Beam Instability Studies for the SSC

W. Chou

Abstract

Beam instability studies for the Superconducting Super Collider (SSC) during the period 1989–1993 are briefly reviewed in this paper. Various topics are covered: single bunch and multi-bunch, single beam and beam-beam, parasitic heating and active feedback, *etc.* Although the SSC will not be built, many of the results obtained from these studies remain as useful references to the accelerator community.

1.0 INTRODUCTION

Studies on the collective beam instability problems for the Superconducting Super Collider (SSC) started in the early 1980s. A set of preliminary results were included in the *SSC Conceptual Design*,¹ which was published in 1986. Since the establishment of the SSC Laboratory in 1989, these studies have been further pursued and numerous new results have been obtained. In this paper we will briefly review these results, including:

- Impedance budget and single bunch instability
- Higher-order modes and coupled bunch instability
- Resistive wall instability
- Feedback systems
- Parasitic heating
- Beam-beam effects.

The SSC is basically a low beam current machine. The beam intensity is primarily limited by the cryogenic system for absorbing the synchrotron radiation power from the 20-TeV proton beams. Generally speaking, therefore, collective effects—such as single bunch instability, parasitic heating, and beam-beam interactions—do not present a threat to machine operations at normal beam intensity. However, there is an exception. That is the coupled bunch instability, which may become a real concern. This is because the number of bunches is enormous (about 17 000 per beam, which is several orders of magnitude higher than in any existing storage rings), and because the required transverse emittance is extremely small (1π mm-mrad, normalized, which is just a fraction of that in any proton machines). These unique features of the SSC call special attention to the multi-bunch phenomena.

2.0 IMPEDANCE BUDGET AND SINGLE-BUNCH INSTABILITY

2.1 Impedance Budget of the Baseline Design

In order to establish the impedance budget, each component in the vacuum system, rf system, diagnostic system, and injection/extraction systems has been carefully analyzed. Computer models for each component have been built, simulations have been carried out, and measurements for some critical components (*e.g.*, the bellows and the liner) have been performed.

Two groups of simulation codes have been put in use. One is numerical, which is of either finite-difference type (such as the TBCI and MAFIA²) or finite-element type (such as the HFSS³). Another is based on an analytical model and is called the bperm (Boundary Perturbation Method), which was developed at the SSC.⁴ Benchmark tests for comparison

purposes have been done, and the results for a given geometry obtained from different codes are in general agreement. As an example, Figure 1 shows the comparison of the wake potentials calculated by bperm and MAFIA for a tapered transition between two beam pipes with different cross sections.

The impedance budget is listed in Table 1, where $Z_{\parallel}/n$ is the longitudinal impedance and $Z_{\perp}$ the transverse one.

There are several remarks about this budget table:

1. Every effort has been made to make the beam pipe as smooth as possible: the bellows are shielded; the valves have rf fingers; the vacuum pump ports are screened; the transitions between two pipes of different sizes are tapered; and the ceramic pipes in the kicker sections are coated with thin metallic layers.
2. The 6000 bellows, even shielded, are a major contributor to the impedance. It is, therefore, worthwhile trying several different rf shield designs and comparing their impedance. The computer model of the baseline design (old design) is shown in Figure 2. The new design, which is similar to the design at the Large Electron-Positron (LEP) collider at CERN, is shown in Figure 3. Table 2 lists the comparison of the impedance of the two designs. It is a factor of four in difference. The significant reduction of the impedance of the new design comes from two facts: (1) The gap size is reduced from 3.4 mm to 2.5 mm; (2) The right-hand-side of the gap is changed from an abrupt drop to a taper. Furthermore, in order to have a realistic estimate of the impedance, one needs to take into account the lateral misalignment during the installation, which would inevitably increase the impedance. The specification of the maximum lateral offset is 2.8 mm. Assuming a uniform distribution in misalignment, the resulting increase in impedance is listed in Table 2.
3. The flange gap must be vacuum sealed. To reduce its impedance, it also needs to be rf sealed. There are several possible solutions to this problem. One is to use a separate rf finger to shield the gap, as the LEP did. Another is to use a thick copper coating on the flange surface that would serve both vacuum and rf sealing, as suggested by Helicoflex Company. A third solution is to use a movable rf finger, which would shield the bellows and flange gap simultaneously, as proposed for the Main Injector at Fermilab.
4. This budget table includes the components in both the cold region and warm region (i.e., the west utility, the east utility, and the interaction region).

Figure 1. Comparison of the Longitudinal (a) and Transverse (b) Wake Potentials Calculated by bperm and MAFIA for a Tapered Structure.

Table 1. Impedance Budget (per ring).

Component	Number	Impedance	
		$Z_{\parallel}/n$ (Ω)	$Z_{\perp}$ ($M\Omega/m$)
Rf cavity (HOM)	8×5 -cell	0.036	0.016
Transition (tapered)	4	0.004	0.003
Bellows (shielded)	6000	0.12	10
BPM (15 cm, 55°)	968	0.05	4.6
Weldment	12 000	0.002	0.2
Valve (shielded)	128	$1E-4$	0.01
Pump port (screened)	650	0.02	2
Flange gap	12 000	TBD	TBD
Resistive wall		0.02	1.7
Scrapers		$1.8E-4$	0.02
Collimators		$2.6E-4$	0.08
Injection Lambertson (laminated)		$1.5E-3$	1.4
Abort Lambertson (solid iron)		-	-
Injection kicker		0.06	2.0
Abort kicker		0.2	4.7
Joint to Lambertson		TBD	TBD
Conical section near IP		-	-
Total		0.51	27
Impedance budget = Total $\times$ 2		1.0	54
Instability threshold:			
At 2 TeV		4.0	270
At 20 TeV		16	1200

Figure 2. Computer Model of the Baseline Design (Old Design) of the Rf Shields for the Bellows. The discontinuity gap size in the radial direction is 3.4 mm.

Figure 3. Computer Model of the New Design (LEP Design) of the Rf Shields for the Bellows. The discontinuity gap size in the radial direction is 2.5 mm.

Table 2. Comparison of Bellows (Shielded) Impedance.

Case	$Z_{\parallel}/n$ (Ω)	$Z_{\perp}$ ($M\Omega/m$)
A. Baseline (old design)	0.12	10
B. New design (LEP design)	0.03	2.5
No misalignment		
C. New design	0.06	6.5
Max lateral offset 2.8 mm		
Uniform distribution		

5. In order to accommodate unforeseen sources in the impedance budget, the calculated total impedance is multiplied by a factor of two, which is then used in the safety margin estimate in Section 2.3.

2.2 Impedance in the Presence of a Liner

One plausible solution to the photodesorption problem is to install a perforated liner inside the beam pipe. This would increase the impedance in two ways:

1. The holes (or slots) on the surface of the liner would introduce additional impedance. At low frequencies (below the cutoff of the liner), the small holes (or slots) behave like a pure inductance. Their impedance can be estimated accurately. The results from the analytical models, code simulations, and wire measurements all agree with each other.⁵ It is also known that, for a given pumping area, short slots give less impedance than circular holes. At high frequencies (above the cutoff), however, the situation is more complex. Resonant peaks in the impedance spectrum are observed when the holes or slots are periodically placed. These peaks can be greatly suppressed when the periodicity is destroyed. It is thus concluded that randomly distributed short slots would be the best choice for the pattern of the perforation.
2. The installation of a liner would also reduce the inner radius (ID) of the pipe seen by the beam. Consequently, the transverse impedance of the components in the cold region would increase.

The baseline beam pipe ID is 33 mm. Assuming the liner ID to be 25.3 mm, hole diameter 2 mm, and area coverage of the holes on the liner surface 4%, the impedance increase is listed in Table 3.

Table 3. Transverse Impedance With and Without Liner.

Case	$Z_{\perp}^{(\text{liner})}$ (M Ω /m)	$Z_{\perp}^{(\text{others})}$ (M Ω /m)	$Z_{\perp}^{(\text{total})}$ (M Ω /m)	Safety Margin
Baseline	–	54	54	5
With liner	37	94	131	2

2.3 Single-Bunch Instability Threshold and Safety Margin

The threshold impedance of the microwave instability (longitudinal) and mode-coupling instability (transverse) can be estimated by the following formulae:

$$|Z_{\parallel}/n| = \sqrt{\frac{\pi}{2}} \left(\frac{Z_0}{r_p} \right) \left(\frac{\eta\gamma}{\beta} \right) \left(\frac{\sigma_z}{N_B} \right) \left(\frac{\sigma_p}{p} \right)^2 \quad (1)$$

$$\text{Im } Z_{\perp} = 2\sqrt{\pi} \left(\frac{Z_0}{r_p} \right) \left(\frac{\eta\gamma\nu\beta}{\beta} \right) \left(\frac{1}{N_B} \right) \left(\frac{\sigma_p}{p} \right). \quad (2)$$

The transverse mode-coupling threshold obtained from Eq. (2) has been compared with that from the code BBI;⁶ they are in agreement. The ratio of the threshold impedance to the impedance budget, called the safety margin, is listed in Table 3.

It is seen that the introduction of a liner would significantly reduce the safety margin. Several measures could be taken to increase the safety margin:

- Enlarge the liner ID. This is the most effective way to reduce the transverse impedance. The scaling is

$$Z_{\perp} \propto (\text{ID})^{-\alpha}, \quad (3)$$

where $\alpha = 4$ for the liner, and $\alpha \approx 3$ for other components. In order to achieve a larger liner ID, one would have to increase the aperture of the quadrupoles and spool pieces from 4 cm to, say, 5 cm.⁷

- Increase the longitudinal emittance ϵ_L . This would increase the impedance threshold:

$$Z_{\perp}^{(\text{thresh})} \propto \epsilon_L^{1/2}. \quad (4)$$

However, there are two concerns about a bigger ϵ_L : (1) the rf bucket to bunch area ratio would be reduced; (2) the beam transfer from the High Energy Booster (HEB) to the Collider would be more difficult.

- Increase the rf voltage at injection from 6.6 MV to 20 MV. This would also increase the impedance threshold:

$$Z_{\perp}^{(\text{thresh})} \propto V_{\text{rf}}^{1/4}. \quad (5)$$

One would have to reconsider the matching between the HEB and the Collider in this scenario.

3.0 HIGHER-ORDER MODES AND COUPLED-BUNCH INSTABILITY

The higher-order modes (HOM) of the rf cavities are the source of the coupled-bunch instability. The original choice of the rf cavity for the SSC is the 5-cell type used at the Positron-Electron Project (PEP) at Stanford. The HOM table is obtained from computer simulation using URMEL.⁸ The impedances of these HOMs are high and would cause coupled-bunch instabilities. The growth time is listed in Table 4.

Table 4. Coupled-Bunch Instability Growth Time.

Direction	Bunch Shape Mode	Growth Time (s)	
		2 TeV	20 TeV
Longitudinal	$m = 1$	0.9	5.0
	$m = 2$	2.2	16
Transverse	$m = 0$	8.6	91
	$m = 1$	16	150

One successful method to cure the instability problem is to damp the HOMs. But it is difficult to do so in a multi-cell cavity. Therefore, a careful search has been carried out for choosing the best type of rf cavity for the SSC.⁹ Four types of rf cavities—multiple-cell and single-cell, superconducting (sc) and normal conducting (nc)—have been compared with respect to the specific needs of the SSC. The single-cell cavity is preferable to the multi-cell one because its HOMs are easier to damp. The sc cavity has a number of advantages over the nc one, but the mechanical complexity and operational reliability of the former may present a concern. The SSC rf committee, which was charged to make a recommendation, has endorsed the single-cell, sc cavity as the first choice for the SSC. With this type of cavity, the coupled bunch instability growth time would be more than an order of magnitude longer than that listed in Table 4.

The HOMs may also be generated if the beam pipes in the dipole and quadrupole sections have different cross sections.¹⁰ In this case, the large beam pipe can be regarded as parasitic cavities with certain eigenfrequencies and eigenmodes. These modes may get excited by a traversing charged particle bunch. When the mode frequencies are below the cutoff

frequency of the small pipe, they will be trapped. If the quality factor of the trapped modes is high enough, they will stay there for a long time and will affect the behavior of the following bunches. The result could be a continuous beam emittance growth, as demonstrated in Reference 10. In order to avoid this effect, it was decided to use a beam pipe of uniform cross section throughout the entire cold region in the SSC.

4.0 RESISTIVE WALL INSTABILITY

The wall resistance of the beam tube may cause beam instability, which is usually of long correlation lengths and, therefore, shows no discrimination against the bunched beams from the coasting beams. The growth rate is

$$\begin{aligned}\frac{1}{\tau_w} &= \frac{N_{\text{tot}} c r_p}{2\pi\gamma \nu_\beta} \frac{\text{Re } Z_\perp}{RZ_0} \\ &= \frac{N_{\text{tot}} c r_p}{2\pi\gamma \nu_\beta} \frac{1}{b^3} \delta_s,\end{aligned}\quad (6)$$

in which $\text{Re } Z_\perp$ is the real part of the transverse impedance $Z_\perp$ of the wall, which is equal to

$$Z_\perp = (1 + i) \frac{Z_0 R \delta_s}{b^3}. \quad (7)$$

The skin depth δ_s is a function of the wall conductivity σ_e and frequency ω :

$$\delta_s = \sqrt{\frac{2}{\mu\sigma_e\omega}}. \quad (8)$$

It is seen that as the frequency is decreased, δ_s is increased as $\omega^{-1/2}$. So is the growth rate $1/\tau_w$. The frequency range of interest is $\omega = (n - \nu_\beta)\omega_0$, in which n is an integer and $\omega_0 = c/R$ is the angular revolution frequency, which equals $2\pi \times 3.441$ kHz for the Collider. During machine operation, the fractional part of ν_β would be scanned in order to find the optimal working point. Therefore, the lowest frequency is taken to be $0.1\omega_0$ in the estimates of the fastest growth time.

In the baseline design, the beam tube of the Collider is made of stainless steel, which is coated on its inner surface with a thin copper layer for low electrical resistivity. In this case, the thickness of the copper layer Δ is smaller than the skin depth δ_s in the frequency range mentioned above, and Eq. (6) needs to be modified.¹¹ With some approximations, the modified equation can be written as

$$\frac{1}{\tau_w} = \frac{N_{\text{tot}} c r_p}{2\pi\gamma \nu_\beta} \frac{1}{b^3} \frac{\delta_s^2}{\Delta}. \quad (9)$$

Plugging in Eq. (8) and expressing the instability in terms of the growth time, one has

$$\tau_w = \left(\frac{2\pi\gamma \nu_\beta b^3}{N_{\text{tot}} c r_p} \frac{\mu\omega}{2} \right) \sigma_e \Delta. \quad (10)$$

In other words, the growth time is proportional to the product of $\sigma_e \Delta$. The specification of the copper layer is

$$\sigma_e \Delta \geq 2 \times 10^5 \text{ } 1/\Omega, \quad (11)$$

in which σ_e is the conductivity of the copper layer at 4 K and 0.66 T. The nominal values are $\sigma_e = 2 \times 10^9 \text{ } \Omega^{-1}\text{m}^{-1}$ (corresponding to RRR = 30), $\Delta = 0.1 \text{ mm}$. For a beam tube ID of 33 mm and at $\omega = 0.1\omega_0$, these parameters would give a wall impedance of 4300 M Ω /m in the cold region. The wall impedance in the warm regions also needs to be considered. Table 5 is a complete list of the wall impedance in the SSC.

Table 5. Resistive Wall Impedance.

Component	$Z_\perp$ (M Ω /m)	
	2 TeV	20 TeV
Cold region beam pipe	4300	4300
Warm region beam pipe (stainless steel)	1300	1300
Graphite shadows:		
Upstream to abort Lambertson	7.1	7.1
Upstream to collimator	10	323
Scrapers (copper)	1.4	46
Collimators (stainless steel)	7.7	250
Abort Lambertson (solid iron):		
Symmetric	22	22
Asymmetric	4.6	4.6
Total	5700	6300

The total wall impedance would give an instability growth time of 25 ms, or 88 turns, during the approximately one hour injection period (2 TeV). This would have to be damped by an active feedback system, as will be discussed in Section 5. At full energy (20 TeV), the growth rate would be slower due to the beam rigidity. In addition, the large betatron tune spread resulting from beam-beam collisions may provide significant Landau damping.

There is an alternative to the copper-coated stainless steel beam pipe: an aluminum alloy beam tube.¹² There are several important reasons for considering this option, *e.g.*, saving the high cost of the copper coating, solving the vacuum problem without a liner,

and avoiding the adhesion problem in a bi-layer tube. As far as the beam instability is concerned, the issue is the surface resistance of the aluminum tube. Table 6 is a comparison of the surface resistance between the copper-coated stainless steel and the aluminum alloy 7039-T61, which is of high strength and high resistivity. The quantity $\sigma_e \Delta$ is comparable in the two cases. Therefore, the use of an aluminum beam pipe should not affect the resistive wall instability growth time.

Table 6. Comparison of Surface Resistance.

Material	σ_e ($\Omega^{-1}\text{m}^{-1}$)	$\delta^\dagger$ (mm)	Δ (mm)	$\sigma_e \Delta$ (Ω^{-1})
Cu layer (RRR = 30)	1.8×10^9	0.6	0.1	1.8×10^5
Al 7039-T61 tube	5.6×10^7	3.6	3	1.7×10^5

† At $\omega = 0.1\omega_0$.

5.0 FEEDBACK SYSTEMS

An effective way to cure beam instabilities is to build active feedback systems. In this paper, we will content ourselves with the discussion of transverse feedback systems. These systems serve four different purposes:

1. *Correction of the injection errors*

At injection there are errors in the beam position, angle, energy, and phase that uncorrected can lead to beam emittance dilution. Because these errors are relatively large compared with other types of perturbations described below, the feedback system must have enough power to quickly kick the beam back to the desired orbit before any significant decoherence occurs.

2. *Damping of the resistive wall instability*

This was discussed in Section 4 above. Because it is a fast beam blowup in the transverse planes, a feedback system with a large gain is needed.

3. *Damping of the coupled bunch instability driven by the HOM of rf cavities*

As discussed in Section 3, if the HOMs of rf cavities are not properly damped and/or staggering-tuned, they may drive the beam unstable. The feedback system needs a wide bandwidth to cure this type of instability.

4. *Control of possible emittance growth from the above and/or other mechanisms (e.g., ground motion, coolant flow, power supply ripples, etc.)*

Because of the long memory of the proton beam (the radiation damping time in the SSC is about 13 h), any external perturbation will be remembered by the beam and may lead to eventual emittance growth. A feedback system that keeps the coherent

motion of the beam below a certain allowable amplitude can effectively reduce the emittance growth rate. This feedback system must have a very low noise level.

It is seen that each purpose imposes different requirements on the feedback systems. This, of course, does not mean that a total of four systems would be required. One system may well serve several different purposes. Table 7 lists three systems and their main parameters.

Table 7. Power, Bandwidth, Gain, and Noise Level Specifications.

Feedback System	A	B	C
Purpose	Injection errors	Resistive wall instability emittance control	Multi-bunch instability
Gain	0.04	0.1	0.02
Damping time	50 turns	20 turns	100 turns
Max. correction	± 2 mm	± 100 μ m	± 40 μ m
Kick angle	0.27 μ rad	0.04 μ rad	0.003 μ rad
Kicker length	4 m	4 m	4 m
Kicker voltage	1 kV	150 V	150 V
Kicker power	40 kW	0.9 kW	0.9 kW
Bandwidth	500 kHz	500 kHz	≥ 30 MHz
Noise level	—	≤ 2 μ m	≤ 1 μ m
Resolution limit	0.02 μ m	0.02 μ m	0.16 μ m

For proton storage rings, one would have to specify the noise level in the feedback systems in order to keep the emittance growth below a certain allowable level. The emittance growth rate due to the noise has been worked out:¹³

$$\frac{1}{\tau_{\text{noise}}} = \frac{1}{\epsilon_0} \frac{f_0 g^2 x_N^2}{2\beta_x} \left(\frac{4\sqrt{2}\sigma_\nu}{g} \right)^2 = 0.64 f_0 \left(\frac{x_N}{\sigma_\beta} \right)^2 \Delta\nu^2. \quad (12)$$

On the other hand, one can also estimate the theoretical limit of the pickup resolution that comes from the thermal and electronic noises:

$$\Delta x = \frac{2d}{I_{av} \sin(\frac{\omega \ell}{c})} \sqrt{\frac{k_B T \cdot \Delta f \cdot 10^{NF/10}}{Z}}. \quad (13)$$

These formulae are used to specify the noise levels and estimate the resolution limits listed in Table 7. In designing a feedback system, the quantity Δx must be smaller than x_N , which is determined by a specified allowable emittance growth rate $1/\tau_{\text{noise}}$.

6.0 PARASITIC HEATING

The parasitic heating attributed to the surface resistance R_s of the beam pipe can be calculated by

$$P = k \frac{I_{av}^2}{M f_0}, \quad (14)$$

in which the loss factor is

$$k = \frac{c^2}{2\pi} \int_{-\infty}^{\infty} \tilde{\lambda}^2(\omega) R_{wall}(\omega) d\omega, \quad (15)$$

where the wall resistance R_{wall} is related to the surface resistance by

$$R_{wall} = \frac{R}{b} R_s. \quad (16)$$

In order not to exceed the heat load budget set for the cryogenic system (which is 1 kW per ring for the parasitic heating), the surface resistance must be kept below a certain level. Because the parasitic heating is a high-frequency phenomenon (the SSC bunch spectrum is centered at about 1 GHz), one would have to consider the anomalous skin effect. But the actual situation is more complicated. To get a complete picture, one should consider the co-existence of the following three extreme conditions:

- Low temperature (4 K).

The wall resistance of many materials at low temperature is lower than that at room temperature. This is usually described by a quantity called the residual resistance ratio (RRR). For pure metals (*e.g.*, copper and aluminum), RRR can be hundreds or even thousands at helium temperature, depending on their purity. For alloys (*e.g.*, stainless steel and aluminum alloy), RRR is in the order of unity. But this quantity is meaningful only at low frequencies and low magnetic field.

- High magnetic field (6.6 T).

In a magnetic field, one would have to consider the magnetoresistance. This can be studied using a Kohler plot, which describes the dependence of the resistance on the magnetic field. At 6.6 T, the RRR values could be an order of magnitude lower than that at zero field.

- High frequency (1 GHz and above).

When the frequency is high enough such that the mean free path of electrons becomes larger than the skin depth, the normal conduction theory based on electron collisions breaks down and the surface resistance becomes independent of the conductivity σ_e of the material. This is called the anomalous skin effect. The surface resistance ratio $R_s(300 \text{ K})/R_s(4 \text{ K})$ of copper at high frequencies is significantly lower than the dc

value. The preliminary results measured by the Los Alamos National Laboratory are listed in Table 8.

Therefore, in order to have an accurate estimate of the parasitic heating, one would have to measure the surface resistance of the beam pipe in the presence of all three conditions. This work is not completed.

Table 8. Surface Resistance Ratio of a Copper-Plated Tube.

Frequency (GHz)	$R_s(300\text{ K})/R_s(4\text{ K})$
dc	107
0.959	4
1.865	3.2
7	3.7

7.0 BEAM-BEAM EFFECTS

There have been extensive studies on proton beam-beam interactions at the Tevatron (Fermilab) and $S\bar{p}pS$ (CERN). Their experiences are important. There are, however, three new features of the SSC with respect to the beam-beam effects: the gaps in the bunch train (which produce the so-called Pacman effect), the short bunch spacing (which leads to long-range beam-beam interactions), and the finite crossing angle (which gives rise to synchro-betatron resonances and reduces the luminosity).

7.1 Strong Beam-beam Interactions

These interactions can result in inelastic scattering and elastic scattering.

1. Inelastic scattering:

Particles are lost in this process. The loss rate is

$$\frac{dN}{dt} = \mathcal{L}\sigma_{\text{inel}}, \quad (17)$$

which is 10^8 s^{-1} per interaction point (IP) at the design luminosity $10^{33}\text{ cm}^{-2}\text{s}^{-1}$. The corresponding beam-beam luminosity lifetime is $180/N_{\text{IP}}$ hours.

2. Elastic scattering:¹⁴

This contributes to the emittance growth. The growth rate is

$$\frac{d\epsilon}{dt} = \frac{N_B f_0}{4\pi\epsilon} \sigma_{\text{el}} \sigma_\theta^2, \quad (18)$$

which is about $4.6 \times 10^{-17}\text{ m-rad/s}$ per IP.

7.2 Electromagnetic Beam-beam Interactions

There are two types of interactions: head-on and long-range (which are also called parasitic crossings). The characteristic quantity of head-on collisions is the beam-beam parameter ξ , which for a round beam is defined by

$$\xi = \frac{r_p N_B}{4\pi\epsilon_N}. \quad (19)$$

It equals 0.0009 at the SSC and is substantially smaller than that at the Tevatron and $Spp\bar{S}$ (0.003–0.006). The strength of long-range interactions is mainly determined by the beam intensity and the beam separation at parasitic crossing points. The latter is about $7.5\sigma_\beta$ for a crossing angle of $75 \mu\text{rad}$.

1. Incoherent effects:

(a) Tune shift and tune spread:

The most significant beam-beam effect observed at the Tevatron and $Spp\bar{S}$ is the slow diffusion caused by high-order betatron resonances. It leads to particle loss, which in turn decreases the beam lifetime and creates background in detectors. The tune shift per IP due to head-on collisions is

$$\Delta\nu_{\text{HO}} = \xi \left(\frac{2R_{\text{re}}^2}{1 + R_{\text{re}}} \right), \quad (20)$$

which is also the tune spread. For long-range interactions, the tune shift per IP is

$$\Delta\nu_{\text{LR}} = \frac{r_p N_B L^*}{\pi\gamma\beta^* \alpha^2 S_B}. \quad (21)$$

The tune spread per IP is

$$\delta\nu_{\text{LR}} = \frac{3r_p n^2 \epsilon_N N_B L^*}{2\pi\gamma^2 \beta^{*2} \alpha^4 S_B}. \quad (22)$$

In order to control the slow diffusion, it is required to keep the total tune spread (head-on + long-range + nonlinear magnetic field) within the tune budget, which is set to be 0.02. The linear tune shift due to long-range tune spread may be compensated in principle by retuning quadrupoles. But the Pacman effect discussed below makes it difficult.

The nominal values at each low- β^* IP are: $\Delta\nu_{\text{HO}} = 0.0009$, $\Delta\nu_{\text{LR}} = 0.0022$, $\delta\nu_{\text{LR}} = 0.0009$. Even with a total of four IPs (two low- β^* and two medium- β^*), it should be possible to keep the total tune shift and tune spread within the tune budget.

(b) Orbit distortion:

This is induced by long-range interactions and is given by

$$\delta x = -\frac{4N_B r_p L^*}{\alpha \gamma S_B} \sqrt{\frac{\beta_x}{\beta^*}} \frac{\sin(\pi \nu_\beta - \phi)}{\sin(\pi \nu_\beta)}. \quad (23)$$

The calculated values are small compared with the beam size at the IPs (less than 10% σ_β). Fine steering is desired near the IPs for orbit corrections.

2. Coherent effects:

Both head-on and long-range interactions can produce coherent beam-beam effects. The rigid dipole modes (π -mode and σ -mode) and high-order multipole modes are studied by theoretical modeling and by computer simulations. The results are expressed in terms of the stability boundary in the (ξ, ν_β) space. There is enough room for the working area during normal SSC operations.

3. Pacman effect:

In the SSC bunch train there are seven injection gaps (1.7 μ s each) and one abort gap (4.1 μ s). Bunches near the edge of the gaps may miss collisions at some IP, thus experiencing an irregular collision sequence. These bunches will have different orbit distortion, different tune shift, and different tune spread from those with a normal collision sequence. This makes the orbit and tune correction difficult. But simulations show that there should be enough working area in the tune space to accommodate the additional tune shift and spread due to the Pacman effect.

4. Synchro-betatron resonance:¹⁵

The finite crossing angle will excite synchro-betatron resonances. Computer simulations show that this is not a serious problem at the SSC. This is because the three main parameters that determine the strength of the resonances are small at the SSC. They are: (a) the beam-beam parameter ξ (0.0009), (b) the synchrotron tune ν_s (0.0012), and (c) the normalized crossing angle $\alpha \sigma_z / \sigma_\beta$ (0.45). With $\alpha = 150 \mu$ rad, only the satellites of the resonances up to the order of six could be harmful to the beams. Between these resonances there is enough space for the working area.

8.0 CONCLUSION

Although the SSC will never be built, the results of beam instability studies during the past four years may still serve as useful references for future accelerators. Moreover, the new tools (*e.g.*, the code bperm), new measurements (*e.g.*, the surface resistance at low temperature, high frequencies, and high magnetic field), and new analysis (*e.g.*, the trapped rf modes effect, the noise level specification in a feedback system, the aluminum

alloy beam tube, and the liner impedance) that have been developed at the SSC will remain as valuable properties of the whole accelerator community.

Glossary

$Z_{\parallel}/n$	longitudinal impedance
$Z_{\perp}$	transverse impedance
Z_0	vacuum impedance
γ	relativistic energy of the particle
β	relativistic velocity
η	slip factor
IP	interaction point
σ_z	rms bunch length
σ_p/p	rms relative momentum spread
N_B	number of particles per bunch
ν_β	betatron tune
r_p	classical radius of proton
ϵ_L	rms longitudinal emittance
V_{rf}	rf peak voltage
τ_w	resistive wall instability growth time
N_{tot}	total number of particles
c	velocity of light
R	average machine radius
δ_s	skin depth
b	beam tube radius
μ	vacuum permeability
σ_e	wall conductivity
ω	angular frequency
ω_0	angular revolution frequency
Δ	coating layer thickness
RRR	residual resistance ratio
ID	inner radius
g	gain of a feedback system
x_N	noise level at the pickup
σ_ν	rms tune spread
$\Delta\nu$	total tune spread
σ_β	rms beam size
β_x	beta function
Δx	theoretical limit of pickup resolution

k_B	Boltzmann constant
T	temperature in Kelvin
Δf	bandwidth of a feedback system
NF	noise factor (in dB) of a feedback system
d	half distance between two pickup electrodes
Z	characteristic impedance
ℓ	length of the electrodes
I_{av}	average beam current
M	number of particle bunches
f_0	revolution frequency
k	loss factor
$\tilde{\lambda}(\omega)$	bunch spectrum
R_{wall}	wall resistance
R_s	surface resistance
$\mathcal{L}$	luminosity
ϵ	transverse emittance
ϵ_N	normalized transverse emittance
N_{IP}	number of interaction points
σ_{inel}	inelastic cross section
σ_{el}	elastic cross section
σ_θ	rms value of pp elastic scattering angle in the center of mass system
ξ	beam-beam parameter
α	crossing angle
R_{re}	luminosity reduction factor due to the crossing angle
L^*	effective interaction distance
S_B	bunch spacing
β^*	β -function at the interaction point
ν_s	synchrotron tune
$\Delta\nu_{HO}$	head-on beam-beam tune shift
$\Delta\nu_{LR}$	long-range beam-beam tune shift
$\delta\nu_{LR}$	long-range beam-beam tune spread
δx	orbit distortion
ϕ	phase advance
n	Betatron oscillation amplitude in unit σ_β
