2. LEGAL NOTICE

This report was prepared as an account of work sponsored by the United States Government. Neither the United States nor the United States Department of Energy (formerly the Energy Research and Development Administration), nor any of their employees, nor any of their contractors, subcontractors, or their employees, makes any warranty, express, or implied, or assumes any legal liability or responsibility for the accuracy, completeness, or usefulness of any information, apparatus, product or process disclosed or represents that its use would not infringe privately owned rights.

3. ABSTRACT

During this contract period we continued our research aimed at finding suitable methods and criteria for determining the success of revegetation in Midwestern prime ag lands strip mined for coal. Particularly important to our experimental design was the concept of reference areas, which were nearby fields from which the performance standards for reclaimed areas were derived.

We tested direct and remote sensing techniques for measuring plant ground cover, production, and species composition. We worked for the first time in 15 mine sites permitted under interim permanent surface mine regulations and in 4 adjoining reference sites. We also continued our studies at 9 prelaw sites. All sites were either in Missouri or Illinois.

Data gathered by us in the 1980 growing season showed that 13 unmanaged or young mineland pastures generally had lower average ground cover and production than 2 reference pastures. In contrast, yields at approximately 40% of 11 recently reclaimed mine sites planted with winter wheat, soybeans, or milo were statistically similar to 3 reference values. Digital computer image analysis of color infrared aerial photographs, when compared to ground level measurements, was a fast, accurate, and inexpensive way to determine plant ground cover and areas. But the remote sensing approach was inferior to standard surface methods for detailing plant species abundance and composition.

4. SCOPE OF INVESTIGATIONS AND SIGNIFICANT RESULTS

4.1. Objectives

As proposed in 1978, we plan to do the following things:

1. To establish objective methods to measure and criteria to judge the diversity, effectiveness, and permanence of vegetation in reclaimed surface coal mines and in reference areas as required under Public Law 95-87.
2. To determine the cost-effectiveness, generality, and utility of our methods and criteria.
3. To transfer our information to interested parties, particularly mine operators and governmental regulators.

This report summarizes our progress during 1980 toward meeting these objectives.

4.2. Research Program

4.2.1. Introduction

Our research approach is to study strip mine and reference sites prepared and managed by midwestern mine operators under the approval of state and federal land reclamation officials. We intend to follow reclamation activities pertinent to our chosen sites for several consecutive years, going from pre-mining planning to post-mining termination. Thus, we are not responsible for the actual grading, seeding, or cropping of any area. Instead, we exploit the agricultural systems created by mine operators who are attempting to comply with various strip mine regulations. This fact is important because it means that all of our data are derived from large, legally permitted plots rather than from small, experimental plots of the sort commonly used by agronomists.

4.2.2. Site Descriptions

Our study sites are located at 4 active surface coal mines, 3 in Missouri and 1 in Illinois (Figure 1). Most of the acreage in these regions is classified as pastureland or cropland. Hence, after being stripped the land must usually be returned to high agricultural capability. However, since the permanent state surface mining rules and regulations were not approved by the federal Office of Surface Mining until late in 1980, only now are mine operators drafting final reclamation plans for areas permitted between 1978 and 1980. Thus, at all 4 mines we are still encountering a transitional situation.

During the 1980 contract period we worked to varying degrees at 4 active coal mines (Table 1). We sampled vegetation in mine and reference sites only at the first three coal mines. Because of limitations imposed by our budget and manpower, we were unable to conduct aerial and field studies at the Empire Coal Mine in southwestern Missouri. We plan to work at all four in the coming contract year.

Different crops prevailed at the three mines we studied in 1980 (Table 2). Forages were planted in all Missouri sites, whereas row crops were planted in Illinois sites. At the Prairie Hill Coal Mine we studied nine mine sites pre-dating Public Law 95-87 to collect our fourth and final consecutive year's data on plant growth. All ten Prairie Hill sites are slated to be re-mined or reclaimed to current standards in the near future. In 1981 four new sites seeded with forages should be available for our research. Hence, these pre-law sites will provide valuable benchmark information to evaluate future revegetation practices at this mine.

4.2.3. Climatological Data

Precipitation and air temperature at the three strip mines we studied

Figure 1. Location of 3 surface coal mines (●) and our laboratory (▲).
Reference sites were near the strip mines.

Table 1. Description of strip mines studied in 1980.

Mine	Operator	Location	Soils	Coal seam	
				Average thickness of seam (ft.)-	Stripping depth (ft.)
Prairie Hill Coal Mine	Associated Electric Cooperative, Inc.	Randolph Co., MO R16W, T55N	Gara-Mexico silt loams	Bevier 4 ft.-120 ft.	
River King Coal Mine	Peabody Coal Company	Randolph Co., IL R6W, T4S	Eva-Darmstadt-Stoy silt loams	Herrin No. 6 6 ft.-120 ft.	
Power Coal Mine	Peabody Coal Company	Henry Co., MO R27W, T39N R28W, T40N	Hartwell-Deepwater-Roseland silt loam and Norris-Rockland-Gasconade shaly loam	Tebo, Weir-Pittsburg 3.5 ft.-65 ft.	
Empire Coal Mine	Pittsburg and Midway Coal Company	Barton Co., MO R15W, T53N	Parsons-Barden silt loam	Rowe 1.5 ft.-65 ft.

	1	1	Post-law	Soybeans
	3	1	Post-law	Milo
Power	4	1	Post-law	Winter wheat nurse crop and fescue-alfalfa mixture
Total	24	5		

were estimated from monthly climatological data provided by four nearby weather stations. The 30 year means were used to assess departures in 1980 from normal climatic conditions.

An extreme drought prevailed this summer in Missouri, but it was less severe in Illinois. As is shown in Figure 2, mean air temperatures at the four stations were slightly below average from March to May, but they greatly exceeded the average from June to September. Rainfall values were below normal from April until August or September, especially in Missouri.

To quantify the deficit in energy available for plant growth at our sites, we calculated a water balance from the data in Figure 2. These results indicate that crops probably were greatly stressed at the Power and Prairie Hill mines, but less so at River King (Table 3). Evapotranspiration deficits estimated by us should be regarded as provisional figures because the validity of applying this methodology to poorly structured mine spoils has not been tested.

4.2.4. Direct and Remote Sensing Methods

Manual and automated methods for measuring plant growth were evaluated at 29 sites listed in Table 2. We timed our efforts so that data collection using both techniques preceded full-scale cropping of fields by 1 or 2 weeks. Forages and winter wheat were examined in early July, whereas soybeans and milo were studied in September 1980.

Method 1: Direct, manual measurements

Twenty-five permanent 0.5 m^2 plots were staked out at random distances along parallel transects spaced at regular intervals across each site. We visited each plot, estimated visually the percent ground covered by plants within

Longwell, T.J., W.L. Parks, and M.E. Springer. 1963. Moisture characteristics of Tennessee soils. Tenn. Ag. Exp. Sta. Bul. 367:1-46.

it, and then harvested all standing material by clipping it at ground level. Plant samples were separated to species, bagged in the field, and brought back to the laboratory where they were dried and weighed. Grains were harvested by threshing and moisture content was measured. Data for percent vegetative cover, species composition, and species abundance were calculated for each plot and for each study site. Yields for total above-ground biomass and grains were also determined. The area of each study site was measured from a recent aerial photograph using a hand-operated planimeter.

Method 2: Remote, computer measurements

Vertical aerial photographs of a mine or reference site were subjected to digital computer image analysis. Color infrared (CIR) photographs at a scale of approximately 1:12,000 were taken in an airplane flown over all study sites in either early July or in September when ground level measurements were being made. Computer interpretations of CIR imagery involved a rapid, multi-step process which is shown in Figure 3. In brief, the photograph was converted to a two-dimensional, black-and-white video image consisting of nearly 250,000 tiny picture points or cells. The grey value of each picture cell was measured on a digital scale ranging from 0 for absolute white to 256 for pitch black. Boundaries delineating a mine or reference site were drawn in the digital video image using a sonic pen. Thereafter all points outside the area of interest were disregarded. Spatial and contrast information was stored on magnetic disk and tape. Classification of cover into various categories was achieved interactively by slicing the spectrum of grey values into two or more subgroups and then by displaying the resultant, simplified digital image for visual verification with the more complex, analog CIR photographic inputs. A variety of new computer programs developed expressly for our research

improved these procedures. Once a classification scheme was established, a spatial rendition of the picture cells was printed or plotted to scale on paper (Figure 4). A summary of the computer boundary values for each grey level slice and the absolute and relative areas of each cover class were also generated.

Interactive Gray Level Slicing

Figure 4. Scale plot automatically produced by digital computer. The area of 4 cover classes and ground covered by vegetation are printed.

4.3. Results and Discussion

Data on the size of sites, plant ground cover, plant productivity, and plant species composition for 1980 are here presented. Other information, such as species similarity indices, will be completed in the first quarter of 1981.

4.3.1. Area Determinations

Total area of 22 sites was measured both by the digital computer and by a manual planimeter. Computer results were based on a single scan of summer or fall CIR aerial photographs. Manual measurements of the same aerial photographs were repeated 5 times and an average was calculated.

Area data, as summarized in Table 4 and Figure 5, show that there was excellent agreement between the two methods ($r^2 = 0.995$). Computer values tended to be slightly larger (10%a, 4 ha) than planimetric ones, but this systematic discrepancy increased very slowly as sites became larger. Based on controls, we knew that the error resided primarily with the planimeter and not with the computer. When standards of known area were used to calibrate each system, the computer error was insignificant ($\approx 5\%$) (Game et al., 1981), whereas the planimeter generally underestimated the real size by a small amount. A second source of discrepancies was the independent delineation of site boundaries. Operators drew the perimeter of each location on two separate occasions, first with the sonic pen on the GRC computer display and later in another building with a planimeter wand drawn over the original CIR aerial photograph.

We could, if we wished, interconvert a computer measurement (Y) and a planimetric one (X) by using the equation $Y = 3.66 + 1.05X$. But considering that the computer outputs for size were automatic and highly accurate (95%), there appeared to be no reason in the future to rely on planimetric methods

Table 4
Comparison of Computer Digital Methods for Determining Area

Site	Planimeter estimate (n=5)		Computer estimate (n=1)
	Total area $\bar{X} \pm SE$ (hectares)	Total area $\bar{X} \pm SE$ (acres)	Total area $\bar{X} \pm SE$ (acres)

Figure 5. Comparison of manual and automatic techniques for measuring area of study sites. Ideal ($Y = X$) and best fit regression lines are shown.

for precise area measurements.

In our 1979 progress report, C00-2758-6, there was an error in Table 1 and Figure 5 due to miscalculation of scale factors for the planimetric area of all sites. When corrected, the regression equation and correlation coefficient were $Y = 2.69 + 0.98X$, $r^2 = 0.986$, $p < 0.001$.

4.3.2. Pastureland Studies

Mine and reference sites seeded with forages at Prairie Hill and Power Coal Mines were studied. Data on plant ground cover, productivity, and species composition are presented.

4.3.2.1. Ground cover of pasturelands

Vegetative cover was measured at 15 sites using 2 techniques (Table 5). Visual estimates were made at ground level in 25 sample plots per site, whereas digital image analysis of CIR aerial photographs taken either in summer or fall 1980 censused 10 entire sites. Photographs for the remaining 5 sites, all of which were at the Power Coal Mine, were not analyzed because the 4 mine areas were mowed and the herbage left on the ground for mulch during the interval between field sampling and aerial reconnaissance.

As we found in 1979, there was excellent agreement between remote and direct measurements of ground cover (Figure 6). Seven of 10 values for Prairie Hill sites had a similarity greater than 90%. Statistical analysis confirmed that the 2 parameters were significantly correlated with each other ($r^2 = 0.648$, $p < 0.01$). Thus, at most sites computer estimates of ground cover equalled at least 90% of the mean for visually determined values with a statistical confidence greater than 90%.

Table 5
Comparison of Vegetative Cover Calculations from Aerial Photographs and Direct
Estimates for Sites Seeded with Forages

Mine	Site	Vegetative Cover (%)	
		Computer analysis	Visual analysis ($\bar{X} \pm SE, n=25$)
Prairie Hill	C1	52.24	53.56 $\pm$ 8.97

*Reference Site

NA - Not available because sites were mowed just before aerial photographs were taken

Figure 6. Comparison of visual and computer measurements of vegetative cover in pastureland study sites. The 90% similarity zone is depicted.

Ground cover at most mine sites in Prairie Hill and Power Coal Mines was significantly less (Student's t-test, $p < 0.05$) than in nearby established reference pastures. Since this condition has prevailed for 2 consecutive years at Prairie Hill, the comparison may be legitimate. However, it certainly is not scientifically justified to make much of the differences at Power Mine because reclaimed fields were but 8 months old and dominated by annual nurse crops, not by perennial forages.

Regardless of method used for acquiring data, ground cover at 7 of the 10 Prairie Hill sites did not change by more than 5% between 1979 and 1980. Since all of these sites were at least 3 years old, perhaps a sort of short-term stability had been achieved. If this was true, it suggests that the effectiveness of forages in the mine sites is not increasing and that alternative management methods might be necessary to achieve complete revegetation.

4.3.2.2. Production of pasturelands

Plant production at 13 mine and 2 reference sites seeded with forages ranged in 1980 from 112.2 to 692.1 g/m² (Table 6). If nurse crops in new sites at Power Coal Mine were excluded from further consideration, the range of yields dropped to 17.8 - 470.7 g/m².

As in 1979, all sites were dominated by forages and other seeded species. Weeds and woody species comprised less than 15% of the entire yield at all sites irrespective of age.

Yields in 7 mine sites at Prairie Hill were not significantly lower than 90% of the reference pasture (R3) harvest both in 1979 and 1980 (Table 7). Production declined at most locations, including the reference site, in 1980 probably because of the severe summer drought (Table 3).

* R3= reference site for which 90% of total yield was used as the standard for comparison with other sites.

** ANOVA test modified with Dunnett's procedure was used to separate means.
Level of significance was set at $p=0.05$.

Rank order of pasture sites at Prairie Hill according to production in 1980 remained similar to what it was in 1979 (Tables 6 and 7). The influences of spoil amendments, recovery time, and weather on forage yields are discussed in detail in a forthcoming paper (Rapp et al. 1981).

Data from Prairie Hill also suggested for a second year that plant ground cover may be a good predictor of pastureland production. There again was a strong regression between percent ground cover and dried biomass harvested at 10 sites studied in 1980 (Figure 7). The regression coefficient was slightly lower this year than in 1979 because yields declined more than cover values during the 1980 drought. But the weakness of the correlation coefficient ($r^2 = 0.506$, $p < 0.05$) meant that the confidence interval for expected yields calculated from our data might be too large to meet certain performance standards.

Standing biomass at the 4 Power Mine sites was equal to or higher than at the matching reference pasture.(Table 6). But this comparison is not valid because all mine sites were dominated by annual grasses sown as nurse crops on these new areas. None of the young fields had virtually any established stands of perennial grasses and legumes. In fact, mulching of the areas by mowing the nurse crops in July did not enable the seedlings to withstand the extreme drought, so all 4 reclaimed sites had to be disked and reseeded in the fall 1980.

4.3.2.3. Species composition of pasturelands

The taxonomic identity, frequency, and abundance of all plant species were calculated for each of 25 replicate clip quadrats within 13 mine and 2 reference sites sampled during June and July 1980. The attempt to discriminate

Figure 7. Relationship between ground cover and standing crop in pastureland study sites. Best fit regression line for 1980 data is shown.

different types of herbaceous species, which we started in December 1979, proved to be costly, non-generalizable, and nonpredictive (Lake 1980), so it was quickly discontinued by March 1980. Hence, this report contains only the results of ground level studies.

All sites at both strip mines were dominated by 9 species of grasses and legumes seeded as a pasture mix or as pasture plus nurse crops. Seeded grasses were Festuca elatior, Dactylis glomerata, Poa pratensis, Panicum virgatum, Triticum aestivum, and Lolium multiflorum. Seeded legumes were Medicago sativa, Lespedeza stipulacea, and Trifolium hybridum.

All sites, regardless of age, locality, or treatment, usually had more weedy species than the 7 or so seeded ones (Table 8). Reference sites and top-soiled mine sites tended to have more weedy species and a higher density of herbaceous species than mine sites covered with raw spoil. This pattern was identical to that found in 1979 at Prairie Hill despite fluctuations in actual numbers of species. Complex species diversity and similarity computations were not completed for this report. The calculations will be finished in January 1981. Species lists for all sites are included as appendix tables.

4.3.3. Cropland Studies

Mine and reference sites seeded with winter wheat, soybeans, and milo were studied at River King Coal Mine. Data on ground cover, productivity, and species composition are presented.

4.3.3.1. Ground cover of croplands

Vegetative cover was measured at 14 sites using both visual and computer techniques (Table 9). One exception was the winter wheat reference field.

Table 8
Plant Species Diversity in Pasturelands in Summer 1980

Mine	Site	S	ΔS	$\bar{S}/m^2$
Prairie Hill	C1	12	0	2.0
	C2	19	+8	2.6
	C3*	22	0	3.9
	C4	21	+7	3.4
	C5	18	-5	4.3
	C6	18	+3	4.5
	B1	12	-8	1.6
	B2*	19	-11	3.4
	B3*	31	-7	5.1
	R3**	43	+6	9.2
Power	D1*	22	NA	6.3
	D2*	20	NA	5.9
	D3*	30	NA	11.9
	D4*	31	NA	10.4
	D5**	40	NA	9.4

S = Number of plant species or species richness.

ΔS = Change in number of plant species between 1979 and 1980.

$\bar{S}/m^2$ = Mean number of plant species per square meter or species density.

* = Topsoiled

** = Unmined reference site

	RK11	91.76	84.28 $\pm$ 3.40
	RK13	96.56	93.56 $\pm$ 2.12

* Reference sites

This site was not subjected to computer analysis because just before the CIR aerial photographs were taken, it was graded as part of pre-mining preparation.

Unlike in pasturelands, there was no significant correlation ($r^2 = 0.001$, $p > 0.5$) between remote and direct measurements of ground cover in various croplands (Figure 8). Ground level estimates ranged from 14 to 93%, whereas computer estimates for the same areas varied only from 85 to 100% canopy cover. This difference was not surprising once the nature of row crops was considered. Bare soil between rows of soybeans, wheat, and milo usually was conspicuous to any trained observer standing in a field or on a platform just above the canopy layer. But these gaps were not resolvable in 1:12,000 scale CIR aerial photographs either when viewed by eye or when enhanced by the computer system. We found the row size varied from field to field, ranging from 6 inches (15 cm) at mine sites to 30 inches (75 cm) at soybean and milo reference sites. A second factor that affected surface observations more than remote ones was the variant structure of crop plants themselves. For example, soybeans had defoliated by time of harvest, so the fields looked relatively barren to the inspectors but the fallen leaves rendered a false image in the CIR so aerial photographs showed a well covered condition.

Although cover estimates made at small plots in croplands might be of questionable value, we reasoned that computer measurements of cover could enable one to detect problem spots of significant size. Weedy crops, bare soil, and ponds having an area greater than 1 - 5 square yards ($1 - 4 \text{ m}^2$) were evident in the CIR aerial photographs and appropriately classified during computerized inventories (Table 10). Scale plots, as shown for reclaimed site RK5 in Figure 4, permanently documented the spatial condition of each field.

Figure 8. Comparison of visual and computer measurements of vegetative cover in cropland study sites. The crops were winter wheat (●), soybeans (□), and milo (■). The 90% similarity zone is depicted.

Table 10
Computer Classification of Cropland Study Sites at River King Mine in 1980

4.3.3.2 Production of croplands

Yields of winter wheat, soybeans, and milo were calculated both for total standing biomass and for grain (Table 11). All grain yields were standardized at 13% moisture using the equation

$$Y = \frac{(\text{mass}) (100 - X)}{(\text{area}) .87}$$

wherein X = percentage moisture measured by us. To derive typical agronomic yields as bushels per acre (bu / a) (Y') from metric values, we used the following grain densities (Z):

wheat	60 bu/a
soybeans	56 bu/a
milo	60 bu/a

in the equation

$$Y' = Y \frac{(g)}{(m^2)} \frac{(1.1b)}{(454 g)} \frac{(10,000 m^2)}{(2.5 a)} \frac{(1 bu)}{(Z lb)} = \frac{8.81 \cdot Y}{Z}$$

As an additional index, estimates of typical 1980 crop yields at farms in southwest Illinois crop reporting district were obtained from Dr. L. V. Boone.

Average production of winter wheat at 7 mine sites ranged from 27.04 to 51.28 bu/a. Yields at 6 of these fields were significantly less than 90% of the reference value, 51.78 bu/a (Table 12). The value for 1 mine site and the reference field were comparable to each other and to the southwest Illinois wheat estimate for 1980, which was placed at 47 bu/a.

The single reclaimed soybean site at River King produced 24.09 bu/a. This figure was significantly less than 90% of the soybean reference yield, which averaged 30.12 bu/a (Table 12). However, the mine site value equalled

Table 11
Production of Croplands at River King Mine in 1980

Table 12
 Statistical Comparison** of Total Production in Mine Croplands Relative to
 Reference Croplands at River King Mine in 1980

Winter Wheat

	Rank Order							
	Less than Reference						Equal to Reference	
Site	RK6	RK4	RK5	RK7	RK2	RK3	RK1	RKX*
Yield (bu/a)	27.04	30.77	36.09	36.97	37.12	39.56	51.28	51.78

Soybeans

	Rank Order			
	Less than Reference		Equal to Reference	
Site	RK9		RK10*	
Yield (bu/a)	24.09		30.12	

Milo

	Rank Order			
	Less than Reference		Equal to or Greater than Reference	
Site			RK13*	RK4 RK8 RK11
Yield (bu/a)			38.91	39.92 48.10 65.84

* Reference sites for which 90% of total yield was used as the standard for comparison with other sites.

** ANOVA test modified with Dunnett's procedure or Student's t-test was used. Level of significance was set at $p=0.05$.

Figure 9. Relationship between standing crop of winter wheat and grain harvested at study sites in 1980. Best fit regression line is shown.

the estimate for soybeans in southwest Illinois, which was set at 25 bu/a.

Milo production at 3 reclaimed mine sites ranged from 39.92 to 65.84 bu/a. Yields at all 3 areas were statistically equal to or greater than 90% of the reference field, which averaged 38.91 bu/a (Table 12). Values for mine sites were similar to the estimate for milo in southwest Illinois, which was bu/a.

Hence, the performance of row crops in reclaimed fields in southwest Illinois was mixed. Four or 5 of 11 mine sites met either of 2 production standards for this region in 1980. Most winter wheat yields were below expected values, whereas all soybean and milo yields were equal to or greater than the reference figures. In many cases poor wheat harvests may have been due to planting at the improper time since seeding was often done more to stabilize the top-soil than to insure healthy growth.

Grain yields for winter wheat were highly correlated with aboveground biomass (Figure 9). Data points for soybeans and milo, although insufficient for individual crop analysis, did follow the same positive trend as was shown by wheat. These results suggest that biomass might be a robust predictor of grain production given species, varietal, and other constraints.

4.3.3.3. Species composition of croplands

The taxonomic identity, frequency, and abundance of all plant species were calculated for each of 25 replicate clip quadrats within 7 mine and 3 reference sites. At 4 mine sites plants other than wheat were labelled as weeds and not systematically described.

All croplands studied by us in 1980 were dominated by the singly seeded species (Table 13). Species richness ranged from 1 to 7, but in most quadrats only the crop species was found.

Table 13
Plant Species Diversity in Croplands in 1980

Mine	Crop	Site	S	$\bar{S}/m^2$
River King	Wheat	RK1	1	1
		RK2	≥ 2	NA
		RK3	1	1
		RK4	≥ 2	NA
		RK5	1	1
		RK6	≥ 2	NA
		RK7	≥ 2	NA
		RKX*	1	1
	Soybeans	RK9	2	1.2
		RK10*	7	1.4
	Milo	RK4	3	1.2
		RK8	5	1.6
		RK11	7	1.4
		RK13*	1	1

S = Number of plant species or species richness.

$\bar{S}/m^2$ = Mean number of plant species per square meter or species density.

NA = Not available.

* = Unmined reference site.

These results contrast greatly with those from Power Mine where more than 10 weedy annuals were found commonly in all 4 newly seeded pastures (Table 8). The absence of weeds at River King was attributed predominantly to the action of herbicides applied to the crops and not to any intrinsic site factor.

Although weedy spots were detected during analysis of CIR aerial photographs (Table 10), we did not always obtain similar results from our clip quadrat samples. For example, RK1, RK3, and RK5 each had at least $\frac{1}{2}$ a (.2 ha) of weedy crops but their species richness values all were 1. This discrepancy was possible because a limited number of small samples were taken in a stratified random fashion for species enumeration rather than a botanic survey of an entire mine. The error, should it occur, was probably insignificant when biomass was considered as an importance index since crop species overwhelmingly dominated every site (Table 11).

4.3.4. Cost and Time Measurements

Both the times and costs required to perform assorted tasks in the field and laboratory were itemized and recorded (Table 14). The expense of a complete study of one 30 a (12 ha) site, as based of our experience during 2 growing seasons, ranged from a low of \$889 to a high of \$1,365.

We found that our remote sensing approaches for vegetation measurements were faster and cheaper than ground level methods (Table 14). However, remotely sensed data did not afford much information about species composition and abundance. Thus, we conclude that a combination of both approaches should be used to gain accurate and timely information about revegetation success in strip mines.

Table 14

COMPARATIVE COST ANALYSIS FOR

4.4. Technology Transfer

We presented the results of our research to the scientific community by publishing several papers in the open literature. A number of other articles will be forthcoming in 1981 and 1982. Most of these are listed in our bibliography, Section 7.

We also gave 8 seminars or poster papers at the following scientific meetings:

XIII Argonne Universities Association - Argonne National Laboratory

Annual Biology Symposium on "Biological Aspects of Ecosystem Restoration",
Argonne, IL. April 21-22, 1980.

Annual Meeting, American Institute of Biological Sciences and the
Ecological Society of America, Tucson, AZ. August 3-7, 1980.

Annual Symposium of the American Council for Reclamation Research,
St. Louis, MO. September 18, 1980.

Conference on "Remote Sensing for Resource Management" sponsored by
the Soil Conservation Society and other societies, Kansas City, MO.
October 28-30, 1980. (C.J. Johannsen was a co-organizer of this
meeting)

For more in-depth discussions, we met informally on many occasions
with mine operators, state and federal regulatory officials, and various
agronomists and engineers.

Currently we are involved in a series of "hands-on" workshops dealing
with "Remote Sensing for Strip Mine Reclamation". The program, which
originates out of the University of Missouri-Rolla campus, uses tapes of
our digital computer data. The workshops are being conducted in 1980-1981
by 3 UMR faculty and 2 reclamation experts from Peabody Coal Company.

5. COMPLIANCE WITH THE CONTRACT.

To our knowledge, we have fully complied with the letter and the spirit of the contract.

6. EFFORT OF SCIENTIFIC PERSONNEL

The principal investigator (PI) devoted at least 50% of his time during the academic year and 50% during 4 summer and fall months to this project. During the remainder of the contract period, from December, 1980 to March, 1981, the PI expects to spend 50% of his effort on the project.

All other scientific personnel have complied with the effort description in the original proposal.
