We review a number of experiments that we have recently performed to investigate the collapse of defect cascades to dislocation loops. This important ion and neutron irradiation phenomenon has been studied with in situ ion bombardment in the Argonne National Laboratory High Voltage Electron Microscope - Ion Accelerator Facility at temperatures of 30 and 300 K in Cu₃Au, Cu, and Fe, and 30, 300 and 600 K in Ni. These experiments have demonstrated that individual defect cascades collapse to dislocation loops athermally at 30 K in some materials (Ni, Cu and Cu₃Au), while in another material (Fe) only overlapped cascades produced dislocation loops. A slight sensitivity to the irradiation temperature is demonstrated in Cu₃Au and Fe, and a strong dependence on the irradiation temperature is seen in Ni. This phenomenon of cascade collapse to dislocation loops in metals at 30 K provides an understanding for previous neutron irradiation data. The more detailed dependencies of the collapse probability on material, temperature, bombarding ion dose, ion energy and ion mass contribute much information to a thermal spike model of the collision cascade which we will describe.

1. Introduction

We highlight in this paper some of the results of an ongoing experimental program of the past several years in which the above authors participate. This program is principally designed to investigate the collapse of defect cascades to dislocation loops. The primary tool for this investigation is transmission electron microscopy, especially using in situ ion bombardment in the Argonne National Laboratory High Voltage Electron Microscope - Ion Accelerator Facility. Special sample stages have allowed ion irradiations and electron microscopy at temperatures over the range of 30 to 600 K.

Defect cascades are formed in metals under fast neutron or ion bombardment. Typically hundreds of vacancy and interstitial pairs are formed in such cascades, within 10^{-12} second of the primary recoil event, and over a volume of 10 nm diameter. The fate of these defects and how they affect material properties depends critically on the metal and the irradiation temperature. Often many of these defects cluster to form dislocation loops and stacking fault tetrahedra which are visible in the transmission electron microscope. These extended defects are important as point defect sinks and sources, as potential nucleation sites for voids or second phases, and they contribute to embrittlement and creep. It has long been known that the

vacancy population in a defect cascade can collapse to form a dislocation loop under irradiation near room temperature [1]. This has been convincingly demonstrated in the ordered alloy Cu_3Au irradiated both with ions and with neutrons [2]. We will show in this paper that this collapse process also takes place in some metals at an irradiation temperature of 30 K, and therefore that many dislocation loops form athermally from defect cascades within 10^{-11} second.

In the first part of this paper we review a completed systematic study of cascade collapse in the ordered alloy Cu_3Au . This summary is based on a more complete paper to be published elsewhere [3]. Three different ions and two energies were chosen for the irradiations to study the effect of cascade size and energy density. Two irradiation temperatures were chosen: one below stage I (30 K), where no long-range thermally activated point defect migration can occur, and one above stage III (300 K) where all point defects are mobile. The advantage of carrying out the experiment in Cu_3Au is that information both on loop formation and on the location and the spatial characteristics of the cascades may be obtained through a study of the disordered zones created at all cascade sites. This technique also eliminates uncertainties introduced by errors in microscope magnification and in ion dosimetry.

In the second part of this paper we report some results from a study in progress on the probabilities for cascade collapse to loops in Fe, Ni and Cu as functions of irradiation temperature and ion dose. Self ions of energies of 50 and 100 keV were employed to simulate cascades produced by fast neutrons. Iron, nickel and copper were chosen to represent a possible range of cascade collapse probabilities based on an interpretation of resistivity damage rate data in Fe at 5 K under fast neutron bombardment [4]. These and other neutron data suggest that loops form from individual cascades produced

at 5 K with increasing probability from Fe to Ni to Cu and that the probability increases with dose in Fe, and possibly to a lesser extent in Ni. We have found this interpretation to be consistent with our own earlier results in Fe [5].

Experimental Procedures

Well ordered foils of Cu_3Au with thickness < 35 nm were formed by vapor deposition and heat treatment. All specimens had $\langle 001 \rangle$ foil normals. Two batches of specimens were irradiated with Ar^+ , Cu^+ and Kr^+ ions at both 50 and 100 keV to doses of 10^{11} ions/cm². The first of these batches was implanted at room temperature at AERE Harwell on the commercial Lintott ion implantation system and the second at 30 K on the HVEM-Accelerator Facility at Argonne National Laboratory [6]. Those specimens irradiated at room temperature were observed using a JEOL JEM100B transmission electron microscope at Oxford, while those irradiated at low temperatures were examined both in situ on the Argonne EM7 HVEM and subsequently on return to Oxford in the 100 kV instrument. The HVEM was operated at an accelerating potential of 300 kV, below the threshold for the production of electron radiation damage in Cu_3Au . Under typical illumination conditions of our experiments the maximum temperature rise of the specimens due to local beam heating effects was estimated always to be < 10 K, using the expression given by Fisher [7].

Disordered zones created in Cu_3Au in all cascades initiated by incident heavy-ions of energy > 10 keV can be rendered visible as dark regions against the lighter, well-ordered background by forming dark-field images using a superlattice reflection of type $\bar{g} = \langle 110 \rangle$. Dislocation loops produced by the collapse of some cascades were imaged using fundamental reflections of type $\bar{g} = \langle 220 \rangle$. The defect yield under any irradiation condition was obtained by comparing micrographs of the same region of foil imaged in superlattice and in

fundamental reflections. The process of loop identification was carried out without reference to the micrographs showing disordered zones. Later a careful comparison of the locations of the disordered zones and of the loops confirmed that all loops were associated with disordered zones, and allowed a direct determination of the defect yield. Examples of the procedure are shown in Fig. 1, where for clarity only one micrograph of each type is displayed. In practice as many as 20 fundamental micrographs of each area were analyzed.

Sample foils of commercially pure Fe and high purity Ni and Cu were produced from bulk material and electropolished using standard techniques. All experiments were performed in the High-Voltage Electron Microscope - Accelerator Facility at Argonne National Laboratory. Samples were irradiated in situ with self ions at dose rates near 3×10^{10} ions/(cm² sec) and at temperatures of 30, 300 and 600 K $\pm$ 2 K. The relative accuracy of ion dosimetry among various irradiations reported here is 10%. The absolute accuracy of ion dosimetry is believed to be about 20% and is currently under investigation using the disordered zone technique in Cu₃Au. Electron micrographs were taken at the irradiation temperatures as a function of ion dose and following annealing, often in the same sample area. The HVEM was operated at voltages below the threshold for electron damage in the foils: 200 keV for Fe and 300 keV for Ni and Cu.

Dislocation loops were imaged in thin regions of the foil (30-40 nm) using strong 2-beam or very slightly s-positive (small positive deviation from Bragg condition) diffraction conditions. Images were recorded in dark field with operating diffraction vectors known to image most or all loops produced in these metals under these irradiation conditions: $\bar{g} = \langle 200 \rangle$ for all Frank loops in fcc Cu and Ni [8], $\bar{g} = \langle 110 \rangle$ in bcc Fe [5]. The smallest loops resolvable varied between 1 and 2 nm depending on metal, foil surface quality

and sample stage temperature. Identification and densities of loops were measured independently by 2 or 3 researchers. Both characteristic black-white and sharp black spot images were counted. Sizes of loop images were also determined in some experiments.

Results and Discussion

A comparison of the defect yields in Cu_3Au for both the room and low temperature irradiation conditions are given in Table 1. Clearly, cascade collapse to dislocation loops occurs even at 30 K where vacancies and interstitials are thermally immobile. Additionally it was discovered that there was no change in the defect yields measured on samples irradiated at low temperatures upon warming them to room temperature. All defect yields obtained from the room temperature irradiated specimens are seen to be significantly higher than those obtained from their low temperature counterparts. No significant changes in defect yield were observed on increasing the ion energy from 50 to 100 keV at either irradiation temperature. An increase in defect yield with increasing ion mass was clearly observed in the results of room temperature irradiations and between Ar^+ and Cu^+ (or Kr^+) irradiations at low temperature. Based on this evidence we conclude that collapse must occur during the phase of collision cascades when extensive vacancy motion is possible, that is the so-called thermal spike phase that occurs within about 10^{-11} second of cascade initiation. A sensitivity to the lattice temperature and cascade energy density (bombarding ion mass) is qualitatively explained within a thermal spike model [3].

While the above results for Cu_3Au were determined at a single low ion dose (isolated cascades), the effect of increasing dose was investigated in Cu and Ni. The results of a self ion bombardment in Ni (100 keV) at room temperature is illustrated qualitatively in the micrograph series of Fig. 2. Vacancy

dislocation loops in the exact same area are imaged at each dose. (It has been determined in many earlier experiments [1] that vacancy loops are formed in many metals by low dose ion irradiation in thin foils at room temperature.) Arrowed loops are not found in the micrographs at the next highest doses. A saturation of the loop densities in Cu and Ni (measured from the micrographs of Fig. 2 and others not shown) is suggested in Fig. 3 for room temperature irradiations. (Representative error bars for density variation within one micrograph and among determinations by several researchers are shown in this and following figures. No correction was made for the presence of subcascades; all loops were counted.) Also note from Fig. 3 that vacancy dislocation loops are formed in Ni at 300 K at a rate of about one third of the initial rate in Cu. Subcascades were observed to form less often in Ni than Cu at 100 keV, and preliminary size distributions (not shown) indicate that loops in Ni are smaller than in Cu.

The saturation behavior of loop density with self ion dose at 100 keV is probably accomplished by loop coalescence. Loops that seem to disappear, as in Fig. 2 (arrowed), are generally quite small. Their disappearance is usually accompanied by the appearance of a new, somewhat larger, loop within about 10 nm of the old loop site. Also, some loops appear to move slightly ($< 5\text{nm}$) and become larger. Both of these observations indicate the occurrence of loop coalescence or the results of nearby cascade events as the dose increases.

The increase in loop density in Ni with 50 keV self-ion dose at 30 K is shown qualitatively in Fig. 4. Due to changing local diffraction conditions it was not possible to follow the same sample area as a function of dose at 30 K or upon annealing to 300 K. Different areas representative of each dose are instead shown. Again a saturation behavior of the loop density was measured

and found to be similar to that observed in the 300 K irradiation data (compare Figs. 6 and 7).

The dependence of the loop production rate (at relatively low self-ion doses) on irradiation temperature is shown in Ni in Fig. 5. The production rates at 30 and 300 K were reproduced in 2 runs at each temperature. Only one experiment at 600 K has been performed to date. No obvious loop annealing occurred at 600 K, so this data reflects the true (within error) loop production rate. The difference in loop production rates at 30 and 300 K is about a factor of 2. This difference easily exceeds the error in the loop counting method on any given micrograph (representative error bars in Fig. 5), but also well exceeds an observable difference in loop resolution at the two irradiation temperatures. The liquid He sample stage is more stable at room temperature than it is with flowing cold gas. There is a shift of 25% of the defects to smaller sizes (1.0-2.0 nm) at 300 K, some of which may be a real temperature effect, the bulk of which is probably a resolution effect. The difference in loop production rates at 30 and 600 K may not be outside the effect of a loss of resolution of small loops at 30 K. However, the differences between 300 K and 30 K and between 300 K and 600 K appear to be real.

In Table 2 a summary is given of the loop production rates for the three elements under the irradiation conditions we have investigated to date. The Ni values are taken from the linear fits to the low dose points. The Cu value at 100 keV (300 K) is from the linear portion of the curve in Fig. 3 and the value at 50 keV (30 K) is from a single dose point. Uncertainties in the Ni and Cu values average ~ 0.03 . The Fe values are previously published [5,9], where a measurable yield is found only at higher doses ($\sim 10^{13}$ ions/cm²). The loop yield in Cu at 30 K is surprisingly low and must be confirmed by another

experiment. The value is also less certain than others in the table due to a change in ion dosimetry methods. However there is no doubt that individual defect cascades collapsed to vacancy dislocation loops in Cu and Ni at 30 K, a temperature below which the free migration of interstitials or vacancies does not occur. Thus the formation of these loops is attributed to a process occurring during the thermal spike phase of the cascade lifetime ($\sim 10^{-11}$ sec).

A measurable loop yield occurring only at much higher doses in Fe indicates that most individual self-ion cascades in Fe do not collapse to loops. Thus in Fe, the cascade energy density, defect density or thermal spike lifetime is insufficient to result in significant loop formation. At higher doses in Fe, with overlapping cascades, loops are formed, probably due to higher defect density or longer thermal spike lifetimes in the overlap case.

A comparison among the three elements of loop yield versus dose is shown in Fig. 6 for room temperature irradiations (100 keV self ions), and in Fig. 7 for irradiations at 30 K (50 keV self ions). In both figures the linear behavior (slope $n=1$) indicates an isolated loop production rate which is constant in dose. The slopes $n < 1$ at high defect densities in Cu and Ni are predominantly due to saturation behavior such as loop coalescence. The slope $n = 0.7$ in Fe at 300 K (Fig. 6) may also be due to a saturation type behavior. The slope $n = 1.5$ in Fe at 30 K (Fig. 7) is probably the net result of a low probability for isolated cascade collapse (linear loop production rate, slope $n=1$) combined with a quadratic loop production rate (slope $n=2$) due to simple overlap of two defect cascades resulting in one dislocation loop.

The differences in loop production rates among elements and between 30 and 300 K for any one element (Table 2) can be qualitatively explained within a thermal spike model for the evolution of the defect cascade. This model

allows for a sufficient energy density and cascade lifetime to permit the defect motion required for the formation of vacancy dislocation loops. The difference among the three elements may be explained by differences in the average thermal spike lifetimes. The difference with irradiation temperatures, 30 and 300 K, may be explained by a more rapid quenching of the thermal spike at 30 K and thus a lower probability of loop formation, as observed in Cu_3Au .

The room temperature yields, or loop production rates, in Fe, Ni and Cu can be compared with recent literature values. If our Cu yield could be corrected for subcascades, at the 100 keV incident self-ion energy, it would probably agree closely with the 30 keV result (0.4-0.5) of Stathopoulos [8]. This latter work is probably the most accurate yield determination in Cu. The Fe yield at 300 K agrees rather well with some recently reported results of Kitagawa, et al [10]. However, our Ni yield disagrees with those of Robinson [11] and Kitagawa [10]. The Robinson yield of 0.44 loops per incident 80 keV self ion was determined with a microscope of higher resolution, but reported size distributions are in approximate agreement with ours, leaving the bulk of the difference unexplained. The Kitagawa yield of 0.9 loops per incident 65 keV self ion, and size distribution peaking between 0.5 and 1.0 nm with no defect sizes > 1.6 nm, we feel are unreliable results due to their use of the weak beam technique. It is known that imaging and sizing small loops is most reliably performed and interpreted using strong 2-beam or slightly s-positive conditions (small positive deviation from Bragg conditions) [8,12].

Finally, a correlation can be made with the resistivity data of low temperature (5 K) fast neutron bombardment in these pure metals [4]. The so-called negative curvature in the resistivity production rate, observed to occur markedly in Fe and less so in Ni, may be due to vacancy loop formation

with cascade overlap at higher neutron doses, and increasing nonlinearly with dose. The change in resistivity per vacancy upon loop formation (as suggested by Dunlap et al. [4]) could explain this negative curvature. Our TEM evidence in Fe strongly supports this. In Ni the continued linearity of loop production with dose, (Figs. 3, 6 and 7) to doses much higher than in Cu, may be due to offsetting effects of loop coalescence and additional loop production with cascade overlap. Resistivity would be more sensitive to the overlap effect, and thus explain a slight negative curvature in the resistivity production rate in Ni. Cu shows no TEM evidence for a cascade overlap effect, but strong loop coalescence. This is in agreement with a lack of negative curvature in the resistivity data of neutron bombarded Cu (at 5 K).
