ABSTRACT

Energy-dependent sensitivity profiles for five responses calculated for the TRX-2 thermal lattice with the ORNL sensitivity code system FORSS are presented here both in graphical form and in SENPRO format. The responses are the multiplication factor, k_{eff}; the ratio of epithermal-to-thermal captures in ^{238}U, $^{28}\rho$; the ratio of epithermal-to-thermal fissions in ^{235}U, $^{28}\delta$; the ratio of fissions in ^{238}U to fissions in ^{235}U, $^{28}\delta$; and the ratio of captures in ^{238}U to fissions in ^{235}U, CR. A summary table of the total sensitivities is also presented.

INTRODUCTION

The ORNL sensitivity code system FORSS,[1,2] a modular computer code system for studying relationships between nuclear cross sections, integral experiments, and calculated performance parameters for a given system, together with the associated uncertainties, has been applied to the CSEWG TRX-2 thermal lattice benchmark.[3] Of special interest are the sensitivity profiles, which show the sensitivity of the calculated responses to the various material cross sections as a function of neutron energy and to the resonance parameters. These profiles may be used in a myriad of ways; however, much insight can be gained merely through studying the profiles themselves. This report presents a set of typical sensitivity profiles for the selected system. In addition, for those interested in applying the sensitivity coefficients, the SENPRO format[4] for reporting sensitivity coefficients is presented in Appendix A, and the data are tabulated in Appendix B.

THE SCOPE OF THE REPORT

The TRX-2 thermal lattice was selected for this study because it represents a well-documented and often-calculated thermal benchmark. It was a slightly enriched (1.3%) water-moderated assembly with uranium metal rods clad in aluminum. The rods were 121.92 cm in length and 0.983 cm in diameter in a hexagonal pitched array with a water-to-fuel ratio of 4.02. This resulted in a spectrum that was considerably softer than that of a typical pressurized water reactor. The calculations were done using a single assembly cell (i.e., a single fuel rod surrounded by water).

A total of five responses were calculated for the assembly:

(1) the multiplication factor, k_{eff};
(2) the ratio of epithermal-to-thermal captures in ^{238}U, ^{28}c;
(3) the ratio of epithermal-to-thermal fissions in ^{235}U, $^{25}\delta$;
(4) the ratio of ^{238}U fissions to ^{235}U fissions, $^{28}\delta$;
(5) the ratio of ^{238}U captures to ^{235}U fissions, CR.

All reaction rate ratios were averaged over the fuel pin. An upper energy bound of 0.625 eV was assumed for the thermal region. The nuclear data

included were fission yields and neutron interaction cross sections for fission, capture, total scattering, and total inelastic scattering, as well as scattering from each inelastic level and from the inelastic continuum. Inelastic scattering sensitivities were considered only for ^{238}U and reported only if the magnitude of the sensitivity was greater than 10^{-6}.

The sensitivities presented represent a portion of what is presently available at ORNL in the thermal reactor field and is in no sense complete. Preliminary sets of sensitivity profiles are available for a number of mixed oxide lattices.[5] It was felt, however, that these data are of sufficient interest to warrant presentation in this report. The sensitivities have been compiled in a computer-readable format and are available from the Radiation Shielding Information Center at Oak Ridge National Laboratory. This RSIC library, which also presently contains a number of fast reactor benchmark sensitivities,[6] continues to grow and will be documented at appropriate intervals in the sense of the "open code package."

THE METHOD

The method of calculating the sensitivity coefficients for TRX-2 has been extensively described elsewhere[7] and only a brief description will be presented here.

A 131 energy group cross-section library[8] was developed for use in this study. The energy boundaries for this library are presented in Table 1. The weight function used for the averaging process consisted of a Maxwellian at 300°K in the thermal range with an upper energy cutoff of 0.625 eV coupled to a 1/E spectrum joined to a fission spectrum at high energies. (The breakpoint was taken to be 67 keV and the temperature of the fission spectrum was taken to be 1.27 MeV, corresponding to the ENDF/B-IV value for the thermal fissions in ^{235}U.) The thermal cross sections generated during this process were not used because of the inability of the MINX code to perform upscatter corrections. The upscatter corrected and self-shielded thermal data, including bound atom effects, used in this

study were supplied by EPRI.[8] These were obtained from a 30-group THERMOS[9] calculation.

The scattering cross section for all the energy groups above thermal were expanded through P_1 except for hydrogen. The hydrogen scattering matrices were expanded through order 5. This was done to correctly account for the forward peaked angular distribution of neutrons scattering from hydrogen in the laboratory system, leading to an energy distribution appropriate for the fine energy mesh used in this study. Later results indicated that a P_3 expansion would have been sufficient. The thermal cross section data consisted of a transport corrected P_0 set. (In practice, this was run as P_5, with the higher moments set to zero.) This involved the assumption that all anisotropic scattering effects can be accounted for by use of the transport cross section instead of the total cross section.

The ANISN discrete ordinate transport code[10] (using an $S_{16}P_5$ approximation) was applied to a one-dimensional model of a TRX-2 cell, described in Table 2, for the calculation of the forward and adjoint fluxes, as well as the multiplication eigenvalue. These in turn were used in the JULIET[2] module for calculating the values of the performance parameters and the corresponding sources for the generalized-adjoint transport equations. The generalized adjoint solutions of these generalized equations were provided by ANISN (modified to allow negative sources and fluxes) and then used in JULIET for the calculation of sensitivity coefficients. Further details concerning these codes and procedures can be found in Ref. 7.

RESULTS

The results of this sensitivity study are presented here in the form of tables and graphs.* The nominal values of the performance parameters calculated using ENDF/B-IV cross sections are in good agreement with previously reported values[11] and experimental values (see Table 3).[12] The calculated resonance parameter sensitivities for the first four s wave resonances in ^{238}U are also in good agreement with previously reported results.[13] The

graphs, Figs. 1-94, present relative sensitivities per unit lethargy as a function of neutron energy. The profiles were plotted in this form because the relative sensitivity per unit lethargy is independent of group structure if the group structure is sufficiently fine. Thus these plots can be compared directly with similar plots which use a different group structure. Note that these are log-log plots in which a solid curve represents a negative quantity and a broken line (dashed) curve represents a positive quantity.

The total sensitivities for each response, nuclide, and reaction are presented in Tables 4-8. The total sensitivity is the sum over all energy groups of the sensitivities of the response with respect to the group reaction cross sections. Such a total sensitivity is actually a relative sensitivity with respect to a single group-independent scale factor λ which affects the associated cross section in the same proportion at all energies and small groups. Thus, if the scale factor λ increases by 10%, all the group cross sections for the associated reaction type increase by the same 10%. For convenience λ may be set to unity when the group cross sections have their nominal values σ_g^0. Then the group cross sections are given by

$$\sigma_g' = \lambda \sigma_g^0. \tag{1}$$

The energy dependent sensitivity profiles provide a quantitative assessment of the rate of change in a particular response, R, with respect to the rate of change in some multigroup constant. Of more immediate interest is the sensitivity with respect to a specific resonance parameter, Γ_χ. The latter can be obtained from

$$\frac{dR/R}{d\Gamma_\chi/\Gamma_\chi} = \sum_g \left(\frac{dR/R}{d\bar{\sigma}_g/\bar{\sigma}_g}\right) \frac{d\bar{\sigma}_g/\bar{\sigma}_g}{d\Gamma_\chi/\Gamma_\chi} \tag{2}$$

The first term in each element of the sum is the sensitivity profile ($dR/R/d\bar{\sigma}_g/\bar{\sigma}_g$), whereas the second derivation ($d\bar{\sigma}_g/\bar{\sigma}_g/d\Gamma_\chi/\Gamma_\chi$) can be obtained numerically.

The numerical derivatives were obtained by direct recalculation of the group averaged cross section with a perturbed set of resonance parameters. The results of these calculations are given in Table 9 for the parameters

of interest with respect to the capture and scattering widths of the first four resolved resonances.

The sensitivities given in Appendix B using the SENPRO format are not per unit lethargy but are simply relative sensitivities to the group cross sections. These relative sensitivities are the quantities currently used in numerical computations.

DISCUSSION

A study of the energy-dependent profiles can provide valuable insight into the interrelations between the various nuclides in the assembly. Large quantities of structure are readily observable in their profiles. This structure can often be traced back to resonances, thresholds, etc. in the cross sections. However, a more detailed examination of these effects is beyond the scope of this report.

The remainder of this discussion is concerned with a few items which are useful in interpreting the profiles presented here. The total sensitivity is a useful figure-of-merit indicating what reactions are likely to be important for a given response. However, since the total sensitivity is often composed of large positive and negative contributions (particularly for epithermal-to-thermal reaction rate ratios), one must be careful not to be misled by relatively small values of the total sensitivity such as that for the sensitivity of $^{28}\rho$ to ^{238}U capture. The graphical displays of the sensitivity profiles illustrate the detailed energy dependence.

The shape of the sensitivity profile of k and $^{28}\rho$ to $^{238}U(n,\gamma)$ show the effects of resonance self-shielding. The major portion of the captures (71%) in each resonance occur in the wings where the sensitivity is the highest. The self-shielded resonance peak, where the flux is depressed, has a low sensitivity. Similar behavior can be seen in other profiles.

The reaction rate ratios, in particular the epithermal-to-thermal ratios, have sensitivities to the hydrogen scattering cross section that are near unity, which is much higher than the sensitivities to most of the other nuclides and reaction types. The dominance of the hydrogen scattering sensitivity is due to the importance of hydrogen in the neutron thermalization process.

This study revealed that the total sensitivities are dominated by the contributions made in the thermal energy region. The lack of a fine energy mesh below 0.625 eV was a definite disadvantage during this study and it is highly recommended that future studies of thermal lattices use a fine energy mesh to perform detailed studies in this energy range.

The sensitivity of the performance parameters to the ^{238}U resonance data is dominated by the resolved resonance parameter of the 6.67 eV resonance. This is as expected since approximately 70% of the captures in ^{238}U occur below 100 eV and the majority of these are in the 6.67 eV resonance. It is also interesting to note that the sensitivity to the neutron width Γ_n is almost identical to the sensitivity to the capture width Γ_γ.

The sensitivities quoted as sensitivity to neutron scattering refer to the total scattering cross section (i.e., the sum of elastic, inelastic, etc.). The DB^2 sensitivity components refer to the pseudo-absorption term which was added to the total cross section to account for leakage from the lattice. The only performance parameters that have a relatively high sensitivity to leakage are k_{eff} and $^{28}\delta$. This is as expected since these are the only two parameters that are affected directly by fission in ^{238}U. A detailed discussion of this leakage treatment can be found in Ref. 7.

For interpreting the summary tables, it is useful to first calculate the direct effect contribution to the total relative sensitivity. This contribution is that which arises from the explicit dependence of the performance parameter on the nuclear data parameter of interest, which, as discussed in the previous section for a total relative sensitivity, is a scale factor. In calculating the direct effect contribution, the shape of the forward flux (as well as that of the adjoint flux) is assumed to remain unchanged.

The following theorem is especially applicable to the calculation of direct effects to total sensitivities of reaction rate ratios: If the mathematical expression for a response is explicitly homogeneous of degree n in a nuclear data parameter, then the direct effect contribution to the relative sensitivity of that response with respect to the nuclear data

parameter is n. Reaction rate ratios are typically homogeneous of degree +1, -1, or 0 in the scale factors (not the group cross sections). Accordingly, the direct effect contribution to the total sensitivity of a reaction rate ratio is typically +1, -1, or 0.

For example, the ratio of ^{238}U capture to ^{235}U fission is homogeneous of degree 1 in the ^{238}U-capture scale factor, of degree -1 in the ^{235}U-fission scale factor, and of degree 0 in the ^{235}U-capture scale factor. The corresponding direct effect contributions to the total relative sensitivities are 1, -1, and 0, respectively.

The direct effect gives the contributions to the sensitivity coefficients ignoring explicit variations in the forward (and adjoint) flux. Frequently, however, it is just those effects due to flux modifications, the indirect effects, which are most interesting. These indirect effects arise largely through the shielding of one reaction by another (or itself) and include self shielding as well as the shadowing of one resonance by another. There are also resulting modifications to the leakage and to the slowing down.

For those total relative sensitivities of reaction rate ratios with a direct effect contribution of unit magnitude, the indirect effect contribution is frequently of opposite sign to the direct effect contribution, resulting in total relative sensitivities with magnitudes less than unity. These illustrate that a reaction cross section commonly shields itself more than it shields another reaction cross section.

On the other hand, there are several examples for which the magnitude of the total relative sensitivity is greater than the unit contribution given by the direct effect. This illustrates shielding (or another cross section) which is a greater effect than the self shielding. Thus, the relative sensitivity of ^{28}p to the scattering cross section of hydrogen is -1.035, which is greater in magnitude than the direct effect (0.0). This shows that an increase in the hydrogen scale factor results in a flux spectrum modification (due to changes in the rate of neutron thermalization) which greatly decreases the epithermal captures relative to the thermal captures. That is, it increases the resonance escape probability.

The above discussion and results apply to sensitivity coefficients for reaction rate ratios, which are generally homogeneous in the nuclear data

scale factors. Generally, they do not apply to sensitivity coefficients for the multiplication factor k because the mathematical expression for k is generally not homogeneous in any scale parameter.

For this and other reasons, it is not convenient to divide k-sensitivities into the direct-effect and the indirect-effect contributions. The sensitivity coefficient for k with respect to nuclear data parameter a naturally breaks up into two terms - one from the source and the other from the losses. The expressions for these are given by

$$\frac{a}{k}\frac{dk}{da} = f_a - k\,\alpha_a \,, \tag{3}$$

where f_a is the fraction of adjoint-weighted fission sources which are of degree 1 in the parameter a and α_a is the ratio of loss terms of degree 1 in the parameter a to the total adjoint-weighted fission source. The mathematical expressions for these are

$$f_a \equiv \frac{(\phi^*, B_a\phi)}{(\phi^*, B\phi)} \,, \tag{4}$$

$$\alpha_a \equiv \frac{(\phi^*, A_a\phi)}{(\phi^*, B\phi)} \,, \tag{5}$$

where B_a is the part of the fission source proportional to parameter a, A_a is the loss operator (everything but fission) proportional to parameter a, and ϕ and ϕ^* are the forward and adjoint fluxes, respectively.

Equation (2) immediately shows that the sum of all the sensitivity coefficients with respect to the neutron fission yields is unity. Another relation which is obvious from Eq. (2) is that the capture sensitivities are simply given by -k times the adjoint-weighted nuclide capture to total fission ratio. Only slightly less obvious is that the difference between the yield sensitivity and the corresponding fission reaction sensitivity is simply k times the nuclide capture sensitivity divided by the nuclide capture-to-fission ratio (adjoint weighted).

The unity sum rule given above for sensitivity coefficients of k with respect to neutron yield $\bar{\nu}$ should be compared with the zero sum rule for sensitivity coefficients of other performance parameters which do not depend explicitly on the multiplication factor or a neutron yield. Such sensitivity coefficients add algebraically to zero when summed over all neutron yields because the resulting change in k (assuming k is not reset) exactly compensates for the changes in the neutron yields.

CONCLUSIONS

The sensitivity coefficients are an important tool for the calculation of many quantities of interest in reactor design. A comprehensive set of sensitivity profiles has been determined for integral performance parameters measured in TRX-2. These sensitivities are being used by the Cross Section Evaluation Working Group in providing additional guidance for future evaluations. These sensitivity profiles and summary tables are contained in this report; the data files in SENPRO format are in Appendix B.

ACKNOWLEDGMENTS

The authors would like to acknowledge the efforts of C. R. Weisbin of ORNL for overseeing this work and Odelli Czer of EPRI in sponsoring of the work. Our thanks are also extended to L. S. Abbott and L. E. Klobe for assistance in the preparation of this document.
