Irradiation Performance Test of UO<sub>2</sub>-Cermet Fuel

#### S. Y. Ogawa

#### SUMMARY

A UO<sub>2</sub>-Mo cermet fuel assembly was fabricated for long-term irradiation performance testing in the Vallecitos Boiling water Reactor. The design and fabrication histories of this assembly are described and pre-irradiation data on each individual rod are presented.

Molybdenum was added to improve the bulk thermal conductivity of the fuel. so that fuel temperatures would remain comparatively low during high-power level operation of the fuel element. The molybdenum was incorporated into the compacts either as fibers or as a thin coating on individual  $IO_2$  particles. Fuel pellets were produced from these materials by vacuum hot pressing. Pellets having the fibers contained 20 vol % (~20 wt %) molybdenum and had densities from 94 to 95% theoretical. The pellets made from the coated  $UO_2$  particles had a metal content of about 16 vol % (~17 wt %) and had densities that ranged from 84 to 96% of theoretical and averaged 89%.

The distribution of the molybdenum in both types of cermet fuels appeared favorable to good heat transfer. The fibers were oriented predominantly in the radial planes of the pellet as a result of the uni-directional compaction during the hot-pressing operation. In the pellets made from the coated particles. a continuous network of molybdenum occurred as a result of the coating welding together during the hot-pressing operation. The test assembly contains eight fuel rods; three contain the  $UO_2$ -Mo fiber cermet, three contain the cermet produced from the coated particles, and two are for reference and contain the conventional sintered  $UO_2$  pellet fuel. The nominal outside diameter of the fuel rods is 1.308 cm (0.515 inch), and the clad wall thickness is 0.051 cm (0.020 inch). The cladding material is Type-304 stainless steel.

The fuel pellets were all centerless ground to achieve a uniform outside diameter and thereby control the pellet-to-clad diametral clearance within a range of 0.076 to 0.102 mm (0.003 to 0.004 inch).

Operation of the fuel rods will be at high specific power levels with surface heat fluxes of about 157 W/cm<sup>2</sup> (~500,000 Btu/h-ft<sup>2</sup>). The assembly was designed for a lifetime of 4.1 x  $10^{20}$  fission/cc (15,000 MWD/T) exposure.

#### I. INTRODUCTION

The operation of bulk  $UO_2$  in a fuel element could be restricted from high levels of specific power generation by the low thermal conductivity of the oxide. The fuel temperatures reached at these high power levels can be objectionably high from the standpoint of fuel element design. Two important temperature-dependent occurrences in this respect are fission gas release from, and thermal expansion of, the  $UO_2$ . An extreme case of thermal expansion results from the melting of the  $UO_2$  in the central region, where a volume increase of about 9.6% can be expected. <sup>(1)</sup> Fuel rods are normally designed to operate at conservative specific power levels at which the  $UO_2$  melting point is avoided and other temperature effects are small and can be accommodated.

3

To operate a fuel element in increased rating, or higher specific power density, without causing the melting point of the  $UO_2$  to be reached, one method is to improve the thermal conductivity of the bulk fuel. Substantial improvements in the bulk thermal conductivity can be made by additions to the bulk fuel. One such means involves the addition of a refractory metal which is dispersed throughout the oxide matrix. By using such a metal-oxide mixture which is made into dense cermet fuel, improvements in the thermal conductivity of about 300% have been achieved over the pure  $UO_2$  system. Molybdenum and niobium metals have been successfully incorporated into urania and thoria-urania fuels. <sup>(2, 3)</sup> The performance testing of cermet fuels containing these thermal conductivity improvers had not been conducted at high-power levels for long irradiation periods.

Further testing of this fuel concept was started in a Vallecitos Boiling Water Reactor (VBWR) test fuel assembly. This fuel assembly was fabricated for the AEC Fuel Cycle Program, Contract No. AT(04-3)-189, Project Agreement 11. In one phase of this program, fuel concepts that show potentials for improving fuel cycle economy through increased performance or lower fabrication costs are being irradiation tested in 12 special assemblies in the VBWR. Performance capabilities of these fuel concepts will be assessed in relation to those from the basic fuel assemblies which represent current fuel design and fabrication processes. <sup>(4)</sup> The assembly for demonstrating the performance of the thermal conductivity improvers is one of these 12 assemblies and is designated Special Assembly 9-L.

The objectives of the test were to operate the cermet fuels at high specific power levels for extended periods and to compare and evaluate their performances with those from the conventional sintered  $UO_2$  fuels. Periodic surveillance inspections of the fuel rods will be performed at convenient intervals during reactor shutdowns. Destructive examination of selected rods will be conducted at an intermediate exposure and the remaining rods continued to be irradiated to high exposures up to the design limit of  $4.1 \times 10^{20}$  fissions/cc (15,000 MWD/T) before they are also destructively examined. Irradiation which was started in the VBWR in September 1962, was prematurely terminated by shutdown of that facility in December 1963. The results of post-irradiation examinations will be presented in a subsequent report.

#### II. FUEL COMPACT DESIGN

#### A PREVIOUS WORK

Experimental work on improving the bulk thermal conductivity of urania and thoriaurania matrices by adding molybdenum or niobium metals were originally conducted by Paprocki, et al., <sup>(2)</sup> at Batelle Memorial Institute (BMI) and by Baskin et al., <sup>(3)</sup> at Argonne National Laboratory (ANL). The molybdenum and niobium metals used were in the form of fibers, fine powder, or as a thin coating on individual fuel particles. The amount of metal in the mixtures ranged from 10 to 30 vol %. Out-of-pile measurements of the thermal conductivity of such compacts demonstrated the vast improvements that could be achieved over unadulterated, sintered UO<sub>2</sub> compacts. These improvements were in the order of 300% and greater.

Subsequent irradiation tests conducted at ANL showed that niobium reacted with the  $UO_2$  at elevated temperatures.<sup>(5)</sup> Because of this reaction, the scope of the testing to be conducted in Special Assembly 9-L included only the molybdenum additives to the  $UO_2$  fuel.

The design and fabrication of the  $UO_2$ -Mo cermets for this irradiation experiment were conducted to take full advantage of the results obtained from the work described above. This, in addition to the experience on coated particles available commercially, minimized the selection and development procedures necessary to obtain the cermets for testing in this particular application.

5

#### **B. MOLYBDENUM ADDITIONS**

#### 1. Metal Content

The molybdenum content of the  $UO_2$ -Mo fuel compacts used in this program was chosen as 20 wt %. This amount is equivalent to 20 vol % in a compact with a density of 95% of theoretical. It is about the same amount of metal used in the cermets fabricated and tested by Paprocki, et al.<sup>(2)</sup>

By this duplication, it was possible to use the thermal conductivity data available in estimating the temperature distributions in the fuel compacts for a range of operating power generation levels. These estimates are useful in determining the optimum level at which the assembly should be operated to achieve the test conditions.

#### 2. Form and Distribution of the Metal Phase

Two types of cermet compacts were made. In one type, the molybdenum was added as fibers, and in the other, as a thin coating on individual  $UO_2$  particles. Of the three forms in which the molybdenum was added and tested previously, (1, 2) the two forms chosen for performance testing in this experiment were considered to represent the widest physical difference in the distribution of the metal phase.

In comparing the two forms of addition, it was seen that the molybdenum deposited originally as a coating on individual  $UO_2$  particles was distributed more uniformly throughout the final matrix. But, for a given amount of metal, this distribution is achieved at the cost of losing the wider metal paths. In contrast, the fibers each have a larger cross-sectional area, but larger volumes of  $UO_2$  without the metal are left between them.

6

It was intended that the fibers be randomly oriented in the mixture, as the cost of pre-orienting them in a radial direction before incorporating them into the matrix would have been prohibitive.

The use of coated particles has a possible additional advantage in retaining fission gases in each of the cells formed by the surrounding metal shell. However, this feature may be insignificant if the molybdenum additions in either form successfully keep the  $UO_2$  temperatures at levels where the fission gas release rates are inherently low.

#### 3. Shape of the Fuel Compacts

The  $UO_2$ -Mo fuel compacts were made into right cylindrical pellets so conventional rod-loading practices could be followed. The outside diameters of the pellets were specified to be centerless ground to give a diametral gap of 0.051 to 0.102 mm (0.002 to 0.004 inch). These clearances are within the nominal range used in current fuel rod design practices for cladding which is free standing.

#### 4. Reference Fuels

Regular sintered UO<sub>2</sub> pellets fabricated by conventional fuel fabrication methods were included in this test. These pellets were also centerless ground to give gap clearances that were the same as those for the cermet pellets. A direct comparison of their performances will be made on the basis of identical initial conditions.

In addition to these reference fuel rods in the assembly, the fuel rods being irradiated in Special Assembly 1-L, <sup>(6)</sup> will also be used for comparison. Conventional sintered UO<sub>2</sub> pellets are being operated to high power levels in the 1-L assembly. Actually, rod outside diameters and the clad wall thickness were purposely made identical in both assemblies to facilitate comparing the fuel performances.

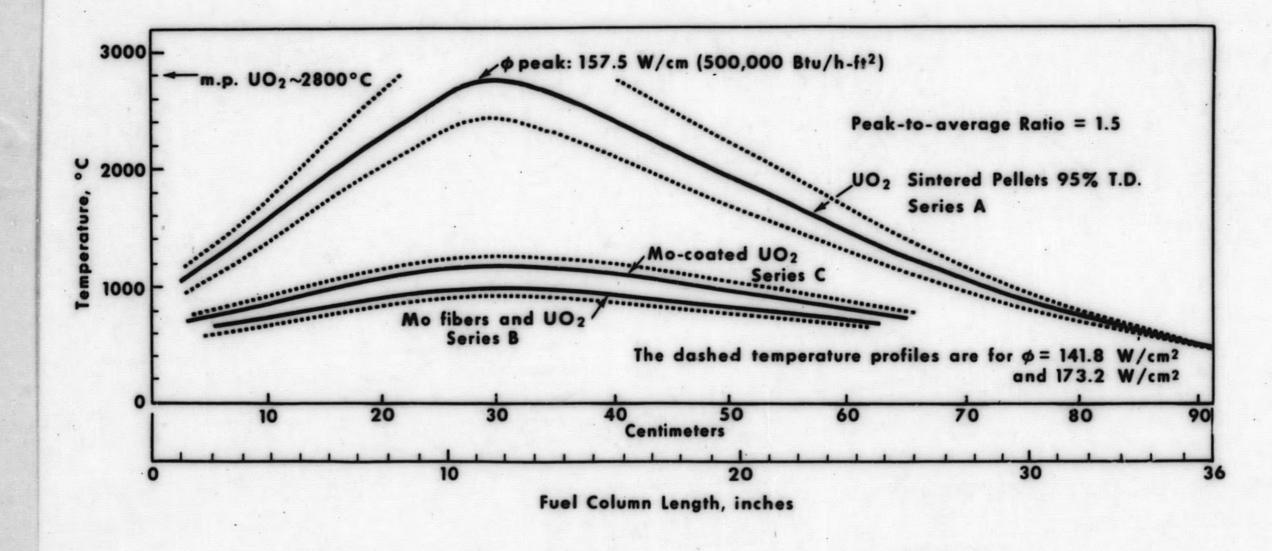

#### 5. Fuel Temperature Profiles

Estimates of the temperatures to be attained within each of the three types of fuels used in this experiment were made. Radial and axial temperature profiles were determined in each case. Three peak heat flux conditions were considered: 141.8, 157.5, and 173.2  $W/cm^2$ . A summary of the calculations is presented in the Appendix. It should be noted that while the best available data were used in these calculations, there are still uncertainties present in them, and the temperatures calculated should be considered as approximations.

Figure 1 shows the axial temperature profiles. Their general shape conforms to the power generation profile of fuel rods operated in the VBWR. A peak-to-average ratio of 1.5 to 1 was assumed. The profiles for the cermet fuels are shown to terminate short of the total fuel column. In these rods, the cermet fuel sections constitute about two-thirds of the column. The balance is made up of regular sintered  $UO_2$  pellets of a lower U-235 enrichment. The temperatures in each fuel section were calculated independently. Thus, transition profiles across the interfaces between the different types of fuels are not shown.

Figure 2 shows the radial temperature profiles determined for the three peak heat flux conditions. It can be seen from these two figures that the improvement in the bulk thermal conductivity, if brought about by the molybdenum additions as anticipated, would cause significant differences in the temperature reached in the sintered  $UO_2$  and cermet pellet fuels.

For the three peak heat flux conditions, the temperatures calculated to be reached in the sintered UO<sub>2</sub> fuel should result in appreciable grain growth extending from the center to about mid-radius. Melting can occur if the rods are operated at surface heat

.

fluxes greater than 157.5 W/cm (500,000  $Btu/h-ft^2$ ). Under the same operating levels, the temperatures in the cermet fuels, even under the highest level of the three heat fluxes studied, are comparatively low, and little, if any, structural changes are expected in the UO, phase.

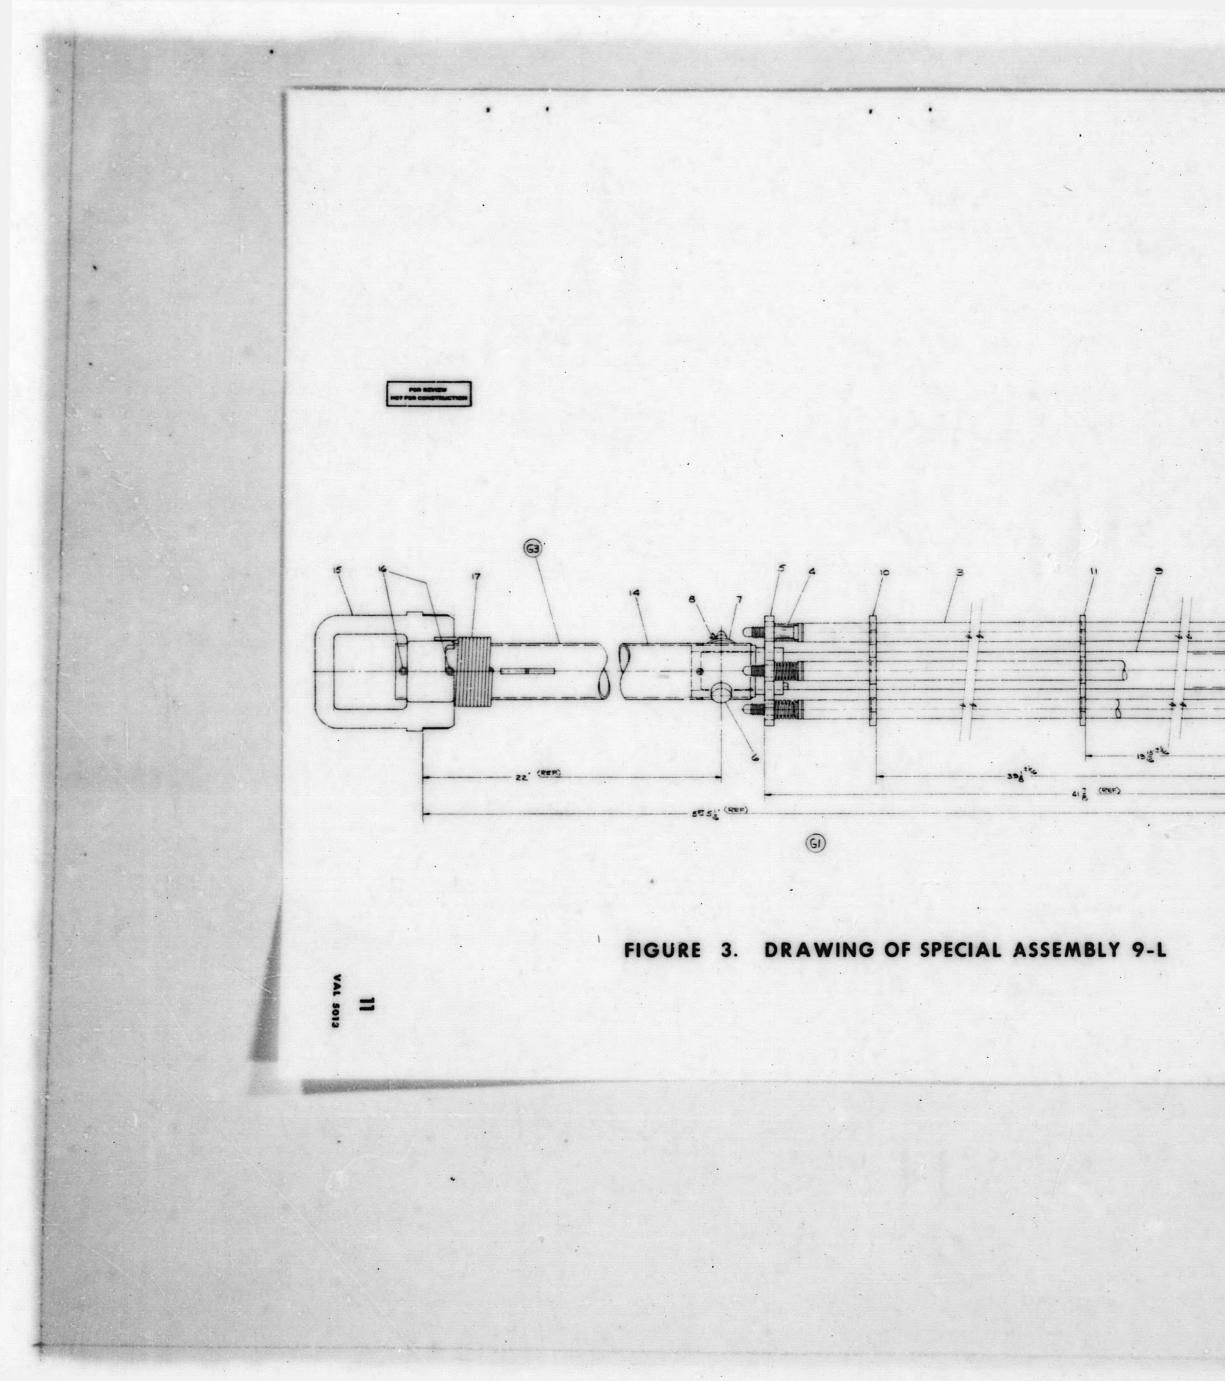

The evaluation of the performance of the cermet fuels will be based for the most part upon the microstructural differences that exist in the  $UO_2$ .

#### III. ASSEMBLY DESIGN

#### A. DESIGN CHARACTERISTICS

Figure 3 is an over-all view drawing of Special Assembly 9-L. The characteristics of this bundle are as follows. There are eight fuel rods in a modified 3 by 3 array, in which the center location is taken up by an empty tube. This tube serves to improve the hydraulic characteristics of the bundle so that the fuel rods can be operated at high surface heat fluxes. This tube is also used as the main structural member to which components, such as the bottom tie plate and two spacer plates, are permanently attached. Both ends of the tube are vented to keep it filled with water during operation so that a favorable water-to-fuel ratio is maintained.

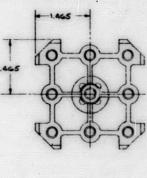

The handle extension and top tie plate can be readily disconnected from the frame so that individual fuel rods can be easily removed for inspection or replacement. This feature is illustrated in Figure 4.

#### B. FUEL ROD CHARACTER ISTICS

Externally, all the fuel rods are identical: internally, different types of fuel pellets and arrangements of these pellets are used. Figure 5 illustrates the arrangements of the three different types of fuels used in the rods.

The Type-I rods are the reference rods. The conventional sintered  $\mathrm{UO}_2$  pellets only are used. In the Types-II and -III rods, the cermet fuels make up approximately twothirds of the total fuel column. The middle of the cermet fuel sections were placed in the region where the heat fluxes are expected to peak.

To achieve this condition with the cermets made from the Mo-coated  $UO_2$  particles, it was necessary to use conventional pellets at the bottom to raise these sections. In each of the rods, a gas plenum about 8.9 cm (~3-1/2 inches) was provided above the fuel column to accommodate the fission gases generated and released by the fuel.

#### IV. MATERIALS

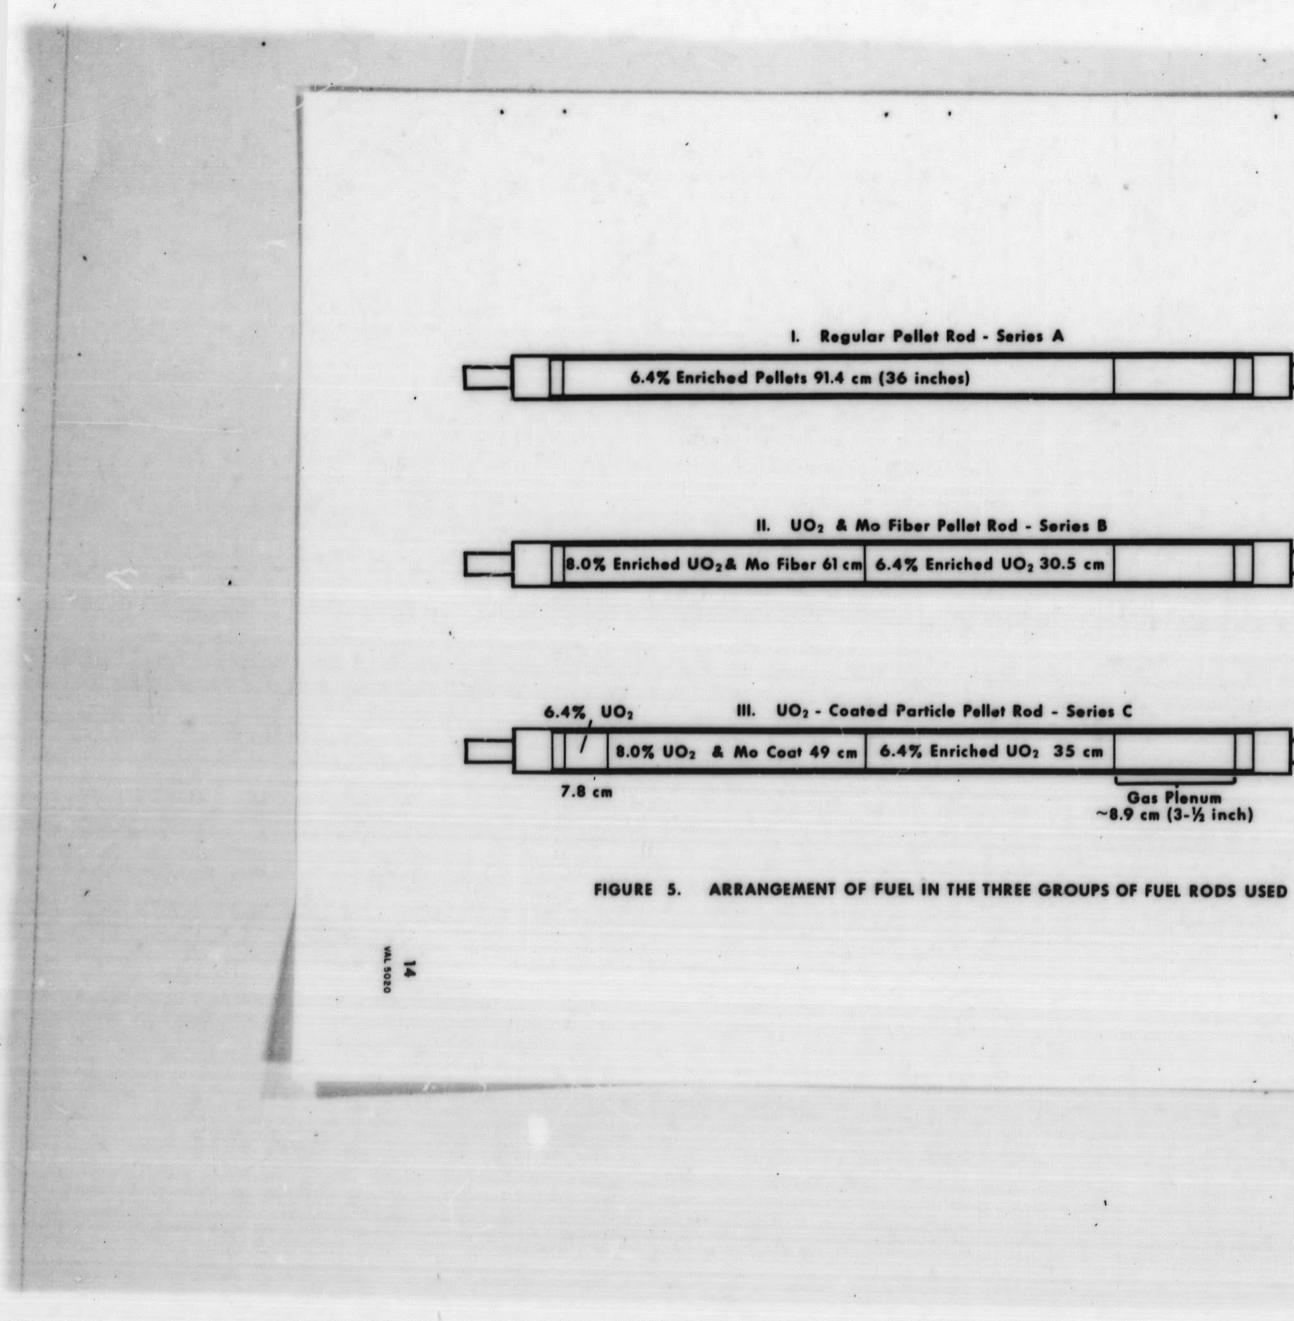

#### A. CLADDING

Type-304 stainless steel tubing was used as the cladding. The chemical analyses and mechanical properties data for this tubing are given in Table 1.

#### B. MOLYBDENUM FIBERS

The fibers were made from pure molybdenum wire 0.076 and 0.152 mm (0.003 and 0.006 inch) in diameter and cut to 0.8 cm (5/16) in length. Equal amounts of each size fiber were randomly mixed. Chemical analyses of the wires are shown in Table 2.

\*Spectrographic Analyses

16

## C. UO2

Ceramic grade  $UO_2$  was used for both the conventional sintered pellets and the cermet pellets. The  $UO_2$  enrichments were 6.4 and 8.0%, respectively. The higher enrichment compensates for the parasitic neutron absorption by the molybdenum in the cermet fuels, so that about equal power generation levels are achieved in both the pure  $UO_2$  and the cermet fuel pellets during irradiation. The high levels of U-235 enrichment were specified to provide sufficient reactivity so that the desired power levels could be reached in the rods when the bundle was placed in the outer regions of the VBWR core.

#### D. COATED PARTICLES

The specifications for the coated particles were based on an evaluation of data available in the literature. The particle size range was selected to be between 100 and 140 meshe, to achieve about the same degree of metal distribution throughout the final cermet compact. Since much of the development of coated  $UO_2$  fuel particles was in this size range, commercial capabilities to handle such particles was presumed to be good so that procurement of this material would be facilitated. It was decided to use essentially one particle size instead of a wider range of sizes, so that better control of the metal content and its distribution could be achieved.

The size range selected was also acceptable from the standpoint of the coating thickness required to obtain the desired metal content of 20 wt %. Calculations performed for estimating were based on the spherical configuration and showed that a coating thickness about 5 microns would be required.

The shape of the UO<sub>2</sub> particles was taken into consideration. Either spherical or angular particles could be used. While the deposits on spherical particles tend to be more uniform in thickness and their integrity much better. a higher cost is associated with the manufacture of the spherical particles. It was felt that the small variation in the thickness of the coating on angular particles would not seriously affect the objective of distributing the metal phase uniformly in the final cermet compact. Furthermoreit was believed that any discontinuities present in the deposit on the angular particle would weld shut during the hot pressing operation at elevated temperatures. Because it appeared that the se of the coated angular particles would be technically acceptable. it was decided to use them and to take advantage of their lower cost.

The coated particles were prepared from the 8% enriched ceramic-grade  $UO_2$  powder. Nuclear Materials and Equipment Corporation (NUMEC) of Appollo, Pennsylvania, was contracted to agglomerate the  $UO_2$  into dense particles and to coat them with molybdenum.

Figure 6 shows the appearance of the individual coated particles. The thickness of the film was measured to range from 1 to 3.3 microns, which was less than the thickness desired. By chemical analysis, the metal content was determined to be 16.7% by weight. The substrate  $UO_{2}$  had a density ranging from 95 to 97% of theoretical.

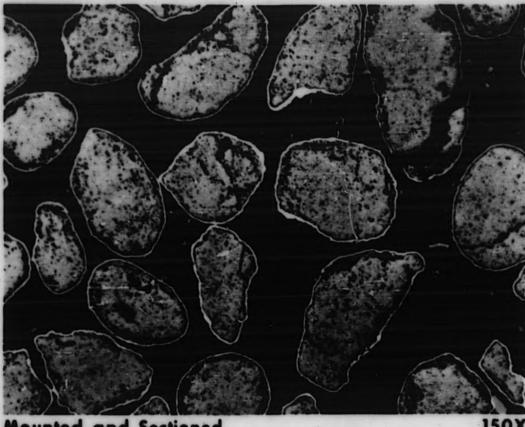

V. FABRICATION PROCEDURE - FUEL COMPACTS

#### A. METHOD OF COMPACTION

The  $UO_2$ -Mo mixtures were compacted in a vacuum induction hot press. It was necessary to use this method of compaction rather than the conventional sintering, procedure on pressed green compacts, because previous tests by Paprocki. et al. <sup>(2)</sup>

18

**Mounted and Sectioned** 

•

Substrate particle size, 0.149 to 0.105 mm (100 to 140 mesh); Mo coating thickness, 1 to 3 microns UO<sub>2</sub> density, 95 to 97% of theoretical; UO<sub>2</sub> enrichment, 8.0%

FIGURE 6. INDIVIDUAL MOLYBDENUM-COATED UO2 PARTICLES

showed that a dynamic compression on the mixture held at an elevated temperature was required to achieve the high bulk densities.

A description of the apparatus used for this compaction is presented by Hoyt. (7)Graphite dies were used in which compacts measuring 12.7 mm (0.5 inch) in diameter and from 2.54 to 3.81 cm (1 to 1-1/2 inches) long were produced.

#### B. HOT-PRESSING

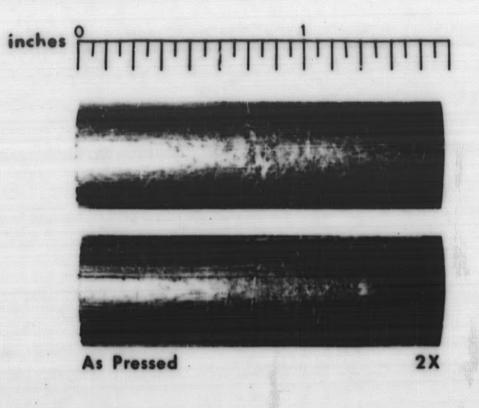

### 1. UO2-Molybdenum Pellets

The fuel pellets containing the molybdenum fibers were fabricated by weighing and mixing required amounts of fibers and  $UO_2$  powder for each charge (pellet) and loading them into the die cavity. The pressing was carried out at 1500° C (2732° F) at 5,000 psi for 30 minutes at temperature. The vacuum stabilized to 10<sup>-5</sup> torr during this operation.

Figure 7 shows the condition of the pellet surfaces in the as-pressed and centerless ground conditions. The distribution of the exposed ends of the fibers on the ground surfaces was uniform and indicates that the fiber distribution in the matrix was also uniform.

Confirmation of the favorable distribution and orientation of the fibers was obtained when sample pellets were sectioned. Figure 8 shows a cross section and a longitudinal section from a typical pellet. It can be seen that the fibers are oriented predominantly in the planes perpendicular to the pellet axis. The excellent contact between fibers and the  $UO_2$  should contribute favorably to good heat transfer (Figure 9).

The pellet structure was permeated with a network of fine cracks. which are clearly visible in the preceding photographs. The fibers served to reinforce this structure and

to hold the integrity of the pellet. There were no problems of the pellets disintegrating during the centerless grinding operation. The density of these pellets was a uniform 94 to 95% of theoretical, corrected for the molybdenum content.

#### 2. Coated-Particle Pellets

The hot pressing of the coated particles into compacts proved to be somewhat more difficult. It was found that high densities could not be achieved in the compacts pressed at 1500° C. As a corrective measure, the temperature was raised to 2200° C (3992° F). This change in practice increased the bulk density to 96% of theoretical. However, at this higher temperature, the pellet surface reacted with the graphite dies and made it impossible to remove the pellet except by breaking the dies. Therefore, further compaction at this temperature was stopped. A compromise temperature of 1700° C (3092° F) was chosen to permit a higher pellet yield per set of dies, although the bulk density of the pellets was lowered to an average of 89% of theoretical. The die pressure was 5000 psi and the duration of the pressing operation was 30 minutes at temperature. A vacuum of 10<sup>-5</sup> torr was maintained during this period.

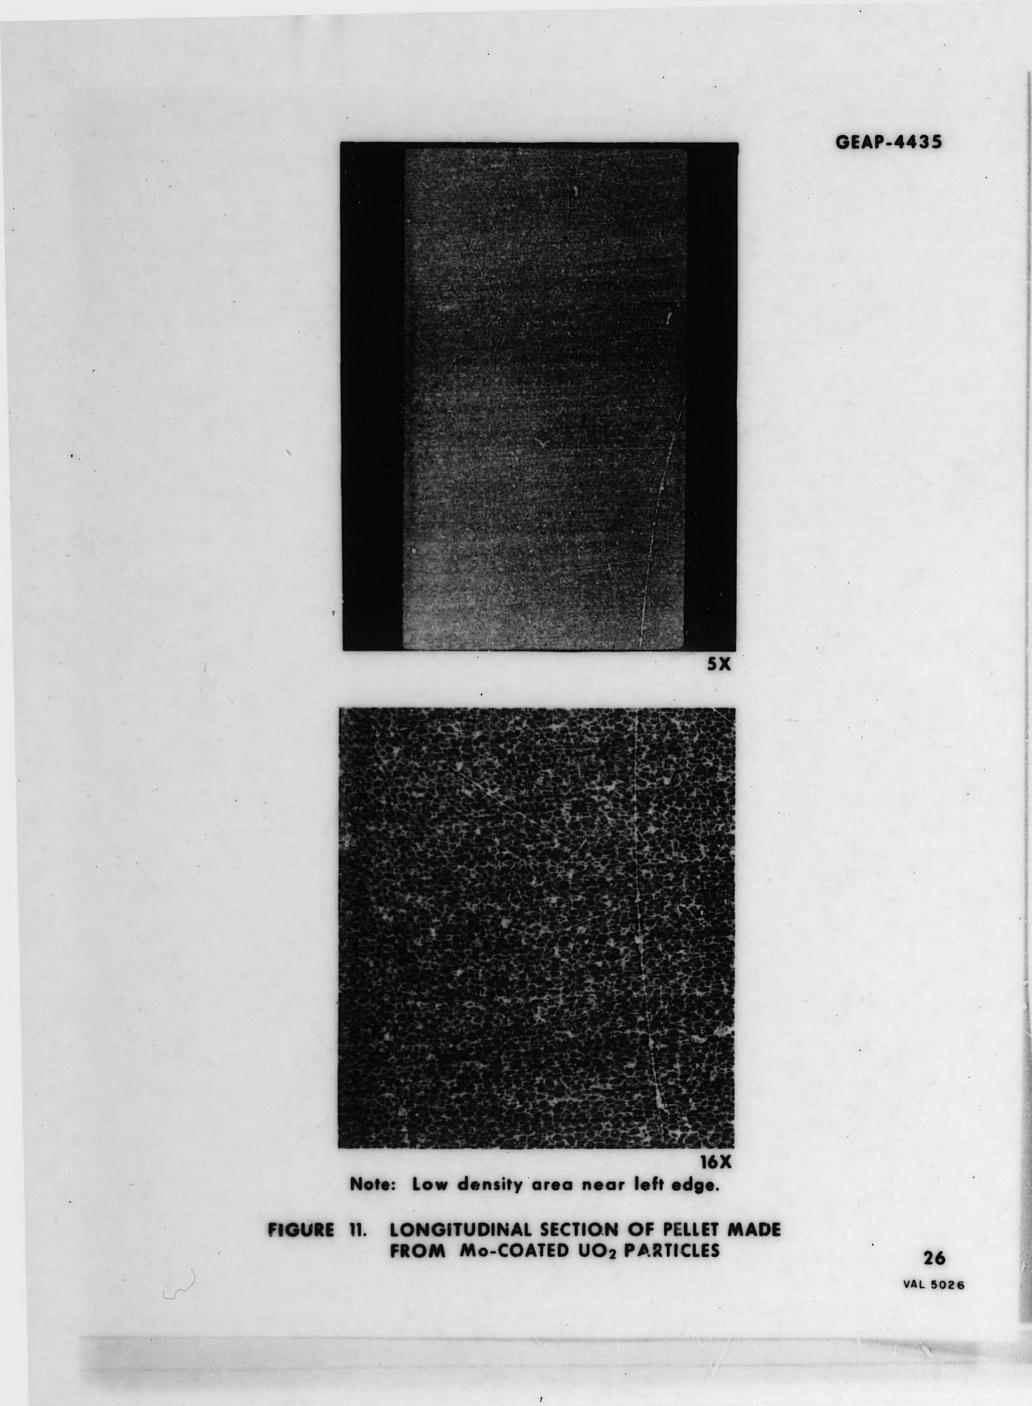

Figure 10 shows the appearance of the pellet surface in the as-pressed and centerless gound conditions. The ground surfaces were smooth and the UO<sub>2</sub> exposed by the grinding remained intact.

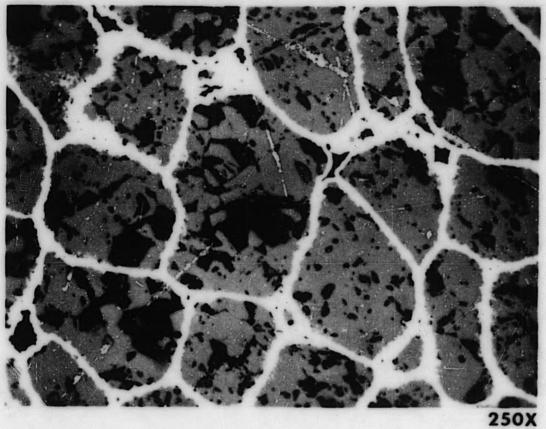

Internally, the structure consisted of continuous networks of metal heat paths, as shown in Figure 11 and 12. The continuity in the heat paths was enhanced by the molybdenum coating welding together. The large voids present in the  $UO_2$  shown (Figures 11 and 12) are pull-outs from the mount preparation and not voids in the original  $UO_2$ particles. Voids between the particles are also present and varied in amount among

### FIGURE 10. HOT-PRESSED PELLETS MADE FROM Mo-COATED UO2 PARTICLES

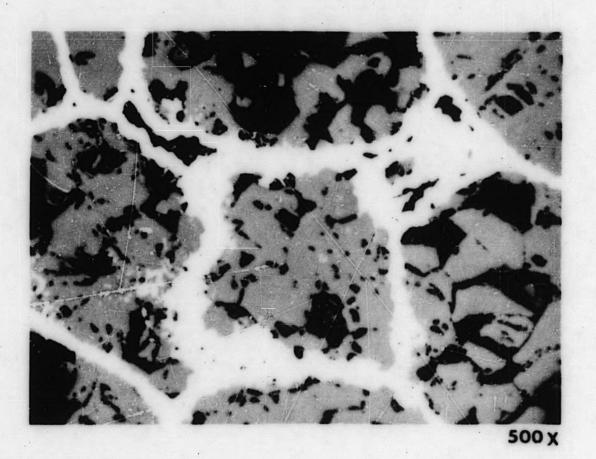

FIGURE 12. REGION OF HIGH DENSITY IN PELLET MADE FROM HOT-PRESSED COATED UO2 PARTICLES

the pellets; these voids were the chief reasons for the variation in the pellet densities. Figure 13 shows an area where the density is low.

# C. CONVENTIONAL SINTERED UO2 PELLETS

The conventional sintered  $UO_2$  pellets were fabricated by the standard procedure in which green compacts were sintered at 1650°C in a hydrogen atmosphere. The density of these pellets was from 95 to 97% of theoretical. The chemical analyses of these pellets are shown in Table 3.

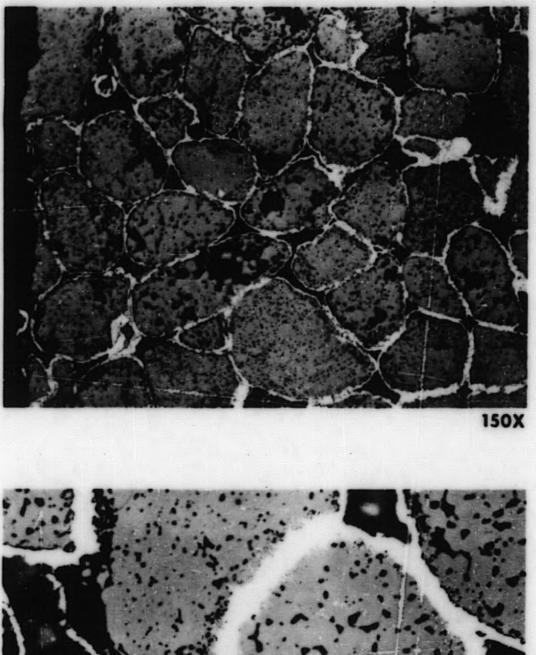

FIGURE 13. REGION OF HIGH VOID CONTENT IN LOW DENSITY HOT-PRESSED PELLET MADE FROM COATED PARTICLES

#### D. GENERAL DESCRIPTION OF THE RODS

Each of the three different types of fuel was kept separated in individual rods. The arrangement of these fuels within the rods was slightly different (Figure 5). The reason for shortening the cermet fuel column was to conserve the high cost fuel containing the molybdenum. For the tests. it was sufficient to place a short fuel column of this type fuel in the peak heat flux region. In the following sections the fabrication procedure followed and the data recorded for each of these fuel rods are described.

#### 1. Reference Fuel Rods

The two reference (Series A) fuel rods were filled with conventional, sintered, 6.4% enriched UO, pellets. Each fuel rod was identified by metal stamping a letternumber combination on the bottom end plug stud (Figure 4a). The outside diameter of the pellets used in these rods was ground to within the tolerance of 1. 194 to 1. 196 cm (0.470 to 0.471 inch). Before loading the pellets into the tubes for each rod, they were placed in a V-trough; the diameter of the first or bottom pellet and of every tenth pellet was measured. Two measurements, 90 degrees apart, were made on each of these pellets: the length of the fuel column was also measured. The measurements are given in Table 4.

TABLE 4. Diameter Measurements of UO<sub>2</sub> Pellets in Series A Rods

Pellet	Rod A-1	Rod A-2
1	0.4705	0.4702
10	0.4705	0.4702
20	0.4705	0.4708
30	0.4705	0.4715
40	0.4698	0.4710
50	0.4698	0.4709
60	0.4705	0.4708
70	0.4712	0.4712
	Fuel Column Length, inches	
•	37-7/8	35-3/4

30

The inside diameter of the tubing was actually 1.204 cm (0.474 inch). The diametral clearance between the pellet surface and the inside surface of the clad was 0.076 to 0.102 mm (0.003 to 0.004 inch). All the pellets used were free from cracks and chips. Additional details on the rods are given in a tabulated summary at the end of this report.

#### 2. Rods Containing the Fuel with the Fibers

The three Series B rods contain the pellets with the molybdenum fibers. Only two-thirds of the fuel column in each of these rods is filled with the  $UO_2$ -molybdenum pellets. The remaining upper third is filled with conventional. sintered 6.4% enriched  $UO_2$  pellets.

Each rod contains 16 molybdenum-bearing pellets and 23 conventional pellets. Diameter measurements were taken of each of the cermet fuel pellets, and of the first and then of every tenth conventional pellet. The location or elevation of the pellet interfaces of the cermet fuel with respect to the bottom of the fuel column was also measured. The results are given in Table 5.

The diametral clearance between the pellet surface and the inside surface of the cladding was between 0.05 to 0.07 mm (0.002 to 0.003 inch) over the cermet fuel column, and 0.05 to 0.102 mm (0.002 to 0.004 inch) over the conventional fuel column. Additional details on these rods are given in a tabulated summary at the end of this report.

#### 3. Rods Containing the Coated Particle Fuel

The three Series C rods\* contain the pellets made from the coated particles. The fuel column in each of these rods also contains both the special and conventional

Rod C-3 was fabricated as a substitute for Rod C-4. which was not completed when the assembly was inserted into the VBWR core. The C-3 was subsequently replaced by C-4 in late December. 1962 after operation at a low power level for one VBWR cycle. Rod C-3 contained conventional sintered UO, pellets of 5.46% enrichment. Since C-3 is not part of the test program. it will not be described further.

fuels. As shown previously in Figure 5. the bottom 7.8 cm ( $\sim$ 3 inches) is filled with the conventional fuel to raise the cermet fuel column so that the midpoint of this section is in the peak heat flux region of the rod.

Since their densities were not uniform, the pellets made from the coated particles were segregated according to their bulk densities and then distributed among the three rods so that in each of the three cermet fuel zones formed. the pellets could be arranged in a cosine-type density distribution. The middle of each zone had the highest density pellets and was placed in the peak heat flux region. The pellet diameters and interface locations were measured. These measurements and the pellet densities are presented in Table 6.

The outside diameters of all the pellets in these three rods were within the tolerance of 0.470 to 0.471 inch leaving a pellet-to-clad diametral clearance of 0.07 to 0.102 mm (0.003 to 0.004 inch). There were three undersized molybdenum-bearing pellets which could not be ground uniformly. The dimensions of these pellets are referenced in Table 7 by an asterisk. Additional details on these rods are given in the tabulated summary.

#### 4. Final End Closure

All the loaded tubes were evacuated in a weld chambor to less than  $10^{-3}$  torr and back-filled with reactor grade helium to 1 atm. The top end plugs were then welded to complete the fabrication. The completed rods were tested for leaks in a belium mass spectrometer leak detector and x-rayed as a final check before they were assembled into the fuel bundle. Figure 14 shows the arrangement of the fuel rods in the assembly.

#### ACKNOW LEDGMENTS

Many thanks are extended to E.W. Hoyt and J.R. Balch for producing all the hot-pressed pellets. The contributions of R. Becker, T. Tillinghast, and J. Worthington are appreciated.

#### APPENDIX

#### CALCULATIONS PERFORMED TO ESTIMATE OPERATION TEMPERATURES OF CERMET FUELS USED IN SPECIAL ASSEMBLY 9-L

Estimates of the operating temperatures to be reached in the  $\text{UO}_2$  and the cermet fuels used in Special Assembly 9-L were calculated. A summary of the calculations performed is presented.

The radial temperature profiles at the peak heat flux region of the fuel rods and the axial centerline temperature profiles were calculated for three peak heat flux conditions:  $\phi = 141.8$ . 157.5. and 173.2 W/cm<sup>2</sup>. The profiles were determined for the sintered UO<sub>2</sub> pellets in the reference rods. the UO<sub>2</sub>-molybdenum fiber mixture. and the pellets made from the UO<sub>2</sub> particles coated with molybdenum.

The calculations were performed in two parts. In Part 1 calculations for estimating the thermal conductivity of the cermet fuels were made. In Part 2 calculations were made of the temperature distribution. Each part is summarized in the following paragraphs.

# THERMAL CONDUCTIVITY FOR THE UO2-MO CERMET FUELS

Thermal conductivity values of  $UO_2$ -Mo cermet fuels up through the temperature of about 1600°C were not available. A suitable theoretical model for calculating the thermal conductivity values for such mixtures also was not available. In the absence of a model. and because of the dependence of the thermal conductivity upon the metal content and the structure of the mixture. accurate values of thermal conductivity can be obtained only by actual measurement of the mixtures in each particular case.

Thermal conductivity measurements of the cermet fuels used in this experiment were not included in this program. In lieu of these measurements, it was planned to use the values reported by Paprocki, et al., \* for similar UO<sub>2</sub>-molybdenum mixtures. The molybdenum contents in the fuel compacts were thus specified to be the same as the BMI compacts, i.e., 20 vol % molybdenum.

In actual practice, however, this target amount of molybdenum was not achieved, particularly in the compacts made from the coated particles. Because of this condition and the need to obtain conductivity values for temperatures beyond those reported, it was decided to calculate the thermal conductivity based on a weighted average procedure. A homogeneous mixture of the  $UO_2$  and molybdenum components was assumed. In this case, the effects of the two different forms in which the molybdenum was added. i.e., as fibers and as coating, were not differentiated. Variations in the metal content only were then taken into account by this procedure.

The curves obtained by plotting the results of calculation from this procedure were modified further to bring them into conformance with the reported values for the lower temperature range. In effect this adjustment was an arbitrary means to compensate for deviations from the ideal case of a perfectly homogeneous mixture.

The thermal conductivities were calculated by

<sup>k</sup>mixture = <sup>k</sup>UO<sub>2</sub> x vol % UO<sub>2</sub> + <sup>k</sup>Mo x vol % Mo.

Paprocki, S. J., et al., "Preparation and Properties of UO<sub>2</sub> Cermet Fuels," BMI-1487, December 19, 1960.

Thermal conductivity values of pure molybdenum were obtained from the "Rare Metals Handbook." Thermal conductivity values of 95% T.D. sintered UO<sub>2</sub> were obtained from M. F. Lyons. \*\*

Figure A-1 shows the thermal conductivity curves for the Series B and C fuel compacts used in this experiement. The Series B compacts contain 20 vol % molybdenum, and the Series C, 15.8 vol % molybdenum.

Two curves taken from Paprocki are shown in Figure A-1. These curves were for compacts having 20 vol % molybdenum. The B' and C' curves show the adjustments made: the referenced curves were used as guides.

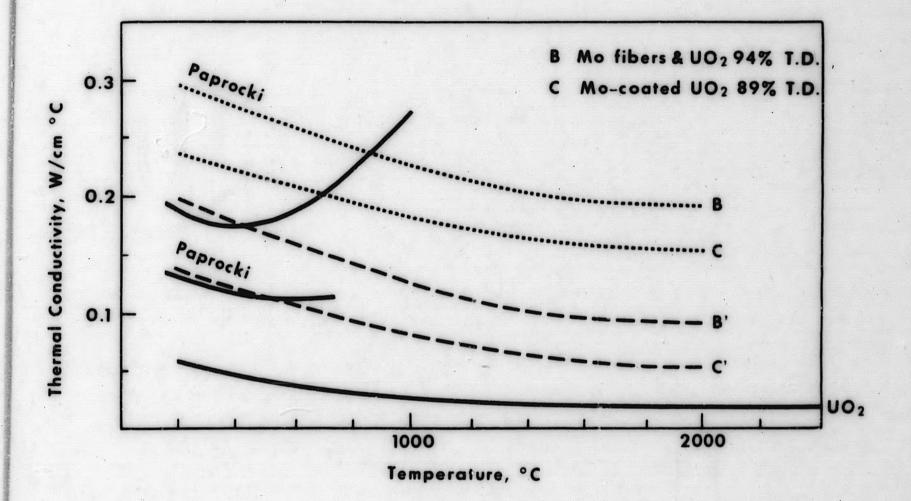

A sharp rise in the thermal conductivity at the higher temperatures is shown for one of the reference curves. A similar kind of trend, though not as pronounced, was reported by Baskin, et al., <sup>\*\*\*\*</sup> for thoria-molybdenum fiber compacts. A possible reason given for this behavior was the closing of gaps between the metal and oxide phases and also the closing of cracks in the UO<sub>2</sub> to increase the heat transfer through the compact. This behavior would probably raise the B' and C' curves from 1000°C. In the traces shown, curves B' and C' do not account for this trend and therefore are believed to be conservative estimates in this respect.

42

The B' and C' curves were replotted on semilog paper and expressions of the thermal conductivity were derived in terms of temperature. For simplification, a straight line function was fitted up to about 1600 C. Preliminary calculations showed that the maximum temperature in these cermet fuels would not exceed this temperature at the operating surface heat fluxes of the rods. The

$$\int_{0}^{T} k dT$$

for T = 0 to T = 1600 values were calculated using these expressions and plotted as shown in Figure A-2. The  $\int kdT$  curve for pure UO<sub>2</sub> is plotted also. \* These were the curves used to calculate the tmperature distribution in the fuels.

TEMPERATURE PROFILE CALCULATIONS

#### **Axial Profiles**

Gross power distribution from the fuel rod was assumed to be as shown in Figure A-3. A peak-to-average ratio of 1.5 to 1 was assumed. The axial profile was determined by calculating the average centerline temperature of 12 equal segments of the fuel rod. The average heat flux in each of these 12 segments was determined by proportion using the gross power distribution assumed. This procedure was repeated for each of the three peak heat flux conditions investigated.

The fuel surface temperatures were calculated using the following thermal resistances. The calculations were performed in English units; sample calculations shown here are shown in these same units. The final results were converted into metric units for plotting in graphs.

$$\pi$$
k  
= 11.58 x 10<sup>-4</sup> Btu/h-ft<sup>2</sup>-° F

.

where r is clad radius and k is thermal conductivity of stainless steel equal to  $11.1 \text{ Btu/h-ft}^2 - \text{c} \text{ F}.$ 

R gap = 
$$1/hA_i$$
  
= 80.70 x 10<sup>-4</sup> Btu/h-ft<sup>2</sup>-°F

where h is gap conductance equal to 1000 Btu/h-ft<sup>2</sup>- $^{\circ}$  F.

 $T_{fuel surface} = 546 + A \Sigma R \phi$ = 546 + 13.45 x 10<sup>-4</sup>

where  $\phi$  is heat flux (Btu/h-ft<sup>2</sup>).

Power generation was assumed to be the same in both the sintered  $UO_2$  and cermet pellets. A parabolic distribution within the fuel was considered. The centerline temperatures determined for each incremental length were plotted for each of the three heat flux conditions. The axial temperatures are shown in Figure 1.

## Radial Profiles

The radial profiles were calculated for the three peak heat flux conditions only in each type of fuel. A parabolic distribution of the power was considered. The temperatures are plotted in Figure 2.
