GEOLOGICAL EVALUATION

Introduction

This project is a detailed analysis of the lithology, stratigraphy, and structure of the New Albany Group in Illinois to determine those characteristics of lithology, thickness, regional distribution, vertical and lateral variability, and deformation that are most relevant to the occurrence of hydrocarbons.

This study will result in the preparation of cross sections, facies maps, and geologic structure maps based on subsurface data available in the Illinois Survey files. Previous work in Illinois is being re-evaluated and updated. New data on the physical, chemical, and mineralogic characteristics of the New Albany will be derived from the studies of new cores in Illinois and will be incorporated into the stratigraphic and structural investigations of existing data.

Advise DOE on Drill Sites and Coring

Progress

A few leads on drilling that might be possible to develop into cores through the New Albany have been received during the past quarter, but none has produced definite commitments. Discussion has continued on the feasibility of taking shallow cores in Illinois. Figure 1 shows the locations of presently available New Albany Group cores in Illinois and western Kentucky. Figure 2 shows the locations of four potential sites for shallow drilling to reach and core the New Albany. Below is an outline of the basic information on each of these potential drill sites.

Hardin County, Illinois

Possible sites:

On the flank of Hicks Dome, in any of Secs. 24, 25, 36, T. 11 S., R. 7 E., or Secs. 19, 20, 29, 30, 31, 32, 33, T. 11 S., R. 8 E. Drilling site should be located on the Fort Payne chert and as close to the center of the structure as possible. The Fort Payne is 280-640 feet thick in this area and will probably be very difficult to drill through, so the site should be selected to minimize the amount of drilling in chert. However, 60 to 70 feet of bedrock overburden will be necessary to accommodate the core barrel.

Thickness:

The New Albany is approximately 400 feet thick in this area and is dipping about 10-20 degrees in all directions away from the center of the structure. Total core thickness will be about 410-420 feet.

Stratigraphy:

We expect to encounter a very thin Hannibal-Saverton equivalent greenish-gray shale, very thick Grassy Creek Shales, and thick Sweetland Creek and Blocher Shales. The Grassy Creek, Sweetland Creek, Blocher, and total New Albany Group are all near their maximum thickness at this site.

Advantages to sites:

- Near the Devonian depositional center of the Illinois Basin
- Thick sequence of potentially gas-bearing black shales
- Only shallow drilling site in entire Illinois Basin where deep basin facies is encountered

Disadvantages to sites:

- Any gas originally present in shale may have been lost due to proximity to outcrops and extensive fracturing.
- Structural dip complicates interpretation of electric logs.
- Extensive fracturing and mineralization may make data on physical properties and geochemical analyses difficult to relate to other areas.
- Most of the eastern and southern flanks of Hicks Dome are U.S. Forest Service land, and drilling on national forest land will probably require an environmental impact statement. This somewhat limits the choice of drilling sites.

References:

- Baxter and Desborough, 1965, Illinois State Geological Survey Circular 385.
Baxter, Desborough, and Shaw, 1967, Illinois State Geological Circular 413.

Union County, Illinois

Possible sites:

Anywhere in eastern Union County, in any of townships T. 11 S., R. 1 W., T. 11 S., R. 1 E., T. 12 S., R. 1 E., or T. 13 S., R. 1 E.

Thickness:

The New Albany Shale is overlain by 200 to 700 feet of Mississippian limestones, cherty limestone, and shale in this area. The New Albany ranges from 30 feet thick near the outcrop in central Union County to approximately 100 feet at the east edge of the county. Both the thickness of shale and amount of overburden increase rapidly eastward.

Stratigraphy:

We expect to encounter a few feet of Chouteau Limestone, a thin Hannibal-Saverton interval, Grassy Creek Shale, Sweetland Creek Shale, doubtfully some Blocher Shale, and Alto and Lingle Formations below the New Albany.

Advantages to sites:

- Proximity to previously studied outcrop localities
- Will provide data on facies transitions associated with the Du Quoin Monocline
- Most of shale is black to olive-black and potentially gas-bearing.
- Area of sparse subsurface data

Disadvantages to sites:

- New Albany Group is relatively thin.
- Most of area is surrounded by Shawnee National Forest and some land belongs to U.S. Forest Service. Drilling on national forest land will probably require an environmental impact statement.
- Might be as much as 100 feet of Fort Payne chert to drill through

Jersey County, Illinois

Possible sites:

The stratigraphically most complete section is probably located in eastern Jersey County (T. 8 N., R. 10 W.). Alternative sites might be found in Greene County (thicker total section and thicker "black" shale interval, but stratigraphically less interesting), in western Pike County, or northwestern Jersey County (T. 8 N., R. 13 W., a thinner section but much shallower and probably posing fewer drilling problems).

Thickness:

The New Albany Shale is overlain by approximately 800 feet of Mississippian and Pennsylvanian rocks and surficial deposits in eastern Jersey County, and is shallower in eastern Greene County (250-500 feet) and northwestern Jersey County (0-200 feet). The total thickness of the New Albany Group ranges from about 100 to 200 feet.

Stratigraphy:

This is a stratigraphically complex area with very few subsurface records (no geophysical logs of the New Albany Group in Jersey County have been found in our files). Based on outcrop stratigraphy and sample studies, we expect to encounter a relatively thick Hannibal sequence that may include a dark gray to black member (the Nutwood) at near maximum thickness; both the "Glen Park" and Louisiana Formations; Grassy Creek and/or Sweetland Creek Shale; and possibly Sylamore Sandstone at the base of the New Albany.

Advantages to sites:

- Proximity to classical type sections of the New Albany Group in Illinois
- Presence of Nutwood, "Glen Park," and Louisiana lithologies. The relationships of these three units are stratigraphically and environmentally very important in developing an overall model for New Albany deposition.
- This is an area with virtually no reliable subsurface data.

Disadvantages to sites:

- Section is predominantly greenish-gray shale, limestone, and siltstone, with little black shale.
- The Burlington Limestone, which lies a few feet above the New Albany in this area, is approximately 120 feet thick and contains several cherty intervals that will be significant drilling problems.
- The presence of coal seams in eastern Jersey County might require casing of the hole.

References:

- Baxter, 1970, Illinois State Geological Survey Circular 448.
- Workman and Gillette, 1956, Illinois State Geological Survey Report of Investigations 189.

Champaign-Douglas Counties, Illinois

Possible sites:

The most promising site is probably along the east flank of the Tuscola Anticline somewhere between the villages of Tolono and Camargo. An alternative site might be in eastern Douglas County in the general vicinity of the town of Newman.

Thickness:

The New Albany Group is generally 80-100 feet thick along the flanks of the Tuscola Anticline and is overlain by generally 200-500 feet of overburden consisting of glacial drift, possibly some Pennsylvanian strata, and Borden Siltstone. In northeastern Douglas County, the New Albany is generally 50-80 feet thick and is overlain by 600-900 feet of overburden, consisting of glacial drift, Pennsylvanian strata, and Borden Siltstone.

Stratigraphy:

In this general area the Chouteau Limestone is thin, and it appears to pinch out in eastern Douglas County. The Hannibal-Saverton Shales are very thin. The Grassy Creek and Sweetland Creek Shales appear to be of about equal thickness, but poorly differentiated, with no deep basin-type dark black shale facies present.

Advantages to sites:

- Very shallow depth, should be easy drilling, especially of flanks of Tuscola Anticline
- May shed light on relationships between depositional facies and early development of La Salle Anticlinal Belt
- May yield interesting data regarding effects of structure on strength of shale

Disadvantages to sites:

- Total New Albany Shale section is relatively thin.
- Little or no "good" black shales, probably little gas potential
- Probably will be lithologically similar to Tazewell County core

Problems

The lack of good core material from the central part of the basin, where the New Albany is 3000 feet or more below the surface, continues to pose a problem for our work. A partial solution would be to take the core in Hardin County where the New Albany is at shallow depth. Direct contract with a driller to take one or more of these shallow cores is possible, if suitable financial arrangements can be made. This may form the best alternative to getting a deep basin core.

It may prove to be difficult or impossible to process new core received later than the fall of 1978 in the time frame specified by the original proposal and contract.

New Albany Well Map and Tabulation

Progress

The listing of holes in the northeastern quadrant of the Illinois Basin is completed. Maps to a scale of 1:1,000,000 have been produced with locations plotted. Figure 3 shows the counties involved in the northeastern quadrant and indicates the total area completed to date.

The tabulation of drill holes through the Devonian black shale in the northwestern quadrant of Illinois is under way.

Stratigraphic Cross Sections

Progress

Stratigraphic cross sections have been essentially completed for several months, except for revising and refining of correlations as more data become available regionally. Supplementary cross sections are produced or extended as needed to help solve stratigraphic problems in certain areas. During the past quarter, supplementary north-south sections have been extended in central Illinois and along the eastern boundary of the state.

Isopach Maps

Progress

Tabulation of data on total thickness for the New Albany Group in Illinois is virtually complete (milestone 6). However, in many parts of the state, formational subdivisions of the New Albany are still only tentative and will require further detailed correlation work. Also, further work is needed in correlating some key geophysical horizons. A preliminary hand-contoured map of the New Albany Group thickness has been done for most of the state. Thickness contours have been drawn for formational units in some portions of the state, but these may be subject to revision as the greater regional picture is developed.

Discussion and Problems

Several stratigraphic problems have been encountered in recognition of mappable subunits on a regional basis. As a result of facies changes, contacts between formal stratigraphic units may need to be shifted vertically from one place to another. In some cases there is a transition zone through which the dominant lithology of one formation grades vertically to that of another, and there is no distinct contact between the two formations.

One stratigraphic nomenclatural problem arises from the lateral changes in the interval encompassing the Sweetland Creek and Grassy Creek Shales. In many areas distant from the center of the Illinois Basin, the distinction between these two shale formations becomes subtle to practically nonexistent, being recognizable in neither geophysical logs nor sample lithologies. In these areas the entire interval is being left undifferentiated and tentatively referred to the Grassy Creek-Sweetland Creek Shales.

In central Illinois the succession from the Grassy Creek Shale to the overlying Saverton Shale is transitional through an interval several feet thick. This transition zone generally exhibits a low electrical resistivity, often only slightly higher than the Saverton above. However, the natural radioactivity of the zone is generally high, very nearly as high as that of the underlying Grassy Creek. Sample lithology, although variable, consists generally of relatively dark shales more similar to the Grassy Creek than the Saverton. For these reasons, the transition zone has in most cases been included with the Grassy Creek.

Stratigraphic problems also pervade the Saverton-Louisiana-"Glen Park"-Hannibal sequence in west-central Illinois. Several inconsistencies are apparent in past recognition of contacts between these formations. The most practical solutions to some of these problems are to define contacts on the basis of key beds that are readily recognizable on geophysical logs. Some past workers have evidently used this approach, although contacts defined in this way are not necessarily correlative with those defined in the type areas and may require some redefining of the age limits of some formations.

Considerable attention has been given to delineating the erosional boundaries of the New Albany Group. In much of west-central Illinois, the New Albany has been thinned by erosion and is disconformably overlain by Valmeyeran (middle Mississippian) strata—the Fern Glen Formation, or the Burlington Limestone. Near the northern limit of the New Albany, the overlying Mississippian rocks, as well as the New Albany itself, have been truncated and are disconformably overlain by Pennsylvanian strata. In some areas the New Albany is overlain by Pleistocene glacial drift.

Facies changes and truncation present special problems in contouring the thickness of the New Albany. The best approach to mapping is to subdivide the map into areas showing these special situations. Where the New Albany is essentially complete (conformably overlain by the Chouteau Limestone), contouring is relatively straightforward. It is, however, slightly complicated by lateral gradation of the Blocher Shale into the upper Lingle Limestone. Here, contours must be offset along an arbitrary vertical cutoff between Blocher and Lingle.

The greatest difficulties in contouring arise where the upper part of the New Albany has been eroded. Erratic distribution of thickness values indicates that the erosion surface is generally far from smooth. Furthermore, in most of the eroded areas, data are rather sparsely distributed, and many are of questionable reliability. For these reasons, in the eroded areas, a larger contour interval, depicting more generalized thicknesses, is probably in order.

Sample Studies

Progress

Sample studies of the New Albany in 35 strategically located wells were completed during February and March. Lithologic information from these studies was correlated with geophysical logs. Chips of various nonshale lithologies were collected for thin-section petrographic studies. Shale samples were taken from approximately 100-foot vertical intervals for vitrinite reflectance, clay mineralogy, and chemical analyses. Sampling was performed with great care to insure noncontamination.

Problems

In a few wells, samples were unavailable for critical stratigraphic intervals. Contamination and mixing of the samples (during drilling) has made interpretation and sampling difficult or impossible in some cases.

Data Formats

Progress

With the recent finalization of data formats for stratigraphic data encoding, five counties in southwestern Illinois have been chosen for a test of the mapping function. The full data set for this area has been punched and will be used to test the data assembly capacity of the MINERS system. The first test maps will be produced during April.

MINERALOGIC AND PETROGRAPHIC CHARACTERIZATION OF NEW ALBANY IN ILLINOIS

Introduction

This project is directed at characterizing in detail the mineralogic and petrographic properties of the New Albany Shale in Illinois. This includes the quantitative and qualitative characterization, by optical and X-ray techniques, of the inorganic mineral constituents, the dispersed organic matter, and the fabric of the shale. The data generated will provide a fundamental basis for regional and local correlations of geologic data, for interpretation of the sedimentology, depositional environment, and diagenetic history, and for evaluation of hydrocarbon potentials based on the degree of thermal maturation of organic matter in the New Albany Shale.

Lithologic and Radiographic Characterization

Progress

Fifty-eight samples from the 04IL (Henderson Co., Illinois), 06IL (Tazewell Co., Illinois), and 07IL (Fayette Co., Illinois) cores were embedded in epoxy and slabbed during the last quarter. Radiography of these samples is still in progress.

Two cores from Survey files were described and sampled during February: one from Fayette County, Illinois (07IL), and one from St. Clair County, Illinois (09IL). Twelve samples were taken from these cores.

Approximately 189 samples of rotary drill cuttings from several wells in Illinois were picked during February and March. The distribution of samples was as follows:

Vitrinite reflectance:	51 samples
Clay mineralogy:	53 samples
Chemical analysis:	53 samples
Thin-section petrography:	32 samples

Problems

Serious problems were encountered during the handling and initial water-sawing of the core samples. The low strength of the greenish-gray shales and their tendency to swell in water caused severe breakage and slaking. Many samples were reimbedded in epoxy between saw cuts, and this slowed our progress considerably. Radiographs of these samples are not expected to be of good quality. Severe difficulties in thin-section preparation are anticipated, and this may delay their preparation and/or reduce the number of thin sections made.

Microscopic Characterization

Progress

Thin-section analysis of the 02IL (Effingham Co., Illinois) core was completed in February. The data have been encoded for computer storage and handling, and a printout should be available soon. We will include a printout with our monthly report at that time.

Nine thin sections from the 03IL core (White Co., Illinois) were made during the quarter and are now being studied. Fifteen thin sections of well cutting samples were prepared, and a total of 33 thin sections of outcrop and well cutting samples were characterized during March. These samples are almost exclusively from sandstone and carbonate units below, within, and above the New Albany Group. Generally the thin sandstones within the New Albany Group are calcite cemented and do not appear to have significant porosity. The carbonate lithologies are quite variable and are principally of interest in deciphering the depositional environments of the shale and lateral facies transitions from shale to carbonate.

Fourteen samples from the 01KY (Christian Co., Kentucky) and the 01IL (Sangamon Co., Illinois) cores have been chosen for analysis with the Scanning Electron Microscope. Evaluation of various methods of sample preparation is in progress.

X-Ray Diffraction Mineralogy and Clay Orientation

Progress

Thirteen whole-rock samples from the 02IL core and 30 samples from the 04IL core were analyzed for silt mineralogy during February. The data are presented in tables 1 and 2.

Clay mineralogy has been determined for 30 samples from the 04IL core and for 22 samples from the 06IL core. The data are presented in tables 3 and 4. Clay orientation index slides are being prepared for all samples. The clay mineralogy of the two cores is very similar (fig. 1). Both are also similar to the 01IL and 02IL cores (fig. 2). At this time it appears that the New Albany contains more chlorite in the northern portion of the Illinois Basin than in the southern portion. Clay mineral analyses now in progress of well cuttings should allow us to map any regional variations more precisely.

Clay mineral analysis of a standard sample (SDO-1) provided by the U.S. Geological Survey was completed, and the data collected are presented in tables 5 and 6. The sample was divided into three splits, and four slides were made of each split: two by the smear technique (which we routinely use) and two by sedimentation. The results in table 5 are from the first slide from each group. Analyses of the duplicate slides are given in table 6.

As can be seen by comparing these two tables, the results within each group of samples are in good agreement, but there are significant differences between the first set of slides and the duplicates that were run a few weeks later.

The following explanation accounts for the differences. To conserve energy, the heat is turned off in our X-ray laboratory overnight. The room temperature drops to about 24°C. This seems to be the temperature at which ethylene glycol can no longer enter between clay layers. Complete glycolation appears to occur at 26-27°C. The difference between the two sets of samples, therefore, is attributed to deglycolation during the night, which results in an apparent reduction of expandable clays when the slides are X-rayed early in the morning (before they re-equilibrate with the glycol atmosphere at higher, daytime room temperatures). This was a previously unsuspected source of error.

Vitrinite Reflectance

Progress

Reflectance analysis of the 02IL core was completed during January, and the results are summarized in table 7 and in figure 3. The reflectance values for this core are slightly higher than the 01KY and 01IL cores (fig. 4), which is consistent with its basinward position relative to those wells.

A single vitrain band was found within the 05IL partial core. Vitrains are generally a very reliable indicator of rank, and even this single sample is probably representative of the New Albany at that location. The measured reflectance of the sample (05IL01L4) was 0.47 ± 0.02 percent Ro.

A sample of New Albany Shale and associated vitrain from Marion County, Indiana, was provided by N. Shaffer of the Indiana Survey and measured during January. Both the macerated shale sample and the vitrain yielded identical results: 0.46 ± 0.06 percent Ro.

Acid separation of dispersed coaly particles for vitrinite reflectance analysis was completed for a set of 8 samples from the 06IL (Tazewell Co., Illinois) core and 8 samples from the 04IL (Henderson Co., Illinois) core. Eight samples from the 07IL (Fayette Co., Illinois) and 21 samples from the supplementary drill cutting sets from various counties were acid digested during March. All samples are now being mounted and polished for reflectance analysis.

Problems

The greenish-gray shales in the 04IL and 06IL cores yielded very little organic matter. Additional samples will be processed if necessary.

Summary of Progress

Analysis of the 02IL and 03IL cores (milestone 16) is complete except for thin-section petrography of the 03IL core. Preparation of thin sections from the 03IL samples has been delayed because the initial sample preparation on the canned samples from the 04IL and 06IL core was deemed of higher priority.

Milestone 17 (acquisition of fluorescence equipment) has been deleted due to budget cuts directed by DOE.

Work towards milestone 18 (completion of 04IL and 05IL cores) is running slightly behind schedule, while work on milestone 19 (completion of 06IL core) is well ahead of schedule. All three cores will probably be completed more or less simultaneously.

PHYSICAL CHARACTERIZATION

Introduction

This project is a study of the index properties, directional properties, and strength of oriented core of Devonian black shale from the Illinois Basin. Index properties include moisture content, specific gravity, bulk density, and Shore hardness. Directional seismic velocities will be determined with an acoustical bench. Strength tests include point-load fracture strength and indirect-tensile strength (Brazilian split). Fracture frequency, drilling rate, and core recovery are also compiled as an additional mechanical index.

Destructive Testing

Testing Procedure

All destructive testing for this study is being performed on a Tinius-Olsen Model 300CT-1 compression testing machine. The machine has electronic-load indicator and servo controls (fig.1). A specially designed subpress with interchangeable flat and point-load platens was used in the load frame for each of the two types of tests being run.

Figures 2 and 3 are typical examples of test results, showing the data-recording sheet and the load-deformation curve. The load curve has proven to be a good record of the test quality as well as a characterization of distinctive modes of failure for the various lithologies designated. While not specifically a part of this study, an analysis of the loading curves is in progress and will be presented at a later date.

The point-load tests are performed with quickly applied compression (approximately 8 cm/min), and the test value is recorded as the point-load index (load at failure divided by the sample thickness squared). The loading points of the compression machine are hardened 60-degree cones with a 5-mm radius point. Point-load samples are approximately half the core diameter in thickness with ends machined to within 0.05 cm parallelism. Sample preparation for the point-load test is not critical, as the credibility of the test is usually determined by splitting subparallel to the bedding. This splitting is caused by irregular bedding, fossils, mineralized nodules, or coring-induced fractures. The fast test rate (maximum machine rate) is the only control that has tended to minimize the effect of splitting.

The indirect-tensile tests are performed at a slow deformation rate (approximately .001 cm/min), and the test value is recorded as the tensile strength ($2 \times \text{load} \div \text{sample diameter} \times \text{sample thickness} \times \pi$). The platens are flat with no cushion. Where the core has very irregular sides (core 02IL only), a thin fiber board cushion was used. As with the point-load test, splitting due to geologic flaws was a problem. There are too few comparable samples (lithology and orientation) to quantitatively assess the influence of this splitting on the test results.

Progress

Core 01KY

The destructive testing and initial analysis of core 01KY has been completed. In summary, there is a preferred orientation (northwest-southeast). The degree of expression and the orientation appear to be controlled by the lithology.

Near-vertical, natural fractures were noted in 22 of the 172 samples tested. The general direction of fracture orientation is northwest-southeast with 13 fractures oriented $135^{\circ}/315^{\circ} \pm 20^{\circ}$, and 7 fractures oriented $90^{\circ}/270^{\circ} \pm 10^{\circ}$. Figure 4a summarizes these data.

The point-load test was performed on 75 samples, most of which were lithologies III (poorly laminated brownish-black shales) or IV (finely laminated brownish-black shales). Figure 5 shows the position of the resulting fractures. The fractures resulting from the point-load tests show a preferred orientation of $130^{\circ}/310^{\circ}$ for lithologies III and IV (poorly laminated and finely laminated brownish-black shales). Lithology II (indistinctly bedded olive-gray shales) had only 10 samples and showed considerable scatter in orientation relative to lithologies III and IV (see figs. 4b,c,d).

The indirect tensile test was performed on 97 samples. Figure 6 summarizes the results. The preferred orientation shown by the indirect tensile strength (normal to axis of testing) is generally compatible with the point-load test data. However, the relative preference (fig. 6) is small (ratio of maximum value to minimum is 1.16) for all test values. Furthermore, subdivision by lithology is inconclusive at this point due to the small number of samples available for testing.

Core 02IL

As a result of poor core recovery and questionable orientation of available core, the results of the destructive testing are of questionable value. Figure 7 shows that one-third of the core was either broken or lost at the time of drilling. Another one-third of the core was either unoriented or unable to be oriented (had multiple orientation grooves or spiraling orientation grooves). Where questionable core was oriented, it was done by comparison with adjacent oriented core.

In summary, this core is of questionable value for orientation work and should probably be regarded as an unoriented core.

The distribution of destructive test samples by lithology is as follows:

Test	Lithology					
	II _a	II _b	III _a	III _b	IV _a	IV _b
Point-Load	5	-	2	-	22	2
Indirect-Tensile	2	2	1	3	29	-

As with core 01KY, most of the samples are the brownish-black shale (lithologies III and IV).

The results of the point-load tests (figs. 8 and 9) show a preferred orientation northeast/southwest. The core had nine data sets, two of which, 02IL06 and 02IL07, offered no destructive test samples. Furthermore, data sets 02IL01 and 02IL09 are largely the limestone from above and below the New Albany.

The indirect-tensile test was performed on 37 samples. Figure 10 summarizes the results. There is a preferred orientation indicated. This is compatible with the point-load test results; however, it is based on a small number of samples.

 Maximum Load: 75.36 kN Tensile Strength: 7.73 MPa
 $S_p = (2) \text{load} / D^2 \pi$
 Cushion Material: —
 Remarks: parallelism 0.02 cm

Fig. 3. Example of an indirect-tensile test (Brazilian split) data sheet. The mode of failure diagram at the right shows the test direction and the resulting fractures, relative to the core orientation.

Fig. 4. Frequency plot of fracture orientations core 01KY.

- a) natural fractures
- b) point-load fractures, all tests
- c) point-load fractures, finely laminated brownish-black shales
- d) point-load fractures, poorly laminated brownish-black shales

Fig. 5. Position of fractures resulting from point-load testing, lithologies II, III, IV, core O1KY. Fractures resulted from a point load applied at the center of the circle (core).

Fig. 6. Relative preference of orientation of indirect-tensile strength. The average strength for each of the six test directions is proportional to the distance from the center of the diagram.

Fig. 7. Quality of oriented core, core 02IL.

Fig. 8. Position of fractures resulting from point-load testing, lithologies II, III, IV and limestone, core O2IL.

Fig. 9. Frequency plot of fracture orientations, core Q2TL.

Fig. 10. Relative preference of orientation of indirect tensile strength, lithologies II, III, IV and limestone, core 02IL.

GEOCHEMICAL CHARACTERIZATION

QUANTITATIVE DETERMINATION OF MAJOR, MINOR, AND TRACE ELEMENTS IN SHALES

Introduction

Determine not less than 49 major, minor, and trace elements in 300-500 shale samples, which are representative cross sections of the cores taken. Include organic and mineral carbon; total hydrogen; pyritic*, sulfate*, and total sulfur; exchangeable cations (Ca, Na, K, Mg); and base exchange capacity. Also, report other elements observed during normal routine analysis. The data generated will be used to evaluate 1) the potential economic importance of trace element concentrations in organic-rich shales, 2) new geochemical exploration techniques for natural gas, 3) trace element enrichment in shale organic matter, 4) the occurrence of heavy metal sulfides in shale, 5) potential catalytic effects of trace elements on shale pyrolysis yields, and 6) potential disposal problems.

* Where total sulfur exceeds 0.5%

Elemental Analysis

Progress

Attached is the latest computer print-out of chemical analyses completed and entered as of March 1978. The print-out data are comprised of an updating of results previously reported for 37 core samples and results of analyses of 20 new shales. Statistical evaluations, interpretations etc. must await completion of additional analyses. In this regard, analytical progress is on schedule and no unsolvable problems are foreseen at this time.

TRACE ELEMENT DISTRIBUTION IN ORGANIC AND INORGANIC FRACTIONS OF SHALE

Introduction

Develop chemical and/or physical methods for the separation of the organic and inorganic phases of shales, and determine the trace elements that are associated with each phase. Methods tested include float-sink gravity separations, mechanical separations (Humphrey Spiral), acid extractions, and zonal centrifugation. Compare results of analyses for ten shales, their gravity fractions, and their separated organic phases to determine the elements closely associated with organic matter. Separation procedures that are most promising will be used to study further the organically combined trace elements in additional shale samples. This research is designed to yield new information concerning chemical variations in shale organic matter, which is the shale component about which little is known and which may be the most characteristic feature of gas-bearing shales.

Development of Separation Methods

Progress

Investigations have continued on the development of methods which can be utilized to demineralize shales. Standard float-sink procedures, the Humphrey Spiral, and froth flotation procedures did not produce an organic fraction deemed satisfactory for this study. Funds have just become available for the purchase of zonal centrifugation equipment, considered necessary for such separations.

However, results of the investigation have led to development of the following scheme which should yield valuable information:

1. Pulverize shale to less than 325 mesh
2. React sample with 1N NH_4AC for exchangeable cations
3. React sample with 1N HCl to remove chelated elements
4. Reflux sample with benzene and methyl alcohol to extract bitumens
5. Reflux sample with HNO_3 to remove pyrite etc.
6. React sample with HF to remove silicates
7. Reflux sample with HCl to remove fluorides
8. Float residue at 1.40 specific gravity to remove insoluble titanium minerals

This procedure will yield significant information about the associations of various elements. Optimization of the scheme is still necessary, but until zonal centrifugation equipment is received, it seems to be a reasonable approach. Data, however, will need careful and, perhaps, qualified interpretation.

Characterization of Elemental Concentrations in Separated Shale Fractions

Progress

Data collected thus far indicate that very few elements show a significant concentration in the shale organic-rich fraction. Most elements are depleted to about 5-10% of concentration found in the whole shale material.

Most of the data acquired so far have been from developmental procedure, and from fractions of different samples. During the next quarter, the procedure outlined above will be applied to fractions of the same shale samples and should allow a much improved characterization of elemental associations.

MODE OF OCCURRENCE AND RELATIVE DISTRIBUTION OF HYDROCARBON PHASES IN SHALE

Introduction

Determine the character of off-gases from approximately 10-foot intervals in cores collected in the Illinois Basin. In addition, determine the relative distribution of hydrocarbons in ten specially prepared core samples, which are the same as those in previous unit. Preserve the samples in airtight containers and subsequently analyze them for evolved gases; highly volatile, low-molecular weight liquids; medium-volatile hydrocarbons; and solvent-extracted, low volatile hydrocarbons using GC-MS methods. Determine non-volatile, high-molecular weight hydrocarbons by GC analysis of shale pyrolytic products.

Determine the carbon isotopic composition of methane in off-gases from core samples whenever sufficient methane can be collected. Compare this data to other pertinent data such as gas composition and vitrinite reflectance for the purpose of making interpretations as to the origin and maturity of the gas. Perform laboratory experiments to study the relative effects and significance of chemical and isotopic fractionation that occur as gas is released from core samples.

Data accumulated can be evaluated to gain a better understanding of the origin, migration, and location of natural gas associated with the shales.

Released Gas Analysis

Progress

Studies of released gases from all cores collected in the Illinois Basin have been completed, and no new core samples have become available.

Medium Volatile Hydrocarbon Analyses

Progress

Progress on this project has been minimal due to the delay in purchase of necessary gas chromatographic equipment. Word has been received indicating that funds are being made available. In the interim the bidding process for the equipment has been completed and the final orders have been prepared.

The project is 7 to 8 months behind schedule. However, with limited equipment already available, the preliminary analysis of two standard black shale samples has been started. Other samples (2) are being prepared for analysis.

Low-Volatile Hydrocarbon Analysis

(See Medium Volatile above.)

Isotopic Analysis of Off-Gases

No additional cores have been made available containing sufficient methane for an isotopic analysis.

Laboratory Study of Chemical and Isotopic Fractionation

(Titled "Carbon-13/Carbon-12 Studies" in January 1978 Report)

Progress

The core sample that was pressurized with natural gas at 1000 psi continued to outgas for more than 6 months after the pressure was released. Because the other samples from this core stopped outgassing a few weeks after they were initially collected, it is apparent that the initial pressure within this core was much lower than that used in this experiment. Future experiments will be carried out at much lower pressures.

The results of the analyses of the gas released from the pressurized shale samples are summarized in figure 1 as a function of the time (in days) after the initial pressure release (a detailed description of the procedure was given in the last annual report). Outgassing had essentially stopped when the last gas sample shown on figure 1 was collected. After this gas sample was collected, the core sample was partially evacuated (to 20" of mercury). Although the pressure is building, it is very slow implying that there is very little gas left in the shale.

The data show that the first gas released (after the initial pressure bleed down) was depleted in methane relative to the gas that was injected. This is not entirely what would be expected. As discussed in the annual report, it is believed that the gas had not equilibrated with the shale before degassing was initiated. Also, all of the gas samples are depleted in CH_4 relative to the initial gas indicating that there must have been a significant loss of CH_4 -rich gas sometime during the experiment. Therefore there must have been a leak in the system, possibly of molecular size such that CH_4 was lost preferentially.

The isotopic data are also not entirely understood. Figure 1 shows that all of the offgas is isotopically lighter than the initial gas. During the period from 10 to 25 days after the initial pressure leak, there was an increase in the δC^{13} value for methane. This may have been the period during which the leakage occurred. Although there was a small leak detected later in the experiment, this leak does not appear to explain the changes observed.

In an attempt to eliminate some of the problems encountered, future experiments will be carried out using 3/4-inch diameter cores instead of the 4-inch core used in this experiment. Several cores will be pressurized simultaneously and the pressure vessels will be kept submerged in water so that leaks can be detected. These samples will then be degassed after having been pressurized for different lengths of time.

Problems

Continuation of the degasification experiments awaits release of funds for the purchase of some necessary equipment.

ADSORPTION/DESORPTION STUDIES OF GASES THROUGH SHALES

Introduction

With nitrogen and carbon dioxide, determine internal surface area on shale core samples; on selected samples, use methane as the adsorbate (sorbate) at pressures within the range of 1 to 80 atmospheres. Comparison of these properties in gas-producing and non-gas-producing shales will be made to determine the relationship of shale physical properties to gas recovery.

Fig. 1. Composition of off-gas during degasification experiments. Arrows indicate the composition of the gas originally injected.

Internal Surface Area Measurement

Progress

Internal surface area measurements with carbon dioxide and nitrogen as adsorbates were completed on twenty-two samples from a Tazewell County, Illinois core. Values were reported in our February, 1978 monthly report. The organic carbon content of samples from this core was relatively low. As a consequence, there was little plugging of pores by organic matter. Internal surface area values using nitrogen as the adsorbate were similar to those obtained with carbon dioxide as the adsorbate.

Samples from the Illinois Basin follow the same pattern. With increasing organic carbon content there is increased pore-plugging in the shales, leading to low internal surface area values (less than $5 \text{ m}^2/\text{g}$) from nitrogen adsorption, whereas the internal surface area values from carbon dioxide remain large (up to $39 \text{ m}^2/\text{g}$).

We recently studied some samples with high organic matter content from the Appalachian Basin that did not behave similarly. They were supplied by Dr. J. Barry Maynard (University of Cincinnati). Values are shown in the accompanying table 1.

The first eight samples in the table do not exhibit the afore-mentioned anomalous characteristic. Although fluctuations in both CO_2 and N_2 values occur, N_2 generally has more difficulty in permeating the shales than does CO_2 due to the partial clogging of pores with organic matter. In contrast, the Wise Co., VA shale samples are just as permeable to N_2 as they are to CO_2 . (Note the low CO_2/N_2 ratios of about 1.0.) The Wise Co. samples are dark, and very likely contain relatively high carbon percentages. This kind of behavior has not been observed in Illinois Basin samples which contain high organic carbon contents, although it is typical behavior for northern Illinois Basin samples which are gray and contain little organic matter.

As we reported at the First Eastern Gas Shales Symposium (Morgantown - October 17, 18, 19, 1977), N_2 internal surface area values can be markedly increased for dark samples from the Illinois Basin without significantly changing the CO_2 ISA values. This was accomplished by outgassing the samples at 300°C , while losing approximately 6% of the volatile matter.

Deeper burial depth, with the consequent higher temperatures for the Wise Co. samples, may have induced a greater loss of low molecular weight volatile matter resulting in a more mature shale than those from the Illinois Basin and the first eight samples shown in the table. However, we have examined one sample from a deep core near the center of the Illinois Basin (White Co., Ill.) - the sample coming from 1673 feet, which is a comparable depth as present to those from Wise Co., Va - and found that the N_2 ISA was $2.55 \text{ m}^2/\text{g}$, the CO_2 ISA was $12.9 \text{ m}^2/\text{g}$, and the CO_2/N_2 ISA ratio was about 5.0. Thus, it is likely that this burial depth is still insufficient to open the pores in the White Co. sample to the same extent as in the Wise Co. samples. Perhaps the Wise Co. samples were at one time more deeply buried than at present, or perhaps there have been forces at work which have generated still greater temperatures in the shale than mere depth of burial would indicate.

Table 1. Internal Surface Area Values for Selected Samples from the Appalachian Basin

Sample		CO ₂ ISA	N ₂ ISA	CO ₂ /N ₂
Ky.	PM 214	21.3 m ² /g	1.64 m ² /g	13.0
Ky.	PM 234	13.0	1.3	10.0
Ky.	Perry Co., 2375	26.2	2.62	10.0
Ky.	Perry Co., 2399	8.63	2.32	3.7
Ky.	Perry Co., 2410	16.0	2.43	6.6
Ky.	Martin Co., 2432.8	11.6	4.88	2.4
Ky.	Martin Co., 2488.4	16.2	3.28	4.9
Ky.	Martin Co., 2504.8	12.95	2.47	5.2
Va.	Wise Co., 4870.0	22.4	18.3	1.2
Va.	Wise Co., 4878.3	28.4	22.2	1.3
Va.	Wise Co., 4887.8	27.7	22.7	1.2
Va.	Wise Co., 4896.1	28.4	24.6	1.15
Va.	Wise Co., 4907.5	23.4	19.5	1.2
Va.	Wise Co., 4916.5	24.4	20.4	1.2
Va.	Wise Co., 4925.4	14.8	11.1	1.3
Va.	Wise Co., 4935.2	14.5	11.9	1.2

Studies at present are being made on thirty samples from Henderson County, Illinois. Data for these samples will appear in the April monthly report.

SDO-1 standard shale sample gave the following values:

CO₂ ISA = 36.4 m²/g
N₂ ISA = 4.57 m²/g
CO₂/N₂ ISA = ~8

Methane Adsorption Isotherms

Progress

Methane adsorption isotherms at high pressures (1 to 80 atmospheres and, in some cases, up to 100 atmospheres) are being obtained on selected shale samples from different cores. Selections are based on variations in the internal surface area measurements made with nitrogen and carbon dioxide. These measurements are non-routine because the diffusion rate of methane into the fine pore structures of samples containing relatively high organic matter contents is low, and several hours are needed for equilibrium to be reached at each experimental pressure. Thus far, nine samples have been evaluated - three from the Christian Co., Ky core, three from the Sangamon Co., Ill core, and three from Effingham Co., Ill core (shown on fig. 2). Greater adsorption of methane at increased pressures is shown by samples containing the higher organic carbon contents. We do not know at this time how much of this increased adsorption is associated with ultramicroporosity (greater surface area) and how much may be associated with increased solubility of methane in the organic matter phases that are present.

To help in this regard, we are obtaining for comparative purposes the methane adsorption isotherms for molecular sieves having different pore sizes. We are also studying the diffusion kinetics of methane from the shales by reducing the pressure (from an initial 80 atmospheres) to 1 atmosphere rather suddenly, and then measuring the release rate while maintaining atmospheric pressure. Sufficient data have not yet been generated for formal presentation.

Fig. 2.

INFORMATION

DATA COMPILATION

Data Encoding

Progress

The Illinois Survey has been designated to receive all data on the DOE Eastern Gas Shales Project that pertain to the Illinois Basin. Some of the data may be sent on to Petroleum Information. A total of six contractors, including the Illinois Survey, plus the U.S. Geological Survey, are generating or gathering data pertaining to the Illinois Basin. Encoding forms in use at the Illinois Survey are being sent to the contractors for their use, if they so desire. MINERS can accept any file format, however.

Mound Laboratory is the only contractor to have sent any data so far. Some determinations on a Kentucky core were sent to the Illinois Survey on a floppy disk.

MINERAL RESOURCES EVALUATION SYSTEM (MINERS)

Introduction

This project involves the development of a Mineral Resources Evaluation System that will store all the data related to Illinois State Geological Survey studies of the Devonian black shale of the Illinois Basin, and retrieve, process in many ways, and display in various ways these data.

File Generation and Maintenance

Progress

The end of the time period covered in this quarterly report is also a milestone. Completion of this portion of MINERS was scheduled for the end of March 1978. Most of the programming required for file generation and maintenance has been completed, and most of it tested. However, we are about 10 percent behind and are still coding some routines.

We have not encountered any problems that present hurdles and are not concerned with the slippage in schedule.

Design of the data base, the record management routines, and file management routines are completed and in most cases tested. Only the operating system interface, and the routines which communicate with the IBM-360 system tables and are written in ASSEMBLER LANGUAGE, are incomplete.

Retrieval

Progress

Many of the routines used in file generation are also used in retrieval. Hence, about one-half the expected programming has already been completed.
