (3.3). Integrating Eq. (3.3) over all speeds and the hemisphere above the surface gives the total rate of vaporization from the surface:

$$\phi = \alpha(T) \frac{P_{eq}(T)}{\sqrt{2\pi mkT}} \text{ molecules/cm}^2 \text{ sec} \quad (3.4)$$

The vaporization rate given by Eq. (3.4) is just $\alpha(T)$ times the maximum rate of vaporization as calculated by Langmuir.³⁷ According to the definition of evaporation coefficient given by Somorjai²³ the condensation coefficient $\alpha(T)$ is identically equal to the evaporation coefficient under the assumptions made in deriving Eq. (3.4). For most metals and other simple substances, evaporation coefficients (and therefore condensation coefficients) are close to unity.³⁶ If the concentration of surface sites from which vaporization can occur is smaller than the concentration of surface atoms, the evaporation coefficient is less than unity.²³

B. Calculated Density of Molecules at the Ionizer

In order to calculate the mass spectrometer signal that the vaporized molecules would produce, it is necessary to calculate the density of molecules at the mass spectrometer ionizer as a function of time. Consideration must be given to the fact that faster molecules arrive at the ionizer before slower ones and that molecules leave the surface at different times during the temperature transient. The analysis that follows is similar to that done by Saltsburg for flash evaporation studies.³⁸ Let

τ = time of emission of a molecule from the surface

t = time of arrival at distance s of speed v molecule emitted
at time τ

Therefore,

$$v = \frac{s}{(t - \tau)} \quad (3.5a)$$

$$dv = \frac{s d\tau}{(t - \tau)^2} \quad \text{for a particular } t \text{ and } s \quad (3.5b)$$

Let $\phi(t, \tau) d\tau d\Omega_s$ = number of molecules per second arriving at distance s along the normal to the surface at time t which are emitted at time $\tau \rightarrow \tau + d\tau$ into solid angle $d\Omega$ from the surface area A_s . This is just equal to A_s times the rate given by Eq. (3.3) with v replaced by Eq. (3.5) and $\theta = 0$:

$$\phi(t, \tau) d\tau d\Omega = A_s \alpha(T) \frac{P_{eq}(T)}{kT} \left(\frac{m}{2\pi kT} \right)^{3/2} \frac{s^4}{(t - \tau)^5} \exp\left(\frac{-ms^2}{2kT(t - \tau)^2} \right) \times d\tau d\Omega \quad (3.6)$$

Since $d\Omega = dA/s^2$, where dA is a differential area at distance s , the number of incident molecules at s and t per unit area at s emitted at $\tau \rightarrow \tau + d\tau$ is $\frac{1}{s} \phi(t, \tau) d\tau$. The number of molecules per unit volume at s and t emitted at $\tau \rightarrow \tau + d\tau$ is the number incident per unit area divided by their velocity $s/(t - \tau)$, or:

$$n(t, \tau) d\tau = A_s \alpha(T) \frac{P_{eq}(T)}{kT} \left(\frac{m}{2\pi kT} \right)^{3/2} \frac{s}{(t - \tau)^4} \exp\left(\frac{-ms^2}{2kT(t - \tau)^2} \right) d\tau \quad (3.7)$$

The total density of molecules at distance s is the integral of Eq. (3.7) over τ where $T = T(\tau)$. Assuming α to be temperature independent, integration yields:

$$n(t) = \frac{s\alpha A}{k} \left(\frac{m}{2\pi k} \right)^{3/2} \int_{\tau=0}^t \frac{P_{eq}(T(\tau))}{(T(\tau))^{5/2} (t - \tau)^4} \exp\left(\frac{-ms^2}{2kT(\tau)(t - \tau)^2} \right) d\tau \quad (3.8)$$

The average density of vapor molecules at the mass spectrometer ionizer (which is a distance s from the surface) is less than that calculated from Eq. (3.8) because the collimating aperture obstructs some of the field of view. This reduction is accounted for by an average "peaking factor", $\bar{\chi}$, which is defined as the ratio of the

actual molecular beam intensity averaged over the ionizer electron sheet to the intensity from an unobstructed point cosine source of the same source strength. (For the geometry used in the experiment, $\bar{\chi}$ is calculated in Appendix A.) The average vapor density over the ionizer electron sheet is $\bar{\chi}$ times $n(t)$ from Eq. (3.8):

$$\bar{n}_{\text{calc}}(t) = \frac{\bar{\chi} s \alpha A_s}{k} \left(\frac{m}{2\pi k} \right)^{3/2} \int_0^t \frac{P_{\text{eq}}(\tau)}{T^{5/2} (t - \tau)^4} \exp\left(\frac{-ms^2}{2kT(t - \tau)^2} \right) d\tau \quad (3.9)$$

For the steady state case such as that used in calibrating the mass spectrometer with an iron molecular beam, T is independent of τ , the above integral is independent of t , and the lower limit of integration is replaced by $-\infty$. Performing the integral gives for the steady state density:

$$\bar{n}_{ss} = \frac{\bar{\chi} \alpha A_s P_{\text{eq}}(T)}{4\pi s^2 kT} \quad (3.10)$$

C. Measured Density of Molecules at the Ionizer

The geometry and electrical circuit of the mass spectrometer ionizer and mass filter are shown in Figs. 12 and 13. Electrons are emitted from a hot tungsten filament and accelerated to energy eV_{electron} . The ions formed by electron-molecule collisions are drawn from the ionizer by the potential $V_{\text{focus}} + V_{\text{ion}}$, focused by the potential V_{focus} , and directed down the quadrupole structure with energy eV_{ion} for singly charged ions. The ions are detected at the end of the quadrupole structure by an electron multiplier which produces a current gain of the order 10^6 .

$$\begin{array}{l} \text{number of ions} \\ \text{produced/sec in} \\ \text{the ionizer} \end{array} = \bar{n}(t) V_i \phi_e \sigma \quad (3.11)$$

XBL 7211- 7 226

Fig. 12 Geometry of the mass spectrometer ionizer and mass filter.

XBL7211-7232

Fig. 13 Electrical circuit of mass spectrometer ionizer and circuit for detection of the mass spectrometer signal.

where V_1 = volume of interaction (cm^3)

ϕ_e = electron flux (electrons/ cm^2 sec)

σ = ionization cross section (cm^2)

$\bar{n}(t)$ = average molecular density (molecules/ cm^3)

But $V_1 = A_1 L$, where L = length of the electron sheet (cm) and A_1 = cross sectional area of the electron sheet (cm^2); and $\phi_e = I_e / e A_1$, where I_e = electron current (coulombs/sec) and e = electron charge (coulombs/electron). Therefore:

$$\text{number of ions produced/sec} = \frac{1}{e} \bar{n}(t) I_e \sigma L \quad (3.12)$$

Only a fraction of the ions produced are drawn into the quadrupole structure, and not all those of the proper mass actually reach the electron multiplier. The overall efficiency of collection of ions of a particular mass depends on the resolution setting of the mass spectrometer as well as the focus and ion potentials. Therefore, the rate of arrival of ions at the electron multiplier is given by:

$$r(t + t_d) = \gamma \times \left[\frac{\text{number of ions}}{\text{produced/sec}} \right] = \frac{\gamma}{e} \bar{n}(t) I_e \sigma L \quad (3.13)$$

where $r(t + t_d)$ = rate of arrival of ions at the electron multiplier which are produced at time t in the ionizer

γ = fraction of ions produced that actually reach the electron multiplier

t_d = acceleration time plus the drift time of ions down the quadrupole structure

The rate of arrival of ions is delayed by the time t_d relative to $\bar{n}(t)$ because of the time required to accelerate and focus the ions and because of the drift time of the ions down the quadrupole structure.

As calculated by Jones³⁹ the acceleration time is much less than the drift time so it will be neglected. Since an ion enters the quadrupole structure with kinetic energy eV_{ion} ,

$$eV_{ion} = \frac{1}{2} m v_z^2 = \frac{1}{2} m \left(\frac{L_d}{t_d} \right)^2 \quad (3.14)$$

Solving for t_d gives

$$t_d = L_d \sqrt{\frac{m}{2e V_{ion}}} \quad (3.15)$$

where L_d = length of quadrupole structure (cm)

m = mass of ion (gms)

e = ion charge (coulombs)

V_{ion} = ion potential (volts)

or

$$t_d = 1.83 \times 10^{-6} L_d \sqrt{\frac{M}{V_{ion}}} \quad (3.16)$$

where L_d is in inches, M is in AMU, V_{ion} is in volts. For $L_d = 5.5$ inches and $V_{ion} = 15$ volts:

$$\begin{aligned} t_d &= 2.6 \text{ } \mu\text{sec for } M = 1 \text{ (hydrogen atom)} \\ &= 3.7 \text{ } \mu\text{sec for } M = 2 \text{ (hydrogen molecule)} \\ &= 19.4 \text{ } \mu\text{sec for } M = 56 \text{ (iron atom)} \\ &= 24.6 \text{ } \mu\text{sec for } M = 90 \text{ (zirconium atom)} \end{aligned} \quad (3.17)$$

An ion impinging on the first dynode of the electron multiplier causes the emission of β electrons on the average. These secondary electrons are accelerated to the second dynode where many more electrons are emitted. The process is repeated down the series of dynodes until the final charge of electrons released is:

$$q_o = \beta e G \quad (3.18)$$

where β = number of secondary electrons produced at the first dynode
per incident ion

q_o = total charge released per incident ion

e = electron charge

G = electron multiplier gain

Figure 13 shows the electrical circuit following the electron multiplier. For the RC time constant of the circuit much larger than the time of deposit of the charge q_o , an individual pulse produces a voltage across the load given by:⁴⁰

$$V(t) = V_o \exp(-t/\tau) H(t) \quad (3.19)$$

where $H(t) = 1$ for $t > 0$

$= 0$ for $t < 0$

$\tau = RC =$ time constant

$R = 0.091 \text{ M}$ or 0.231 M for 0.1 M or 0.3 M load, respectively,
in parallel with the 1 M scope load

$C = C_{\text{scope}} + C_{\text{lines}}$

Since $\int_{t=0}^{\infty} \frac{V(t)}{R} dt = q_o$ by the conservation of charge, $V_o = q_o R/\tau$.

The current pulse to ground produced by an individual ion is equal to

$V(t)/R$:

$$I_o(t) = \frac{q_o}{\tau} \exp(-t/\tau) H(t) \quad (3.20)$$

The current at time $t + t_d$ due to those ions reaching the electron multiplier at time $t' \rightarrow t' + dt'$ is

$$\begin{aligned} dI(t + t_d) &= \text{number of ions arriving in time } t' \rightarrow t' + dt' \\ &\quad \text{times the current at time } t + t_d - t' \text{ per ion} \\ &\quad \text{arriving at time } t' \\ &= r(t') dt' I_o(t + t_d - t') \end{aligned} \quad (3.21)$$

Therefore, the total current at time $t + t_d$ is the integral of Eq. (3.21) over t' :

$$I(t + t_d) = \int_{t'=t_d}^{t+t_d} I_o(t + t_d - t') r(t') dt' \quad (3.22)$$

In Eq. (3.22) let $t'' = t' - t_d$, and use Eq. (3.13) for $r(t'' + t_d)$, Eq. (3.20) for $I_o(t - t'')$, and Eq. (3.18) for q_o , which gives:

$$I(t + t_d) = \frac{K}{\tau} \int_0^t \exp\left[-\frac{(t - t'')}{\tau}\right] \bar{n}(t'') dt'' \quad (3.23a)$$

$$\text{where} \quad K = \gamma I_e \sigma L B G \quad (3.23b)$$

Rather than compare $I(t + t_d)$ predicted by Eqs. (3.23) with the measured current, the latter is analyzed to calculate a measured vapor density at the ionizer, which is then compared with the calculated vapor density. Taking the Laplace transform of both sides of Eq. (3.23a) and inverting gives the result:

$$\bar{n}_{\text{meas}}(t) = \left[I(t + t_d) + \tau \frac{dI}{dt}(t + t_d) \right] / K \quad (3.24)$$

Therefore the measured current $I(t + t_d)$, which is equal to the measured $V_{\text{scope}}(t + t_d)$ divided by R , can be shifted in time by t_d and differentiated to calculate the measured $\bar{n}(t)$ according to the above equation. The effect of the time constant τ is to shift the

measured signal to larger times relative to $\bar{n}(t)$. τ may be determined by analyzing individual mass spectrometer pulses (see Section II-E-3).

The parameters comprising the instrumental constant K of Eq. (3.23b) are not all known a priori, but their product can be determined by measuring the signal due to a steady and known density of molecules in the ionizer. At steady state, $\bar{n}$ and I are independent of time, so Eqs. (3.24) and (3.10) give the steady state current I_{ss} :

$$I_{ss} = K\bar{n}_{ss} = \frac{K\bar{\chi}\alpha_A P_{eq}(T)}{4\pi s^2 kT} \quad (3.25)$$

The value of K for iron and hydrogen can be determined from Eq. (3.25) using the results of the calibration on the atomic iron beam and on the background pressure of molecular hydrogen. The values of K_{Fe} and K_{H_2} that are obtained are discussed in Section VI-A-2 and Section VI-B-3, respectively.

Once K is known, Eqs. (3.9) and (3.24) can be used to compare theory with experiment.

IV. TEMPERATURE CALCULATIONS

A. Energy Equation for Iron

In order to predict the rate of vaporization from the surface, it is necessary to calculate the time variation of the temperature of the surface resulting from the heating by the laser pulse. The heat and mass transport processes in the solid are assumed to occur at constant volume in order to simplify the calculations. If thermal expansion were considered, it would be necessary to calculate the convection currents in the heated solid and would unduly complicate the problem. The energy equation for a single component solid at constant volume is:⁴¹

$$\rho C_v \frac{\partial T}{\partial t} = \bar{\nabla} \cdot (k \bar{\nabla} T) + A(x, y, z, t) \quad (4.1)$$

where C_v = specific heat at constant volume (cal/cm³ °K)

ρ = density (gm/cm³)

k = thermal conductivity (cal/cm sec °K)

T = temperature of the material (°K)

$A(x, y, z, t)$ = volumetric heat source (cal/cm³ °K)

For pulsed laser heating of the surface, it will be shown that for the laser configuration used, the depth of material heated is much less than the dimensions of the surface area heated. Therefore, to good approximation, heat conduction occurs only in a direction normal to the surface. For uniform heating over the surface, Eq. (4.1) becomes:

$$\rho C_v \frac{\partial T(x, t)}{\partial t} = k \frac{\partial^2 T}{\partial x^2} + \left(\frac{\partial T}{\partial x} \right)^2 \frac{dk(T)}{dT} + A(x, t) \quad (4.2)$$

To account for the possibility of significant ablation from the surface, the semi-infinite solid ($x > 0$) can be considered to be moving

in the negative x-direction at speed $v(T_s)$ relative to the surface. Consider x as the distance from the moving surface rather than the original surface (that is, consider Lagrangian coordinates rather than Eulerian). Therefore, replace the partial derivative with respect to time by the substantial or total derivative,⁴² that is, replace $\frac{\partial T}{\partial t}$ by $\frac{\partial T}{\partial t} - v(T_s) \frac{\partial T}{\partial x}$. Equation (4.2) then becomes

$$\frac{\partial^2 T(x,t)}{\partial x^2} = \frac{1}{K(T)} \frac{\partial T(x,t)}{\partial t} - \frac{v(T_s)}{K(T)} \frac{\partial T(x,t)}{\partial x} - \frac{1}{k(T)} \frac{dk(T)}{dT} \left(\frac{\partial T}{\partial x} \right)^2 - \frac{A(x,t)}{k(T)} \quad (4.3a)$$

subject to the boundary conditions

$$T(x,0) = T_o ; T(\infty,t) = T_o \quad (4.3b)$$

$$-k \frac{\partial T}{\partial x} \Big|_{x=0} = -\phi(T_s) \Delta H_{\text{vap}}(T_s) - \epsilon \sigma (T_s^4 - T_o^4) + A_s(t) \quad (4.3c)$$

where

T_o = initial temperature

T_s = surface temperature

$\phi(T_s)$ = flux of vaporized molecules (moles/cm² sec) given by Eq. (3.4)

$\Delta H_{\text{vap}}(T_s)$ = heat of vaporization (cal/mole)

$\epsilon \sigma (T_s^4 - T_o^4)$ = heat loss from the surface by thermal radiation (cal/cm² sec)

K = thermal diffusivity = $k/\rho C_v$ (cm²/sec)

$A_s(t)$ = surface heat source (cal/cm² sec)

$v(T_s)$ = ablation speed (cm/sec)

If the laser radiation is considered as a volumetric heat source $A(x,t)$, then $A_s(t) = 0$. If it is considered a surface source $A_s(t)$, then $A(x,t) = 0$.

The ablation speed is related to the total flux of molecules vaporizing from the surface by the relation

$$V(T_s) = \Phi(T_s) M/\rho \quad (4.4)$$

where M is the molecular weight of the vaporizing species in AMU and $\Phi(T_s)$ depends on the vapor pressure and temperature of the surface according to Eq. (3.4).

Equations (4.3) are non-linear because of the temperature dependence of the material properties and because at high temperatures the boundary condition at the surface is strongly temperature dependent. Therefore, it is desirable to calculate the temperature by a numerical procedure as described in Appendix B.

B. Approximate Solutions for Iron Temperature

1. Approximate Energy Equation

There are several approximate analytic solutions to Eq. (4.3) that are of use either to check numerical solutions or to show the relative importance of certain effects. Make the approximation that $\Phi(T_s) = A(x,t) = \epsilon = 0$ and that material properties are independent of temperature. Equation (4.3) then becomes:

$$\frac{\partial^2 T(x,t)}{\partial x^2} = \frac{1}{K} \frac{\partial T}{\partial t}$$

$$T(x,0) = T_0; \quad T(\infty,t) = T_0 \quad (4.5)$$

$$K \left. \frac{\partial T}{\partial x} \right|_{x=0} = -A_s(t)$$

2. Rectangular Heat Source Over Entire Plane

The solution to Eq. (4.5) for the surface heat flux $A_s(t)$ a rectangular pulse in time is the simplest approximation for the temperature transient resulting from a laser pulse. The solution for

$$A_s(t) = F_o \quad \text{for} \quad 0 < t < \tau$$

$$= 0 \quad \text{for} \quad t > \tau$$

is given by Carslaw and Jaeger.⁴³ The surface temperature is:

$$T_s(t) - T_o = \frac{2F_o}{k} \left(\frac{Kt}{\pi} \right)^{1/2} \quad \text{for} \quad 0 < t < \tau$$

$$= \frac{2F_o}{k} \left(\frac{K}{\pi} \right)^{1/2} \left[t^{1/2} - (t - \tau)^{1/2} \right] \quad \text{for} \quad t > \tau \quad (4.6)$$

3. Triangular Heat Source Over Entire Plane

The solution to Eq. (4.5) for a triangular surface heat flux in time is useful as an approximation for the temperature profile resulting from a Q-switch pulse (see Fig. 4), the average power of the conventional mode pulse (Figs. 5 and 6), and the power shape of the individual spikes in the conventional mode pulse. Let $A_s(t)$ be given by:

$$A_s(t) = \frac{F_p \tau}{\tau_1} \quad \text{for} \quad 0 < t < \tau_1$$

$$= \left(\frac{\tau_2 - t}{\tau_2 - \tau_1} \right) F_p \quad \text{for} \quad \tau_1 < t < \tau_2 \quad (4.7a)$$

$$= 0 \quad \text{for} \quad t > \tau_2$$

where F_p = absorbed power density at the peak of the triangular pulse

τ_1 = time corresponding to the peak of the pulse

τ_2 = time of the end of the triangular pulse

Equation (4.5) can be solved with the above $A_s(t)$ by the method of Laplace transforms. The solution for $T(x,t)$ evaluated at $x = 0$ is

$$T_s(t) - T_o = \frac{4F_o}{3k} \left(\frac{K}{\pi} \right)^{1/2} \left[\frac{t^{3/2}}{\tau_1} - \frac{\tau_2}{\tau_1} \frac{(t - \tau_1)^{3/2}}{(\tau_2 - \tau_1)} H(t - \tau_1) + \frac{(t - \tau_2)^{3/2}}{\tau_2 - \tau_1} H(t - \tau_2) \right] \quad (4.7b)$$

where $H(t - \tau_1)$ is the Heavyside function:

$$H(t - \tau_1) = 1 \quad \text{for } t > \tau_1 \\ = 0 \quad \text{for } t < \tau_1$$

4. Steady Heat Source Over Circular Area of the Plane

Consider the solution to Eq. (4.5) with $\frac{\partial^2}{\partial x^2}$ replaced by $\frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2}$ and $A_s(t)$ given by

$$A_s(t) = F_o \quad \text{for } t > 0 \quad \text{and} \quad 0 < r < a \\ = 0 \quad \text{for } t > 0 \quad \text{and} \quad r > a \quad (4.8a)$$

The solution to this problem is useful to show the validity of neglecting conduction parallel to the surface. The solution at $r = 0$ given by Carslaw and Jaeger⁴⁴ evaluated at the surface is:

$$T_s(t) \Big|_{r=0} = T_o + \frac{2F_o}{k} \left(\frac{Kt}{\pi} \right)^{1/2} \left[1 - \sqrt{\pi} \operatorname{ierfc} \left(\frac{a}{2\sqrt{Kt}} \right) \right] \quad (4.8b)$$

Of interest is the fractional difference between this solution and the solution obtained for uniform flux over the entire plane. Using Eq. (4.6) (with $\tau \rightarrow \infty$) for the uniform flux solution gives:

$$\frac{T_s(t)_{(\text{plane})} - T_s(t)_{(\text{circle})}}{T_s(t)_{(\text{plane})} - T_o} \Big|_{r=0} = \sqrt{\pi} \operatorname{ierfc}\left(\frac{a}{2\sqrt{Kt}}\right) \quad (4.8c)$$

The function $\operatorname{ierfc}(x)$ is a very rapidly decreasing function of x . For $x = 2.5$, $\sqrt{\pi} \operatorname{ierfc}(x) \approx 10^{-4}$, so the assumption of a plane source is good at $r = 0$ for $\frac{a}{2\sqrt{Kt}} > 2.5$. For a Q-switch pulse the assumption is very good since $\frac{a}{2\sqrt{Kt}} \approx 100$. The worst case to consider is a conventional mode pulse focused on iron. For spot size radius $a = 0.05$ cm, $K = 0.1$ cm²/sec, and $t = 10^{-3}$ sec, $\frac{a}{2\sqrt{Kt}} = 2.5$. Therefore, even in this case the assumption is still quite good, but the assumption gets worse for longer times and smaller spot sizes.

5. Steady Volumetric Heat Source Over Entire Plane Decreasing Exponentially into the Material

Consider the solution to Eq. (4.5) with an exponentially decreasing volumetric source rather than a surface source. That is:

$$\begin{aligned} A(x,t) &= A_o \exp(-x/\delta) \quad \text{for } t > 0 \\ A_s(t) &= 0 \quad \text{for all } t \end{aligned} \quad (4.9a)$$

where $\delta = \text{absorption depth} \approx 100\text{\AA}$ for metals⁴⁵

$$A_o = \frac{F_o}{\delta}$$

$F_o = \text{absorbed power density (cal/cm}^2 \text{ sec)}, \text{ assumed constant for } t > 0$

Since the laser radiation is actually absorbed in this manner it is of interest to compare this solution with the solution for a plane source at the surface. Again, according to Carslaw and Jaeger⁴⁶ the solution in this case at $x = 0$ is:

$$T_s(t) = T_o + \frac{2F_o}{k} \left(\frac{Kt}{\pi} \right)^{1/2} - \frac{F_o \delta}{k} \left[1 - \exp\left(\frac{Kt}{\delta^2}\right) \operatorname{erfc}\left(\frac{\sqrt{Kt}}{\delta}\right) \right] \quad (4.9b)$$

Therefore, the fractional difference between this solution for $\frac{\sqrt{Kt}}{\delta} \gg 1$ and the surface source solution (Eq. (4.6), with $\tau = \infty$) is:

$$\frac{T_s(t)_{\text{(surface source)}} - T_s(t)_{\text{(volume source)}}}{T_s(t)_{\text{(surface source)}} - T_o} \cong \frac{\sqrt{\pi}}{2} \frac{\delta}{\sqrt{Kt}} \quad (4.9c)$$

For a conventional mode pulse on iron ($K \approx 0.1$ and t of interest $\approx 10^{-5} \rightarrow 10^{-4}$ sec):

$$\frac{T_{s(\text{surface source})} - T_{s(\text{volume source})}}{T_{s(\text{surface source})} - T_o} \lesssim 10^{-3}$$

so in this case the surface source assumption is good.

For a Q-switch pulse on iron, t of interest is greater than 25×10^{-9} sec giving:

$$\frac{T_{s(\text{surface source})} - T_{s(\text{volume source})}}{T_{s(\text{surface source})} - T_o} \lesssim 0.02$$

so in this case the surface source assumption is in error by several per cent.

6. The Effect of Spikes in the Conventional Mode Pulse

As seen in Fig. 5, the conventional mode power output consists of a series of discrete spikes rather than a smooth triangular pulse. To account for the effect of the power spikes on the temperature transient, the following simpler problem is considered: Assume that the laser heat input to the surface consists of a series of individual symmetric spikes each with the same peak power F_p , full width $t_1 = 0.5 \mu\text{sec}$, and spacing $t_2 = 1.5 \mu\text{sec}$. This does not represent the real conventional

mode pulse because the peak power of the spikes first increases with time, then decreases in a roughly triangular pattern. The spikes are also more closely spaced in time early in the pulse than at the end of the pulse (see Fig. 5).

The effect of the spikes on the temperature transient at the surface can be determined by first calculating the surface temperature due to this series of uniformly spaced spikes of equal peak power. Then the temperature of the surface is calculated for a constant surface heat flux equal to the time average of the heat flux of the series of spikes. A comparison of these two calculated temperature profiles gives an indication of the effect of the spikes on the temperature transient which should be applicable to the real case where the spikes are not uniformly spaced and not of equal peak power.

First consider the case of a series of spikes of equal peak power.

Let $T_{\text{spike}}(F_p, t - it_2)$ be the change in surface temperature at time t produced by a single spike of peak power F_p which started at time it_2 with the initial solid temperature equal to T_0 . $T_{\text{spike}}(F_p, t - it_2)$ is given by Eq. (4.7b) with t replaced by $t - it_2$, $\tau_2 = t_1$ and $\tau_1 = t_1/2$. The surface temperature due to a series of such spikes spaced in time by t_2 is given by the superposition principle:

$$T_{\text{series}}(F_p, t) = T_0 + \sum_{i=0}^j T_{\text{spike}}(F_p, t - it_2) \quad (4.10)$$

where j is the largest value of i such that $(t - it_2) > 0$, (i.e., j is the number of spikes up to time t).

Now consider the case in which the surface is subject to a constant heat flux whose magnitude is given by the average of the spikes,

$F_{avg} = F_p t_1/2t_2$. The surface temperature is given by Eq. (4.6) with $\tau \rightarrow \infty$:

$$T_{avg}(t) = T_o + \frac{2 F_{avg}}{k} \left(\frac{Kt}{\pi} \right)^{1/2} \quad (4.11)$$

Therefore the temperature oscillation induced by the spikes is given by

$$\Delta T(F_p, t) = T_{series}(F_p, t) - T_{avg}(t) \quad (4.12)$$

The surface temperature calculated by Eqs. (4.10) and (4.11) is shown in Fig. 14 for early times. It is apparent that after several spikes, the shape of the temperature oscillation stabilizes. By expanding Eq. (4.12) in a Taylor series for large j is seen that for $j \gtrsim 15$, ΔT is a function only of t' (the time from the beginning of a spike) and not t , that is, the shape has stabilized. The result for ΔT for $j > 15$ is:

$$\Delta T(F_p, t') = T_{spike}(F_p, t') \quad (4.13)$$

$$- \frac{2 F_{avg}}{k} \sqrt{\frac{Kt_2}{\pi}} \left\{ \left(\ell - \frac{1}{2} \right)^{1/2} + \frac{t'}{2 t_2 \left(\ell - \frac{1}{2} \right)^{1/2}} \right. \\ \left. - \frac{8}{3} \sqrt{\frac{t_2}{t_1}} \sum_{i=1}^{\ell-1} \left[g_i^{3/2} + (g_i - 1)^{3/2} - 2 \left(g_i - \frac{1}{2} \right)^{3/2} \right] \right\}$$

where $g_i = (t' + i t_2)/t_1$

$$\ell \approx 15$$

The summation in Eq. (4.13) is required because the terms under the summation are not accurately given by a Taylor series expansion for small i and the summation is not accurately approximated by an integral for small i .

For the real case of temperature dependent material properties and time dependent peak spike power, it is assumed that the temperature

XBL 7210-5785

Fig. 14 Surface temperature resulting from a series of equally spaced spikes of equal height (oscillating curve) and from a constant surface heat flux whose magnitude is equal to the average of the power in the series of spikes.

oscillation is still given by Eq. (4.13). However, F_p and F_{avg} are now functions of time, and the thermal conductivity k and thermal diffusivity K are taken at the average temperature calculated numerically. This assumption should be valid if k and K are approximately constant during a spike and if F_{avg} varies slowly during several spikes.

The most probable velocity of an atom of mass m vaporized from a surface at temperature T is $\tilde{v} = \sqrt{3kT/m}$. The time of flight of an iron atom vaporized from a surface at 2000°K to the mass spectrometer ionizer is ~400 μ sec. For an instantaneous pulse of atoms from the surface, the time spread of the pulse observed by the mass spectrometer is also ~400 μ sec, as can be shown by calculating the velocity at which $vF(v)$ is a factor of e less than $\tilde{v}F(\tilde{v})$ and converting the former to time. Since the width in time due to the velocity spread of the atoms is much greater than the time between laser spikes, the mass spectrometer signal does not see the individual temperature oscillations. Since the vapor pressure is an exponentially increasing function of reciprocal temperature, the average vapor pressure during one temperature oscillation is greater than the vapor pressure at the average temperature during the oscillation. This effect was found to give predicted mass spectrometer signals approximately 10% larger than would be obtained by taking the vapor pressure at the average temperature. The effect of the spikes on the temperature transient was therefore neglected, and the conventional mode pulse was approximated by the average power determined by taking the time derivative of the Korad energy trace. As shown in Section II-C-2, the shape of the average power is approximately triangular with the peak at 0.15 msec and the end of the pulse at 1.0 msec.

C. Energy and Hydrogen Diffusion Equations for Zirconium Hydride

For a two-component material such as zirconium hydride in which one component is very mobile, the energy and species conservation equations are interrelated. The diffusing species transports energy as well as mass, and, in addition, a temperature gradient implies the existence of the Soret mass flux and Dufour energy flux according to the thermodynamics of irreversible processes. The general energy equation for a binary system neglecting terms involving convective velocity and body forces is:⁴⁷

$$\rho \frac{dE}{dt} = - \nabla \cdot \mathbf{q} - \nabla \cdot \sum_{i=1}^2 j_i \bar{h}_i + A(x,y,z,t) \quad (4.14)$$

where

ρ = mass density

E = specific internal energy

$\mathbf{q}$ = "second law heat flux"

j_i = diffusive mass flux of component i relative to the mass average velocity

$\bar{h}_i$ = partial specific enthalpy of component i

$A(x,y,z,t)$ = external volumetric energy source

For the case of hydrogen diffusing in zirconium, make the following assumptions:

- a) Each volume element maintains constant volume during the heating and diffusing process.
- b) The zirconium atoms are on a fixed, rigid lattice so that the zirconium is immobile and there is no change in the number of zirconium atoms in each volume element during the process.
- c) Since the mass of hydrogen is only about 1% of the mass of zirconium, the mass average velocity will be considered to be zero.

Note that according to assumption (b), surface ablation which produces the recession velocity in iron vaporization is absent in this case.

To evaluate $\frac{dE}{dt}$ consider an element of volume of energy e containing m_H grams of H and m_{Zr} grams of Zr. By the definition of E , $E = e/(m_{Zr} + m_H)$ which is approximately equal to e/m_{Zr} since m_H is much smaller than m_{Zr} . Since the volume and number of zirconium atoms are assumed constant, e (and therefore E) are functions only of m_H and T . Since the mass average velocity is assumed to be zero, the substantial derivative $\frac{dE}{dt} = \frac{\partial E}{\partial t}$. Therefore,

$$\frac{\partial E}{\partial t} = \left(\frac{\partial E}{\partial m_H} \right)_T \left(\frac{\partial m_H}{\partial t} \right) + \left(\frac{\partial E}{\partial T} \right)_{m_H} \left(\frac{\partial T}{\partial t} \right) \quad (4.15)$$

By the definition of specific heat at constant volume:

$$\left(\frac{\partial E}{\partial T} \right)_{m_H} = \left(\frac{\partial E}{\partial T} \right)_{m_H, m_{Zr}, v} = C_v \quad (4.16)$$

Since $E \approx e/m_{Zr}$,

$$\left(\frac{\partial E}{\partial m_H} \right)_T = \frac{1}{m_{Zr}} \left(\frac{\partial e}{\partial m_H} \right)_T = \frac{1}{m_{Zr}} \left(\frac{\partial e}{\partial m_H} \right)_{T, p, m_{Zr}} \quad (4.17)$$

where the last equality is due to assumptions (a) and (b). By the definition of partial specific quantities:

$$\begin{aligned} \left(\frac{\partial e}{\partial m_H} \right)_{T, p, m_{Zr}} &\equiv \bar{e}_H = \text{partial specific energy of H} \\ \left(\frac{\partial h}{\partial m_H} \right)_{T, p, m_{Zr}} &\equiv \bar{h}_H = \text{partial specific enthalpy of H} \\ \left(\frac{\partial v}{\partial m_H} \right)_{T, p, m_{Zr}} &\equiv \bar{v}_H = \text{partial specific volume of H} \end{aligned} \quad (4.18)$$

From the thermodynamic definition of enthalpy it can be shown that

$$\bar{h}_H = \bar{e}_H + p\bar{v}_H \quad (4.19)$$

Because of the constant volume assumption, $\bar{v}_H = 0$, so

$$\bar{e}_H = \bar{h}_H \quad (4.20)$$

Combining Eqs. (4.17), (4.18) and (4.20) gives

$$\left(\frac{\partial E}{\partial m_H} \right)_T = \frac{1}{m_{Zr}} \bar{h}_H \quad (4.21)$$

Therefore,

$$\begin{aligned} \rho \frac{\partial E}{\partial t} &= \rho C_v \frac{\partial T}{\partial t} + \frac{\rho}{m_{Zr}} \bar{h}_H \frac{\partial m_H}{\partial t} \\ &= \rho C_v \frac{\partial T}{\partial t} + \bar{h}_H \frac{\partial c_H}{\partial t} \end{aligned} \quad (4.22)$$

where c_H is the mass density of H in the solid (gms H/cm³). By assumptions (b) and (c), $j_{Zr} = 0$ so the energy equation (with spatial variation in the x direction only) becomes:

$$\rho C_v \frac{\partial T}{\partial t} + \bar{h}_H \frac{\partial c_H}{\partial t} = - \frac{\partial q}{\partial x} - \frac{\partial}{\partial x} (\bar{h}_H j_H) + A(x,t) \quad (4.23)$$

The equation representing the conservation of hydrogen mass is:

$$\frac{\partial c_H}{\partial t} = - \frac{\partial}{\partial x} j_H \quad (4.24)$$

Using this in Eq. (4.23) gives:

$$\rho C_v \frac{\partial T}{\partial t} = - \frac{\partial q}{\partial x} - j_H \frac{\partial \bar{h}_H}{\partial x} + A(x,t) \quad (4.25)$$

Because $j_{Zr} = 0$ and $\bar{e}_H = \bar{h}_H$ the second law heat flux is equal to the first law heat flux of ordinary heat condition.⁴⁷ The heat flux and hydrogen flux are given by Shewmon:⁴⁸

$$q = - \frac{DQ^*}{M_H} \frac{\partial c_H}{\partial x} - k \frac{\partial T}{\partial x} \quad (4.26)$$

$$j_H = - D \frac{\partial c_H}{\partial x} - \frac{DQ^*c_H}{RT^2} \frac{\partial T}{\partial x} \quad (4.27)$$

where D = diffusion coefficient of hydrogen in zirconium hydride

Q* = heat of transport of hydrogen in zirconium hydride

k = thermal conductivity of the zirconium hydride

M_H = molecular weight of H

The first term in Eq. (4.26) is the Dufour energy flux due to a concentration gradient in the material. The form given is derived assuming that the diffusing species is dilute and obeys Henry's law. Although this is not true for a large concentration of hydrogen in zirconium, the difference is neglected since the Dufour flux is generally very small. The second term in Eq. (4.27) is the Soret mass flux due to a temperature gradient in the material. This can be a significant term in the presence of large temperature gradients such as exist in the laser-heated material.

Substituting Eqs. (4.26) and (4.27) in Eqs. (4.24) and (4.25) gives the hydrogen and energy conservation equations in the form:

$$\frac{\partial c_H}{\partial t} = \frac{\partial}{\partial x} \left[D \frac{\partial c_H}{\partial x} + \frac{DQ^*c_H}{RT^2} \frac{\partial T}{\partial x} \right] \quad (4.28)$$

$$\rho C_v \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left[\frac{DQ^*}{M_H} \frac{\partial c_H}{\partial x} + k \frac{\partial T}{\partial x} \right] + \left[D \frac{\partial c_H}{\partial x} + \frac{DQ^*c_H}{RT^2} \frac{\partial T}{\partial x} \right] \frac{\partial \bar{h}_H}{\partial x} + A(x,t) \quad (4.29)$$

The initial and boundary conditions for T and c_H are:

$$T(x,0) = T_0 ; T(\infty,t) = T_0 \quad (4.30a)$$

$$c_H(x,0) = C_0 ; C(\infty,t) = C_0 \quad (4.30b)$$

$$-j_H \Big|_{x=0} = D \frac{\partial c_H}{\partial x} \Big|_{x=0} + \frac{DQ^*c_H}{RT^2} \frac{\partial T}{\partial x} \Big|_{x=0} = 2\phi(T_s, c_s) M_H \quad (4.30c)$$

$$\begin{aligned} -q \Big|_{x=0} = \frac{DQ^*}{M_H} \frac{\partial c_H}{\partial x} \Big|_{x=0} + k \frac{\partial T}{\partial x} \Big|_{x=0} = -A_s(t) + \epsilon\sigma(T_s^4 - T_o^4) \\ + 2\phi(T_s, c_s) \Delta H_{vap}(T_s, c_s) \end{aligned} \quad (4.30d)$$

where the coefficient "2" of ϕ is due to the fact that Eq. (3.4) gives the flux of H_2 . $\Delta H_{vap} \frac{1}{2} H_{H_2}^o - \bar{H}_H$ is the heat of vaporization per mole of H atoms which equals the negative of the relative partial molar enthalpy of H in zirconium hydride, where $\bar{H}_H$ is simply equal to $M_H \bar{h}_H$. ΔH_{vap} is found in terms of the H_2 vapor pressure, as described in Section V-B-4. The remaining terms in Eq. (4.30) have been defined previously.

The boundary conditions can be separated to find $\frac{\partial c_H}{\partial x} \Big|_{x=0}$ and $\frac{\partial T}{\partial x} \Big|_{x=0}$ explicitly. It is also convenient to put the equations in terms of H/Zr atom ratio y rather than mass concentration c_H . After making these changes, the conservation equations become:

$$\frac{\partial y}{\partial t} = \frac{\partial}{\partial x} \left[D \frac{\partial y}{\partial x} + \frac{DQ^*y}{RT^2} \frac{\partial T}{\partial x} \right] \quad (4.31a)$$

$$\rho C_v \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left[DQ^*N_o \frac{\partial y}{\partial x} + k \frac{\partial T}{\partial x} \right] + DN_o \left[\frac{\partial y}{\partial x} + \frac{Q^*y}{RT^2} \frac{\partial T}{\partial x} \right] \frac{\partial \bar{H}_H}{\partial x} + A(x, t) \quad (4.31b)$$

with boundary conditions:

$$T(x,0) = T_0 ; T(\infty,t) = T_0 \quad (4.31c)$$

$$y(x,0) = y_0 ; y(\infty,t) = y_0 \quad (4.31d)$$

$$\left(\frac{\partial T}{\partial x} \right) \bigg|_{x=0} = \frac{2\phi(\Delta H_{\text{vap}} - Q^*) - A_s(t) + \epsilon\sigma(T_s^4 - T_0^4)}{k - \frac{DQ^*^2 N_0 y_s}{RT_s^2}} \quad (4.31e)$$

$$\left(\frac{\partial y}{\partial x} \right) \bigg|_{x=0} = \frac{2\phi}{N_0 D} - \frac{Q^* y_s}{RT_s^2} \left(\frac{\partial T}{\partial x} \right) \bigg|_{x=0} \quad (4.31f)$$

where $N_0 = \rho_0 / (M_{\text{Zr}} + y_0 M_{\text{H}})$ = number of zirconium atoms per unit volume

ρ_0 = initial density (gm/cm³)

y_0 = initial H/Zr atom ratio

y_s = H/Zr atom ratio at the surface

T_s = surface temperature

An approximate solution for the zirconium hydride temperature can be obtained analytically from Eqs. (4.31b, c and e) by assuming Q^* , ϕ , and $\frac{\partial \bar{H}}{\partial x}$ are zero and that k and C_v are constant. The solution for a triangular pulse is the same as that given for heating of iron by Eq. (4.7). However, there is no useful analytic solution for y because of the strong temperature dependence of D and the strong temperature and H/Zr ratio dependence of ϕ . Therefore, it is desirable to calculate both T and y by a numerical solution as described in Appendix B.

V. MATERIAL PROPERTIES USED IN THE NUMERICAL CALCULATIONS

A. Iron Properties

1. Vapor Pressure

The vapor pressure of iron is given by Nesmeianov⁴⁹ as:

$$\log_{10} P = 19.00206 - 21.67992 \times \left(\frac{10^3}{T}\right) + 0.09398 \times \left(\frac{T}{10^3}\right) - 2.59964 \log_{10} T \quad (5.1a)$$

for solid iron $29^\circ\text{K} < T < 1812^\circ\text{K}$

$$\log_{10} P = -25.93396 - 14.1245 \times \left(\frac{10^3}{T}\right) - 1.1331 \times \left(\frac{T}{10^3}\right) + 10.59505 \log_{10} T \quad (5.1b)$$

for liquid iron $1812^\circ\text{K} < T < 3045^\circ\text{K}$

where P is the vapor pressure in mm Hg, and T is in $^\circ\text{K}$.

For temperatures greater than the boiling point (3045°K) it is assumed that the vapor pressure is still given by Eq. (5.1b). The vapor pressure is a very rapidly increasing function of temperature. The vapor pressure at the melting point (1812°K) is only 0.0546 mm Hg, while at 3045°K it is 1 atmosphere or 760 mm Hg (by definition of boiling point).

2. Heat of Vaporization

The heat of vaporization is determined from the expression for the vapor pressure (Eqs. (5.1)) using the Clapeyron equation:⁵⁰

$$\Delta H_{\text{vap}} = -R \frac{d \ln P}{d(1/T)} \quad (5.2)$$

where R = gas constant = 1.987 cal/ $^\circ\text{K}$ mole.

The value of ΔH_{vap} varies from 96.7 kcal/mole at 298°K to 80 kcal/mole

at 3045°K. These values are about 3% lower than those given in the JANAF tables.²⁸

3. Specific Heat

The specific heat of iron exhibits several discontinuities in going from room temperature to above the melting point because of changes in crystal structure. According to the JANAF tables²⁸ there is an alpha to gamma transition at 1184°K with a heat of transition $\Delta H_{t_1} = 0.225$ kcal/mole, a gamma to delta transition at 1665°K with a heat of transition $\Delta H_{t_2} = 0.260$ kcal/mole, and a solid to liquid transition at 1809°K with $\Delta H_m = 3.630$ kcal/mole. In addition, the specific heat exhibits a sharp peak at the Curie point (1042°K) because of a magnetic transformation.

The molar enthalpy of a material at temperature T can be expressed in terms of the heats of transition and melting and the molar heat capacity at constant pressure C_p as follows:

$$H^\circ(T) = H^\circ_{298} + \sum_i \Delta H_{t_i} + \int_{298}^T C_p dT' \quad (5.3)$$

where H°_{298} = standard molar enthalpy at $T = 298^\circ\text{K}$ and the sum of ΔH_{t_i} includes all transitions occurring between 298°K and T.

The heats of transition and melting could be taken into consideration by defining an apparent molar heat capacity C'_p equal to:

$$C'_p(T) = C_p(T) + \sum_i \Delta H_{t_i} \delta(T - T_{t_i}) \quad (5.4)$$

where $\delta(T - T_{t_i})$ = Dirac delta function

T_{t_i} = transition or melting temperature

Since the integral of the delta function across a transition temperature is unity:

$$H^{\circ}(T) = H_{298}^{\circ} + \int_{298}^T C_p' dT' \quad (5.5)$$

Since discontinuities in material properties are not desirable in the numerical solution of the conduction equation, the heat capacity is approximated by a continuous function of temperature. Instead of using a delta function to account for the heat of melting, a Gaussian function of finite width centered at the melting point is used. The sharp peak at the Curie point is also approximated by a Gaussian function. The heats of transition are taken into account by uniformly increasing the specific heat in the range between the two transition temperatures. The numerical values for heat capacity and enthalpy given in the JANAF tables²⁸ were used in conjunction with the graph of heat capacity vs temperature given by Lange⁵¹ to obtain the following approximate form for the apparent specific heat in (cal/gm°K).

$$C = \frac{1}{55.85} \left[\frac{766}{\sqrt{\pi}\sigma_1} \exp\left(-\frac{(T-1000)^2}{\sigma_1^2}\right) + \frac{3630}{\sqrt{\pi}\sigma_2} \exp\left(-\frac{(T-1809)^2}{\sigma_2^2}\right) \right] \quad (5.6)$$

$$+ \frac{1}{55.85} \begin{cases} 3.369 + 7.289 \left(\frac{T}{10^3}\right) & \text{for } 298^{\circ}\text{K} < T < 800^{\circ}\text{K} \\ 9.2 & \text{for } 800^{\circ}\text{K} < T < 1200^{\circ}\text{K} \\ 13.768 - 7.748 \left(\frac{T}{10^3}\right) + 3.284 \left(\frac{T}{10^3}\right)^2 & \text{for } 1200^{\circ}\text{K} < T < 1809^{\circ}\text{K} \\ 10.50 + 4.0 \times 10^{-4}(T - 1809) & \text{for } T > 1809^{\circ}\text{K} \end{cases}$$

where σ_1 = half width of the Curie peak = 130°K

σ_2 = half width of the heat of melting peak = 50°K

The fit was made so that the $\int_{298}^T C_d T'$ was approximately equal to

the increase in specific enthalpy in going from 298°K to T. The above equation gives the specific heat at constant pressure rather than constant volume as used in the conduction equation (Eq. (4.3)). The small difference between these is neglected since the actual process probably occurs closer to constant pressure than constant volume.

4. Thermal Conductivity

Like the specific heat, the thermal conductivity of iron exhibits discontinuities at the phase transition temperatures. An approximate continuous form was made by a least squares fit of U. S. National Bureau of Standards data⁵² for temperature less than 1200°K and by linear approximations of the Lange data⁵¹ for temperature greater than 1200°K. The thermal conductivity is assumed to be constant in the liquid range. The form used for k, given in (cal/cm sec K) is:

$$\begin{aligned} k &= 0.2770 - 0.3144 \left(\frac{T}{10^3} \right) + 0.1173 \left(\frac{T}{10^3} \right)^2 \text{ for } 298^\circ\text{K} < T < 1200^\circ\text{K} \\ &= 0.0395 + 0.02428 \left(\frac{T}{10^3} \right) \text{ for } 1200^\circ\text{K} < T < 1700^\circ\text{K} \\ &= -0.0858 + 0.0980 \left(\frac{T}{10^3} \right) \text{ for } 1700^\circ\text{K} < T < 1900^\circ\text{K} \\ &= 0.100 \text{ for } T > 1900^\circ\text{K} \end{aligned} \tag{5.7}$$

5. Density

Although the conduction equation was derived under the assumption of constant volume and therefore constant density, the small variation of density with temperature was considered in order to give a more

realistic value for the thermal diffusivity. The density data of Lange⁵¹

$$\begin{aligned}\rho &= 7.990 - 0.388 \left(\frac{T}{10^3} \right) \text{ for } 298^\circ\text{K} < T < 1700^\circ\text{K} \\ &= 10.82 - 2.05 \left(\frac{T}{10^3} \right) \text{ for } 1700^\circ\text{K} < T < 1900^\circ\text{K} \\ &= 8.63 - 0.90 \left(\frac{T}{10^3} \right) \text{ for } T > 1900^\circ\text{K}\end{aligned} \quad (5.8)$$

where ρ is in (gm/cm^3) .

6. Reflectivity

The reflectivity of iron at $6943\text{\AA}$ is the most difficult of the iron properties to characterize. Data from Ref. 53 indicates that the reflectivity of solid iron varies from 0.45 to 0.66 depending on the surface condition and temperature.

Since the reflectivity is not well known, the numerical calculations are made assuming the reflectivity has some adjustable constant value R . The calculations are made for varying absorbed energy densities. The incident energy density is then hypothesized to be equal to the absorbed energy density divided by $(1 - R)$.

B. Zirconium Hydride Properties

1. Zirconium-Hydrogen Phase System

Zirconium is an exothermic absorber of hydrogen which forms solid solutions and hydrides of varying composition depending on temperature and hydrogen content. The phase diagram of the Zr-H system as given by Beck and Mueller⁵⁴ is shown in Fig. 15. The alpha and beta phases are low and high temperature solid solutions of hydrogen in alpha and

XBL 7211-7225

Fig. 15 Zirconium-hydrogen phase diagram. $\text{ZrH}_{1.63}$ was the composition used in the present studies.

beta zirconium respectively. The delta and epsilon phases are high hydrogen content hydride phases with maximum hydrogen content at the stoichiometric composition ZrH_2 .

Experimental evidence indicates that the hydrogen exists as H atoms rather than H_2 molecules in the zirconium lattice. At low hydrogen concentration the solubility of hydrogen is proportional to the square root of H_2 pressure.⁵⁵ This is the behavior predicted by Sieverts law⁵⁶ for the hydrogen existing as atoms in solution. Neutron diffraction studies have shown that the delta phase has a fluorite structure with the zirconium atoms on a face-centered cubic lattice and the hydrogen atoms in tetrahedral sites.⁵⁴ The beta phase consists of zirconium atoms on a body-centered cubic lattice with the H atoms in solid solution.

If the behavior of the zirconium hydride during the Q-switch laser pulse is truly an equilibrium process, the phase structure at all times would be given by the equilibrium phase diagram Fig. 15. As the delta phase hydride heats up, vaporization from the surface depletes the hydrogen concentration. When the temperature and hydrogen concentration are at the boundary between the delta and beta plus delta regions, further depletion of hydrogen would bring the material into the beta plus delta phase region. Delta phase hydride would be converted to beta phase until all delta phase is converted. Still further hydrogen depletion would be all in the beta phase.

In order for this complete equilibrium model to hold, the delta to beta phase transition would have to occur in times the order of 10^{-8} seconds, which is many orders of magnitude smaller than times of normal phase changes. In the process of changing from delta to beta phase,

the zirconium lattice must change from FCC to BCC structure and the hydrogen must redistribute so that the beta phase has a low hydrogen concentration. It is possible, but not probable, that these changes could take place in such a short time since the time scale is large compared to atom oscillation times (10^{-13} sec), the hydrogen atoms are very mobile at high temperatures, and since hydrogen migration need occur only over very short distances (10^{-6} cm). Experiments on pulse-heating of zirconium-uranium hydride rods have shown⁵⁷ that the delta to beta phase change can occur at least in times on the order of 10^{-1} sec.

If the temperature transient is too rapid for the phase change to occur, the sample would stay in the delta phase configuration but could have hydrogen content lower than that given by the equilibrium phase diagram. This will be denoted as the quasi-equilibrium case since the phase structure is not that given by the equilibrium phase diagram for hydrogen content less than that at the delta-beta plus delta boundary. Material properties for this case are extrapolated from known values in the delta phase.

Both the equilibrium and quasi-equilibrium models are used to predict the behavior of the zirconium hydride when heated by a Q-switch laser pulse. The actual behavior is probably somewhere between the two models. Possibly, the quasi-equilibrium model is valid for hydrogen concentration not much less than that at the delta-beta plus delta boundary. For hydrogen concentrations much less than at this boundary the delta phase zirconium lattice would probably collapse to the equilibrium beta zirconium lattice.

2. Vapor Pressure

a. Equilibrium model

The equilibrium vapor pressure of hydrogen over Zr-H is a strong function of both hydrogen content and temperature. Simnad and Dee⁵⁸ give an empirical fit by Raymond for the vapor pressure of delta and epsilon phase as follows:

$$\begin{aligned} \log_{10} P_{\delta} = & -3.8415 + 38.6433 y - 34.2639 y^2 + 9.2821 y^3 \\ & + [-31.2982 + 23.5741 y - 0.0280 y^2] \left(\frac{10^3}{T} \right) \end{aligned} \quad (5.9a)$$

for $y > y_{\delta}$

where P_{δ} = vapor pressure of H_2 in atmospheres

T = temperature in °K

y = H/Zr atom ratio

y_{δ} = H/Zr atom ratio at the delta-beta plus delta boundary

A least squares fit of the vapor pressure data for the beta plus delta region compiled by Beck and Mueller⁵⁴ is:

$$\ln P_{\beta+\delta} = 28.684 - 25.496 \left(\frac{10^3}{T} \right) \quad \text{for } y_{\beta} < y < y_{\delta} \quad (5.9b)$$

where $P_{\beta+\delta}$ = vapor pressure of H_2 in mm Hg

y_{β} = H/Zr ratio at the beta-beta plus delta boundary

An approximate fit of the Beck and Mueller data⁵⁴ for the beta phase vapor pressure (in mm Hg) is:

$$\begin{aligned} \ln P_{\beta_1} = & 10.753 + 15.750 y - (10.610 + 12.503 y) \left(\frac{10^3}{T} \right) \\ & \text{for } 0.1 < y < y_{\beta} \end{aligned} \quad (5.9c)$$

$$P_{\beta_2} = P_{\beta_1} \Big|_{y=0.1} \times \left(\frac{y}{0.1} \right)^2 \quad \text{for } 0 < y < 0.1 \quad (5.9d)$$

Equation (5.9d) requires the vapor pressure to obey Sieverts law for y less than 0.10. Figure 16 shows the $\log_{10} P$ vs y as given by Eqs. (5.9) for temperature increments of 50°C from $T = 550^\circ\text{C}$ to 1100°C .

b. Quasi-equilibrium model

For no delta to beta phase change, the vapor pressure is assumed to be given by Eq. (5.9a) for y greater than 1.425. For y less than 1.425, two models are proposed: a) the vapor pressure at constant temperature is extrapolated to lower y with some constant slope (see Fig. 17) or b) it is extrapolated with a continuous slope that depends on temperature (see Fig. 18). In both cases, Sieverts law is assumed for y less than 0.1.

3. Total and Partial Molar Enthalpies of ZrH_y

The total enthalpy of a mole of ZrH_y is equal to

$$H = \bar{H}_{\text{Zr}} + y \bar{H}_{\text{H}} \quad (5.10)$$

where $\bar{H}_{\text{Zr}}$ = partial molar enthalpy of Zr

$\bar{H}_{\text{H}}$ = partial molar enthalpy of H

In a one phase region, the relative partial molar enthalpy of H is given in terms of the slope of the vapor pressure curve at constant y by the relation:⁵⁶

$$\bar{H}_{\text{H}} - \frac{1}{2} H_{\text{H}_2}^\circ = \frac{R}{2} \left[\frac{\partial \ln P}{\partial (1/T)} \right]_y \quad (5.11)$$

XBL 7210-5778

Fig. 16 H_2 pressure-composition isotherms for zirconium-hydrogen system, equilibrium model.

XBL 7210-5779

Fig. 17 H_2 pressure-composition isotherms, quasi-equilibrium model with vapor pressure extrapolated to lower composition with constant slope.

XBL 7210-5780

Fig. 18 H_2 pressure-composition isotherms, quasi-equilibrium model with vapor pressure extrapolated to lower composition with continuous slope.

where $H_{H_2}^{\circ}$ = standard molar enthalpy of H_2 gas

R = gas constant

P = vapor pressure in a single phase region given by

Eq. (5.9a,c,d)

In the two phase beta pulse delta region in the equilibrium model, the true composition of ZrH_y in terms of $ZrH_{y_{\beta}}$ and $ZrH_{y_{\delta}}$ is given by the lever rule:

$$ZrH_y = \frac{(y_{\delta} - y)}{(y_{\delta} - y_{\beta})} ZrH_{y_{\beta}} + \frac{(y - y_{\beta})}{(y_{\delta} - y_{\beta})} ZrH_{y_{\delta}} \quad (5.12)$$

The total enthalpy of ZrH_y in this two phase region is then:

$$H = \frac{(y_{\delta} - y)}{(y_{\delta} - y_{\beta})} \left[\bar{H}_{Zr_{y_{\beta}}} + y_{\beta} \bar{H}_{H_{y_{\beta}}} \right] + \frac{(y - y_{\beta})}{(y_{\delta} - y_{\beta})} \left[\bar{H}_{Zr_{y_{\delta}}} + y_{\delta} \bar{H}_{H_{y_{\delta}}} \right] \quad (5.13)$$

Identifying $\bar{H}_{Zr}$ and $\bar{H}_H$ from Eqs. (5.10) and (5.13) gives

$$\bar{H}_{Zr} = \frac{(y_{\delta} - y)}{(y_{\delta} - y_{\beta})} \bar{H}_{Zr_{y_{\beta}}} + \frac{(y - y_{\beta})}{(y_{\delta} - y_{\beta})} \bar{H}_{Zr_{y_{\delta}}} \quad (5.14)$$

and

$$\bar{H}_H = \frac{y_{\beta}}{y} \frac{(y_{\delta} - y)}{(y_{\delta} - y_{\beta})} \bar{H}_{H_{y_{\beta}}} + \frac{y_{\delta}}{y} \frac{(y - y_{\beta})}{(y_{\delta} - y_{\beta})} \bar{H}_{H_{y_{\delta}}} \quad (5.15)$$

where $\bar{H}_{y_{\beta}}$ = partial molar enthalpy of H in beta phase at composition y_{β}

$\bar{H}_{y_{\delta}}$ = partial molar enthalpy of H in delta phase at composition y_{δ}

4. Heat of Vaporization

The heat of vaporization is equal to the negative of the relative partial molar enthalpy of H. Therefore, for a single phase region

ΔH_{vap} is given by Eq. (5.11):

$$\Delta H_{\text{vap}} = - (\bar{H}_H - \frac{1}{2} H_{H_2}^{\circ}) = - \frac{R}{2} \left[\frac{\partial \ln P}{\partial (1/T)} \right] \bigg|_y \quad (5.16a)$$

For a two phase region, ΔH_{vap} is found from Eqs. (5.15) and (5.16a):

$$\Delta H_{\text{vap}} = \frac{y_{\beta}}{y} \frac{(y_{\delta} - y)}{(y_{\delta} - y_{\beta})} \Delta H_{\text{vap}}_{y_{\beta}} + \frac{y_{\delta}}{y} \frac{(y - y_{\beta})}{(y_{\delta} - y_{\beta})} \Delta H_{\text{vap}}_{y_{\delta}} \quad (5.16b)$$

The heat of vaporization calculated from Eqs. (5.16) and the given vapor pressure equations varies with composition, but is on the order of 20 kcal/mole of H atoms.

5. Specific Heat

The heat capacity data given in Ref. 54 was found to fit the form:

$$C_p = C_{\text{Zr}} + y \bar{C}_H \quad (5.17a)$$

where C_p = heat capacity of ZrH_y per mole of Zr

C_{Zr} = molar heat capacity of pure Zr

$\bar{C}_H$ = partial molar heat capacity of hydrogen in ZrH_y

C_{Zr} in (cal/°K-mole Zr) is fit to the form:

$$\begin{aligned} C_{\text{Zr}} &= 5.3 + 3.33 \left(\frac{T}{10^3} \right) \quad \text{for } T < 600^{\circ}\text{K} \\ &= 6.46 + 1.4 \left(\frac{T}{10^3} \right) \quad \text{for } 600^{\circ}\text{K} < T < 1100^{\circ}\text{K} \\ &\approx 8.0 \quad \text{for } T > 1100^{\circ}\text{K} \end{aligned} \quad (5.17b)$$

$\bar{C}_H$ was fit to the form for lattice heat capacity according to the Einstein model:⁵⁹

$$\bar{C}_H = 7.0 \left(\frac{\theta_E}{T} \right)^2 \frac{\exp(\theta_E/T)}{(\exp(\theta_E/T) - 1)^2} \left(\frac{\text{cal}}{^\circ\text{K mole H}} \right) \quad (5.17c)$$

where θ_E = Einstein temperature, which was chosen to be 1650°K. This relatively large value for the Einstein temperature is due to the low hydrogen atom mass, which causes a high frequency of vibration of hydrogen atoms in the lattice.

The specific heat is equal to the heat capacity given by Eqs. (5.17) divided by the gram molecular weight of ZrH_y . That is,

$$C \cong \frac{C_p}{92.2} \left(\frac{\text{cal}}{^\circ\text{K gm}} \right) \quad (5.18)$$

In the beta plus delta region in the equilibrium model, there is an additional contribution to the apparent heat capacity because of the change in enthalpy in converting delta phase to beta phase at constant y . This contribution is neglected, however, because its effect is small.

As in the iron case, the value of specific heat at constant pressure is used instead of the specific heat at constant volume.

6. Thermal Conductivity

The thermal conductivity data given in Ref. 54 shows a large amount of scatter and no regular variation with hydrogen concentration or temperature. The only exception to this is an apparent decrease of thermal conductivity of delta phase hydride with increasing temperature. The thermal conductivity values fall in the range $0.05 \pm 0.02 \text{ cal/cm sec } ^\circ\text{C}$ for varying compositions and temperatures.

For the equilibrium model, the thermal conductivity is assigned the constant value

$$k = 0.05 \text{ (cal/cm sec } ^\circ\text{C)} \quad (5.19)$$

For the quasi-equilibrium model, the thermal conductivity is that of delta phase hydride, given approximately by

$$\begin{aligned} k &= 0.05 + 0.01[1 - \exp(-(723 - T)/150)] \quad \text{for } T < 723^\circ\text{K} \\ k &= 0.05 - 0.01[1 - \exp(-(T - 723)/150)] \quad \text{for } T > 723^\circ\text{K} \end{aligned} \quad (5.20)$$

7. Diffusion Coefficient

The diffusion coefficient of delta phase zirconium hydride as measured by Albrecht and Goode (given in Ref. 54) is

$$D_\delta = 599 \exp(-54,900/RT) \text{ (cm}^2\text{/sec)} \quad (5.21)$$

However, the activation energy for diffusion measured in two nuclear magnetic resonance studies has the value 12.3 kcal/mole rather than 34.9 kcal/mole. Beck and Mueller attribute this difference to the fact that some of the Albrecht and Goode data were made on epsilon phase hydride rather than delta phase. This could have given an approximately correct magnitude for D_δ in the temperature range of the measurements, but an inaccurately determined activation energy.

Therefore, a more realistic diffusion coefficient is defined to have the magnitude at 700°C given by Eq. (5.21) but with activation energy of 12.3 kcal/mole. This modified form for D_δ used in the numerical calculations is:

$$D_\delta = 5.02 \times 10^{-3} \exp(-12,300/RT) \quad (5.22)$$

In the equilibrium model, the diffusion coefficient in the beta phase region is that measured by Gelezunas, et al. (given in Ref. 54):

$$D_{\beta} = 5.32 \times 10^{-3} \exp(-8320/RT) \text{ (cm}^2\text{/sec)} \quad (5.23)$$

In the beta plus delta region, the diffusion coefficient is taken as the average of D_{δ} and D_{β} weighted by the relative amount of each phase present according to Eq. (5.12). That is:

$$D_{\beta+\delta} = \frac{(y_{\delta} - y)}{(y_{\delta} - y_{\beta})} D_{\beta} + \frac{(y - y_{\beta})}{(y_{\delta} - y_{\beta})} D_{\delta} \quad (5.24)$$

8. Heat of Transport

The heat of transport Q^* of hydrogen in delta phase zirconium hydride was measured by Sommer and Dennison⁶⁰ to be:

$$Q^*_{\delta} = 1.3 \text{ kcal/mole of H atoms} \quad (5.25)$$

The heat of transport of hydrogen in beta phase zirconium was measured by Droege (given in Ref. 54) to vary from 5.5 kcal/mole at 630°C to 11.5 kcal/mole at 860°C and was found independent of composition. Since the results of the numerical calculations depend only weakly on the heat of transport, a representative value of Q^*_{β} is used:

$$Q^*_{\beta} \approx 9 \text{ kcal/mole of H atoms} \quad (5.26)$$

In the beta plus delta region, Q^* is taken as the average of Q^*_{δ} and Q^*_{β} weighted by the amount of H in each phase:

$$Q^*_{\beta+\delta} = \frac{y_{\beta}}{y} \frac{(y_{\delta} - y)}{(y_{\delta} - y_{\beta})} Q^*_{\beta} + \frac{y_{\delta}}{y} \frac{(y - y_{\beta})}{(y_{\delta} - y_{\beta})} Q^*_{\delta} \quad (5.27)$$

9. Density

The density of delta phase hydride according to Ref. 54 is approximately:

$$\rho_{\delta} = 5.70 \text{ (gm/cm}^3\text{)} \quad (5.28)$$

Although the energy and H conservation equations (Eqs. 4.31) were derived on the assumption of constant density, a concentration dependent density is used in the equilibrium model. A linear fit between the density at $y = 0$ and that at $y = 1.63$ is used:

$$\rho_{\text{equil}} = 6.50 - 0.521 y \text{ (gm/cm}^3\text{)} \quad (5.29)$$

VI. RESULTS

A. Iron Results

1. Numerical Results

For a particular absorbed energy density, the numerical program calculates the complete temperature history of the iron, the Fe flux from the surface, and the density of iron atoms in the ionizer by Eq. (3.9). The following values of the parameters in Eq. (3.9) were employed: $\bar{\chi} = 0.44$, $\alpha = 1$, $s = 40$ cm, and $A_s = A_{eff}$ given by Eq. (2.10). It was assumed that the laser is absorbed at the surface and that the absorbed power density has a triangular shape in time with the peak at 0.15 msec and the end of the pulse at 1.0 msec.

The surface temperature as a function of time is shown in Fig. 19 for various absorbed energy densities. Significant features of these curves are (a) the maximum temperature occurs after the peak of the absorbed power, (b) the time corresponding to the maximum temperature (and therefore maximum Fe flux) decreases as energy density increases, (c) the spacing between temperature curves decreases with increasing energy density because of increasing energy loss from the surface by vaporization and (d) after the end of the laser pulse, the surface temperature temporarily stays near the melting point because of the energy returned from the heat of fusion.

The relative Fe flux vs time for various absorbed energy densities is shown in Fig. 20. The duration of time over which there is significant Fe flux is approximately 400 μ sec and increases with increasing energy density.

The relative mass spectrometer signal is shown in Fig. 21. The time corresponding to the peak signal decreases with increasing energy

density. This is expected because at higher energy densities the atoms are emitted sooner and with a higher velocity than at lower energy densities.

The width of the predicted mass spectrometer signal increases with increasing energy densities because the atoms are emitted over a longer duration at higher energy densities. This effect obscures the narrowing of the predicted signal due to the increase in spread of velocities at higher surface temperatures. The width of the predicted signal is only about 20% larger than the width of the corresponding flux curve. This indicates that the signal width is primarily a measure of the duration of significant vaporization rather than the spread in time due to the velocity distribution of the emitted atoms.

Calculated solid temperature profiles presented in Fig. 22 show that iron becomes melted to a depth of approximately 10^{-3} cm, and that temperature gradients of approximately 10^6 °C/cm exist near the surface.

The various results of the calculations useful in comparing theory with the measured mass spectrometer signal are:

$T_{\max}$ = maximum surface temperature

$\phi_{\max}$ = maximum Fe flux

A_{eff} = effective emitting area

$\bar{n}_{\max}$ = maximum value of $\bar{n}(t)$, the average density of atoms at the ionizer

t_{peak} = time corresponding to $\bar{n}_{\max}$

$t_{1/2}^-$ = time at which $\bar{n}(t)/\bar{n}_{\max} = 1/2$ for $t < t_{\text{peak}}$

$t_{1/2}^+$ = time at which $\bar{n}(t)/\bar{n}_{\max} = 1/2$ for $t > t_{\text{peak}}$

These results are given in Table 1 for various values of $E_{\text{abs}}(0)$, the energy density at the center of the interaction area.

2. Experimental Results

A typical measured mass 56 signal is shown in Fig. 23. The origin represents the time the laser is triggered rather than the time of the beginning of the laser pulse. The time delay between triggering and the onset of lasing can be determined from the trace of the Korad energy pulse. The mass spectrometer signal relative to the beginning of the laser pulse and corrected for the drift time of ions down the quadrupole structure is shown in Fig. 24 for incident energy densities at $r = 0$ of 49.5, 77.6 and 133 cal/cm². The time constant correction given by Eq. (3.24) is small for the iron signals because the time constant of 30 μ sec is much less than the duration of the measured signal. The net effect of τ in Eq. (3.24) is to shift the measured signal 30 μ sec toward the origin.

The results shown in Figs. 24a,b,c are proportional to the measured atom density in the ionizer. The proportionality constant K_{Fe} can be determined from the iron calibration results of Section II-E-1 using Eq. (3.25). Using the calibration measurements for the 3/16 in. source aperture (for which $\bar{\chi} = 0.44$, see Appendix A) at 1573°K (where $P_{\text{eq}} = 1.14 \times 10^{-3}$ torr) and increasing the measured signal by the factor 1/0.92 to account for the isotopic bundance of Fe⁵⁶ in Eq. (3.25) yields $K_{\text{Fe}} = 2.8 \times 10^{-16}$ amp cm³/atom. If the calibration data on the 1/16 in. source aperature data had been used, the value of K_{Fe} would have been 1.8 times that obtained using the 3/16 in. aperture. As calculated in Appendix A, the average peaking factor $\bar{\chi}$ is approximately

independent of the source diameter for diameters less than 3/16 inch. However, if the efficiency of extracting ions from the ionizer into the quadrupole structure is greater near the center of the ionizer than at the ends, the effective $\bar{\chi}$ for the 1/16 in. aperture will be larger than the effective $\bar{\chi}$ for the 3/16 in. aperture. This effect would explain the different values of K_{Fe} determined from the different calibration source apertures. This behavior is typical of the fact that, in general, estimates of absolute mass spectrometer sensitivities are generally no better than a factor of 2 to 3.⁶¹

The measured signals may be compared to the predictions of the equilibrium model given in Table 1 by the measured values of t_{peak} , $t_{1/2}^+$, $t_{1/2}^-$ and $\bar{n}_{max}$ (the only quantity listed that depends on K_{Fe}). Values of these quantities are given in Table 2 for the conventional mode laser shots on iron of varying incident centerline energy densities $E_{inc}(0)$, which have been determined from the total incident energy by using Eq. (2.7). Several low energy density points were rejected because the signals were attributed to degassing from the iron surface. The evidence for this was that for $E_{inc}(0) \approx 45 \text{ cal/cm}^2$, the signal measured on a fresh surface was much larger than the signal from a previously pulsed surface. In addition, the signal widths were about twice as large as calculated and as measured on previously pulsed surfaces.

The appearance of the iron surface after a laser shot is shown in Fig. 25 for $E_{inc}(0) = 45$ and 72 cal/cm^2 . The central crater has approximate area $1 \times 10^{-3} \text{ cm}^2$ for $E_{inc}(0) = 45 \text{ cal/cm}^2$ and area $3 \times 10^{-3} \text{ cm}^2$ for $E_{inc}(0) = 72 \text{ cal/cm}^2$. If it is assumed that the

Fig. 25a Crater produced by conventional mode laser on iron. Incident energy density at center of interaction area = 45 cal/cm^2 . (50 $\times$ magnification)

XBB 7210-5373

Fig. 25b Crater produced by conventional mode laser on iron. Incident energy density at center of interaction area = 72 cal/cm^2 . (50 $\times$ magnification)

reflectivity is approximately 0.5, the calculated effective areas A_{eff} are 0.99×10^{-3} and $2 \times 10^{-3} \text{ cm}^2$ respectively. This agreement is very good considering that the edge of the crater occurs where the energy density is sufficient for significant melting, while the boundary of A_{eff} occurs where the energy density is sufficient for significant vaporization.

No Fe^+ ions emitted from the surface were detected. Thermal ions cannot be detected since the mass spectrometer can only detect ions with energy greater than 15 eV. No high energy ions were detected because the laser power density was not high enough for the formation of a plasma and subsequent conversion of the plasma thermal energy into a large directed energy of expansion.

3. Comparison Between Calculated and Experimental Results

Calculated and experimental values of $\bar{n}_{\text{max}}$, t_{peak} , $(t_{\text{peak}} - t_{1/2}^-)$, and $(t_{1/2}^+ - t_{\text{peak}})$ are plotted vs $E_{\text{inc}}(0)$ in Figs. 26, 27 and 28. The data exhibit quite a large amount of scatter because of variations in surface reflectivity, nonuniformities in the incident energy density, and because t_{peak} , $t_{1/2}^+$ and $t_{1/2}^-$ can be determined experimentally only to within ± 0.04 msec.

The calculated and experimental values of t_{peak} and $(t_{\text{peak}} - t_{1/2}^-)$ are in good agreement for $R \approx 0.5$. The calculated values of $\bar{n}_{\text{max}}$ are larger than the experimental values for R in the expected range 0.5 to 0.6. At low energy density, the calculated and experimental values of $\bar{n}_{\text{max}}$ are in satisfactory agreement, but as the energy density increases, the calculated value becomes approximately an order of magnitude larger than the measured value.

XBL7211-7250

XBL7211-7246

Fig. 27 Comparison between the experimental and calculated t_{peak} vs $E_{\text{inc}}(0)$, for iron.

XBL 7211-7244

Fig. 28 Comparison between the experimental and calculated $(t_{1/2}^+ - t_{peak})$ and $(t_{peak} - t_{1/2}^-)$ vs $E_{inc}(0)$, for iron.

There is also a discrepancy between the calculated and measured values of $(t_{1/2}^+ - t_{\text{peak}})$. At low energy density, the agreement is good, but at higher energy density the calculated value of $(t_{1/2}^+ - t_{\text{peak}})$ is approximately 1.8 times the measured value.

The discrepancies between the calculated and measured values of $\bar{n}_{\text{max}}$ and $(t_{1/2}^+ - t_{\text{peak}})$ can be attributed to the flow of liquid iron. The calculations were made assuming that the iron maintained a fixed structure. However, when the surface temperature is large and there is a considerable amount of molten iron beneath the surface, the pressure exerted by the vaporizing atoms causes some of the liquid iron to flow to the sides of the interaction area to form a crater as shown in Fig. 25. When the liquid iron flows outward, the iron beneath the surface at the center of the crater is cooler than calculated, so the surface is cooled by conduction more quickly than it would if the iron structure were fixed. This effect would cause the actual maximum surface temperature to be less than that calculated, so the actual $\bar{n}_{\text{max}}$ would be less than that calculated. This effect would also cause the surface temperature to decrease at a faster rate than calculated. Since $(t_{1/2}^+ - t_{\text{peak}})$ is largely a measure of the rate at which the surface flux decreases, the measured value would therefore be less than the calculated value. The value of $(t_{1/2}^+ - t_{\text{peak}})$ is determined both by the duration over which iron atoms are emitted and by the spread in velocities of the emitted atoms. If the flux of iron atoms at the surface (Fig. 20) decreases much faster than calculated, the value of $(t_{1/2}^+ - t_{\text{peak}})$ will be due solely to the spread of velocities of the emitted atoms. The observed value of $(t_{1/2}^+ - t_{\text{peak}})$ of approximately

0.2 msec is approximately the half width due to the spread of velocities from an effusive Maxwellian source, which indicates that the surface cools much more rapidly than calculated. However, the measured and calculated values of $(t_{\text{peak}} - t_{1/2}^-)$ are in agreement, which indicates that the rate of increase of the surface temperature (and therefore flux of iron atoms) is calculated correctly.

Because of the flow of liquid iron, the comparison between theory and experiment must be partly qualitative. Since the calculated and experimental values of t_{peak} and $(t_{\text{peak}} - t_{1/2}^-)$ are in agreement, and since the discrepancy between the calculated and experimental values of $\bar{n}_{\text{max}}$ and $(t_{1/2}^+ - t_{\text{peak}})$ can be qualitatively explained, the equilibrium model for the process appears to be valid. The results obtained are consistent with the following equilibrium assumptions: (a) the vaporized atoms have the velocity distribution of an effusive Maxwellian source, (b) the atoms are vaporized at a rate given by the Langmuir equation with condensation coefficient of unity and (c) the temperature transient is governed by the conduction equation with the appropriate boundary conditions.

B. Zirconium Hydride Results

i. Numerical Results

In the numerical calculation of the behavior of zirconium hydride heated by a Q-switch laser, it is assumed that the laser is absorbed at the surface and that the absorbed power density has a triangular shape in time with the peak at 40 nanoseconds and the end of the pulse at 80 nanoseconds. The energy density is assumed to have the constant value $E_{\text{abs}}(0)$ over the interaction area. This is valid because the

energy density at the edge of the rod is approximately 80% of that at the center and because most of the emitted hydrogen comes from the area with the highest absorbed energy density. The calculations are made with the assumption that the condensation coefficient α is equal to unity.

Results of the numerical calculations are shown in Figs. 29-33 for the equilibrium model (that is, for H_2 vapor pressure given according to Fig. 16). The spacing between surface temperature profiles in Fig. 29 does not decrease with increasing energy density as it did in the iron calculations (see Fig. 19). This is because the power loss by vaporization from the zirconium hydride surface is much less than the absorbed power.

The H/Zr atom ratio at the surface as a function of time is shown in Fig. 30 for various absorbed energy densities. For the energy densities considered, substantial depletion of hydrogen occurs at the surface. The surface H/Zr ratio profiles pass through a minimum at approximately the same time as the maximum surface temperature. After the surface H/Zr ratio reaches a minimum, it increases because hydrogen diffuses from the bulk to the surface faster than it is lost by vaporization. The final H/Zr ratio is "frozen in" at a value less than the initial value because vaporization and diffusion of hydrogen become negligible as the temperature returns to ambient.

The maximum H_2 flux occurs when the equilibrium H_2 pressure at the surface is a maximum. This occurs before the maximum temperature is reached because the H_2 vapor pressure is a function of both temperature and H/Zr atom ratio. As shown in Fig. 31, the H_2 flux is a very sharp function of time, indicating that the emission occurs over a relatively

narrow temperature range (on the order of several hundred °C).

Typical calculated mass spectrometer H_2 signals are shown in Fig. 32. The H_2 molecules are emitted over a time duration of less than $0.1 \mu\text{sec}$ whereas the time of flight of the H_2 molecules from the zirconium hydride sample to the mass spectrometer ionizer is approximately $100 \mu\text{sec}$. Therefore the H_2 molecules are emitted effectively as an instantaneous source at zero time. The width of the calculated signal is then due entirely to the spread of velocities of the emitted H_2 molecules. As energy density increases, the calculated signal shifts toward the origin because of the increase in the velocity of the emitted molecules due to the higher surface temperature. There is a time delay of approximately $30 \mu\text{sec}$ between the time the molecules are emitted and the beginning of the calculated signal because of the time required for the molecules in the high speed tail of the Maxwell-Boltzmann distribution to reach the ionizer.

As shown in Fig. 33, the hydrogen concentration is partially depleted up to a depth of approximately 10^{-5} cm from the surface. The temperature transient penetrates to a depth of approximately 10^{-4} cm. Temperature gradients at the surface reach values greater than 10^7 °C/cm.

The Soret effect and the effect of the enthalpy transported by the diffusing hydrogen atoms are both negligible. The numerical solution of the solid energy equation and hydrogen diffusion equation (Eqs. (4.31)) were made with the heat of transport (Q^*) and the gradient of the partial molar enthalpy of hydrogen ($\frac{\partial \bar{H}_H}{\partial x}$) set to zero. Each effect made a less than 10% difference on the magnitude of the predicted signal ($\bar{n}_{\text{max}}$) and a negligible effect on t_{peak} and FWHM.

To compute the average density $\bar{n}(t)$ of molecules at the ionizer according to Eq. (3.9), the following numerical constants are used: $\bar{\chi} = 0.44$, $\alpha = 1$, $s = 40$ cm and $A_S = 0.079$ cm² (this is the area of the end of the zirconium hydride rod). The results of the calculations that are useful in comparing the calculated signal with the measured signal are:

$T_{\max}$ = maximum surface temperature

$y_{\min}$ = minimum H/Zr atom ratio at the surface

yield = $\int_0^{\infty} \phi(t) dt$ = total amount of H₂ vaporized per cm²

$\bar{n}_{\max}$ = maximum value of $\bar{n}(t)$

t_{peak} = time corresponding to $\bar{n}_{\max}$

FWHM = full width of $\bar{n}(t)$ at half maximum

These results for H₂ are given in Table 3 for the equilibrium and quasi-equilibrium models.

If the heating and vaporization processes are described by equilibrium thermodynamics, a small amount of atomic hydrogen should also be emitted from the surface. There is a three-way equilibrium between atomic hydrogen, molecular hydrogen and hydrogen in the zirconium hydride. Consider the equilibrium between atomic and molecular hydrogen:

The equilibrium constant of this reaction is related to the partial pressures of H and H₂ by the thermodynamic relation:

$$\frac{P_H}{P_{H_2}^{1/2}} = \exp \left(- \frac{\Delta G_f^\circ}{RT} \right) \quad (6.1)$$

where ΔG_f° is the standard Gibbs free energy of formation of atomic hydrogen from molecular hydrogen, which was fit from the JANAF tables data as:

$$\Delta G_f^\circ = 52.387 - 12.274 \left(\frac{T}{10^3} \right) - 0.575 \left(\frac{T}{10^3} \right)^2 \frac{\text{kcal}}{\text{mole}} \quad (6.2)$$

The results of the calculations of predicted atomic hydrogen signals for the equilibrium model are given in Table 4. For a particular surface temperature, the average velocity of emitted H atoms is $\sqrt{2}$ times that of H_2 molecules, so $t_{\text{peak}}^H/t_{\text{peak}}^{H_2}$ should be approximately equal to 0.7. The ratio of the calculated peak amplitudes of the H and H_2 signals (i.e., $(\bar{n}_{\text{max}})_H/(\bar{n}_{\text{max}})_{H_2}$) varies from 10^{-7} to 10^{-3} over the energy density range 0.04 to 0.10 cal/cm².

2. Experimental Results for Low Energy Densities

A typical measured H_2 signal is shown in Fig. 34. The trace is triggered at the beginning of the giant pulse, so the origin represents true zero time. To calculate the corrected signal from the measured signal using Eq. (3.24), it is necessary to differentiate the measured signal. This is done as follows: (a) values of the measured signal are read from the oscilloscope trace, (b) these data points are fit to a curve that is made of several piecewise cubic functions which have slope and value matched at the end points and which give an overall least squares fit to the data, and (c) this analytical fit of the data is then differentiated. The time constant correction of the measured signals is significant because it is of the same order of magnitude as the signal width. A typical measured H_2 signal and the signal obtained after the time constant correction are shown in Fig. 35a.

Typical measured H_2 signals (corrected) are shown in Fig. 35b for three different incident energy densities. The pulse shapes agree closely with the calculated pulse shapes shown in Fig. 32. Figure 36 shows a typical measured H-atom signal before and after the time constant correction.

3. Comparison Between Calculated and Experimental Results (Low Energy Density)

The experimental and theoretical results may be best compared by utilizing several aspects of the waveforms such as those shown in Figs. 32 (predicted H_2), 35b (measured H_2) and 36 (measured H). As in the case of iron, these quantities are: the maximum density of molecules in the mass spectrometer ionizer ($\bar{n}_{\max}$); the time at which this peak density occurs (t_{peak}); and the full width at half maximum (FWHM) of the waveform. Predicted values of these three quantities can be obtained directly from the results summarized in Tables 3 and 4. The measured values of t_{peak} and FWHM are easily determined from the measured waveforms such as in Figs. 35b and 36. The determination of the absolute magnitude of the peak of a measured signal, however, requires that the sensitivity of the mass spectrometer be estimated. This is accomplished as follows.

The measured output signal current (corrected for time constant by Eq. (3.24)) is related to the density of neutral molecules in the ionizer by:

$$I = K\bar{n} \quad (6.3)$$

where K is the collection of constants given by Eq. (3.23b).

The value of K for H_2 can be determined from the calibration described in Section II-E-2, in which the signal current is measured for a known hydrogen pressure in the mass spectrometer chamber. This calibration gave a sensitivity of 48 amps/torr for room temperature hydrogen gas. Using the ideal gas law to convert pressure to number density ($\bar{n} = P/kT$), the constant K for H_2 is found to be 1.5×10^{-15} amps cm^3 /molecule. This value may be used if it is assumed that the mass spectrometer ionizer responds in the same way to a random background gas as it does to a directed molecular beam of the same particle density. This assumption is discussed in greater detail in Ref. 62.

The constant K for atomic hydrogen is obtained from the above value for H_2 by correcting for species dependent factors in Eq. (3.23b). The two quantities which are different for H_2 and H are the ionization cross section (σ) and the secondary electron coefficient of the electron multiplier (β). The K -value for H is obtained from:

$$K_H = \left(\frac{\sigma_H}{\sigma_{H_2}} \right) \left(\frac{\beta_H}{\beta_{H_2}} \right) K_{H_2} \quad (6.4)$$

Based on the electron impact ionization cross-section data given in Ref. 63, the value of $(\sigma_H/\sigma_{H_2}) \approx 0.68$ for 90 eV electrons. A rough estimate of (β_H/β_{H_2}) can be made by assuming that the number of secondary electrons produced at the first dynode of the electron multiplier is proportional to the inverse square root of the mass of the detected ion ($\beta_H/\beta_{H_2} \approx 1.4$), although such a correction is not well verified and is therefore subject to some doubt.⁶⁴ With these approximations, $K_H \approx K_{H_2}$

(within a possible uncertainty of a factor of 2). As mentioned in the discussion of the iron results, estimates of absolute mass spectrometer sensitivities are generally no better than a factor of 2 or 3.

Utilizing the instrumental constant K determined as described above, the peak amplitudes of the measured signals (after time constant corrections) can be converted to measured values of $\bar{n}_{\max}$ for H and H_2 . The three quantities characteristic of the measured waveform (t_{peak} , FWHM, and $\bar{n}_{\max}$) are tabulated in Table 5 for two series of experiments in which the H_2 signal was measured and another series of laser shots in which the mass spectrometer was tuned to H (mass 1).

To complete the comparison between theory and experiment, the surface reflectivity must be known to relate incident energy density (E_{inc}) to absorbed energy density (E_{abs}). To eliminate this additional uncertainty (and that of the magnitude of E_{inc} as well), we first compare plots of t_{peak} vs FWHM, which is independent of surface reflectivity. Since the molecules are emitted over a time much less than t_{peak} , the ratio $t_{\text{peak}}/\text{FWHM}$ is characteristic only of the velocity distribution of the emitted molecules. The calculated and experimental values of t_{peak} vs FWHM are plotted in Fig. 37. Although the data are scattered, they do cluster about the straight line representing the calculated variation of t_{peak} vs FWHM for a Maxwellian beam. This indicates that the H_2 molecules and H atoms are emitted with the velocity distribution of an effusive Maxwellian source.

The calculated and experimental values of t_{peak} vs incident energy density E_{inc} are plotted in Fig. 38. The H_2 data points cluster about the theoretical curve for surface reflectivity $R = 0$, although the

scatter is too great to determine whether the equilibrium model or the quasi-equilibrium model is more appropriate. The theoretical H_2 curve for $R = 0.45$ is clearly out of the range of the data points. The apparent surface reflectivity is therefore approximately equal to zero, rather than 0.45 as measured with the He-Ne laser on room temperature $ZrH_{1.63}$ (see Section II-D-2). The reflectivity during a Q-switch pulse may be much less than the measured reflectivity because (a) the zirconium hydride reflectivity may be very small at high temperatures, or (b) the change in surface condition during the vaporization process may cause the reflectivity to be very small. Several experiments on metals using conventional mode pulses^{65,66} and Q-switch pulses⁶⁷ have shown that the surface reflectivity during a laser pulse can be much less than the initial reflectivity. The agreement between the measured and calculated values of t_{peak} vs E_{inc} indicates that the emitted H_2 molecules are in thermal equilibrium with the surface. The surface temperature is apparently calculated correctly from the simultaneous solution of the energy and mass transport equations in the binary solid.

The values of t_{peak} for the H-atom data points are substantially smaller than t_{peak} for the H_2 data points at the same incident energy density. This indicates that the H-atom is due to H atoms emitted from the surface rather than from cracking or double ionization of H_2 molecules. The H-atom data fall between the calculated H-atom curves for $R = 0$ and $R = 0.45$, which suggests that the H atoms are apparently emitted at a lower temperature than the H_2 molecules (because the t_{peak}^H values are larger than predicted by theory for $R = 0$).

The calculated and measured values of $(\bar{n}_{\max})_{H_2}$ vs E_{inc} are plotted in Fig. 39. The series A and B points were taken about a month apart under slightly different conditions. The series A and B points were taken with a 0.3 M and 0.1 M resistor respectively in parallel with the oscilloscope, and the two series of points were made with different flashlamps and different laser alignment. The H_2 data points exhibit a large amount of scatter. The three H_2 data points with $\bar{n}_{\max}$ much less than the band drawn through the other H_2 points are attributed to misalignment of the laser on the surface so that the actual incident energy density was smaller than measured. The band through the H_2 data agrees fairly well with the calculated curve for $R = 0$ for E_{inc} less than 0.04 cal/cm^2 . However, for E_{inc} greater than 0.04 cal/cm^2 , the measured values of $(\bar{n}_{\max})_{H_2}$ flatten off at $10^9 \text{ molecules/cm}^3$ while the calculated values increase to greater than $10^{10} \text{ molecules/cm}^3$. Therefore, for E_{inc} greater than 0.04 cal/cm^2 , the H_2 data do not fit either the equilibrium or quasi-equilibrium models. The slope of the calculated curve is steep at low energy density because the vapor pressure in this region is primarily a function of temperature. As the energy density increases, the slope decreases because hydrogen is depleted from the surface. The theoretical $(\bar{n}_{\max})_{H_2}$ vs E_{inc} curve therefore levels off because the flux from the surface is limited by the rate at which hydrogen can diffuse to the surface.

From the calculated H_2 and H-atom results in Tables 3 and 4, it is found that $\bar{n}_{\max}$ is proportional to the yield:

$$\bar{n}_{\max} = 1.04 \times 10^{17} \times (\text{yield}) \quad (6.5)$$

XBL 7211-7233

Fig. 39 Comparison between calculated and experimental $(\bar{n}_{\max})_{H_2}$ vs E_{inc} .

The yield for $(\bar{n}_{\max})_{\text{H}_2} = 10^9$ molecules/cm³ is therefore equal to 10^{-8} moles H₂/cm². To see the significance of the diffusion process in obtaining this yield, we calculate the number of monolayers of hydrogen to which this yield corresponds. The number of moles of hydrogen atoms per monolayer per cm² of ZrH_y is:

$$\frac{\# \text{ moles H}}{\text{monolayer cm}^2} = \frac{y}{N_A} \left(\frac{\rho N_A}{M} \right)^{2/3} \quad (6.6)$$

where $y = 1.63$

N_A = Avogadro's number

ρ = ZrH_y mass density = 5.7 gm/cm³

M = ZrH_y gm molecular weight ≈ 93 AMU

which gives $(\# \text{ moles H/monolayer cm}^2) = 3 \times 10^{-9}$. Therefore the measured value of $(\bar{n}_{\max})_{\text{H}_2}$ of 10^9 molecules/cm³ for E_{inc} greater than 0.04 cal/cm² corresponds to a yield of $(2 \times 10^{-8}/3 \times 10^{-9}) = 7$ monolayers. Assuming that the initial surface coverage of hydrogen is approximately 1 monolayer (i.e., approximately 1.63 surface H atoms per surface Zr atom), most of the emitted hydrogen must have reached the surface by diffusing from the bulk. The diffusion process is apparently not as effective as assumed in the calculations, however, since the measured $(\bar{n}_{\max})_{\text{H}_2}$ is an order of magnitude smaller than the calculated values for E_{inc} greater than 0.04 cal/cm².

There are several possible effects that could cause a restriction of the bulk diffusion process: (a) there could be a diffusion barrier such as an oxide coating at the surface, (b) after some of the hydrogen is emitted, restructuring of the surface layers may present an interface

which could act as a diffusion barrier, or (c) there may be a kinetic barrier at the surface if the time for an H atom in the lattice to hop from just beneath the surface to a surface site is comparable to or greater than the time for an H atom to diffuse from one lattice site to another. In each case, the diffusion coefficient at the surface would be smaller than the bulk diffusion coefficient.

Another possible explanation for the measured values of $(\bar{n}_{\max})_{\text{H}_2}$ being smaller than the calculated values is that the condensation coefficient α could be less than unity. This would imply that the rate at which surface H atoms can combine to form H_2 molecules is less than the maximum rate given by the Langmuir equation. This is not considered as a plausible explanation because: (a) the relatively good agreement between measured and calculated values of $(\bar{n}_{\max})_{\text{H}_2}$ for $E_{\text{inc}} < 0.04 \text{ cal/cm}^2$ indicates that $\alpha \approx 1$ in this range, (b) the approximately constant measured value of $(\bar{n}_{\max})_{\text{H}_2}$ for $E_{\text{inc}} > 0.04 \text{ cal/cm}^2$ suggests that the amount of hydrogen that is emitted is limited by the amount that can diffuse to the surface, and (c) if the constant value of $(\bar{n}_{\max})_{\text{H}_2}$ for $E_{\text{inc}} > 0.04 \text{ cal/cm}^2$ were due to a temperature dependent condensation coefficient, the rapid increase in hydrogen vapor pressure with temperature would have to be just balanced by a decrease in α , which is unlikely.

The measured values of the maximum H-atom density are also shown in Fig. 39. These data were obtained in the same set of experiments as the series A points for H_2 . In the plateau region of $E_{\text{inc}} > 0.04 \text{ cal/cm}^2$, the data show that

$$\left\{ \frac{(\bar{n}_{\max})_{\text{H}}}{(\bar{n}_{\max})_{\text{H}_2}} \right\}_{\text{exp}} \approx 0.2$$

This ratio is much larger than the value of 0.03 which represents the fraction of H^+ due to electron impact on H_2 in the mass spectrometer ionizer. Therefore, the large H/H_2 ratio is truly the result of a surface process.

The value of the H/H_2 ratio expected from the equilibrium model is calculated for $E_{\text{inc}} = E_{\text{abs}} = 0.10 \text{ cal/cm}^2$ as follows: Extrapolating the results shown in Table 4 show that $(\bar{n}_{\max})_{\text{H}}$ should be $\approx 2.5 \times 10^7$ atoms/ cm^3 at this laser pulse energy. Similarly, the ordinate of the equilibrium model curve for H_2 on Fig. 39 for $R = 0$ predicts $(\bar{n}_{\max})_{\text{H}_2} \approx 2 \times 10^{10}$ molecules/ cm^3 at $E_{\text{inc}} = 0.10 \text{ cal/cm}^2$. Therefore, the H/H_2 ratio predicted by equilibrium considerations is:

$$\left\{ \frac{(\bar{n}_{\max})_{\text{H}}}{(\bar{n}_{\max})_{\text{H}_2}} \right\}_{\text{equilibrium model}} \approx 10^{-3}$$

which is indeed far below the experimental value of 0.2. Such a discrepancy could arise if the H-atoms were emitted at a much higher "temperature" (and hence higher vapor pressure) than the temperature at which H_2 emission occurred. This is apparently not the case, however, since the measured time of flight corresponding to the peak H atom density in the ionizer (Fig. 38) is approximately that expected for emission at the calculated surface temperature, and the measured values of $t_{\text{peak}}/\text{FWHM}$ are consistent with a Maxwellian gas at the same temperature as the H_2 emission (Fig. 37).

The large H-atom signals therefore must be due to some non-equilibrium chemical process on the surface. Apparently the H atoms are emitted at thermal equilibrium because their velocity distribution is consistent with the calculated surface temperature. However, the existence of thermal equilibrium does not imply that the surface is at chemical equilibrium. One possible explanation for the large H-atom signals can be inferred by calculating the number of monolayers to which the measured H-atom signals correspond. From Eq. (6.5) the measured yield of H is approximately 2.4×10^{-9} moles H/cm², which corresponds to 0.8 monolayers of hydrogen. Since this is less than 1 monolayer, the H signal could be due to the vaporization of an adsorbed layer of H initially on the surface. This possibility can be explained as follows:

At complete equilibrium, the desorption of surface hydrogen proceeds according to the two processes:

According to the principal of detailed balance, the H(g)/H₂(g) ratio produced by the above process under conditions of complete equilibrium should be just equal to the $P_{\text{H}}/P_{\text{H}_2}$ ratio of the equilibrium gas above the surface (ignoring small differences due to the masses of the two species and assuming unit condensation coefficients). If the flash desorption of the surface population caused by the laser pulse passed through a series of equilibrium thermodynamic stages, then the maximum H/H₂ signal ratio arising from surface desorption should be equal to that predicted by the equilibrium model, namely $\sim 10^{-3}$. However, the

"flash" initiated by the laser pulse ($\sim 10^{-8}$ sec) is very much more rapid than that attainable by conventional flash filament techniques. If the surface recombination of $H(ads)$ to $H_2(ads)$ (followed by instantaneous desorption) requires surface migration and collisions of $H(ads)$, the rapidity of the temperature increase may mean that it is more likely than $H(ads)$ simply desorbs to give $H(g)$ rather than recombine to produce $H_2(g)$ as it would do in a slow transient. By this model, the desorbed H could be in thermal equilibrium with the surface, but not in chemical equilibrium with respect to H_2 emission for the existing surface population.

According to this model, the observed H signal is due entirely to atomic hydrogen desorbed from the surface, while the hydrogen emanating from the bulk of the $ZrH_{1.63}$ is released to the gas phase as H_2 molecules.

4. Experimental Results for High Energy Densities

When the incident energy density is greater than about 0.25 cal/cm^2 , the mass spectrometer signals no longer show a pulse shape characteristic of thermal behavior of the zirconium hydride. Visible damage to the surface occurs (Fig. 7), which indicates that the surface temperature is sufficient for vaporization of the zirconium lattice. As shown in Fig. 40, in this high energy range, the H_2 signal consists of a high energy peak with $t_{\text{peak}} \approx 18 \text{ } \mu\text{sec}$ and a thermal peak with $t_{\text{peak}} \approx 60 \text{ } \mu\text{sec}$. The high energy peak corresponds to an energy of approximately 5 eV, while the thermal peak corresponds to a temperature of approximately 3000°K , which is higher than temperatures calculated at lower energy densities. Roughly 20 to 30% of the total H_2 emission is in the high energy peak.

For $E_{\text{inc}} > 0.25 \text{ cal/cm}^2$, the H and Zr signals are very large and occur at very short times, as shown in Figs. 41 and 42. These are

XBL 7210-5787

Table 6. Results of Zr-H measurements for high incident energy densities.

Shot Number	Species	E_{inc} (cal/cm ²)	Peak Incident Power Density (watts/cm ²)	t_{peak} (μ sec)	Energy E (eV)
15	H ₂ (*)	0.281	2.9 E+7	18	5.3
16	H ₂ (*)	0.272	2.8 E+7	18	5.3
17	H ₁ ⁺	0.357	3.7 E+7	7.5	15.3
18	H ₁ ⁺	0.443	4.6 E+7	5.5	28.4
19	Zr ⁺	0.251	2.6 E+7	32	75.0
20	Zr ⁺	0.454	4.7 E+7	35	63.0
21	Zr ⁺	0.276	2.9 E+7	36	60.0

* High energy peak only.

attributed to H^+ and Zr^+ because they are detected even when there is zero electron current in the ionizer. The small peak in Fig. 41 with $t_{peak} \approx 35 \mu\text{sec}$ is due to atomic hydrogen emitted at approximately 4000°K rather than H^+ because the peak does not appear when the ionizer electron current is off. It is difficult to estimate what fraction of the atomic hydrogen is emitted as ions since the mass spectrometer sensitivity to ions is not known. No H_2^+ ions were detected.

The mass spectrometer can only detect ions with energy greater than 15 eV because the ionizer is at a potential of 15 volts relative to the target and ground. Less energetic ions are deflected from the ionizer region as they approach it. An approximate analysis of the electric field around the ionizer showed that the electric field increases the time of flight by less than 5% for ions with energy greater than 15 eV. Since ions are detected much more efficiently than neutrals, the ion pulses mask the signal on neutral molecules.

The energy of the particles in eV can be determined from the measured time of flight t_{peak} by using Eq. (3.16):

$$E(\text{eV}) = \frac{860 M(\text{AMU})}{[t_{peak}(\mu\text{sec})]^2} \quad (6.7)$$

The results of the high energy density measurements are given in Table 6 as a function of E_{inc} and peak incident power density in $(\text{watts}/\text{cm}^2)$, which is the power density at $t \approx 40 \text{ nsec}$ corresponding to the peak of the laser pulse.

The H^+ ions are emitted with a lower energy than the Zr^+ ions. The range of ion energies (15-30 eV for H^+ , 60-75 eV for Zr^+) for laser power densities of $3-5 \times 10^7 \text{ watts}/\text{cm}^2$ is consistent with the ion

energies measured by other investigators on metals and other solids at comparable power densities. For example, measurements of the ions emitted from a Ti-D target indicate an ion energy of 7.5 eV for power density of 10^8 watts/cm².⁸ Measurements on W surfaces heated with laser power density of approximately 5×10^7 watts/cm² show that the emitted ions have energies up to 180 eV.¹⁷ As discussed in Section I-C, the probable mechanisms for the production of these high energy ions are the formation of a partially ionized plasma in front of the surface, subsequent heating of the plasma by photons by the inverse Bremsstrahlung process, and a rapid directed expansion of the plasma away from the surface. The relatively high energy H₂ molecules are probably accelerated by collisions with the energetic H⁺ and Zr⁺ ions.

C. Conclusions

Many aspects of the transient behavior of zirconium hydride heated by a Q-switch laser are properly predicted by the equilibrium model. Since the measured time of flight of the H-atoms and H₂ molecules are in agreement with calculations, it can be concluded that the molecules are emitted at thermal equilibrium. The temperature transient at the surface is properly calculated by the simultaneous solution of the heat conduction and hydrogen diffusion equations with the heat source at the surface equal to the absorbed laser power density. Since the calculated and measured ratio of signal width to the time of flight for the H and H₂ signals are in agreement, the molecules are apparently emitted with the velocity distribution of an effusive Maxwellian source, as expected for an equilibrium process. The magnitudes of the H₂ signals for incident energy density less than 0.04 cal/cm² are in agreement with the values

determined from the solution of the conduction and diffusion equations with unit condensation coefficient.

Two aspects of the zirconium hydride behavior are not well predicted by the equilibrium model. Although hydrogen is emitted primarily as H_2 rather than H , the measured H/H_2 ratios are much larger than expected from the equilibrium model, and the H_2 signals for incident energy density greater than 0.04 cal/cm^2 are smaller than expected from the same model. The large H/H_2 ratios are attributed to the desorption of a layer of chemisorbed hydrogen that is not vaporized in the H/H_2 ratios predicted from chemical equilibrium when the surface temperature is rapidly increased. In this aspect, the laser pulse differs from conventional flash filament experiments, such as described in Refs. 68 and 69. The small H_2 signals are attributed to the existence of a diffusion barrier at the surface. However, significant diffusion of hydrogen must occur to account for the measured H_2 signal amplitudes.

The conclusions that can be drawn from the iron experiments are less definitive than those that can be made from the zirconium hydride experiments are less definitive than those that can be made from the zirconium hydride experiments. This is because the duration of the conventional mode laser pulse is on the same order as the time of flight of the iron atoms from the target to the mass spectrometer, which means that the waveforms do not represent solely spreading due to the velocity distribution of the emitted atoms. In addition, the iron results are complicated by the unpredictable surface temperature that results when the molten iron flows. Allowing for these uncertainties,

the results are consistent with an equilibrium model in which the iron atoms are emitted at thermal equilibrium with the velocity distribution of an effusive Maxwellian source.

ACKNOWLEDGEMENTS

This work has been supported by the U. S. Atomic Energy Commission through the Lawrence Berkeley Laboratory and by a three year fellowship administered by Oak Ridge Associated Universities through the "Special Fellowships in Nuclear Science and Engineering" program.

I would like to thank Professor Donald R. Olander of the Department of Nuclear Engineering, University of California for always being accessible for guidance and providing many fruitful suggestions for performing the experiment and analyzing the results.

I would also like to thank my former colleague Dr. Richard H. Jones for his assistance in solving many experimental problems. Thanks also to John Souza and Dan Winterbauer for promptly fabricating needed parts and providing a little humor.

The swift, accurate typing by Jean Wolslegel is appreciated.

APPENDIX A: AVERAGE PEAKING FACTOR IN THE IONIZER

The vapor density at the mass spectrometer ionizer varies with position in the ionizer because of the presence of the collimating aperture between the target and mass spectrometer chambers. The collimating aperture causes the formation of a penumbra at the ionizer such that only part of the target is viewed. This decrease in intensity (and therefore density) can be accounted for by a peaking factor, which is the ratio of true intensity to the centerline intensity for a cosine point source. Defining the problem in the same manner as an analysis by Olander⁷⁰ on molecular beam geometry, let

r_s = radius of the source

r_c = radius of the collimating aperture

d_c = source to collimator distance

d = source to mass spectrometer distance

ρ = variable radius at the mass spectrometer

$Q = r_s/r_c$ = dimensionless source radius

$T = d_c/d$ = dimensionless source to collimator distance

$V = \rho/r_c$ = dimensionless radius at the mass spectrometer

For the case of a cosine source with source to collimator distance much larger than the source or collimator dimensions, the peaking factor at position ρ is simply the ratio of unobstructed source area to the total source area. The area of the source that contributes to the intensity at a particular ρ is the overlapping area of the source disk and the projection from ρ of the collimating aperture the source plane. This projection is also a circle and has radius $r_c d/(d - d_c)$. In dimensionless terms relative to r_c ,

$W_1 = 1/(1 - T)$ = dimensionless radius of the projection of the collimator on the source plane.

$W = TV/(1 - T)$ = dimensionless distance of the center of the projection to the center of the source disk.

The geometry of the problem is shown in Fig. A1 and A2. The easiest method to determine the overlapping area is to calculate the area of segments of the source and collimator image circles. There are three ranges of W to consider:

(1) $0 < W < W_1 - Q$:

The total source disk is within the collimator projection so the effective area is $A_1 = \pi Q^2$.

(2) $W_1 - Q < W < (W_1^2 - Q^2)^{1/2}$:

The effective area is less than A_1 and is equal to A_1 minus the area of segment of the source disk plus the area of segment of the collimator image.

(3) $(W_1^2 - Q^2)^{1/2} < W < W_1 + Q$:

The effective area is the area of the segment of the source disk plus the area of segment of the collimator image.

Let α = half angle subtended by the intersection of the circles at the center of the collimator image

ϕ = half angle subtended by the intersection of the circles at the center of the source disk

It can be shown that α and ϕ can be expressed in terms of W by:

$$\cos \alpha = \frac{1}{2WW_1} [W_1^2 - Q^2 + W^2] \quad (\text{A.1a})$$

$$\cos \phi = \frac{1}{2QW} [W_1^2 - Q^2 - W^2] \quad (\text{A.1b})$$

XBL7211-7229

Fig. A2 Geometry for calculation of the peaking factor. The shaded area represents that area of the source disk that contributes to the signal at the particular value of W .

The area of a segment of circle of radius r with half angle θ is

$$A = r^2[\theta - \sin\theta \cos\theta]$$

Using this equation for regions 2 and 3 gives:

$$A_2 = \pi Q^2 + W_1^2[\alpha - \sin\alpha \cos\alpha] - Q^2[\phi - \sin\phi \cos\phi]$$

$$A_3 = W_1^2[\alpha - \sin\alpha \cos\alpha] + Q^2[(\pi - \phi) - \sin(\pi - \phi) \cos(\pi - \phi)] \quad (A.2)$$

$$= \pi Q^2 + W_1^2[\alpha - \sin\alpha \cos\alpha] - Q^2[\phi - \sin\phi \cos\phi]$$

Therefore, A_3 is the same function as A_2 , the only difference being that $\phi > \pi/2$ in region 3.

Dividing the effective areas by the source area and putting limits in terms of V rather than W gives for the peaking factor:

$$\begin{aligned} \chi(V) &= 1 \quad \text{for} \quad 0 < V < [1 - Q(1 - T)]/T \\ \chi(V) &= 1 + \frac{W_1^2}{\pi Q^2} [\alpha - \sin\alpha \cos\alpha] - \frac{1}{\pi} [\phi - \sin\phi \cos\phi] \\ &\quad \text{for} \quad \frac{1}{T} [1 - Q(1 - T)] < V < V_{\max} \\ \chi(V) &= 0 \quad \text{for} \quad V > V_{\max} \end{aligned} \quad (A.3)$$

where

$$V_{\max} = \frac{1}{T} [1 + Q(1 - T)]$$

and ϕ and α are found from Eqs. (A.1)

Figure A3 shows $\chi(V)$ plotted for the case $Q = 1$, $T = 0.5$ and for $Q = 1.5$, $T = 0.5$. It is evident that a good approximation to $\chi(V)$ would be a linear approximation in the penumbra region:

XBL 7211-7235

Fig. A3 Peaking factor as a function of dimensionless radius V .

$$\chi(V) = 1 \quad \text{for} \quad 0 < V < [1 - Q(1 - T)]/T$$

$$\chi(V) \cong \frac{[1 + Q(1 - T) - TV]}{2Q(1 - T)} \quad \text{for} \quad [1 - Q(1 - T)]/T < V < V_{\max} \quad (\text{A.4})$$

$$\chi(V) = 0 \quad \text{for} \quad V > V_{\max}$$

The quantity of real interest is the average peaking factor over the length of the electron sheet. Assuming that the electron sheet stays relatively flat over the length of the ionizer, the average peaking factor is

$$\bar{\chi} = \frac{2r_c}{L} \int_0^{V_{\max}} \chi(V) dV \quad (\text{A.5})$$

where L = length of the ionizer

Using the approximate relation for $\chi(V)$ from Eq. (A.4) and assuming that $V_{\max}$ is less than $L/2r_c$ gives:

$$\bar{\chi} \approx \frac{2r_c}{TL} \quad \text{which is independent of } Q \quad (\text{A.6})$$

For $r_c = 1/16$ inch, $L = 9/16$ inch and $T = 1/2$; the above equation gives $\bar{\chi} \approx 0.44$.

APPENDIX B. NUMERICAL SOLUTION TO THE CONDUCTION AND DIFFUSION EQUATIONS

A. Description of the Crank-Nicolson Method

The conduction equation for iron (Eq. (4.3)) and the conduction and diffusion equations for ZrH_y (Eqs. (4.31)) are solved numerically by a Crank-Nicolson finite difference method.⁷¹ This method is second order correct in both the time and space increment Δt and Δx , and the finite difference solution converges to the true solution for all values of $\Delta t/(\Delta x)^2$. Rather than use a constant Δx as is usually the case, Δx increases geometrically into the material according to the relation:

$$\Delta x_i = \epsilon \Delta x_{i-1} = \epsilon^{i-1} \Delta x_1 \quad (B.1)$$

where ϵ = a constant greater than 1, taken to be 1.035

Δx_1 = space increment following grid plane 1

The use of this variable Δx is advantageous because $\frac{\partial T}{\partial x}$ and $\frac{\partial y}{\partial x}$ are largest near the surface and decrease into the material. Therefore, for a particular temperature difference between adjacent grid planes, a closer grid spacing is required near the surface than in the bulk. The variable Δx is also useful because the conduction and diffusion equations can be solved on the same grid even though they have different characteristic lengths.

The conduction equation in iron can be put in the form

$$\frac{\partial^2 T}{\partial x^2} = \psi(x, t, T, \frac{\partial T}{\partial x}, \frac{\partial T}{\partial t}) \quad (B.2)$$

The Crank-Nicolson finite difference approximation to this equation is

$$\frac{1}{2} \Delta_x^2 (w_{i,n+1} + w_{i,n}) = \psi(x_i, t_{n+1/2}, \frac{1}{2}(w_{i,n+1} + w_{i,n})) , \quad (B.3)$$

$$\frac{1}{2} \Delta_x (w_{i,n+1} + w_{i,n}) , (w_{i,n+1} - w_{i,n})/\Delta t)$$

where: $\Delta_x^2 w_{i,n}$ = centered second difference of $w_{i,n}$

$\Delta_x w_{i,n}$ = centered first difference of $w_{i,n}$

$w_{i,n}$ = finite difference solution for the temperature at the i^{th} x grid plane at the n^{th} time step

The boundary condition to Eq. (B.2) can be put in the form

$$\left. \frac{\partial T}{\partial x} \right|_{x=0} = g(T, t) \Big|_{x=0}$$

The finite difference approximation to this is:

$$w'_{1,n+1} = g(w_{1,n+1}, t_{n+1}) \quad (B.5)$$

where $w'_{1,n} = 2^{nd}$ order correct forward first difference of $w_{1,n}$.

For the case of Δx a constant, it can easily be shown that the second order correct differences are:

$$\Delta_x f_i = (f_{i+1} - f_{i-1})/2\Delta x$$

$$\Delta_x^2 f_i = (f_{i+1} - 2f_i + f_{i-1})/(\Delta x)^2 \quad (B.6)$$

$$f'_1 = (-3f_1 + 4f_2 - f_3)/2\Delta x$$

For the case of Δx varying according to Eq. (B.1) the second order correct differences are considerably more complicated. By expanding $f(x)$ and df/dx in Taylor series about x_1 , it can be shown that the second order correct differences are

$$\Delta_x f_1 = \frac{1}{\Delta x_1 \epsilon^{i-1}} \left[\frac{f_{i+1}}{(1+\epsilon)} + (\epsilon - 1)f_i - \frac{\epsilon^2}{(1+\epsilon)} f_{i-1} \right] \quad (B.7a)$$

$$\begin{aligned} \Delta_x^2 f_1 = \frac{2}{(\Delta x_1 \epsilon^{i-1})^2} & \left[\frac{(\epsilon^2 + \epsilon - 1)}{\epsilon(1+\epsilon)} f_{i+1} - \frac{(\epsilon^2 + 2\epsilon - 1)}{(1+\epsilon)} f_i \right. \\ & \left. + \frac{\epsilon^3(2+\epsilon)}{(1+\epsilon+\epsilon^2)(1+\epsilon)} f_{i-1} - \frac{(\epsilon-1)}{\epsilon(1+\epsilon)(1+\epsilon+\epsilon^2)} f_{i+2} \right] \end{aligned} \quad (B.7b)$$

$$f_1' = \frac{1}{\Delta x_1} \left[\frac{-(2+\epsilon)}{(1+\epsilon)} f_1 + \frac{(1+\epsilon)}{\epsilon} f_2 - \frac{1}{\epsilon(1+\epsilon)} f_3 \right] \quad (B.7c)$$

At each new time, Eqs. (B.3) and (B.5) comprise a set of non-linear equations that are to be solved for $w_{i,n+1}$ for all i . The system can be solved by an iterative technique using Gaussian elimination to solve the set of equations for each iteration, as suggested by Douglas.⁷¹

B. Numerical Solution of the Conduction Equation in Iron

The conduction equation for iron (Eq. (4.3)) can be written:

$$\frac{\partial^2 T}{\partial x^2} = A_1 \frac{\partial T}{\partial t} - \left[A_2 \frac{\partial T}{\partial x} + A_3 \left(\frac{\partial T}{\partial x} \right)^2 + A_4 \right] \quad (B.8a)$$

where $A_1 = 1/K(T)$

$$A_2 = v(T_s)/K(T)$$

$$A_3 = \frac{dk(T)}{dT}/k(T)$$

$$A_4 = A(x,t)/k(T)$$

with boundary condition:

$$\left. \frac{\partial T}{\partial x} \right|_{x=0} = g(T,t) \Big|_{x=0} = \frac{1}{k} \left[\phi(T_s) \Delta H_{\text{vap}}(T_s) + \epsilon \sigma (T_s^4 - T_o^4) - A_s(t) \right] \quad (B.8b)$$

Let
$$\psi_1(x, t, T, \frac{\partial T}{\partial x}) = - \left[A_2 \frac{\partial T}{\partial x} + A_3 \left(\frac{\partial T}{\partial x} \right)^2 + A_4 \right]$$

then the Crank-Nicolson Eq. (B.3) becomes

$$\Delta_x^2 w_{i,n+1} - \frac{2A_1}{\Delta t} w_{i,n+1} = -\Delta_x^2 w_{i,n} - \frac{2A_1}{\Delta t} w_{i,n} + 2\psi_1(x_i, t_{n+1/2}, \frac{1}{2}(w_{i,n+1} + w_{i,n}), \frac{1}{2}\Delta_x(w_{i,n+1} + w_{i,n})) \quad (B.9a)$$

for $i = 2, M$

with boundary condition at $i = 1$:

$$w'_{1,n+1} = g(w_{1,n+1}, t_{n+1}) \quad (B.9b)$$

and initial condition:

$$w_{i,0} = T_0 \quad \text{for all } i \quad (B.9c)$$

For the first iteration of Eqs. (B.9) let $w_{i,n+1}$ in A_1 , ψ_1 and g be equal to $w_{i,n}$. Solve Eq. (B.9) for $w_{i,n+1}^{(1)}$ and use this value in A_1 , ψ_1 and g for $w_{i,n+1}$ and calculate $w_{i,n+1}^{(2)}$. This iteration is repeated until successive iterations are equal to within some arbitrary value.

The system of equations to be solved for each iteration at each time step can be put in the matrix form:

$$Aw = e \quad (B.10)$$

where w is a column vector $w_{1,n+1}, w_{2,n+1}, \dots, w_{M,n+1}$.

e is a column vector with e_1 = right hand side of Eq. (B.9a) and (B.9b).

The matrix A is an $M \times M$ quaddiagonal matrix since all elements are zero except those on the principal diagonal, one below, and one and two above the principle diagonal. This form of matrix equation is easily solved by Gaussian elimination. The value of M is determined by a criterion on the temperature gradient. If the gradient at grid plane

i is less than some arbitrary small value, M is set equal to i. In all cases M was less than 300. Values of w_{M+1} and w_{M+2} are approximated by a linear extrapolation of w_{M-1} and w_M so that the number of unknowns is equal to the number of equations.

The value of Δx_1 in this case was set at 5×10^{-6} cm, and Δt was calculated at the end of each time step so that the maximum change in temperature at any grid plane during a time step was 10 to 20°C.

C. Numerical Solution of the Conduction and Diffusion Equations in ZrH_y

The conduction and diffusion equations in ZrH_y (Eqs. (4.31)) can be put in the form

$$\frac{\partial^2 T}{\partial x^2} = A_1 \frac{\partial T}{\partial t} - A_2 \frac{\partial^2 y}{\partial x^2} - A_3 \frac{\partial y}{\partial x} \frac{\partial T}{\partial x} - A_4 \left(\frac{\partial T}{\partial x} \right)^2 - A_5 \left(\frac{\partial y}{\partial x} \right)^2 - A_6(x, t) \quad (B.11a)$$

$$\frac{\partial^2 y}{\partial x^2} = B_1 \frac{\partial y}{\partial t} - B_2 \frac{\partial^2 T}{\partial x^2} - B_3 \frac{\partial y}{\partial x} \frac{\partial T}{\partial x} - B_4 \left(\frac{\partial y}{\partial x} \right)^2 - B_5 \left(\frac{\partial T}{\partial x} \right)^2 \quad (B.11b)$$

with boundary conditions:

$$\left. \frac{\partial T}{\partial x} \right|_{x=0} = g(T_s, y_s, t) \quad \text{given by Eq. (4.31e)} \quad (B.11c)$$

$$\left. \frac{\partial y}{\partial x} \right|_{x=0} = h(T_s, y_s, t) \quad \text{given by Eq. (4.31f)} \quad (B.11d)$$

where

$$A_1 = \frac{\rho C_v(T, y)}{k(T, y)} = \frac{1}{K(T, y)}$$

$$A_2 = \frac{DQ^* N_o}{k}$$

$$A_3 = \frac{1}{k} \left[\left(\frac{\partial k}{\partial y} \right)_T + \left(\frac{\partial (DQ^*)}{\partial T} \right)_y N_o + DN_o \left(\frac{\partial \bar{H}_H}{\partial T} \right)_y + \frac{DQ^* N_o y}{RT^2} \left(\frac{\partial \bar{H}_H}{\partial y} \right)_T \right]$$

$$A_4 = \frac{1}{k} \left[\left(\frac{\partial k}{\partial T} \right)_y + \frac{N_0 DQ^* y}{RT^2} \left(\frac{\partial \bar{H}_H}{\partial T} \right)_y \right]$$

$$A_5 = \frac{N_0}{k} \left[\left(\frac{\partial (DQ^*)}{\partial y} \right)_T + D \left(\frac{\partial \bar{H}_H}{\partial y} \right)_T \right]$$

$$A_6 = A(x, t) / k$$

$$B_1 = 1/D$$

$$B_2 = \frac{Q^* y}{RT^2}$$

$$B_3 = \frac{1}{D} \left[\left(\frac{\partial D}{\partial T} \right)_y + \frac{DQ^*}{RT^2} + \frac{y}{RT^2} \left(\frac{\partial (DQ^*)}{\partial y} \right)_T \right]$$

$$B_4 = \frac{1}{D} \left(\frac{\partial D}{\partial y} \right)_T$$

$$B_5 = \frac{1}{DRT^2} \left[y \left(\frac{\partial (DQ^*)}{\partial T} \right)_y - \frac{2DQ^* y}{T} \right]$$

In general all material properties are functions of both T and y.

Let

$$\psi_T = \psi_T \left(x, t, T, y, \frac{\partial T}{\partial x}, \frac{\partial y}{\partial x}, \frac{\partial^2 y}{\partial x^2} \right)$$

and

$$\psi_y = \psi_y \left(T, y, \frac{\partial T}{\partial x}, \frac{\partial y}{\partial x}, \frac{\partial^2 T}{\partial x^2} \right)$$

denote the right hand side of Eqs. (B.11a) and (B.11b) not including the partial derivatives with respect to time. That is:

$$\frac{\partial^2 T}{\partial x^2} = A_1 \frac{\partial T}{\partial t} + \psi_T \quad (B.12a)$$

$$\frac{\partial^2 y}{\partial x^2} = B_1 \frac{\partial y}{\partial t} + \psi_y \quad (B.12b)$$

By analogy with the conduction equation for iron, the Crank-Nicolson finite difference approximations to these simultaneous equations are:

$$\Delta_x^2 w_{i,n+1} - \frac{2A_1}{\Delta t} w_{i,n+1} = - \Delta_x^2 w_{i,n} - \frac{2A_1}{\Delta t} w_{i,n} \quad (B.13a)$$

$$+ \psi_T \left[x_{i,t_{n+1/2}} + \frac{1}{2} (w_{i,n+1} + w_{i,n}), \frac{1}{2} (v_{i,n+1} + v_{i,n}), \right.$$

$$\left. \frac{1}{2} \Delta_x (w_{i,n+1} + w_{i,n}), \frac{1}{2} \Delta_x (v_{i,n+1} + v_{i,n}), \right.$$

$$\left. \frac{1}{2} \Delta_x^2 (v_{i,n+1} + v_{i,n}) \right]$$

$$\Delta_x^2 v_{i,n+1} - \frac{2B_1}{\Delta t} v_{i,n+1} = - \Delta_x^2 v_{i,n} - \frac{2B_1}{\Delta t} v_{i,n}$$

$$+ \psi_y \left[\frac{1}{2} (w_{i,n+1} + w_{i,n}), \frac{1}{2} (v_{i,n+1} + v_{i,n}), \right.$$

$$\left. \frac{1}{2} \Delta_x (w_{i,n+1} + w_{i,n}), \frac{1}{2} \Delta_x (v_{i,n+1} + v_{i,n}), \right.$$

$$\left. \frac{1}{2} \Delta_x^2 (w_{i,n+1} + w_{i,n}) \right]$$

$$w'_{1,n+1} = g(w_{1,n+1}, v_{1,n+1}, t_{n+1}) \quad (B.13c)$$

$$v'_{1,n+1} = h(w_{1,n+1}, v_{1,n+1}, t_{n+1}) \quad (B.13d)$$

with initial conditions:

$$w_{i,0} = T_0 \quad \text{for all } i \quad (B.13e)$$

$$v_{i,0} = y_0 \quad \text{for all } i \quad (B.13f)$$

where $w_{i,n}$ and $v_{i,n}$ are the finite difference solutions for T and y at the i^{th} grid plane at the n^{th} time step.

The method of solution of Eqs. (B.13) is similar to that for the iron case. For the first iteration of Eq. (B.13a) $w_{i,n+1}$ and $v_{i,n+1}$

in A_1 , ψ_T and g are approximated by $w_{i,n}$ and $v_{i,n}$. Equations (B.13a) and (B.13c) are then solved for $w_{i,n+1}^{(1)}$. For the first iteration of Eq. (B.13b), $w_{i,n+1}$ and $v_{i,n+1}$ in B_1 , ψ_y and h are approximated by $w_{i,n+1}^{(1)}$ and $v_{i,n}$. Equations (B.13b) and (B.13d) are then solved for $v_{i,n+1}^{(1)}$. The values of v and w from the first iteration are then used to calculate values for the second iteration. The process is repeated until the successive iterations are sufficiently close to each other.

As in the iron case, the sets of Eqs. (B.13a,c) and (B.13b,d) are each in a quaddiagonal configuration and are solved by Gaussian elimination. The value of Δx_1 in this case was set at 1×10^{-7} cm. The value of Δt was calculated at the end of each time step so that either the maximum change in any grid plane temperature during a time step was 10 to 20°C or the maximum change in H/Zr atom ratio was 0.02. Up to five iterations were allowed at each time step.
