Workshop on Possibilities \& Limitations of Accelerators and Detectors, Fermilab, 10/15-21/78

BUNC:ED-bEAM p-p AND p-p COLEISIONS *
E.D. Courant and E. Keil

1. Introauction

In the following, we study collisions between buncied beans of protons and/or antiprotons. We assume, for simplicity, that the bunches collide head-on, and that the two beams have the same number of particles N and rms bearn radii $\sigma_{x}$ and $\sigma_{y}$ at the crossing point.
2. Basic luminosity formulae

The luminosity $L$ and beam-beam tune sinifts $\Delta v$ are given by the stancara formulae for $e^{+} e^{-}$storage rings ${ }^{1)}$ :

Nomel 'm.

$$
\begin{equation*}
\Delta v_{y}=\frac{\Delta r_{0} \beta_{y}}{2 \pi k_{b} \gamma\left(\sigma_{x}+\sigma_{y}\right) \sigma_{y}} \tag{3}
\end{equation*}
$$

$$
\begin{equation*}
\Delta v_{x}=\frac{N r_{o}{ }^{3} x}{2 \pi \dot{\kappa}_{b} \gamma\left(\sigma_{x}+\sigma_{y}\right) \sigma_{x}} \tag{2}
\end{equation*}
$$

Here $f$ is the revolution frequency, $k_{b}$ the number of bunches in each beam, $\beta_{x}$ and $\beta_{y}$ the amplitude functions at the crossing point, $r_{0}$ the classical proton radius and $\gamma$ the usual relativistic factor.

If we make

$$
\begin{equation*}
\sigma_{x} / \sigma_{y}=B_{x} / B_{y} \tag{4}
\end{equation*}
$$

as we shall assume in the following, the beam-bean tune shifts $\Delta v_{x}$ and $\Delta v_{y}$ becone the same. Using. (3) to eliminate one power of $N$ in (1) yields, assuming that $\sigma_{y} \ll \sigma_{x}$ :

There is no reason not to build p-p colliding-beam machines with the highest possible magnetic fields in the dipoles $B_{H}$ at all energies. Bence, the procuct fy is incependent of the energy. We concluce tinat the luminosity does not depenc explicitly on the energy of the machine, but only on the number of particles, the field in the dipoles and the value of $B_{y}$.

## 3. Stored bearn intensity

The number of particles necessary for obtaining a given luminosity is obtained by solving (5) for N:

$$
\begin{equation*}
N=\frac{2 L r_{0}{ }^{B} y}{f \gamma \Delta v} \tag{6}
\end{equation*}
$$

The invariant emittances of the beans $\sum_{x}$ and $E_{y}$ are obtained from (2) and (3), again assuming $\sigma_{y} \ll \sigma_{x}$ :

$$
\begin{align*}
& E_{x}=\frac{4 \pi \gamma \sigma_{x}^{2}}{B_{x}}=\frac{2 N r_{0}}{k_{b} \Delta v}=\frac{4 L I_{o}^{2} B_{y}}{k_{b}{ }^{2}{ }_{\gamma}(\Delta v)^{2}}  \tag{7}\\
& E_{y}=\frac{4 \pi \gamma \sigma_{y}^{2}}{B_{y}}=\frac{B_{y}}{B_{x}} \frac{2 N r_{o}}{k_{b} \Delta v}=\frac{4 L r_{o}^{2} B_{y}^{2}}{k_{b} E_{\gamma} \beta_{x}(\Delta v)^{2}} \tag{8}
\end{align*}
$$

Secause of the factor fy, the invariant emittances do not depend on the design energy. In deriving (7) and (8) we have assumed that the crossings occur in regions without dispersion.

## 4. Limits on interaction region design

It is clear from (5) that the amplitude function $\beta_{y}$ should be small in order to obtain a high Iuminosity. Lower limits on $\beta_{y}$ are imposed by
(i) the bunch length
(ii) chromaticity correction
(iii) the strength of the nearest guadrupole.

The value of $\beta_{y}$ should be large compared to $\sigma_{z}$, in order to avoid a reauction of the luminosity by the $\mathcal{F}_{y}$-variation in the interaction region. The difficulty of chromaticity correction is proportional to $f_{\text {int }} / 3$ where $h_{\text {int }}$ is the distance from the crossing point to the nearest ouadrupole. In ete- storage rings, $l_{\text {int }} / \beta_{y}$ must be less than about 50 to 100 in order to correct chromatic effects over a monentum range of about $\pm 1 \%$.

The effect of the quadrupole strength on $\beta_{y}$ is obtained by calculating the horizontal aperture of the first quadrupole $A_{x}$ which must be a factor $F_{a}$ larger than the rms bean size at the quadrupole entrance.

$$
\begin{equation*}
A_{x}=F_{a} \sigma_{x Q} \tag{9}
\end{equation*}
$$

The beam size $\sigma_{x Q}$ is given by:

$$
\begin{equation*}
\sigma_{x Q}=\sigma_{x}\left(\frac{\beta_{x Q}}{\beta_{x}}\right)^{h} \approx \frac{\sigma_{x}^{l} l_{\text {int }}}{\beta_{x}} \tag{10}
\end{equation*}
$$

Substituting from (7) yields for the necessary quadrupole aperture:

The quadrupole must have a focal length of about $\frac{3 l}{}$ int Hence, its length ${ }^{2} Q^{\prime}$ magnetic field $B_{Q}$ at a distance $A_{x}$ from the centre ("poletip field") and the proton rigidity Bo are related by

$$
\begin{equation*}
A_{x}=\frac{{ }_{Q} Q^{2}{ }_{\text {int }}{ }^{2} Q}{2 B Q} \tag{12}
\end{equation*}
$$

Equating (11) and (12) yields an equation for $2_{2}$ :

$$
\begin{equation*}
\varepsilon_{Q}=\frac{e z_{0} F_{a}}{2 \pi B_{Q} \Delta U}\left(\frac{L B_{y}}{\pi K_{b} B_{x}}\right)^{\frac{2}{2}}=\frac{e z_{0} \dot{F}_{a}}{2 \pi B_{Q}}\left(\frac{N Y}{2 \pi B_{x} k_{b} \Delta V r_{0}}\right)^{\frac{2}{2}} \tag{13}
\end{equation*}
$$

Here $e$ is the elementary charge and $z_{0}$ is the impedance of free space. Experience with the design of $e^{+} e^{-}$interaction regions indicates that there is a relation between $\ell_{Q}$ and $z_{i n t}$ of the form

$$
\begin{equation*}
\ell_{\text {int }}=G_{Q} \tag{14}
\end{equation*}
$$

where the coefficient $G_{2}$ is of the order of 2 or tore. In addition, chromaticity correction imposes relation of the form

By combining (13) to (15) we finally arrive at equations for $s_{y}$ :

$$
\begin{align*}
& B_{y}=\frac{G_{l}^{F} F_{a}}{G_{c}} \frac{e z_{o}}{2 \pi B_{Q} \Delta v}\left(\frac{L B_{y}}{k_{b} A_{x}}\right)^{\frac{1}{2}}  \tag{16}\\
& B_{y}^{3 / 2}=\frac{G_{l}^{F} F_{a}}{G_{c}} \frac{e z_{o}}{2 \pi B_{Q}}\left(\frac{N \gamma B_{y}}{2 \pi k_{b}^{\Delta v r_{o} B_{x}}}\right)^{\frac{1}{2}} \tag{17}
\end{align*}
$$

These equations include $2 l l$ the limitations on the interaction region design imposed by the poletip field $B_{Q}$, optical constraints ( $G_{\ell}$ ) and chromaticity ( $G_{C}$ ); they contain only the ratio $\beta_{Y} / B_{X}$ on the right-hand side.
5. Application to $p-\vec{p}$ collisions

For p-5 collisions we make the assumptions and obtain the scaling laws shown in Table 1.

Table 1. Assumptions and scaling laws for $p-\bar{p}$ collisions

Assumed independent of $\gamma: N, \Delta v, f_{b}, F_{a}, G_{\ell}, G_{C}, B_{Q}, B_{y} / B_{x}, B_{M}$ proportional to $\gamma^{\circ}=\quad E_{x}, E_{y}$
Proportional to $\gamma^{1 / 3}$ :
$B_{x}, B_{y}, \ell_{Q}, \ell_{i n t}$
Proportional to $\gamma^{-1 / 3}$ : L, $A_{x}$

A few comments are in order on the fixed parameters used in the detailed examples. The aperture allowance $F_{a}$ includes the extra space required at the injection energy which is about twenty times smaller than the design energy. The chromaticity factor $G_{c}$ is smaller than in $e^{+} e^{-}$storage rings because the tolerances on the cinromaticity correction may be tighter in $p-\bar{p}$ schemes. The limit $\Delta v$ on the beam-beam tune shift is the conventional value for coasting proton beams. There are strong doubts whether it also applies to bunched proton beams.

The number of particles corresponds to that of the CEPN p-p project ${ }^{21}$. It is used here as a lower limit of what might be achieved in an optimized $\bar{p}$-factory fed from a 20 GeV proton synchrotron with a flux of $10^{13}$ protons/s, or from one of its injectors with even higher fluxes.

When actual numbers arc inserted into the equations above, it turns out that the apertures of the interaction region quadrupoles are rather small by compariseme
with present values. The physical reason for this is the constant invariant enittance which zesults in decreasing bean size with energy. In orcer not to deviate too much from present practice in cuacrupole construction, we have assumed rather a low value of the poletip field ${ }_{Q}$.

The number of bunches is 4 in each beam, because we assume that the machine has 8 equidistant interaction regions. This choice avoids the complications of a higher number of bunches where the beams have to be separated in the unwanted crossings while they are in collision at the interaction regions. As a consequence of this choice; the total number of events in each collision between bunches increases as $\gamma^{2 / 3}$.

Table 2 shows tine gain machine garameters for three different different energies, namely about $200 \mathrm{GeV}, 2$ and 20 TeV . The 200 GeV machine has parameters winich are fairly close to those of the CESN p-p project ${ }^{2}$. It is included here as a useful check of the interaction region design procedure. There is fairly good agreement between the actual and the computed parameters.

As the design energy increases, the cuadrupole aperture and bean size decrease, and the guadrupole length increases. The mechanical toiarances of the quadropole must be zoughly proportional to the aperture. Avoiding the Eield errors associated with the tolerances is the essential reason for the choice of ${ }^{B}{ }_{Q}$. At the low value chosen, the windincs of a superconducting quadrupole could be 'far away from the beam, thus relaxing considerabiy the tolerances on the coil position.

So far, we have tacitly assumed that the synchrotron can be modified to include $p-\bar{p}$ interaction regions with the properties described above. This must also hold during synchrotron operation, with injected bean sizes which are larger than those at the design energy. This problem can be alleviated by increasing the amplitude functions at the crossing points during synchrotron operation, or circunvented by taking the synchrotron beam through a by-pass around the interaction region ${ }^{31}$.

We studied neither the Re syistem required for kesping the beans bunched, nor the magnet lattice outside the interaction regions and space-cinarge phenomena. fle do not expect fiaticular difficulties with the pa system. The magnet́lattice is similar to thet of the coesting-bean p-p collisions ${ }^{4}$.

A luninpsity well doove $10^{30}$ cn $\cos ^{-1}$ is within reach over tre whole energy rangein As the energy increases, the number of events in a single collision between bunches increases. It reaches abouth at 20 TeV , assuming totalicross-section of about 100 mbarn. If this turns out to be
too inconvenient for event analysis, th: . our concept of colliding a few bunches breaks down somewhere in the TeV range.

The only two alternatives are increasing the number of buncines and changing to coasting bears. Increasing the number of bunches implies bean separation at the unwanted crossing points at the same time as bear collisions In the interaction regions, and all the difficult tolerances associated with separation. Coasting beams imply a reduction of the luminosity to about $\mathcal{L}=10^{28} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ at $\mathrm{N}=10^{12}$. Hence, in order to obtain a luminosity of about $\mathcal{L}=10^{30} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$, approximately $10^{13}$ protons and antiprotons must be stored.

## 6. Avolication to p-p collisions

If a storage ring is acded to the syncirotron, p-p collisions can be obtained. Ne assume that the circumference and the number of bunches in the synchrotron and in the storage ring are chosen to be svoh that the bunch spacings in the two machines are identical.

For the time being, we also assume that no proton accumulation takes place in the storage ring, but that the available protons are arranged in a suitable number of bunches. It then seems natural to make the number of protons in a bunch the same as in the $p-\bar{p}$ scheme. In this case the bean sizes at the crossing points are the same as in the $p-\bar{p}$ scheme, and the conclusions on the interaction region design also apply to p-p collisions.

The number of protons is the same as in the syncinrotron; we take $\mathrm{n}=6 \times 10^{14}$. The technical problems associated with the stored energy in the beam are all the same as in the synchrotron, provided that the bean transfer between the machines is clean enough, and can be considered solved. Iith $0.25 \times 10^{12}$ protons in a bunch we chus arrive at 2400 bunches and a bunch spacing of about 25 m . The performance which might thus be achieved is sumnarized in Table 3.

Table 3. Parameters for p-p collisions at 20 TeV

| $N=6 \times 10^{14}$ | $F_{\mathrm{a}}=40$. | $6_{Q}=1 T$ |
| :---: | :---: | :---: |
| $\Delta v=0.05$ | $\mathbf{G}_{\dot{2}}=5$ | $B_{x} / B_{y}=4$ |
| $k_{b}=2400$ | $G_{c}=20$ | $c / 2 \pi \rho=1.5$ |
| $\beta_{y}=6.2 \mathrm{~m}$ | $\ell_{\text {int }}=124 \mathrm{~m}$ | $E_{x}=48 \pi \mu m$ |
| $B_{x}=25 \mathrm{~m}$ | $2_{Q}=5 \mathrm{~m}$ | $E_{Y}=12 \pi \mu m$ |
| $B_{M}=10 \mathrm{~T}$ | $\underline{\mathrm{I}}=4.8 \mathrm{kHz}$ | $L=1.6 \times 10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ |
| $A_{x}=23 \mathrm{~mm}$ | $\sigma_{x}=0.12 \mathrm{~mm}$ | $\sigma_{y}=31 \mu m$ |
| $W=1900: 1$ |  |  |

Since head-on collisions are assumed, and the close bunch spacing is neglected, the luminosity figures must be considered optimistic.

Since the bunch population is the same as in the $p-\bar{p}$ scheme, the nunber of events for a single collision is again about 7 . inence the renarks made above also apply.

## 7. Conclusions

We have studied schemes fox p-p and p-p collisions between bunched beans. With zather conservative assumptions about available j Eluxes we obtain a Iuminosity in the $10^{30} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ range which hes rather a weak variation with the energy. The most natural schene where the number of bunched beans is half the number of interaction regions, has the difficulty that the number of events in a single collision increases with the energy.

For p-p collisions, we make use of the full current available fron the synchrotron. ve find luminosities in the $10^{33} \mathrm{cn}^{-2} 5^{-1}$ range, and tine same difficulties with the number of events in a single collision as in tine $p-\bar{p}$ schere. Since the luminosities are not much larger tinan For coasting p-p collisions ${ }^{4)}$, there does mot seen to be a gooa reason for bunched p-p collisions.
