1. ABSTRACT

Equilibrium, kinetic and X-ray diffraction data show the existence of two stability regions in the Pu-H system. A metastable solid solution between CaF_2 -type $\text{PuH}_{1.9}$ and anti- Fe_3Al -type $\text{PuH}_{3.0}$ forms at low temperature and behaves as an ideal solid solution. Equilibrium and calorimetric results show that the enthalpy of formation varies linearly from -38 to -50 kcal/mol between the lower phase boundary and the trihydride. The phase relationships established at high temperature are similar to those of the lanthanide difluoride-lanthanide trifluoride systems. A series of CaF_2 -related phases apparently forms between $\text{PuH}_{1.9}$ and $\text{PuH}_{2.5}$; a nonstoichiometric hexagonal (LaF_3 -type) hydride exists in the range $\text{PuH}_{2.9}$ - $\text{PuH}_{3.0}$. A procedure for preparing pure hexagonal $\text{PuH}_{3.00}$ is described and the hysteresis behavior of the Pu-H system is discussed.

2. INTRODUCTION

The formation of plutonium hydride is a facile reaction which finds application in plutonium recovery procedures and in powder metallurgy. As noted in a recent report on the decomposition kinetics of plutonium hydride, many fundamental properties of importance to these applications are poorly defined. [1]

Various physicochemical properties which have been described for the Pu-H system include phase equilibria [2-4], structural properties [5,6], reaction kinetics [1,7-9] and thermodynamic properties. [1-3,10-12] These studies have shown that Pu and H_2 form a CaF_2 -type dihydride, a cubic hydride, PuH_x , of variable composition with $2 \leq x \leq 3$, and a hexagonal trihydride. Diffraction data show that the solid solution obeys Vegard's law for $2.0 < x < 2.5$. [3,6] For $x > 2.5$, the cubic parameter is invariant, but a second phase is not observed. [6] Although the formation of a hexagonal phase is documented [4], neither the

conditions for its preparation nor its phase relationship with the cubic hydride is defined. Discrepancies in the enthalpy of formation of the hydride have recently been reviewed. [12] In addition, hysteresis loops are observed at high hydride compositions [4], and marked differences in the reactivities of hydrides prepared at different temperatures are reported. [7] The present report is a result of a continuing effort to clarify the equilibria and thermochemistry of the Pu-H system using a variety of experimental techniques.

3. EXPERIMENTAL PROCEDURES

Plutonium metal (0.13 wt % impurity) stabilized in the delta phase by 1.0 wt % Ga and ultra-high purity hydrogen (Matheson) were used in all tests. Since earlier work has shown that the hydrides of alpha and delta metal behave identically, Ga was treated as an inert component. In all experiments at $P < 500$ torr, pure H_2 was generated by thermal decomposition of UH_3 .

Low pressure TX isobars (1.0, 3.2, 10.0, 31.6, 100, 316 torr) were obtained over the composition range $2.0 \leq X \leq 2.9$ by microbalance methods. [1] H_2 pressures were fixed by thermal control of the U- UH_3 purifier; the temperature range (25-500°C) was scanned at a linear rate of 2°/min. Hydriding rates and equilibrium data of higher pressure H-rich (initial H:Pu ratio > 3) systems were measured by PVT methods. During the rate studies, heat loss by the reactants was retarded by containment of the 25 g Pu sample in a silica cup; temperature and pressure data were recorded with an acquisition system. X-Ray data were obtained with a powder diffractometer. PuH_x samples (0.05-0.08 g) for solution (6M HCl) calorimetric determinations of the enthalpy of formation were prepared using a high temperature vacuum procedure and were analyzed by microbalance methods. [1]

4. RESULTS AND DISCUSSION

4.1 The Cubic Solid Solution.

4.1.1 Equilibria. Microbalance data for the low pressure regime (1.0-316 torr) show the existence of linear TX isobars over the composition range $2.0 \leq X \leq 2.9$. Non-linearity from hysteresis behavior similar to that described by Mulford and Sturdy [4] was observed at low temperatures and high pressures with the initial hydride prepared from the bulk metal. Hysteresis was not observed with subsequent hydrides prepared from powdered metal formed by thermal decomposition of hydride. X-Ray diffraction data for PuH_X samples in the range $2.0 \leq X \leq 2.8$ showed only the cubic phase. The accuracy of the isobars obtained by scanning TX space at $2^\circ/\text{min}$ was verified at several constant temperatures; in all cases the differences in X from the two techniques were less than 0.01. This observation and the results of similar tests to determine the response of X to pressure changes at constant T demonstrate that the reaction rate and hydrogen transport rates of PuH_X are rapid.

As demonstrated by the graphs of $\log P (\text{H}_2)$ at specific X values vs $1/T$ in Fig. 1, the vapor pressure of the cubic hydride changes continuously over the range $1.9 < X < 3.0$. Hysteresis effects are excluded from the data. The dashed line describes the equilibrium vapor pressure in the two-phase region $0 < X < 1.90 \pm 0.05$. [1] The constants obtained by linear ($\log P = A - B/T$) least-squares refinement of the data are listed with the respective graphs in Fig. 1. The average intercept for $X=1.9$ and for all compositions in the range $2.2 \leq X \leq 2.8$ is 9.81 ± 0.16 . Slope values for $X=2.0$, 2.2 and 2.9 have been calculated from the average intercept and single pressure values. Since the average slope change per 0.1 change in X is 550 ± 1.40 , the estimated pressure equation for cubic $\text{PuH}_{3.0}$ is defined by $A=9.81$ and $B=1650$.

The results in Fig. 1 support the conclusions of earlier workers [2,4] that the cubic hydride behaves as a solid solution formed by occupancy of octahedral sites in the CaF_2 -type dihydride. The results also suggest that the solution is nearly ideal. The family of curves in Fig. 1 have the characteristic features of a Cox chart, a $\log P$ vs $1/T$ graph used to correlate vapor pressure data for organic liquids forming ideal solutions. [13] In organic systems, a common intercept and "wagon wheel" behavior of the pressure curves is observed as the solution composition changes. Since similar behavior is evident in Fig. 1, cubic PuH_x apparently behaves as an ideal solid solution over the range $1.9 \leq x \leq 3.0$; i.e., the hydride structure gradually changes from a defect CaF_2 -type phase to an anti- Fe_3Al -type phase as x increases.

4.12 Hysteresis. The present observations provide new insight into the hysteresis phenomenon. Loops in TX isobars for the initial hydrides resulted from the fact that higher x values were observed on ascending T than on descending T for $x > 2.6$. At lower x , equilibrium points were reproducible in both directions and generated a linear isobar that was reproducible at all x values (1) on descending T , (2) on all subsequent thermal cycles with a given sample, and (3) for all hydrides prepared from thermally dehydrided metal. As noted by Mulford and Sturdy [4], the size of the loop increased with increasing H_2 pressure; ΔT values across the loops at 1, 10 and 100 torr were 11° , 20° and 38° , respectively. The presence of hexagonal hydride was detected in earlier work with hysteresis samples [4], but only the cubic phase was observed in the present study.

Additional experiments to characterize the hysteresis phenomenon included controlled rehydriding tests and a thermal scan of the loop. Since the hydriding rate of dehydrided metal powder was faster than that of bulk metal and produced

a thermal spike which could easily self-heat the sample beyond the hysteresis range, several samples were rehydrided slowly at low pressures. Hysteresis could not be induced. In an attempt to scan the 10 torr loop, the temperature was repeatedly increased to 120°C (50° below the closure point of the loop) and decreased to 25°C. The initial TX behavior was not reproducible on cycling; measured points decayed rapidly and were coincident with the linear isobar during descent of the second cycle.

Our observations suggest that the hysteresis results from the presence of a thermally unstable contaminant in the bulk metal. A reasonable candidate is hydroxide, which would readily substitute for hydride in the lattice, would be destroyed by high temperature and would be absent during rehydriding. Since H_2 and PuO_2 are the anticipated products of thermal decomposition, an increase in H_2 pressure should stabilize hydroxide and increase the loop size.

4.13 Thermodynamic Properties. The variation of the enthalpy of formation of the hydride across the composition range of cubic PuH_x has been determined both from equilibrium and calorimetric data. Enthalpy values were obtained by Gibbs-Duhem integration of the pressure data in Fig. 1. The respective ΔH_f° values for PuH_x at $x=1.9$, 2.5 and 3.0 are (-37.3 ± 0.5) , (-45.9 ± 0.8) and (-49.6 ± 0.8) kcal/mol. Calorimetric results based on multiple measurements of the enthalpies of solution of delta-stabilized metal and cubic PuH_x samples in 6 M HCl give ΔH_{soln}° (δ -Pu,s) = (-140.81 ± 0.55) kcal/mol, ΔH_{soln}° ($PuH_{2.21}$,s) = (-98.27 ± 0.39) kcal/mol and ΔH_{soln}° ($PuH_{2.62}$,s) = (-93.52 ± 0.62) kcal/mol and yield the following enthalpies of formation: ΔH_{f298}° ($PuH_{2.21}$) = (-42.54 ± 0.34) kcal/mol and ΔH_{f298}° ($PuH_{2.62}$) = (-47.29 ± 0.50) kcal/mol.

The thermodynamic results obtained by the two techniques are in excellent agreement and indicate that the enthalpy of formation of the hydride varies

linearly with X from (-38 ± 1) kcal/mol at $\text{PuH}_{1.9}$ to (-50 ± 1) kcal/mol at $\text{PuH}_{3.0}$. The phase boundary value is in excellent agreement with the second-law result of Mulford and Sturdy [3], and those in the miscibility range are in good agreement with previous measurements [12] if probable uncertainties in X are considered. The linear change in ΔH_f° with X confirms the conclusion that behavior of the cubic solid solution is ideal.

4.2 The Ordered Hydrides

4.21 Preparation of Hexagonal Trihydride. Samples of stoichiometric plutonium trihydride, $\text{PuH}_{3.00 \pm 0.01}$, have been reproducibly obtained by rapid reaction of 25 g samples of delta-phase plutonium in the presence of an excess H_2 concentration of 0.06 mol/l. Products from preliminary tests in which the metal was in direct contact with the stainless steel reactor were found to contain hexagonal hydride, but PVT data showed that the bulk composition was approximately $\text{PuH}_{2.8}$. The reaction was successful when the metal was insulated by containment in a silica cup so that the sample temperature exceeded 400°C for several minutes. $\text{PuH}_{3.00}$ was produced by cooling the sample in the residual H_2 (1.4 atm at 25°C).

4.22 Equilibria. Results of kinetic, X-ray diffraction and PVT measurements show that an ideal solid solution is not formed in the Pu-H system at the conditions used for preparing hexagonal trihydride. Rates of hydrogen consumption, R , for a typical hydriding reaction are graphed on a logarithmic scale as a function of bulk composition in Fig. 2. Interesting variations in the rate are evident. In the metal-hydride two-phase region not shown, $\ln R$ increases linearly from negative values to a maximum of 7.0 near $X=1.0$ and then decreases to a minimum at $X=1.90$. As shown in Fig. 2, R increases for $1.90 < X < 2.00$, decreases in the range $2.00 < X < 2.20$, and is essentially constant for $2.20 < X < 2.45$. A

small increase in R near $X=2.45$ is followed by a steady decline to $X=2.85$ and a second decline for $2.85 < X < 3.00$. As shown by the elapsed time (upper abscissa), the initial reaction is rapid and the $X=2.85$ composition is reached after approximately 7 min; an additional hour is required for X to reach 3.00.

The validity of the rate measurements is reflected by the gas phase temperature in Fig. 2. This temperature profile and that (not shown) of the solid sample closely track the kinetic results. The relative magnitudes of the exotherms accompanying the rate increases near $X=2.00$ and 2.45 are particularly interesting. Although the changes in X are similar ($1.90-2.20$ vs $2.45-2.85$) the area of the second peak is 5-6 times larger than that of the first. The appearance of this large exotherm is characteristic of reactions in which hexagonal hydride is formed.

Several properties of the hexagonal product are also different from those of the cubic hydride. Cubic products formed by slow (low sample temperature) reaction are finely divided powders which readily ignite in air at 25°C . The products of rapid (high temperature) reaction are primarily composed of large (cm-sized) hydride particles and are less pyrophoric than the cubic products. Temperatures of $200-300^{\circ}\text{C}$ are frequently required for ignition in air. Thermal decomposition of a single 0.5 g hydride particle on a microbalance showed a bulk composition of $X=(2.80\pm 0.05)$ for the sample in vacuum at 25°C . On heating at $2^{\circ}/\text{min}$, H_2 loss was detected at 150°C and occurred in four distinct steps in the composition ranges $2.80 > X > 2.45$, $2.45 > X > 2.25$, $2.25 > X > 1.90$ and $1.90 > X > 0$. The behavior in the lower composition regions is similar to that of cubic PuH_x , but the decomposition rate of the sample at 2.80 is much slower than that of the cubic phase at the same composition. [1]

The formation of hexagonal hydride has been verified by X-ray diffraction analysis of two samples from a $\text{PuH}_{3.00}$ product which had been stored in air (low H_2 pressure) for several days. Analysis of fine powder showed approximately 10% hexagonal and 30% cubic phase. The surface of a large particle showed only the cubic phase. After the same particle had been crushed, re-analysis showed greater than 90% hexagonal phase. The lattice parameter of the CaF_2 -type hydride, $(5.341 \pm 0.003) \text{ \AA}$, is in excellent agreement with the value reported for $\text{PuH}_{2.5}$. [4-6] The lattice parameters of the coexisting substoichiometric (see below) hydride, PuH_{3-z} , are $a = (3.779 \pm 0.005)$ and $c = (6.771 \pm 0.008) \text{ \AA}$. The data indicate that the phase has the disordered LaF_3 -type ($\text{P6}_3/\text{mmc}$) structure. [14] Superstructure reflections characteristic of an ordered LaF_3 -type (P3c1) structure or of a phase with ordered anion vacancies are not observed.

PVT equilibrium measurements with a sample of $\text{PuH}_{3.00}$ demonstrate that the hexagonal hydride is nonstoichiometric. A PX isotherm at 125°C shows that the equilibrium pressure decreases exponentially from 9.6 atm at $\text{PuH}_{3.00}$ to 0.014 atm at $\text{PuH}_{2.89}$ and remains constant at lower compositions. Although the existence of a two-phase region below $X=2.89$ is established, the composition of the second phase has not been determined by equilibrium measurements. A partial isotherm at 25°C shows that the equilibrium pressure of $\text{PuH}_{3.00}$ is 0.030 atm, but the data are insufficient for evaluation of thermodynamic values.

Kinetic, structural and equilibrium data indicate that the Pu-H system enters an ordered regime at moderate pressures and temperatures above $350\text{--}400^\circ\text{C}$. The existence of a substoichiometric hexagonal hydride, PuH_{3-z} , and a two-phase region is certain, but the behavior of the system at lower compositions remains somewhat unclear. The kinetic results indicate that the hydride

system is closely modeled by lanthanide fluoride systems. Recent structural studies of the MF_2 - MF_3 systems of Sm, Eu, and Yb show that a series of ordered CaF_2 -related phases exist between the CaF_2 -type difluorides and the LaF_3 -related trifluorides. [15-17] A CaF_2 -type solid solution is observed between $\text{MF}_{2.00}$ and $\text{MF}_{2.20}$; stoichiometric phases include tetragonal M_3F_7 ($X=2.333$), rhombohedral $\text{M}_{14}\text{F}_{33}$ ($X=2.357$), and cubic $\text{M}_{27}\text{F}_{64}$ ($X=2.370$). A rhombohedral solid solution forms between $\text{M}_{13}\text{F}_{31}$ ($X=2.385$) and $\text{M}_{13}\text{F}_{32}$ ($X=2.462$), and a two-phase region exists between $\text{MF}_{2.46}$ and MF_3 . The correspondence of the rate profile and the fluoride phase diagram in Fig. 2 is remarkable.

If one accepts the conclusion that different plutonium hydride phases react with hydrogen at slightly different rates, there is little doubt that hydride and fluoride systems are similar. Since the known lower hydride phase boundary at $X=1.9$ [1,3,12], the existence of the $\text{PuH}_{2.45}$ - $\text{PuH}_{2.89}$ two-phase region, and the formation of a substoichiometric trihydride are accurately predicted by the rate results, it is reasonable to assume that the rate profile is applicable at intermediate compositions. The rate increase between $X=1.9$ and 2.0 is attributed to the filling of vacant tetrahedral sites in PuH_{2+z} . For the test in Fig. 2, a constant rate is observed over the range of the CaF_2 -related phases; however, in some tests small rate and thermal spikes occur between $X=2.20$ and 2.35, an anticipated two-phase region. It should be noted that the $X=(2.85\pm0.05)$ boundary for PuH_{3-z} has been established by examining gas phase cooling curves ($\ln\Delta T$ vs time) to determine the time and corresponding X value at which the rapid exothermic process stopped.

Insight into the origin of the hysteresis phenomenon is gained by comparison of the equilibrium data for the cubic and hexagonal hydrides. At 125°C and 0.014 atm ($\log P = 1$ in Fig. 1), the composition of the cubic phase is

fixed at $\text{PuH}_{2.66}$. At this PT condition the presence of the hexagonal phase confines the composition to the two-phase region $2.45 < X < 2.89$. The exact value of X depends on the molar ratio of cubic and hexagonal products. The reproducible hysteresis composition at 25°C and 0.014 atm is $X=2.69$. Although earlier workers have attributed the hysteresis to the presence of the hexagonal phase [4], the identical mole fraction of hexagonal phase must form in every hydride product in order for the loop to be reproducible. This possibility seems rather remote.

Careful structural and equilibrium studies are needed for complete definition of the phase relationships in the range $2.00 < X < 2.45$. The potential for success of such work has been strengthened by recent results for the hydrides of La, Ce, Pr and Nd. Although earlier work had shown the existence of MH_X solid solutions for $1.9 < X < 3.0$ [18], re-examination of these systems has shown obedience to Vegard's law in the range $2.0 < X < 2.5$. [19] Recent high resolution diffraction studies on the Pr and Nd systems has verified the existence of the M_3H_7 phase. [20]

5. CONCLUSIONS

The primary conclusion of this study is that two stability regimes exist in the Pu-H system. A metastable CaF_2 -anti- Fe_3Al -type solid solution formed by reaction of Pu and H_2 or PuH_2 and H_2 at low temperatures. Solution of hydrogen in the phase is nearly ideal; cubic $\text{PuH}_{3.0}$ can be prepared at 25°C and 25 atm pressure. A regime of ordered (stable) CaF_2 -related hydrides and a hexagonal LaF_3 -type PuH_{3-2} phase is attained at moderate pressures and temperatures $\geq 400^\circ\text{C}$. The effect of temperature is dramatic because ordering can occur only if sufficient kinetic energy is available. The preparation of hexagonal PuH_{3-2} is especially temperature sensitive because the metal atoms

must undergo a ccp to hcp transition.

An understanding of the stability differences of products formed in the two regimes is essential for interpreting the reactivity differences described by Bowersox. [7] The relative stabilities of hexagonal and cubic hydrides are demonstrated by their respective equilibrium pressures (0.03 vs 25 atm) at 25°C. The relatively low pyrophoricity of the hexagonal phase is attributed to its lower equilibrium pressure.

Although substantial insight has been gained into the equilibrium behavior of the Pu-H system, the results have revealed several avenues which need investigation. Efforts to define the equilibria, thermodynamics, structural chemistry and kinetics of the ordered hydride phases are in progress.
