ABSTRACT

Recent extensions of the peak power capabilities of planar triodes have made possible the latter's use as very fast pulse amplifiers, to drive optical gates within high-power Nd:glass laser chains. These pulse amplifiers switch voltages in the 20 kV range with rise times of a few nanoseconds, into crystal optical gates that are essentially capacitive loads.

This paper describes a simplified procedure for designing these pulse amplifiers. It further outlines the use of bridged-T constant resistance networks to transform load capacitance into pure resistance, independent of frequency.

Introduction

Many optical gates in the Shiva laser system at the LLL are Pockels cells. An approximate electrical model of the Pockels cell is a capacitor,¹ whose capacitance must be charged very quickly to optimize the rise time of the cell.

The planar triode is a small, rugged, microwave vacuum triode² designed for operation to 3 GHz. A cutaway drawing of a class of these centimeter-wave planar tubes is shown in Fig. 1. The three tube types of most interest to us as Pockels cell drivers are shown in Table 1. Note that the 8941 and the X2172 both have peak power capabilities approaching 500 kW for short (50-nsec) pulses.

Circuit Development

To minimize the Miller effect of the grid to cathode capacitance, the planar triode is generally used in the grounded grid configuration. This requires that the preceding stage be capable of supplying the full plate current as well as any current drawn by the grid. The common cathode connection of the tube can provide current gain, and a bridged-T network employed in the grid circuit overcomes the bandwidth limitation of the common cathode configuration. This greatly reduces the current drive requirement of the preceding stage.

Ginzton et al.³ describe a negative mutual inductance circuit, termed a bridged-T connection, which is used on broad-band distributed amplifiers. This circuit can mask the input capacitance of a tube or

Pockels cell. Figure 2 shows the bridged-T network and its various equivalents. Choosing the values from Fig. 2(c), we can show that the image impedance is constant, resistive, and frequency independent. This eliminates the need for terminating half sections and permits us to terminate the line with a resistor. The cutoff frequency across the midshunt capacitance in terms of Z_0 , L , and C , is shown in the appendix (Fig. 6).

Triode Pulse Amplifier

The schematic of a pulse amplifier circuit to drive a 10-mm aperture Pockels cell is shown in Fig. 3. The Eimac 8941 planar triode is configured as a common cathode amplifier, biased just beyond cutoff.

The end-to-end capacitance of the Pockels cell is 15 pF. Choosing Z_0 as 130 Ω , and using the design charts in the appendix, $L = 0.25 \mu\text{H}$ and the cutoff frequency across the cell is $\sim 145 \text{ MHz}$. A similar network is designed for the grid circuit with Z_0 equal to 50 Ω .

The load impedance for the planar triode is then 130 Ω resistive, and for a half-wave voltage at the Pockels cell of 3500 V, the peak current is 26.9 A. A load line for this case is shown on the constant current characteristics for the tube in Fig. 4. It requires that the grid be driven about 135 V positive, to achieve the necessary plate voltage swing and peak current. The voltage pulse measured at the output of this amplifier into an attenuator is shown in Fig. 5.

From Fig. 4, the grid will draw almost 5.5 A, when it is driven positive by 135 V. The driver for the grid is an avalanche-transistor transmission line pulser that does not work into this changing load too well; so the input rise time to the triode is limited to about 2.5 nsec. This also means that when the tube grid draws current, the bridged-T network is no longer balanced; so at this time a reflection will be sent toward the driver.

The combination of high peak power and large bandwidth requires the circuit to be laid out carefully. It is essential that tube lead inductances be kept low, so that the resonance associated with these electrodes will lie well above the operating band of the amplifier. Many small capacitors connected in parallel, and mounted on a low-inductance printed circuit board, serve as a bypass or coupling network. Low-value series resistors, connecting decoupling capacitors, are an effective way to isolate the modes of the B+ supply wiring from the amplifier circuitry.

Discussion

Let us summarize our design of a planar triode amplifier for broad-band performance and consider the various tradeoffs involved. Normally, the load is specified first and, if it can be modeled as a capacitor it can be broad-banded in a bridged-T configuration by using the design charts in the appendix; this sets a cutoff frequency and an impedance level. The bridged-T network can be used up to ~400 MHz. Above this figure, the small value of the components make them difficult to fabricate. The voltage necessary at the load and the impedance of the

load determine the tube to be used. The cutoff frequency of the load sets the parameters of the broad-banded grid circuit. Careful component layout then assures optimum amplifier performance.

We have used the techniques presented here to design a pulse amplifier for driving a 10-mm Pockels cell. The amplifier performed as predicted. Its output characteristics are: 3600 V into 130 Ω with 2.5-nsec rise time, 3-nsec fall time, and pulse width of 8-9 nsec. The jitter is less than 100 psec.

Appendix⁴

Of the various lumped-constant lines for the anode and grid circuits studied by Ginzten et al.³, the bridged-T network provides the highest-gain bandwidth product. For a given gain, the bridged-T line provides about twice the bandwidth of the constant-K line.

We obtain the midshunt inductance from the mutual coupling between the two halves of the coil, as shown in Fig. 2(b). If we choose m to be 1.27, the inductance to the midpoint of the coil must be 40.3% of the total coil inductance.

By using the equation

$$L = \frac{r^2 n^2}{q_r + 10\ell} \text{ } \mu\text{H}$$

where n is the number of turns, and ℓ and r are the length and radius of the coil, respectively, the correct coupling results when the length of the coil is 1.35 times the coil's diameter.

The output voltage, taken across capacitor C in Fig. 2(c), has a cutoff frequency

$$F_1 = \frac{1}{\pi\sqrt{LC}}$$

and the characteristic impedance

$$Z_0 = \sqrt{\frac{L}{C}}$$

Figure 6 is a design chart for the bridged-T constant resistance network of Fig. 2(c), with the values of L and C plotted as functions of Z_0 and F_1 . Figure 7 is a design chart for the inductor in this network.
