ABSTRACT

Analytic elimination of the two magnetic surface components of the
displacement vector permits the normal mode ideal MHD equations to be reduced
to a scalar form. A Galerkin procedure, similar to that used in the PEST
codes, is implemented to determine the normal modes computationally. The
method retains the efficient stability capabilities of the PEST 2 energy
principle code, while allowing computation of the normal mode frequencies and
eigenfunctions, if desired. The procedure is illustrated by comparison with
earlier various of PEST and by application to tilting modes in spheromaks, and
to stable discrete Alfvén waves in tokamak geometry.

MASTER
§1. INTRODUCTION

Ideal MHD linear stability codes [1-3] have played an important role in helping to assess the stability properties of axisymmetric toroidal plasma configurations. As practical tools they are used on a daily basis at major tokamak laboratories to aid in the design of new experiments and in the analysis of experimental data. Since these applications frequently involve parameter surveys and, therefore, the running of many cases, a number of different versions of the codes exist. These take advantage of various optimizations that can be made when the interest is focused on specific stability issues. Additional improvements have occurred because the increased understanding of the nature of the instabilities, much of which has come from the computational studies, has led to various improvements in the numerical methods.

The necessity of carrying out some of these enhancements led to the development of PEST 2 [4], a code designed primarily to enable rapid computation of stability boundaries in parameter studies. This was achieved by the reduction of $\delta W$ to a scalar form involving only one component of the displacement vector, $\xi$, thereby reducing the size of the matrix eigenvalue problem which has to be solved numerically to determine stability. In addition to the factor of 10-50 reduction obtained in typical execution times, improvements in the numerical representation of $\xi$ greatly improved the convergence of the representation, so that for normal operation the time-consuming convergence studies can frequently be forgone [5].

While this procedure, which is basically a numerical treatment of the Energy Principle [6], is well-suited for studying many stability issues, it has a major shortcoming in that it does not provide accurate estimates for the growth rates or eigenfunctions of the unstable normal modes. These can be
valuable in attempting to make comparisons with experimental measurements and in assessing the need to include additional physics effects to the MHD model.

In the PEST 2 approach, the potential energy functional, \( \delta W(\xi^*, \xi) \), was minimized subject to the constraint \( \int d\xi^* \rho^* \xi = 1 \), with tensor density, 
\[
\rho = \rho(\psi) \frac{\nabla \psi}{|\nabla \psi|^2},
\]
rather than just the usual scalar, \( \rho(\psi) \). Close to marginal stability, comparisons with the PEST 1 code showed that this procedure often gave approximations to the component \( \xi \cdot \nabla \psi \) with many of the correct qualitative features of the true solution. However, the eigenvalue estimate, \( \omega^2 \equiv \text{extremum} \frac{\delta W(\xi^*, \xi)}{\delta \xi} \), has no relation (other than the sign) between the two norms.

Since many of the instabilities of interest have the property that \( \xi \cdot B \) and \( \nabla \cdot \xi_1 \) are very small, a "test function" approximation to \( \omega^2 \) can be easily obtained from the PEST 2 calculation of \( \xi \cdot \nabla \psi \). The approximation \( \nabla \cdot \xi_1 \approx 0 \) is used to find the \( B \times \nabla \psi \) component of \( \xi \), which is then added into an improved estimate of the kinetic energy form, \( \int d\tau |\xi_1|^2 \). Then \( \omega^2 = \frac{\delta W(\xi^*, \xi_1, \xi_\psi)}{\delta \xi} |\xi_1|^2 \). An implementation of this technique showed that, for a variety of straightforward instabilities, growth rate estimates with errors of the order of 10-20% could be obtained. However, since the approximations are not good away from marginal stability or for small aspect ratio cases (where \( \xi \cdot B \) and \( \nabla \cdot \xi_1 \) are not necessarily small), such an approach has only limited value. Moreover, since the calculation of \( \delta W \) is done with considerably more accuracy, it is not at all aesthetically pleasing to have to rely on such an approximation.

The PEST 2 approach can, however, be straightforwardly generalized to obtain nonlinear eigenvalue formulation of the complete normal mode equations, which is of similar scalar form involving only the single component, \( \xi \cdot \nabla \psi \), of the displacement vector. This is the subject of this report. We briefly
describe the algebra involved and present the eigenvalue problem in the next section. In §3 a discussion of the numerical methods used to solve the equations is presented. Examples, illustrating the technique, are given in §4.

§2. FORMULATION

The procedure we follow to reduce the normal mode equations to an eigenvalue problem involving only one dependent variable is analogous to that carried out in cylindrically symmetric systems, where the components \( \xi_\theta, \xi_z \) are eliminated to give a second-order, differential equation for \( \xi_r \) \[7\]. The algebraic steps are, however, more complicated because of the coupling of different poloidal harmonics which occurs in toroidal geometry. The procedure depends on the fact that the two magnetic surface components of \( \xi \) can be eliminated surface-by-surface, involving only the inversion of surface operators, since in the appropriate coordinates no radial derivatives of these components occur in the original Euler equations. Because of this, it is essential to employ a flux coordinate system and to adopt an appropriate decomposition of \( \xi \) to obtain a form useful for numerical work.

The basic equations we begin with are the linearized normal mode equations of ideal MHD \[6\]

\[-a^2 \rho \xi = g(x)\]

where the displacement \( \xi(x,t) = \xi(x)\exp(i\omega t)\),

\(\xi(x,t) = \xi(x)\exp(i\omega t)\)
\[ F = \left[ \nabla \times (Q + \xi_n \n \times \n) \right] \times \n - \n [\n \times n \cdot (Q + \xi_n \n \times \n)] \]

\[ + 2u|\n| \xi_n + 2(\gamma p \mathbf{T} \cdot \xi) \]

\[ \psi = \n \times (\xi \times \n), \quad n = \n / |\n|, \quad \xi_n = \xi \cdot n, \quad \n = \n \times \xi \]

\[ 2u = 2p' k_s + \sigma^2 B^2 / |\n| \cdot B - (q(B \cdot B) / B^2) \]

\[ \text{with } \sigma = J \cdot B \cdot B^2 \text{ and } k_s = B \times s \cdot (B / B \cdot V / B / B) / B^2. \]

In Eq. (2) through (4) we adopt the generalized PEST coordinate system \( (\psi, \theta, \xi) \) with Jacobian, \( \mathcal{J} = |\n \times \n / \n / \n|^{-1}. \)

\[ B = \n \times \n \n + q \theta \phi \hat{\xi} = \xi \times \n \]

\[ \text{with } s = \n \phi - q \n. \]

The safety factor, \( q(\psi) \), is given by

\[ q(\psi) = g(\psi) <f / x^2> \]

\[ \text{where } g(\psi) = x^2 B \cdot V \psi, \text{ and } < > \text{ denotes a surface average. The generalized toroidal angle } \xi \text{ is related to the usual angle } \phi \text{ by } \xi = \phi - q \delta(\psi, \theta) \text{ and satisfies} \]

\[ \delta \delta(\psi, \theta) = (g f / q x^2) - 1 \]
In Eq. (4), and throughout, a prime denotes differentiation with respect to $\Psi$.

Following previous work, we write

$$\xi = \xi \Psi B \times \frac{s}{B^2} + i \xi B \times \frac{\Psi B}{B^2} + i \xi B s \times \frac{\Psi B}{B^2}$$

so that the two surface components of Eq. (1) (obtained by taking the scalar products with $B$ and $B \times \frac{\Psi B}{B}$) can be written

$$-i \omega^2 \rho \xi_B = B \cdot \nabla (\gamma \frac{\Psi}{B} \cdot \xi)$$

and

$$-\omega^2 \rho [i |\Psi|^2 \xi_S + (s \cdot \frac{\Psi}{B})\xi^\Psi] = -B \Psi \cdot \nabla \times (q + \xi n \times n)$$

$$+ B \times \Psi \cdot \nabla (\gamma \frac{\Psi}{B} \cdot \xi)$$

To take advantage of algebraic simplifications which occur in the detailed analysis, we introduce new variables,

$$\xi_B = \left( i \xi B \left( s \Psi \times \frac{s}{B^2} + \frac{\Psi}{B} \cdot \frac{s}{B} \right) \exp(\imath q \delta) \right)$$

$$\xi_S = \left[ \xi_S + \imath (q \delta) \cdot \xi^\Psi \right] \exp(\imath q \delta)$$

and

$$\xi^\Psi = \xi^\Psi \exp(\imath q \delta)$$

(11)
and solve Eq. (9) and (10) to express $\xi^b$, $\xi^s$ in terms of $\xi^\psi$.

The algebraic steps are straightforward, but tedious. In the following we present the results for the case of an axisymmetric toroidal equilibrium, which allows some simplification since we can write $\xi(x) = \xi(\psi, \theta) \exp(-in\zeta)$ and consider each toroidal harmonic, $n$, separately. The procedure can obviously be generalized to any configuration with nested flux surfaces. We find that Eq. (9) can be written in the form,

$$\pi_0 \xi^b = \pi_1 \xi^s + \pi_2 \xi^\psi$$

where the operators $\pi_1$ are

$$\pi_0 = -\rho \omega^2 \frac{\partial^2 \phi}{(\gamma_p)} + \pi$$

$$\pi = \ing \phi / x^2 + n^2 g^2 \phi / x^4 + \ing \delta_{gg} + (2\ing \phi / x^2) a_g - a_g a_{-1} a_g$$

$$\pi_1 = \ing^2 \phi / x^2 - n a_g - i\pi \phi / (\phi^2)$$

and

$$\pi_2 = -\rho \omega^2 \frac{\partial^2 \phi \cdot \phi \gamma / (\gamma_p)} - \ing \phi / x^2 + a_g a_{-1} a_g - (2\ing \phi / x^2) \phi + a_g a_{-1}$$

Similarly, Eq. (10) yields

$$\Gamma_0 \xi^b = \Gamma_1 \xi^s + \Gamma_2 \xi^\psi$$

with
\[ r_0 = i|\psi|^2(\omega^2/B^2 - n^2/x^2) + i\int^{-1}\partial_\theta x^{2}/\theta^{-1}\partial_\theta - i\gamma n^2|\psi|^2/(x^2 B^2) \]

\[ -\gamma n g/(B^2)\partial_\theta - i\gamma g/(B^2) \]

\[ r_1 = -\gamma [g^{-1}\partial_\theta - \partial_\theta g]/[\partial_\theta - \partial_\partial g] + \left(\ln|\psi|^2 - g^2/x^2\right) \partial_\theta \]

\[ + \ln|\psi|^2\partial_\theta/x^2 + n^2 g|\psi|^2/x^4/B^2 \]

\[ r_2 = \rho x^{2}/g \ln|\psi|^2/(x^2 B^2) - \ln(x^2 p + gg')/x^2 - n^2 g|\psi|^2/x^4 \]

\[ -\gamma g/(B^2)\partial_\theta^2 - \gamma g/(B^2)\partial_\theta^2 - (g x^2/\partial^2) \partial_\theta^2 - \gamma g/(B^2) \partial_\theta^2 (\partial_\theta^2/\partial x^2) \partial_\theta \]

\[ + g^{-1}[\partial_\theta x^2/\partial x^2] \]

In these expressions we have adopted the notation that subscripts with respect to \( \theta \) represent \( \theta \)-derivatives of equilibrium quantities; thus, for example, \( \theta \partial_\theta \equiv \partial_\theta \). Also, all explicit \( \psi \) and \( \theta \) derivatives act on whatever quantities appear to the right.

The formal solution of Eqs. (12) and (17) gives
\[ \xi^b = \pi^{-1}_0 (\pi_x + \pi_2) \xi \equiv \phi \xi \quad , \]  
\[ \xi^b = \pi^{-1}_0 (\pi_x + \pi_2) \xi \equiv \phi \xi \quad . \]  

Inspection of the explicit forms for these operators show that derivatives with respect to \( \psi \) occur only in \( \pi_2 \) and \( \Gamma_2 \), so that \( \xi^b \) and \( \xi^b \) can be formally eliminated by inverting operators which involve only derivatives in the magnetic surfaces.

To proceed further, we follow the variational formulation of the normal mode equations; i.e., we extremize the quadratic form [4]

\[ \delta \omega = \int \frac{d\tau}{\rho} (|Q + \psi^B \times \psi^B| |\psi^B|^2)^2 + \int \frac{d\tau}{\rho} (|V \cdot \psi^B|^2 - 2U |\psi^B|^2) + \int \frac{d\tau}{\rho} (|A^B|^2) , \]  
\[ \tag{23} \]  
where \( A \) is the vector potential for the perturbed vacuum magnetic field, subject to the norm \( \int \frac{d\tau}{\rho} |A|^2 d\tau = 1 \). From Eqs. (8) and (11) we find

\[ |\xi|^2 = \left[ (1 + g^2 \mathcal{I}^2(\psi_\theta \cdot \psi_\theta)^2, x^2, \mathcal{E}_1^2) + |\psi^B|^2 \right] |\psi^B|^2 - \mathcal{I}^2 \mathcal{I}^2 (\psi^B \psi^B - \xi \psi^S) / x^2 \]  
\[ + |\psi^B|^2 |\xi|^2 / x^2 + |\xi|^2 / x^2 \]  
\[ \tag{24} \]  
\[ |Q + \psi^B \times \psi^B| |\psi^B|^2 = |A_1 \psi^B|^2 / |\psi^B|^2 + |A_2 \psi^B|^2 / |\psi^B|^2 + |A_3 \psi^B|^2 / |\psi^B|^2 \]  
\[ \tag{25} \]  

with
\begin{align}
\Lambda_1 \xi^\psi & = \mathcal{G}^{-1} (\partial_\theta - \text{i} n q) \xi^\psi \\
\Lambda_2 \xi^\psi & = \left[-g \frac{\nabla \psi \cdot \nabla \psi}{x^2} (\partial_\theta - \text{i} n q) + \frac{n |\nabla \psi|^2}{x^2} \mathcal{G} \right] \xi^\psi \\
& \quad + \frac{1}{x^2} \exp(-\text{i} n q \delta) \partial_\theta \chi \exp(\text{i} n q \delta) + \frac{n |\nabla \psi|^2}{x^2} \exp(-\text{i} n q \delta) \chi \exp(\text{i} n q \delta) \\
& \quad - \frac{g (p^2 + g^2)}{x^2} \xi^\psi ,
\end{align}

\begin{align}
\Lambda_3 \xi^\psi & = \left\{ \left[-g \frac{(\mathcal{G}/x^2)}{x^2} + \text{i} n q \delta \right] \mathbb{B}^2 + \frac{\nabla \psi \cdot \nabla \psi}{x^2} \left( \frac{x^2}{p^2 + g^2} \right) \mathbb{B}^2 \right\} \xi^\psi \\
& \quad - \frac{i g [\exp(-\text{i} n q \delta)]}{x^2} \partial_\theta \chi \exp(\text{i} n q \delta) \\
& \quad + \frac{n |\nabla \psi|^2}{x^2} \chi \exp(\text{i} n q \delta) \xi^\psi ,
\end{align}

and

\begin{align}
\gamma_p |\nabla \cdot \mathbb{E}|^2 & = \gamma_p \left[ \frac{|\mathcal{G} \xi^\psi|^2}{\mathcal{G}} + \partial_\theta \xi^\psi + n \left( \frac{g^2}{x^2 \mathbb{B}^2} - 1 \right) \xi^\psi + \frac{i g}{\mathcal{G}} \partial_\theta (\xi^\psi / \mathbb{B}^2) - \text{i} n g \xi^b \right] \\
& \quad + \mathcal{G}^{-1} \partial_\theta (\mathcal{G} \xi^b) |^2 \equiv \gamma_p |\mathcal{A} \xi^\psi|^2 .
\end{align}

Thus, since the perturbed vacuum potential energy contribution is given in terms of \( \xi^\psi \) on the plasma-vacuum interface \([1]\), the quadratic forms can be written entirely in terms of \( \xi^\psi \) by using Eqs. (21) and (22) for \( \xi^S \) and \( \xi^B \). The final result can be expressed schematically as

\begin{align}
\gamma^2 K(\xi^\psi, \xi^\psi | \omega^2) = \delta W(\xi^\psi, \xi^\psi | \omega^2) ,
\end{align}
where $K$ and $&i$ are quadratic forms in $\xi^0$, each explicitly involving the eigenvalue $\omega^2$. The eigenvalue problem, which is obtained after extremizing with respect to $\xi^0$, is therefore nonlinear in $\omega^2$, and its numerical solution must be found by iteration.

### §3. NUMERICAL METHODS

#### 3.1 Overview

The eigenvalue problem corresponding to Eq. (30) is solved by a straightforward generalization of the Galerkin method used in previous PEST codes [1,4]. We begin by introducing the mixed finite-element Fourier expansion,

$$\xi^0(\psi, \theta, \zeta) = \sum_{m=1}^{M} \xi_{m} e^{i \theta m} u_{m} (\psi) \exp(i \omega m) , \quad (31)$$

into the quadratic forms associated with Eq. (30). The weak form of the normal mode equations can then be written as the generalized matrix eigenvalue problem,

$$w_{m} e^{i \omega m} \xi_{m} = \omega^2 k_{m} e^{i \omega m} \xi_{m} , \quad (32)$$

where the matrix elements of $w(\omega^2)$ and $k(\omega^2)$ are very complicated expressions obtained by following through the analysis of the last section. Each can be written in the form,

$$w_{m} e^{i \omega m} = (2\pi)^2 \int d\theta [u_{m} u_{m}'] [w^{\dagger}(\omega^2) \ Y_{m}^{\dagger}(\omega^2) \ u_{m} ] [Y_{m}(\omega^2) \ Z_{m}(\omega^2) \ u_{m}'] , \quad (33)$$
where the matrices \( W, Y, \) and \( Z \) are functions of \( \psi \) and depend in a known way on \( = \). These subsidiary matrices are evaluated surface-by-surface in the calculation, and involve the explicit inversion of the operators \( \pi_0 \) and \( \Gamma_0 - \Gamma_1 \pi_0^{-1} \pi_1 \) of Eqs. (21) and (22) in the Fourier space corresponding to the coordinate \( \theta \). The final result is too tedious to present in full detail here; instead we continue this section by briefly describing some of the most important steps in the calculation.

### 3.2 Elimination of \( \widetilde{\xi}^a, \widetilde{\xi}^b \)

The elimination of \( \widetilde{\xi}^a \) and \( \widetilde{\xi}^b \) proceeds by finding the Fourier matrix representation of the operators \( \chi \) and \( \Phi \) of Eqs. (21) and (22). We introduce the bracket notation,

\[
\langle \ell' \mid \chi \mid \ell \rangle = \frac{1}{2\pi} \int d\theta \exp(-i\ell'\theta) \chi \exp(i\ell\theta) ,
\]

so that

\[
\langle \ell' \mid \chi \mid \ell \rangle = \langle \ell' \mid (\Gamma_0 - \Gamma_1 \pi_0^{-1} \pi_1)^{-1}(\Gamma_1 \pi_0^{-1} \pi_2 + \Gamma_2) \mid \ell \rangle
\]

and

\[
\langle \ell' \mid \Phi \mid \ell \rangle = \langle \ell' \mid \pi_0^{-1}(\pi_1 \chi + \pi_2) \mid \ell \rangle
\]

These expressions are evaluated in a straightforward manner and attention need only be given to two complications, viz., the treatment of the convolutions that occur in evaluating operator products and, secondly, the complications which occur because \( \pi_2 \) and \( \pi_2 \) explicitly involve \( \psi \)-derivatives.

To illustrate the convolution treatment we consider the evaluation of Eq
(35). This can be written formally as the infinite matrix product,

\[ x_{\xi} = \langle \xi' | (I_0 - \Gamma_1 \pi_0^{-1} \pi_1)^{-1} | k \rangle \langle k | \Gamma_1 \pi_0^{-1} \pi_1 + \Gamma_2 | \xi \rangle , \]  

(37)

where \(|k\rangle \langle k| = I\), the identity operator, and summation convention is assumed. Numerically, we truncate the infinite product, taking \( L^* \) terms, so that I is approximated by

\[ I = \sum_{k=-L^*}^{L^*} |k\rangle \langle k| . \]  

(38)

In the calculations we let \( L^* \) be an additional input parameter and, for fixed \( L \), varied it until the results were satisfactorily converged. For every case we considered, taking \( L < L^* < L + 5 \) was sufficient. This is illustrated in Table I where we present some convergence results for analytic equilibrium studies in Ref. 5. With this prescription for evaluating matrix products, the remaining steps are straightforward; considering the first term of Eq. (37),

\[ \langle \xi' | (I_0 - \Gamma_1 \pi_0^{-1} \pi_1)^{-1} | k \rangle = \langle \xi' | I_0 - \Gamma_1 \pi_0^{-1} \pi_1 | k \rangle^{-1} \]

\[ = (\langle \xi' | I_0 | k \rangle - \langle \xi' | \Gamma_1 | k' \rangle \langle k' | \pi_0^{-1} \pi_1 | k \rangle^{-1} \langle k'' | \pi_1 | k \rangle^{-1} \]

which can be evaluated from the expressions given in Eqs. (13), (14), (15), (18), and (19).

In the preceding discussion we have assumed that all the operators remain bounded, which they do, at least almost everywhere in the domain of \( \omega^2 \). The exceptions are at the set of values of \( \omega^2 \) which are eigenvalues of the...
operators $\tau_0$ and $\Gamma_0$. This set excludes all the eigenvalues of the normal modes (including the continuous spectra), except possibly marginally stable axisymmetric perturbations for which a proper treatment would have to follow the treatment in the Appendix of Ref. 4. For a given value of $L$, these $2(2L+1)$ values of $\omega^2$ are the toroidal analogues of those which separate Sturmian from anti-Sturmian behavior of the spectrum of the cylindrical, diffuse linear pinch [8]. As in the cylindrical problem, it is our experience that the numerical solution, which involves iteration in $\omega^2$, is for all practical purposes oblivious of these possible difficulties.

The second issue to comment on is the treatment of the $\psi$-derivatives in $\tau_2$ and $\Gamma_2$. These give rise to terms in $Y$ and $Z$ of Eq. (33), coming explicitly from the elimination of $\tilde{\xi}^a$ and $\tilde{\xi}^b$, as can be seen, for example, in the second term of Eq. (37). They are handled in a simple manner by splitting each of the operators as, for example,

$$\tau_2 = \bar{\tau}_2 + \tilde{\tau}_2 \partial_\psi$$

where $\bar{\tau}_2$ and $\tilde{\tau}_2$ do not involve $\psi$-derivatives. Then

$$\chi = \bar{\chi} + \tilde{\chi} \partial_\psi, \quad \phi = \bar{\phi} + \tilde{\phi} \partial_\psi$$

with

$$\bar{\phi} = \tau_0^{-1} (\tau_1 \bar{\chi} + \bar{\tau}_2), \quad \tilde{\phi} = \tau_0^{-1} (\tau_1 \tilde{\chi} + \tilde{\tau}_2)$$

Thus, corresponding to the form Eq. (31) chosen for the representation of $\xi_\psi$, the two surface components can be expressed as
where

\[ \xi_0 = \chi_{0m}, \quad \xi_0 = \chi_{0m}, \quad \xi_0 = \chi_{0m} \]

with similar forms for \( \xi^b \). The terms involving barred (twiddled) quantities eventually contribute to \( \mathbf{w}(2) \) matrix elements in Eq. (33).

As in previous work we have employed piecewise linear finite elements for the \( u_0(\psi) \), which are the lowest order elements allowed for \( \xi \), since it appears differentiated once with respect to \( \psi \) in Eq. (23). Lower order elements (the \( u_0^b \) are Heaviside functions) are permitted for the two surface quantities, since no \( \psi \)-derivatives of these occur. It is interesting to note that, for finite \( M \), Eq. (42) is distinctly different from previous methods [9,10] in which Eq. (23) was varied with respect to each of the three components of \( \xi \), and in which only the terms corresponding to \( \xi^s_{0m} \) were included in the representation for \( \xi^s \) and \( \xi^b \). Since, when \( \omega^2 \) is an exact normal mode frequency, Eq. (42) is the discretization corresponding to Eq. (31), pollution of the spectrum [9] cannot be a serious problem in this constrained minimization. On the other hand, with respect to the convergence properties with the numerical parameter \( M \), this method has no particular advantage over the previous schemes; both are \( O(M^{-2}) \) methods.

3.3 Iteration in \( \omega^2 \)

Since the matrix elements in Eq. (32) depend on \( \omega^2 \), it is necessary to iterate to obtain the normal mode frequencies. To do this we use the simplest of schemes,
\[ w(\omega_p^2) \cdot \xi = \omega_p^2 \chi(\omega_p^2) \cdot \xi, \quad p = 0, 1, 2, \ldots \]  \hspace{1cm} (44)

and continue, until \(|\omega_{p+1}^2 - \omega_p^2| < \epsilon|\omega_p^2|\), with \(\epsilon\) an appropriate small number.

To commence the iteration, \(\omega^2\) must be chosen. Often, as for example when carrying out analysis of a sequence of slightly different equilibria, some prior knowledge of \(\omega^2\) will exist. If not, and the interest is in the issue of the stability of the equilibrium configuration, it is useful to take \(\omega_0^2 = 0\).

Then, this first step is essentially identical to the original PEST 2 formulation, the matrix elements representing \(\delta W\) must be the same, and the sign of \(\omega_1^2\) determines stability. Since the kinetic energy norm used here includes terms involving \(\xi^S\) and \(\xi^b\), both of which are generally nonzero, the value of \(\omega_1^2\) will not be the same as that obtained from PEST 2. However, in the sense of Eq. (44), it is an approximation to the normal mode frequency.

An example of the convergence properties of Eq. (44) is shown in Table II. It is seen that convergence can be quite rapid, typically requiring 2-3 steps to give 3-4 figures accuracy, which is about the maximum one should aim for with numerically determined equilibria.

This iteration is, of course, expensive computationally, since Eqs. (21) and (22) must be resolved at each stage. While many of the matrices involved can be saved from previous iteration steps, most of the computational time is involved in the surface-by-surface inversions for \(\chi\) and \(\Phi\), and in the present coding of this method we have not gone to this effort. Consequently, the execution times scale comparably to the PEST 1 procedure. For practical applications, the present advantages lie in the fact that the PEST 2 formulation gives more accurate results for smaller values of \(M\) and \(L\) than with PEST 1. For example, for some internal kink mode calculations, the value of \(M\) for which instability is first detected can be typically 2-3 times smaller with this new procedure.
3.4 Summary of the Numerical Steps

The implementation of the steps described in the previous sections closely follows that of the PEST 2 code. We begin with a numerical equilibrium in flux coordinates, mapped onto an appropriate equally spaced \( \psi, \theta \) mesh, typically with 97 surfaces and 128 3-grid points. We select values of \( M, L, \) and \( L^* \) and remap the equilibrium to the new \( \psi \) mesh, which may be nonequally spaced, if desired. With piecewise linear elements the new \( \psi \) mesh has \( 2M + 1 \) grid points.

The calculation proceeds by computing the matrices \( W, Y, \) and \( Z \) of Eq. (33) on each \( \psi \) grid surface. This involves constructing the \( \pi \) and \( \Gamma \) matrices of \$2$, inverting the appropriate combinations to obtain \( \chi \) and \( \phi \), and then taking the appropriate Fourier transforms (using FFT routines) of the expressions in Eqs. (24) - (29). The \( W \) and \( K \) matrices of Eq. (32) are then obtained by carrying out the integrations over the radial finite elements by numerical quadrature (Simpson's rule). These matrices are block tridiagonal, consisting of \( (M + 1) \) blocks each of rank \( (2L + 1) \). The calculation of perturbed vacuum magnetic energy is identical to previous work [4] and leads to contributions to the elements \( W_{\psi'}, \mathbf{R}_{\psi', \psi} \). The eigenvalues, \( \Omega_{p+1}^2 \), of Eq. (44) are found by inverse iteration, using \( \omega_p^2 \) as the accelerating parameter in the eigenvalue shift.

When the eigenvalue iteration is converged to the required accuracy, Eqs. (21) and (22) [or more precisely Eq. (43) and the equivalent form for \( \tilde{\xi}_p \)] are used to construct the eigenvector \( \tilde{\xi} \). For this purpose, the matrices \( \tilde{\chi}, \tilde{X}, \tilde{\phi}, \) and \( \tilde{\phi} \) are saved in disk files when they are computed, during the calculation of the matrix elements.

Because of the modular structure of the PEST code, while the algebra associated with this procedure is more tedious than with PEST 2, the actual
coding changes are quite modest. They amount essentially to the replacement of one subroutine of about 300 statements with new coding of about 1000 lines. Several additional arrays used as working storage to hold temporarily the $\pi$ and $\Gamma$ matrices slightly increased the memory requirements.

§4. APPLICATION

In this section we give several examples to show the usefulness of these modifications to the PEST 2 code. First we consider two cases which illustrate the convergence properties and allow a comparison with PEST 1. These are a simple external kink instability, which has been studied previously [5] when comparisons were made between various stability codes, and an internal kink mode, which provides a more difficult test because the growth rate is very small and the mode is highly localized. We then go on to compute a tilting mode in a spheromak configuration, because it was the desire to obtain growth rates for comparison with the Proto-S1 experiment which originally motivated this work. Finally, we find a stable, discrete shear Alfvén wave to illustrate that the techniques developed here are not restricted to instability studies.

4.1 Tokamak External Kink Mode

We consider the simple analytic equilibrium studied in Ref. 5, a small aspect ratio, elliptic cross-sectional configuration specified by

$$\psi = \frac{1}{2} \frac{1}{\cal E R q(0)} \left[ x^2 z^2 + \frac{E^2}{4} (x^2 - R^2 z^2)^2 \right], \quad (45)$$

with $R = 1$, $q(0) = 1.2$, $q(s) = 2.09$, $E = 2$, and $\varepsilon = 1/3$. With no external conducting wall, so that the plasma torus is surrounded by an infinite vacuum
region, the $n = 1$ external kink mode is unstable, and its growth rate (measured in units of the poloidal Alfvén time at the plasma surface, $\omega_a^2 = \rho q^2(s) \alpha^2 R^2/\beta_0^2$) was computed previously by the PEST and ERATO codes as 0.75 and 0.78, respectively [5]. Here we repeat the calculations using PEST and equal arc length $\theta$-coordinates, and present the results in Table III. For each case we took $L^* = 51$ (see Table I), and set $\varepsilon$, the relative error between successive iterates in Eq. (44), to $10^{-6}$ (see Table II). Table III presents the results for a set of three different radial meshes ($M$) and three different sets of Fourier modes (-L < $l$ < L). For both coordinate systems we see that the estimates are essentially converged out in $\varepsilon$ with $L = 15$; the equal arc system (Table IIIb) is extremely accurate even with $L = 10$, while the PEST coordinate system begins to display some departure at this point. Both systems have a $1/M$ variation with the number of finite elements, and extrapolation to infinity gives $\omega_a^2 = 0.7755$ and 0.7757 [for IIIa and IIIb, respectively], in good agreement with the previous estimates.

4.2 Tokamak Internal Kink Mode

The internal $\ell = 1$, $n = 1$ ideal MHD mode is usually unstable in tokamak configurations when a $q = 1$ surface lies in the plasma region and $\beta$ is finite [11]. This mode has a small growth rate of typically several orders of magnitude smaller than the external kinks. Its eigenfunction is localized inside the $q = 1$ surface and decreases rapidly to zero outside. Because of the need to resolve this region accurately, studying such an instability provides a good test for a stability code. The mode is particularly difficult to determine near to the points of marginal stability, and in these regions grid packing near the $q = 1$ surface and the addition of specially tailored finite elements have been used to obtain very accurate results with
PEST 2 [12]. The purpose here is not to address this aspect specifically, but to show that with this new version of PEST 2 it is possible to compute the growth rate and eigenfunction as well.

We consider an aspect ratio 3 toroidal equilibrium with circular plasma surface, computed from a flux coordinate equilibrium code, using the profiles \( p(\psi) = p_0(1 - \psi^3) \), \( q(\psi) = q_0(1 + \psi^2) \), with \( \alpha_1 = 1.1 \), and \( \alpha_2 = 1.5 \). The parameters \( p_0 \) and \( q_0 \) are such that \( \beta_p \equiv 2\mu_0 \langle p \rangle / I \phi^2 = 1.25 \). A sequence of equilibria with constant \( \beta_p \) can be obtained by scaling the vacuum toroidal field to alter \( q(0) \). We examine the stability of \( n = 1 \) internal modes with \( q(0) \) varying between 0.63 and 0.96, and present the results in Fig. 1. We give four sets of results; PEST 1 calculations with 200 radial elements, the new PEST 2 results \( \ell = 200 \) and no iterating on the eigenvalue (i.e., similar to the original PEST 2), and results after iterating with PEST 2, using 96 elements and after extrapolating to infinity. In all cases the mesh was uniformly spaced in the radial coordinate \( \psi \), and the PEST 6 angle was used with \( -4 < \xi < 13 \). In the PEST 2 calculations \( L^* = 16 \). The poloidal projection of the displacement vector \( \xi \) for \( q(0) = 0.9 \) computed from the new PEST 2 code is shown in Fig. 2.

Several comments can be made from the results shown in Fig. 1. Firstly it is clear that with respect to determining the instability, both PEST 2 codes are considerably more accurate than PEST 1, which is expensive to run computationally (~5 minutes CRAY I time) with 200 elements. This is especially true when the \( q = 1 \) surface lies close to the magnetic axis \( (q(0) \approx 1) \), because the equally spaced \( \psi \) mesh in PEST 1 tends to weight regions near the plasma surface more heavily than near the axis. However, it can be seen that PEST 1 gives reasonable results when the \( q = 1 \) surface lies further out towards the plasma surface. Even with 200 elements the PEST 1 code has
difficulty finding instability, except where the growth rate is relatively
large. With $M<200$ it is also difficult to carry out a reliable extrapolation
to the limit procedure, since the region where the errors scale as $1/M^2$ has
not been reached. PEST 2 does not suffer these problems, except very close to
the marginal points. By comparing the results near to the marginal point for
the extrapolated curve and the results obtained by running in the original
PEST 2 mode, we see that these can be accurately evaluated with $M = 200$. With
$M = 200$ the new code follows the converged curve over most of the range with
an error $< 5\%$ of the maximum growth rate. Thus, except near the marginal
points, convergence studies are not really essential for many applications.

4.3 Spheromak Tilting Mode

The tilting mode was predicted analytically for force-free spherical and
near-spherical spheromaks [13] and is observed experimentally [14]. Its
presence is generally found to be highly destructive; therefore, a thorough
understanding of the mode is required. The PEST 1 code has difficulty with
small aspect ratio $(a+1)$ spheromak geometry which is alleviated in PEST 2 by
switching from PEST 8 coordinates to equal arc 8 coordinates and using a
different representation of $\xi$. PEST 2 has been used to examine the stable
points of the tilting and shifting modes for different shapes with and without
nearby conducting walls [15]. However PEST 2's lack of physically meaningful
growth rates have made comparison with experimental results difficult. The
new formulation presented here allows accurate determination of these growth
rates.

For this particular example we have numerically generated equilibrium
with a shape described by:
\[ x = x_0 + a \cos(\theta + d \cdot \sin \theta) \]
\[ z = \epsilon \cdot a \sin(\theta) \]

with \( x_0 = 2.75 \), \( a = 1.55 \), \( \epsilon = 2.0 \), \( d = 0.35 \).

The surface quantities \( g(\psi) \) and \( p(\psi) \) are chosen to be:

\[ g(\psi) = g_s + \Delta g \cdot y \]
\[ p(\psi) = p_\circ y^2 \]

where

\[ y = \frac{\psi_{\text{edge}} - \psi}{\psi_{\text{edge}} - \psi_{\text{axis}}} \quad \text{and} \quad g_s / \Delta g = 10^{-3} \]

The resulting safety factor \( q \) is 0.582 at the magnetic axis and 0.00419 at the edge, and the volume-averaged beta is 2.25%.

With no external conducting wall the fully converged growth rate is

\[ y^2 = 0.50 \omega_A^2 \]

where the Alfvén transit frequency is defined as:

\[ \omega_A = \frac{B_0}{R_0 \sqrt{\rho_0}} \]

and \( R_0 = \) major radius, \( B_0 = \) toroidal field at the magnetic axis, and the density, \( \rho_0 \), is assumed spatially constant.

The poloidal projection of the displacement vector \( \xi \) is shown in
Fig. 3. These results are in good agreement with results from the Erato stability code [16].

4.4 Stable Shear Alfven Wave

In addition to the calculation of unstable perturbations, there is interest in modes in the stable part of the MHD spectrum. This is because the ability to compute the eigenfunctions can aid in our understanding of the instability driving mechanisms, and also because these stable oscillations are of interest for wave heating schemes. In the stable part of the spectrum there are both discrete modes and continuous bands of eigenfunctions associated with the shear Alfven branch. The global shear Alfven modes occur in cylindrical configurations [17,18] and in a torus [18,19], where additional discrete modes arise in the gaps between the continuum bands because of toroidal coupling of modes with different poloidal harmonics.

Because of the large number of stable eigenvalues associated with any reasonably accurate numerical representation of linearized ideal MHD equations, computation of the global Alfven waves is complicated. One approach, which has been tried with PEST 1, entails calculation of all the eigenvalues of the discretized linear normal mode equations, using a wide resolution. By examining the radial structure of the eigenfunctions, it is possible to identify the discrete modes of interest. This gives an approximate eigenvalue estimate which can be used in an iterative eigenvalue scheme with more spatial resolution. Alternatively, an eigenvalue estimate can be obtained from a WKB local (ballooning mode) analysis of the problem, which determines the gaps between the shear Alfven wave continua surface by surface [20]. We consider an n = 1 internal mode in an aspect ratio 4 toroidal equilibrium, with $\beta \approx 2\%$ and $1.05 < q < 2.3$. Using the approximation
given from the localized analysis, we used the method of this paper to compute the global mode. The calculations were carried out with \( M = 48 \) and \(-8 < \ell < 12\). The radial structure of various Fourier harmonics is displayed in Fig. 4, and the poloidal projection of \( \ell \) is given in Fig. 5. The mode is seen to consist primarily of \( \ell = 1 \) and 2 components, with a small coupling to \( \ell = 3 \) towards the plasma surface. In terms of the numerical calculation, the procedure behaves similarly to when it is used to compute unstable modes; with respect to the number of iterations required, and no difficulties associated with inverting the operators in Eqs. (21) and (22) were observed. We also computed modes in the continuum, an example is given in Fig. 6.

§5. DISCUSSION

In this paper we have described a numerical procedure which extends the efficient techniques of the PEST 2 stability code to enable an accurate estimate of the growth rates and eigenfunctions associated with the normal modes. The formulation followed that of PEST 2 in the reduction of \( \delta W \) to a quadratic form involving only one component of the displacement vector, but, by employing the correct kinetic energy normalization, the resulting eigenvalue problem was nonlinear. Utilizing identical numerical procedures, the normal mode frequencies and eigenfunctions were obtained by a straightforward iteration.

The numerical method was applied to several typical problems to illustrate the convergence properties and to make comparison with previous results. When implemented on a modern large scale computer (such as the CRAY 1), these results show that sufficient resolution can be obtained and that careful convergence studies, which were essential with the first generation of stability codes, can now frequently be avoided. It was also
shown that the method can be applied to determine modes in the stable part of the MHD spectrum.

For axisymmetric toroidal equilibria, the full range of features available with the extended PEST 2 formulation should provide for an accurate ideal MHD analysis of most interesting confinement systems with $n < 10^{-20}$. The improved efficiency of this scalar formulation will probably allow for an analogous examination of fully three-dimensional configurations, such as stellarators, where constraints imposed during the accurate calculation of MHD equilibria have the stability to low-$n$ modes unresolved [21]. Finally, since the method does not rely implicitly on the variational properties of the ideal MHD equations, the successful iteration for the eigenvalues demonstrated here suggests that similar techniques may be usefully applied to other toroidal systems, where the normal mode equations are not Hermitean. This situation occurs when additional physics (such as equilibrium flows and various dissipative processes) is included to improve the ideal MHD description of the confined plasma.

ACKNOWLEDGMENTS

The authors are grateful for many useful discussions with Dr. J. Manickam. He kindly provided the equilibrium and PEST 1 results for Fig. 5. We also wish to thank Dr. M. S. Chance and Dr. F. Cheng who provided the incentive and the data for the calculation of §4.4. We gratefully acknowledge the computational assistance of the A. E. Miller.
