Abstract

The results of the 1980 and 1981 well drilling activities at the Cerro Prieto geothermal field are summarized. Details are given on the new series of deeper wells completed in the western ("older") part of the field (Cerro Prieto I), and on the development and step-out wells drilled in the eastern part of the field (Cerro Prieto II and III). Production characteristics of on-line and stand-by wells are discussed. Recent changes in well completion procedures are also described.

Introduction

During the last two years significant advances have been made in the development of the Cerro Prieto field. The purpose of this paper is to update the information presented during the Fifth Geothermal Reservoir Engineering Workshop (Alonso et al., 1979).

The installed electrical power capacity at the field continues to be 150 MW (four 37.5-MW

high-pressure turbogenerators). A 30-MW lower-pressure unit has been undergoing testing since mid-1981. Before going into full operation, some installations of the flashing plant for this unit will have to be modified to improve its performance. At this plant, water at about 169°C separated from the high-pressure steam is flashed at 4.36 and 2.11 kg/cm² abs. The construction of two 220-MW power plants, each with two 110-MW turbogenerators, has begun. These plants are scheduled to go into operation during 1983 and 1984, respectively.

Drilling program

In November 1981 there were five drilling rigs and two work-over rigs active in the area; about 96 deep wells have been completed. Between December 1979 and November 1981 27 wells were drilled. These wells are shown in Figure 1, with the exception of well G-1, located about 6 km ENE of well NL-1. The total depths and maximum temperatures measured in these wells are given in Table 1.

NOTE:

* well filled with drilling mud

Figure 1. Location of wells at Cerro Prieto. Wells indicated with concentric circles were drilled between December 1979 and November 1981.

In the eastern part of the field the purpose of the drilling activity has been to increase the number of production wells for the power plants under construction, and to explore for the boundaries of the geothermal system. The temperature profiles obtained in the most recently drilled wells confirmed the temperature distributions developed earlier this year by Castillo et al. (1981) (See Figures 2 and 3). The wells drilled during 1980 and 1981 have essentially delineated the northern, eastern and southeastern boundaries of the thermal anomaly. Outside of this region, the 1977 Prian well (3496 m depth) and the recent G-1 well (3000 m depth) have shown very low temperatures.

In the western part of the field, new production and stand-by wells were drilled for the existing power plant. In that region the wells of the deeper "E-series" (average total depth: 1900 m) have confirmed the presence of a hotter aquifer (about 335°C) below the reservoir which has been under exploitation since 1973, and whose average temperature and depth are about 280°C and 1250 m, respectively.

Well pressures and production rates

Shut-in wellhead pressures in the northwestern part of the field (CP I Norte), excluding the E-wells, have reached up to about 800 psi; in the southwestern part (CP I Sur) about 900 psi; in the southeastern part (CP II) about 1300 psi; and in the northeastern region (CP III) about 1200 psi.

In CP I Norte (excluding the deeper E-wells) the maximum steam production ever measured in a well was 125 t/h. In CP I Sur, some wells reached 140 t/h of steam. In CP II, where the reservoir is at 2700-3000 m depth, steam productions of up to 300 t/h have been measured. In CP III, the reservoir is at 2000-2500 m depth, and some wells have produced above 100 t/h of steam. (Domínguez and Sánchez, 1981).

The production characteristics of the wells supplying steam to the power plant as of August 1981 are given in Table 2. At that time, the average electrical power generation

was 112.5 MW (only three of the four turbogenerators were on line because of repairs to one of the cooling towers). Table 3 shows the production characteristics of the stand-by wells.

Well completion

A number of modifications have been made in the way the wells are completed at Cerro Prieto, partly because deeper production and exploration wells are being drilled, and partly to reduce mechanical and corrosion problems in the casings (Table 4).

The casing completion described by Alonso et al. (1979, Table 2) using production casings with API N-80 tubing was not very successful. The lifetime of these casings is about 6 months (Domínguez et al., 1981). Corrosion, collapses and fractures have been detected.

Up-to-date results have shown that the wells completed during 1977-78 using API K-55 production casings have performed well. These heavier, soft steel casings have shown greater resistance to mechanical stresses and corrosion. The damages observed in some of the 1977-78 wells are believed to be related to faulty cementing of the casings caused by circulation losses and/or failure of casing accessories during the cementing operations.

Presently API C-75 grade production casings are being installed at Cerro Prieto (Table 4). Because of the recent installation, it has as yet not been possible to evaluate their performance.

To reduce circulation losses while cementing long strings of casings (up to 2000 m long), low-density cement slurries have been used. Recently, good results have been obtained by adding small diameter ceramic spherules to the slurry, reducing its specific gravity to about 1.3 (10.8 lb/gal).

In some wells, mainly because of circulation losses, none of the cement slurry returns to the surface. Recently, the non-cemented annular space behind casings has been filled by pouring fine silica sand. It not only reduces the open space behind the partially cemented casing, but also gives it mechanical support. Up to now the wells where this procedure was used have not shown problems.

Final remarks

The drilling of production and exploration wells will continue at Cerro Prieto. The immediate goal is to drill enough wells to satisfy the long-term steam requirements of the power plants. It is estimated that the existing plant will need 30 wells (6 MW/well), while each of the two power plants under construction will require the steam from about 25 wells (8.8 MW/well) to reach a total generating capacity of 620 MW_e by 1984.

In order to establish the areal extent and the energy potential of the southern parts of the field (CP I Sur and CP II) a number of wells are planned to be drilled soon in the area between wells M-101, 93, 189 and 92.
