EXECUTIVE SUMMARY

One of the initial stages in ecological risk assessment for hazardous waste sites is the screening of contaminants to determine which of them are worthy of further consideration as "contaminants of potential concern." This process is termed "contaminant screening." It is performed by comparing measured ambient concentrations of chemicals to benchmark concentrations. Currently, no standard benchmark concentrations exist for assessing contaminants in soil with respect to their toxicity to plants. This report presents a standard method for deriving benchmarks for this purpose (phytotoxicity benchmarks), a set of data concerning effects of chemicals in soil or soil solution on plants, and a set of phytotoxicity benchmarks for 34 chemicals potentially associated with U.S. Department of Energy (DOE) sites. Chemicals that are found in soil at concentrations exceeding both the phytotoxicity benchmark and the background concentration for the soil type should be considered contaminants of potential concern.

1. INTRODUCTION

An important step in ecological risk assessment is screening the chemicals occurring on a site for contaminants of potential concern. Screening may be accomplished by comparing reported concentrations in media to a set of toxicological benchmarks. If a chemical concentration or the reported detection limit exceeds the screening benchmark, more analysis is needed to determine the hazards posed by that chemical (i.e., it is a contaminant of potential concern). If, however, the chemical concentration or its detection limit falls below the proposed benchmark, the chemical may be ignored during further study unless public concern or ancillary evidence suggest that it should be retained.

The purpose of this report is to present plant toxicity data and discuss their utility as benchmarks for determining the hazard to terrestrial plants caused by contaminants in soil. Benchmarks are provided for soils and solutions.

Tests of the toxicity of chemicals in the rooting medium of plants are conducted using a variety of rooting media. We have divided them into three categories: soil, solution, and other. Tests conducted in natural soils (even when brought into the laboratory, dried, sieved, fertilized, etc.) are assumed to be representative of the exposure of plants to contaminants measured in field soils. Tests conducted in nutrient solutions are assumed to be representative of exposures of plants to contaminants measured in soil solutions (e.g., from lysimeter samples or possibly from aqueous extracts of soil) or in very shallow groundwater (e.g., plants in the vicinity of seeps and springs). The other category includes media that are neither soils nor solutions, such as silica sand and vermiculite. Data from such studies are not clearly related to any contaminant measurements in ambient media. However, they are included in the review for purposes of comparison.

Soil benchmarks are based on data provided only by toxicity studies in either the field or pots. The reported toxic concentrations are not all equivalent to concentrations reported from field sites. Most of the soil concentrations of metals reported from waste sites are from extractions with hydrochloric acid (HCl) or other mineral acids which are intended to provide total concentrations. Similarly, concentrations of organic contaminants in waste site soils are total concentrations derived from rigorous solvent extractions. In some cases, toxicity tests report concentrations extracted from contaminated soils, but various extractants are used that may not yield total concentrations. More commonly, the concentrations reported are nominal concentrations of a soluble form (i.e., a highly bioavailable form) of the chemical added to soil.

Solution benchmarks include data from toxicity tests conducted using whole plants rooted in aqueous nutrient solutions. Tests are commonly conducted in this manner because plants are assumed to be exposed to contaminants in the solution phase of soil and the presence of soil in test systems reduces the experimenter's degree of control over exposure. Groundwater samples from waste sites are typically acidified before analysis to obtain total concentrations, but some samples are filtered before acidification.

In general, the concentrations in prefiltered samples are likely to be more comparable to the concentrations reported from solution toxicity tests and should be used if available.

These benchmarks are to serve for contaminant screening only. Plant toxicity may be affected by many variables: pH, Eh, cation exchange capacity, moisture content, interactions with other elements, and organic matter and clay content of the soil. In addition, different species react to different contaminants with varying degrees of toxicity, and the sensitivity of plants may be affected by its physiological condition. No systematic tests that thoroughly examine the effects of these variables on plant toxicity are known to these authors. An assessor must realize that these soil characteristics play a large part in plant toxicity and incorporate these site-specific considerations in the evaluation of the potential hazards of a chemical. If chemical concentrations reported in field soils that support vigorous and diverse plant communities exceed one or more of the benchmarks presented in this report or if a benchmark exceeds background soil concentrations, it is generally safe to assume that the benchmark is a poor measure of risk at that site.

2. METHODS

2.1 DATA

References on the toxicity of selected chemicals to terrestrial plants were obtained from searches of bibliographic data bases (BIOSIS, POL TOX I), a numeric data base (PHYTOTOX), review articles, and conventional literature searching. The target was reports of toxicity tests of individual chemicals in laboratory, greenhouse, or field settings.

Data presented in this report were derived mainly from primary sources. Secondary sources were used if the primary source cited in the secondary source was unavailable, if only a little data for a particular chemical were available, and if secondary sources suggested that a benchmark derived from limited primary source material was too high. The general criteria for inclusion of a study in the data set used to derive phytotoxicity benchmarks were:

1. Methodology was clearly stated (especially concentrations of applied chemicals) and followed in the experiment.
2. Results were quantified as measures of plant growth or yield (e.g., weight, height). Measures of metabolic activity or tissue chemical concentration were used if measures of growth or yield were not available for a particular chemical of interest.
3. Results were presented in numeric form or graphical presentations of data were clearly interpretable.
4. An unambiguous reduction existed in the measured parameter within the range of applied concentrations of the chemical of interest.

The data selected using these criteria were assigned to the following categories for analysis:

1. Chemical—The effects of individual chemicals of interest were analyzed. In the case of

metals, the metal itself is listed in the "Chemical" field, with the salt listed in the "Form" field. For organics, the specific compound is listed in the "Chemical" field, except in the case of polychlorinated biphenyl (PCB) for which the specific Aroclor mixture is listed in the "Form" field.

2. Growth Medium—Methodologies were divided into three general groupings of growth media:

- a. Solution: this category includes experiments in which the roots of plants were submerged in solutions of variable composition containing the chemical of interest. In most studies, plant growth nutrients were added. Solution pH was noted when given.
- b. Soil: this category includes soils derived from field soil profiles, regardless of subsequent preparation and experimental location. Soil pH and organic matter content were noted when given. Percentage organic carbon was converted to the more frequently cited measure of percentage organic matter, by the equation (Nelson and Sommers, 1982):

$$\% \text{organic carbon} \times 2 = \% \text{organic matter}$$

- c. Other: this group is made up of alternative growth media such as pure quartz or silica sand, vermiculite, and peat moss. Medium pH was noted when given.
3. Plant Species—The analysis was limited to terrestrial vascular plants, mainly domestic cultivars. Plant growth stages were seed germination and early growth, seedling, or seedling to maturity (e.g., grains and vegetables).
 4. Exposure duration—The durations of exposure of the test plants to chemicals of interest ranged from 2 to 279 days, with trees generally being exposed longer than plants with shorter life spans.
 5. NOEC—The no observed effect concentration (NOEC) is defined here as the highest applied concentration of the chemical of interest which gave a reduction of 20% or less in a measured response.
 6. LOEC—The lowest observed effect concentration (LOEC) is defined here as the lowest applied concentration of the chemical of interest which gave a greater than 20% reduction in a measured response. In some cases, the LOEC for the test was the lowest concentration tested (LCT) or the only concentration tested, as of when the EC_{50} was reported.
 7. Response parameter—The majority of the responses were oven-dry weights of whole plants or their parts. Others included root length, plant height, relative growth rate, grain yield, seeds per plant, percent seed germination, and fresh and air-dry weights. Responses other than these growth and yield parameters were included only if growth or yield parameters were unavailable for a chemical. Transpiration rate, CO_2 uptake, and chlorophyll content of needles were recorded for methyl mercury; chlorophyll content of needles for mercury also was recorded.

2.2 SELECTION OF TYPES AND LEVELS OF EFFECTS

Growth and yield parameters were used for two reasons. First, they are the most common class of response parameters reported from phytotoxicity studies thereby using those parameters allowed for derivation of reasonably consistent benchmarks for a large number of contaminants. Second, growth and yield are ecologically significant responses both in terms of the plant populations and the ability of the biota to support higher trophic levels.

Twenty percent reduction in growth or yield was used as the threshold for significant effects to be consistent with other screening benchmarks for ecological risk assessment and with current regulatory practice (Suter et al., 1992). In brief, most regulatory criteria are based on concentrations that cause effects that are statistically significantly different from controls, which on average correspond to greater than 20% effects. In addition, regulatory actions may be based on comparisons of biological parameters measured on contaminated sites to those from reference sites. Differences between sites generally must be greater than 20% to be reliably detected in such studies. Therefore, the 20% effects level is treated as a conservative approximation of the threshold for regulatory concern.

2.3 DERIVATION OF BENCHMARKS

Because of the diversity of soils, plant species, chemical forms, and test procedures, it is not possible to estimate concentrations that would constitute a threshold for toxic effects on the plant communities at particular sites from published toxicity data. This situation is analogous to the problem of deriving benchmarks for sediments. In this report, the method used for deriving soil benchmarks is based on the National Oceanographic and Atmospheric Administration's method for deriving the Effects Range Low (ER-L) (Long and Morgan, 1990) which has been recommended as a sediment screening benchmark by U.S. Environmental Protection Agency (EPA) Region IV. The ER-L is the tenth percentile of the distribution of various toxic effects thresholds for various organisms in sediments.

This approach can be justified by assuming that the toxicity of a chemical in soil is a random variate, that the toxicity of contaminated soil at a particular site is drawn from the same distribution, and that the assessor should be 90% certain of protecting plants growing in the site soil. Any bias in the data set would mitigate against that assumption. In this implementation of the approach, the bias most likely to be significant is the use of soluble salts of metals in the toxicity tests which are likely to be more toxic than the mixture of forms encountered in field soils. That bias would result in conservative benchmark values. Other possible sources of bias include the use of predominately domestic plant species that may not be representative of plant species in general, use of predominately agricultural soils which may not be representative of soils in general, and the laboratory test conditions which may not be representative of field conditions. The direction and magnitude of these potential biases is unknown.

The phytotoxicity benchmarks were derived by rank ordering the LOEC values and then picking a number that approximated the tenth percentile. As with the ER-Ls, statistical fitting was not used because there was seldom sufficient data and because these benchmarks are to be used as screening values and do not require the consistency and precision of regulatory criteria.

If there were 10 or fewer values for a chemical, the lowest LOEC was used. If there were more than 10 values, the tenth percentile LOEC value was used. If the tenth percentile fell between LOEC values, a value was chosen by interpolation. In all cases, benchmark values were rounded to one significant figure.

Another possible source of benchmark values is values recommended in published reviews of the phytotoxicity literature. When primary literature is unavailable for a particular contaminant, concentrations identified in reviews as thresholds for phytotoxicity are used as benchmarks. In addition, when fewer than three LOEC values were found for a chemical in soil or solution, and a toxicity threshold from a review is lower than the lowest LOEC, the toxicity threshold is used as the benchmark for that chemical.

Any scheme for deriving a set of standard ecotoxicological benchmarks is based on assumptions that may be questioned by readers. The procedure used here is one that is consistent with current regulatory practice and contains a minimum of assumptions or factors. Those who care to make other assumptions or to add safety factors may make use of the data presented here to calculate their own benchmarks.

3. RESULTS

Results of the literature review are summarized in Table 1. Proposed screening benchmarks for phytotoxic effects of contaminants in soils and solutions are presented in Table 2.

4. RECOMMENDATIONS AND CONCLUSIONS

The values presented in Table 2 are intended for contaminant screening in the hazard identification (problem formulation) phase of ecological risk assessments. Chemicals with soil concentrations that exceed both the phytotoxicity benchmark for soil and the background soil concentration for the soil type, and which may be derived from waste disposal, are contaminants of potential concern. Background soil concentrations have been derived for the Oak Ridge Reservation and should be generated for other Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) sites as well. Similarly, soil solution or shallow groundwater concentrations that exceed both the phytotoxicity benchmark for solutions and the background water concentration for the aquifer, which may be derived from waste disposal, and to which plant roots may be exposed are contaminants of potential concern.

For baseline ecological risk assessments, and other assessments that may lead to regulatory actions, assessors should consult the primary sources of toxicity data and then determine the applicability of the data to their specific site. In addition, assessments should not blindly rely on laboratory toxicity data. Where phytotoxicity is suspected, phytotoxicity tests should be performed with the contaminated soil. In addition, the site should be surveyed for signs of phytotoxicity such as inexplicable bare areas, low plant diversity, low plant vigor, or symptoms of toxic injury.
