ABSTRACT. A new generation of synchrotron radiation light sources covering the VUV, soft x-ray, and hard x-ray spectral regions is under construction in several countries. These sources are designed specifically to use periodic magnetic undulators and low-emittance electron or positron beams to produce high-brightness near-diffraction-limited synchrotron radiation beams. Some of the novel features of the new sources are discussed, along with the characteristics of the radiation produced, with emphasis on the Advanced Light Source, a third-generation 1.5 GeV storage ring optimized for undulator use. A review of the properties of undulator radiation is presented, followed by a discussion of some of the unique challenges being faced by the builders and users of the new undulator sources. These include difficult mechanical and magnetic tolerance limits, a complex interaction with the storage ring, high x-ray beam power, partial coherence, harmonics, optics contamination, and the unusual spectral and angular properties of undulator radiation.

1. Introduction

Undulators are now established as operational sources of ultraviolet and x-ray radiation at many synchrotron radiation facilities around the world. They are providing qualitatively new and better types of radiation beams and have been involved in many of the most creative new experiments. The success of undulators can be credited to the combined efforts of the originators of the undulator concepts (Motz, 1951; Motz *et al.*, 1953; Madey, 1971; Alferov *et al.*, 1974; Kincaid, 1977), and to more recent activities such as the work of magnet specialists in the realization of practical undulators (Halbach 1981, 1983; Halbach *et al.*, 1981), accelerator designers (Chasman *et al.*, 1975; Green, 1977; Vignola, 1985), builders who incorporated wigglers and undulators into real storage rings (Bazin *et al.*, 1980; Artamonov *et al.*, 1980A, 1980B; Brown *et al.*, 1983; Krinsky *et al.*, 1983), and users applying the undulator radiation to scientific problems (Rarback *et al.*, 1986; Johnson *et al.*, 1992). A primary motivation for investment in undulators is that undulator beams concentrate the x-ray output into fairly narrow spectral peaks that can be arranged to cover the desired photon energy range. This greatly reduces the amount of unwanted x-ray power and the associated engineering challenges. The experimental benefits of the higher-brightness beams provided by undulators fall into two main classes: (1) the possibility for improved performance of monochromators, and (2) the ability to focus the x-ray beam to a small probe. These are essentially applications of the small optical-phase-space area of undulator beams and, in general, they use a multiplicity of wave modes. A third related benefit, which we consider to be separate, is that a useful amount of power is now available in a *single* mode. This is one of the qualitatively new features of undulator radiation and opens the way for a class of experiments that use coherent beams.

In this report, we consider the physical basis and characteristics of undulator radiation and the calculation of its spectral and angular distribution. We describe the coherence properties of undulator beams and show how to calculate the coherence functions needed for applications. We examine the effect of real-world variables on the production of undulator radiation, including the beam optics of the storage ring, radiation from the upstream and downstream bending magnets, and failure of the far-field assumption that is conventionally used in calculating undulator output. We give a brief analysis of the effect of undulator magnetic field errors on the electron beam and on the radiated spectrum and discuss several examples from the Advanced Light Source (ALS) undulator program. Finally, we make some comments on the capability of present-day undulator technology and the performance trade-offs now available.

2. Fundamentals of Radiation Emission by Fast Electrons: Time Compression

Following Kim, 1989, we consider an electron with an instantaneous velocity $\mathbf{v} = \beta c$ (c being the velocity of light) on an arbitrary trajectory $\mathbf{r}(t')$ relative to an origin O as shown in Fig. 1. An observer is located at $\mathbf{x}$, whose position relative to the electron is specified by the unit vector $\mathbf{n}$ making an angle θ with $\mathbf{v}$. An electromagnetic signal emitted by the electron at time t' and traveling in a straight line will arrive at the observer at a later time t , where

$$t = t' + \frac{|\mathbf{x} - \mathbf{r}(t')|}{c} \quad (1)$$

The stationary observer sees the electron's motion as a function of time t , which is different from $\mathbf{r}(t')$ due to the change in time scale represented by Eq. (1). The scale-change factor is given by

$$\frac{dt}{dt'} = 1 + \frac{d|\mathbf{x} - \mathbf{r}(t')|}{dt'} \frac{1}{c} = 1 - \mathbf{n} \cdot \boldsymbol{\beta} = 1 - \beta \cos \theta \quad (2)$$

If we now define γ for the electron as the ratio of its mass to its rest mass, then we have

Figure 1. Electron trajectory, observer and notation for time compression.

$$\gamma = \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}} = \frac{1}{\sqrt{(1 - \beta)(1 + \beta)}} \quad (3)$$

$$1 - \beta \equiv \frac{1}{2\gamma^2} \quad .$$

If we now expand the cosine in Eq. (2) and use Eq. (3), we arrive at

$$\frac{dt}{dt'} = \frac{1}{2} \left(\frac{1}{\gamma^2} + \theta^2 \right) , \quad (4)$$

which allows us to estimate the size of the “time-compression” effect represented by dt/dt' . For typical storage rings, the electrons are extremely relativistic and γ is of the order of a few thousand. This means that if $\theta \approx 0$, then the time is compressed by a factor of a few million. On the other hand, if θ is greater than a few times $1/\gamma$, then the θ^2 term dominates in Eq. (4) and the time compression is much less. The time compression is the factor by which the wavelength of signals radiated by the electron is shortened. We see from this argument that, in practical cases, the time compression is a very large effect, but it is mainly confined to emission angles within a cone of half angle $1/\gamma$ around the line from the observer to a “tangent point” on the electron trajectory.

Physically, the time compression is due to the fact that a highly relativistic electron follows very closely behind the signals it emitted at earlier times. Moreover, the strength of the electric field at the observer is proportional to the apparent transverse acceleration of the electron as seen by the observer, which will be large when the time compression is large. Thus, the amount of radiation will be large within the $1/\gamma$ emission cone. To see this more quantitatively, consider a tangent point P on an electron trajectory with local radius of curvature ρ , and define a curve segment AB centered on P and subtending an angle $2/\gamma$ at the center of curvature (Fig. 2a). In terms of the emission time, the electron moves from A to P in a time $\Delta t' = \rho/\gamma$ and, during that time, suffers a transverse displacement Δx of ρ/γ^2 (Fig. 2b). In terms of observation time, the displacement Δx happens in the much shorter time $\Delta t = \Delta t' \gamma^2 = \rho/2\gamma^3 c$. Thus, the motion seen by the observer has the form shown in Fig. 2c. The sharp kink at P corresponds to a very large transverse acceleration as seen by the observer,

$$\frac{d^2x}{dt^2} \approx \frac{\Delta x}{(\Delta t_{A \rightarrow P})^2} = \frac{4c^2\gamma^4}{\rho} , \quad (5)$$

which is of order γ^4 times larger than the acceleration in the emission time frame. On this basis, the typical frequency of the radiation should be about $1/\Delta t$ or $2\gamma^3 c/\rho$. This is in reasonable agreement with the so-called “critical frequency” $\omega_c = 3\gamma^3 c/2\rho$, which is conventionally used to characterize a bending magnet spectrum.

3. Undulators

3.1. BASIC DESCRIPTION

An undulator is a device intended to drive the electron in a sinusoidal trajectory. Most commonly, this is accomplished by applying an alternating magnetic field in the vertical direction

XBL938-5146

Figure 2. The effect of time compression: (a) the electron trajectory in space, (b) radial coordinate as a function of emission time t' , (c) the apparent variation of the radial coordinate as a function of observation time t . (From Kim, 1989.) See text for further explanation.

so that the oscillations lie in the horizontal plane. We begin with the case of an exactly sinusoidal field and trajectory as shown schematically in Fig. 3. For this case,

$$\begin{aligned} x &= -a \cos(k_u z) \\ \frac{dx}{dz} &= k_u a \sin(k_u z) \\ \left(\frac{d^2x}{dz^2} \right)_{\max} &= k_u^2 a = \frac{1}{\rho} \end{aligned} \quad (6)$$

where z is along the undulator axis, x is horizontal, y is vertical, and $k_u = 2\pi/\lambda_u$. The centripetal force at maximum curvature (radius = ρ) is that corresponding to the peak field $\mathbf{B}$ and is given by

$$e\mathbf{v} \times \mathbf{B} = \frac{m_e v^2}{\rho} \quad \text{or} \quad \rho = \frac{m_0 \gamma c}{eB} \quad (7)$$

where e , m_e , and m_0 are the electronic charge, mass, and rest mass, respectively. Eliminating a and ρ between Eqs. (7), (8), and (9), we can determine a value for $(dx/dz)_{\max}$ that we define to be equal to K/γ . When defined in this way, the deflection parameter K is given by

$$K = \frac{eB}{k_u m_0 c} = 0.934 \lambda_u (\text{cm}) B (\text{T}) \quad (8)$$

and is equal to the maximum angular excursion of the beam in units of $1/\gamma$. From Eqs. (6) and (7), we can also obtain the following expressions for a and $\beta_x = v_x/c$:

Figure 3. Basic undulator layout and notation.

$$a = \frac{K}{k_u \gamma}$$

(9)

$$\frac{dx}{dz} = \frac{dx}{dt} \frac{dt}{dz} = \beta_x = \frac{K}{\gamma} \sin(k_u z) ,$$

The value of a is normally rather small (about 10 μm or so), which makes it much less than the horizontal width of most storage ring electron beams.

A device that deflects the beam by about $1/\gamma$ or less is known as an undulator ($K \lesssim 1$). One that deflects the beam by much more than $1/\gamma$ is known as a wiggler ($K \gg 1$). According to our earlier discussion of time-compression, the synchrotron radiation beam can be regarded as a kind of "searchlight," of angular half width about $1/\gamma$, pointing along a tangent to the electron trajectory. The above definitions, therefore, suggest that the time variation of the electric field as seen by the observer will be roughly sinusoidal for an undulator and will consist of a series of pulses for a wiggler. It is, consequently, quite understandable that the spectrum (the Fourier transform of the field) of an undulator has a sharp peak with a few harmonics while the spectrum of a wiggler has a broad distribution of harmonics. Two representative spectra are shown in Fig. 4. It is noteworthy that the wiggler spectrum extends as far as a harmonic number approximately equal to K^3 .

3.2. THE FUNDAMENTAL EQUATION

The fundamental equation of undulator action sets a relationship between the wavelength of the undulator and the wavelength of the emitted radiation. The undulator output wavelength is determined essentially by the Doppler shift due to the motion of the radiating electron. The amount of the shift, or "time-compression factor," which is also the compression factor between lengths, is given by Eq. (2) as

$$\lambda_1 = \lambda_u (1 - \bar{\beta}_z \cos \theta) . \quad (10)$$

Figure 4. Wiggler and undulator comparative spectra.

Here, $\bar{\beta}_z$ is the average forward velocity of the electron and is given by

$$\bar{\beta}_z = \beta \overline{\cos \psi} \equiv \beta \left(1 - \frac{\overline{\psi^2}}{2} + \dots \right) = \beta \left(1 - \frac{1}{2} \frac{\psi_{\max}^2}{2} + \dots \right) = \beta \left(1 - \frac{K^2}{4\gamma^2} + \dots \right), \quad (11)$$

where $\beta_z = \beta \cos \psi$ and ψ is the angle of the electron trajectory to the axis. By expanding the cosine in Eq. (10), using Eq. (3) for $1 - \beta$, and allowing for harmonics, we get

$$\lambda_m = \frac{\lambda_u}{2m\gamma^2} \left(1 + \frac{K^2}{2} + \gamma^2 \theta^2 \right). \quad (12)$$

This is the fundamental equation describing undulator action derived from the principle of time compression. Another point of view, applicable to the on-axis radiation, is that the factor $\lambda_u/2\gamma^2$ represents two separate effects: (1) the Lorentz contraction of the undulator period as seen by the moving electron (a factor $1/\gamma$), and (2) a relativistic Doppler shift of the emitted wavelength due to the relative velocity of the electron and observer (a factor $1/2\gamma$).

We have introduced the deflection parameter K as a measure of the angular excursion. It is also a dimensionless measure of vector potential and scales as $\lambda_u \cdot B$ for a pure sine-wave undulator. In actual undulators, the magnetic field is non-sinusoidal and can be represented as a Fourier series with only odd spatial harmonics, as in Eq. (54). The even spatial harmonics are normally forbidden by the symmetry of the magnetic structure. We can regard our results in Section 3.1 as applying to the first harmonic of such a series and then repeat the development of Eqs. (6) through (8) for the m th harmonic. This leads to

$$K_m = \frac{eB_m}{mk_u m_0 c}. \quad (13)$$

The undulator output wavelength is determined essentially by the time compression due to the motion of the radiating electron. The amount of time compression is given by Eq. (10), which leads to the fundamental equation as shown above. For an undulator field described by a Fourier series like Eq. (54), the average forward velocity is modified. The output wavelength is still determined by K via the same fundamental equation, but K is now defined as

$$K = \sqrt{\sum_m K_m^2} = \frac{eB_{\text{eff}}}{k_u m_0 c}, \quad \text{where } B_{\text{eff}} = \sqrt{\sum_m \frac{B_m^2}{m^2}}. \quad (14)$$

The relations in Eq. (14) are proved in Appendix 1. It is noteworthy that B_{eff} is neither the rms field nor the peak field.

3.3. DIFFRACTION LIMITS AND THE CENTRAL CONE

From Eq. (12), we see that the on-axis wavelength is lengthened (red-shifted) if the receiving point moves off the axis or, equivalently, if the electron trajectory has an angle to the axis. We also know that the fundamental wave train radiated by the undulator must have N periods, where $N\lambda_u = L$ and L is the length of the undulator. Therefore, even a single electron emission pattern on axis must have a spectral spread of about $\Delta\lambda/\lambda = 1/N$ for the fundamental or $\Delta\lambda/\lambda_m = 1/mN$ for the m th harmonic. From Eq. (12), we find that the amount of red shift is

$$\frac{\Delta\lambda}{\lambda_m} = \frac{\lambda_m(\theta) - \lambda_m(0)}{\lambda_m(0)} = \frac{\gamma^2\theta^2}{1 + \frac{K^2}{2}} \equiv \gamma^{*2}\theta^2 \quad (15)$$

Equation (15) defines a useful quantity, γ^* . Further, let us define an angle σ'_r corresponding to a spectral spread $\Delta\lambda/\lambda_m = 1/2mN$ as

$$\sigma'_r = \frac{1}{\gamma^*} \sqrt{\frac{1}{2mN}} \equiv \sqrt{\frac{\lambda_m}{L}} \quad (16)$$

The angle σ'_r turns out to be important in the analysis of undulator beams. It is the rms width of the one-electron undulator beam due to diffraction. One can see this in a rough way by calculating the angle of the first minimum of the diffraction pattern of an ideal longitudinal line source. Consider a parallel beam of rays emitted coherently at angle θ from every point on the source. The diffraction minimum will occur when the path difference between the rays from the upstream and downstream ends of the source ($L - L\cos\theta$) is equal to $\lambda/2$. This leads directly to $\theta = \sqrt{\lambda/L}$.

Equations (15) and (16) show that, provided the collection half angle θ_{cc} is less than σ'_r , then the intrinsic spectral width $1/mN$ is not much spoiled by red shifting. The radiation within θ_{cc} is called the central cone and is the most useful part of the undulator emission. The central cone of an undulator beam is even more highly collimated than normal synchrotron radiation. Equation (16) shows that it has a characteristic angular width $1/(\gamma\sqrt{N})$, which is substantially smaller than the $1/\gamma$ width of a bending magnet beam. Because every harmonic is red shifted according to Eq. (12), the wavelength of each harmonic will equal that of the fundamental at a sufficiently large off-axis angle. The radiation pattern at the fundamental frequency thus consists of a bright central peak on the axis and a series of partially illuminated rings of angular radius $\sqrt{m-1}/\gamma^*$. A similar argument holds for higher harmonics which have rings due to the harmonics of higher number than themselves.

For the case of a real electron beam, it may happen that the electron beam angular spread σ'_x is greater than θ_{cc} . In this case, the central cone width has to be defined equal to σ'_x , and this will represent a degradation of the spectral brightness of the undulator. Storage rings such as the ALS, which are intended to operate with undulators, are designed to have electron beam angular spreads that are small compared to θ_{cc} .

3.4. PRACTICAL REALIZATION OF UNDULATORS

The practical realization of undulators is now nearly always by means of permanent magnets following the methods developed by Halbach, 1981, 1983, and Halbach *et al.*, 1981. We do not have space for a review here, but the most common design for building high-field devices (the so-called hybrid scheme) consists of blocks of permanent magnet material combined with soft iron pole pieces as shown in Fig. 5. The materials used for the recently completed ALS undulators were neodymium-iron-boron blocks and vanadium permendur pole pieces. The ALS devices are the largest and most demanding yet attempted, and their achieved field quality and projected performances are treated in more detail in a later section.

The technology of the undulator magnetic structure and the physics of the resulting magnetic field distributions set limits on the range of devices that can, in principle, be built. Usually, one starts with a knowledge of a photon energy operating range and a magnetic gap defined by the requirements of the storage ring injection system. As a start, we may safely assume that the output of an undulator falls to zero as K approaches zero. In fact, as we shall see in Section 4, it

CSEM-Steel Hybrid Insertion Device

Figure 5. Construction of a hybrid undulator from current-sheet-equivalent material (CSEM) and steel .

falls to about half maximum at $K = 0.5$, and fairly rapidly below that, so that we may reasonably regard $K = 0.5$ as a limit. Using Eq. (12) with $K = 0.5$ and $\theta = 0$, we obtain the value for λ_u that delivers the required minimum wavelength. Accepting this value, we then find that the maximum wavelength obtainable will be determined, via Eq. (12), by the highest achievable value of K , which depends on the field.

A certain amount of information about the field can be calculated from formulas that apply to magnet structures of optimum design (Halbach, 1983);

Neodymium – iron:

$$B_0 = 3.44 \exp \left[-\frac{g}{\lambda_u} \left(5.08 - 1.54 \frac{g}{\lambda_u} \right) \right] \quad 0.085 < \frac{g}{\lambda_u} < 0.8 \quad (17)$$

Samarium – cobalt:

$$B_0 = 3.33 \exp \left[-\frac{g}{\lambda_u} \left(5.47 - 1.8 \frac{g}{\lambda_u} \right) \right] \quad 0.07 < \frac{g}{\lambda_u} < 0.7 \quad (18)$$

In these formulas, B_0 is the peak field and, hence, is an overestimate of B_{eff} . Using B_0 to compute K or λ would, therefore, be incorrect. An accurate evaluation of the value of K via Eq. (14) (and thence λ) requires a knowledge of the Fourier expansion of the field. This can be obtained using a program such as POISSON (see for example, Warren *et al.*, 1987). In pursuing this type of design exercise, one possible variation is to reduce λ_0 somewhat to gain some brightness (larger N for a given L) and reduce the total power. The trade-off would be a reduction in the spectral range. We consider this question further in Section 7.1.

Although Eqs. (17) and (18) are correctly given in the reference quoted, they have, nevertheless, often been misunderstood. Accordingly, we wish to point out several things that these equations do *not* imply.

1. They can only be used in the stated ranges of values of the gap-to-period ratio. Outside the stated ranges they can give meaningless results.
2. They give the maximum total field obtainable by good design for a single gap-to-period ratio. They do not predict what field this same well-designed undulator will produce at other gap-to-period ratios.
3. The field given is the *peak* field, not the rms field or the B_{eff} used in Eq. (14). Consequently, one cannot obtain a correct value for K using B_0 from Eqs. (17) or (18).
4. The total field may contain a strong harmonic content. For the smallest gap-to-period ratios, the field is highly non-sinusoidal. The greater the harmonic content, the greater the difference between B_0 and B_{eff} .

4. Characteristics of Undulator Radiation

4.1. CALCULATION OF THE SPECTRAL AND ANGULAR DISTRIBUTIONS

The general problem of calculating radiation from accelerated electrons has received extensive attention in the literature as reviewed as reviewed, for example, by Blewett, 1988. The first derivation of a synchrotron radiation spectrum was in the 1912 publication by G.A. Schott (Schott, 1912), although not much could be done with it at the time. After the experimental discovery of synchrotron radiation, Schwinger derived expressions in terms of known functions describing bending magnet radiation and clarified the physics of the process (Schwinger, 1949). A lucid treatment of the problem, and one which has been widely used by other authors, is provided by Jackson, 1975. If the coordinate system is the one shown in Fig. 6, then according to Jackson, the flux per unit solid angle is given (in SI units) exactly by

$$\frac{dI(\omega)}{d\omega d\Omega} = \frac{1}{4\pi\epsilon_0} \frac{e^2\omega^2}{4\pi^2c} \left| \int_{-\infty}^{+\infty} \left\{ \frac{\mathbf{n} \times [\mathbf{n} - \boldsymbol{\beta}] \times \dot{\boldsymbol{\beta}}}{(1 - \mathbf{n} \cdot \boldsymbol{\beta})^2 R} + \frac{(\mathbf{n} - \boldsymbol{\beta}) c}{\gamma^2 (1 - \mathbf{n} \cdot \boldsymbol{\beta})^2 R^2} \right\} e^{i\omega(\tau + R(\tau)/c)} d\tau \right|^2, \quad (19)$$

which reduces in the far field to

$$\frac{dI(\omega)}{d\omega d\Omega} = \frac{1}{4\pi\epsilon_0} \frac{e^2\omega^2}{4\pi^2c} \left| \int_{-\infty}^{+\infty} \mathbf{n} \times (\mathbf{n} \times \boldsymbol{\beta}) e^{i\omega(\tau - \mathbf{n} \cdot \mathbf{x}_e/c)} dt \right|^2. \quad (20)$$

Figure 6. Notation and coordinate systems for radiation calculations.

Not all applications of these equations are in the far field, and, to avoid the complication of Eq. (19), Wang, 1993B, has shown that it can be simplified to

$$\frac{dI(\omega)}{d\Omega} = \frac{\alpha \hbar \omega^4}{4\pi^2 c^2} \left| \int_{-\infty}^{+\infty} \mathbf{n}(t') e^{i\omega t'} dt' \right|^2, \quad (21)$$

provided that the distance R to the observation point satisfies $R \gg \gamma\lambda$. This requirement is much less restrictive than the far-field condition and is satisfied in all cases of interest in synchrotron radiation applications. Equation (21) has been used for numerical calculations (discussed in a later section) of the radiation pattern to be expected from the ALS undulators based on the actual measured fields of the devices. It also provides a much greater degree of physical insight into the relationship between the electron's trajectory and its radiation pattern.

The full calculation of the angular and spectral distribution of undulator radiation in terms of known functions was first given by Alferov *et al.*, 1974. Helical undulators have been treated by Kincaid, 1977. More recent treatments of the calculations, starting from Eq. (20), have been provided by Hofmann, 1986, and Krinsky *et al.*, 1983, and an *ab initio* calculation has been given by Kim, 1989. Hofmann's calculation of the spectral power per unit solid angle due to a single electron in an undulator leads to the following expression:

$$\frac{\partial^2 P_m}{\partial \Omega \partial \omega} = P_u \frac{3m^2 \gamma^{*2}}{\pi(1 + K^2/2)^2 K^{*2}} \frac{\left[(2\gamma^* \theta \cos \phi S_{m1} - K^* S_{m3})^2 + (2\gamma^* \theta \sin \phi S_{m1})^2 \right]}{(1 + \gamma^{*2} \theta^2)^3} \frac{N}{\omega_1} \left(\frac{\sin \left(\frac{\Delta \omega}{\omega_1} \pi N \right)}{\frac{\Delta \omega}{\omega_1} \pi N} \right)^2, \quad (22)$$

where

$$\begin{aligned}
\Delta\omega &= \omega - m\omega_1 \\
\omega_1 &= \frac{2\pi c / \lambda_u}{1 + K^2/2 + \gamma^2\theta^2} \\
P_u &= \frac{c}{3} \left(eK\gamma \frac{2\pi}{\lambda_u} \right)^2 \\
S_{m1} &= \sum_{l=-\infty}^{+\infty} J_l(ma_u) J_{m+2l}(mb_u) \\
S_{m3} &= \sum_{l=-\infty}^{+\infty} J_l(ma_u) (J_{m+2l+1}(mb_u) + J_{m+2l-1}(mb_u)) \\
a_u &= \frac{K^{*2}}{4(1 + \gamma^2\theta^2)}, \quad b_u = \frac{2K^*\gamma\theta^*\cos\phi}{(1 + \gamma^2\theta^2)^2} \\
K^* &= \frac{K}{\sqrt{1 + \frac{K^2}{2}}}
\end{aligned} \quad , \quad (23)$$

and θ and ϕ are the radial and azimuthal angles, respectively. In comparing Eq. (22) with the corresponding equation given by Krinsky *et al.*, 1983, and after translation of Krinsky's notation to Hofmann's, one finds that there is still an apparent disagreement in the S_{m3} term of Eq. (22), which Krinsky expresses in terms of different Bessel function series. However, upon application of the recurrence relation $J_{\mu+1}(x) + J_{\mu-1}(x) = 2\mu J_{\mu}(x)/x$, the two expressions can be seen to be fully identical.

The first term in the square bracket of Eq. (22) describes the σ polarization and the second term describes the π . Obviously, the π contribution is zero in the horizontal plane ($\phi = 0$). In fact, as shown by Kitamura, 1980, the undulator radiation is plane-polarized in the σ direction out to several central-cone widths so that this is the prevailing form for essentially all applications. The only frequency dependence in Eq. (22) is that of the sinc function, which represents the intrinsic fractional bandwidth $1/mN$ due to the presence of N undulator periods as we have noted above and can see in Fig. 4.

The shape of the light intensity distribution for the first four harmonics is depicted in Fig. 7. One can see that the strength of the even harmonics is zero on the undulator axis and that the m th pattern has m lobes along the horizontal axis of the receiving plane and none along the vertical axis. The *amount* of each harmonic present depends, in a complicated way, on all the variables and is not represented in the diagram. An important quantity, in practice, is the on-axis flux per unit solid angle $\partial \mathcal{F}_m / \partial \Omega$. We can obtain this under the approximation of zero electron beam emittance by setting $\theta = \phi = 0$ in Eq. (22). Considering the exact harmonic frequencies and using the Bessel function properties $J_{\mu}(0) = \delta_{\mu 0}$ and $J_{-\mu}(x) = (-1)^{\mu} J_{\mu}(x)$, we find that the S_1 terms of Eq. (22) vanish and

$$\begin{aligned}
S_{m3} &= \frac{J_{\frac{m+1}{2}}(ma_u) - J_{\frac{m-1}{2}}(ma_u)}{2} \quad m \text{ odd} \\
&= 0 \quad m \text{ even}
\end{aligned} \quad , \quad a_u = \frac{K^{*2}}{4}, \quad b_u = 0. \quad (24)$$

Using these values in Eq. (22), multiplying by the number of electrons in the undulator at any instant (IL/ec), and changing from power to photon flux, we finally get the flux per unit solid angle

$$\left. \frac{\partial \mathcal{F}_m}{\partial \Omega} \right|_{\theta=\phi=0} = \alpha N^2 \gamma^2 \frac{\Delta\omega}{\omega} \frac{I}{e} F_m(K) \quad , \quad (25)$$

where

Figure 7. Intensity distribution (in arbitrary units) for the first four harmonics.

Figure 7. (continued).

$$F_m(K) = \frac{K^2 m^2}{(1 + K^2/2)^2} \left(\frac{J_{m+1}(ma_u)}{2} - \frac{J_{m-1}(ma_u)}{2} \right)^2 \quad \begin{matrix} m \text{ odd} \\ = 0 \quad m \text{ even} \end{matrix} \quad (26)$$

This function is easier to calculate and is shown in Fig. 8 for several values of m . We can recast Eq. (25) in a useful way in terms of σ_r' as

$$\left. \frac{\partial \mathcal{F}_m}{\partial \Omega} \right|_{\theta=\phi=0} = \frac{\pi \alpha N \frac{1+K^2/2}{m} \frac{\Delta \omega}{\omega} \frac{I}{e} F_m(K)}{2 \pi \sigma_r'^2} \quad (27)$$

This shows that the denominator of the right hand side of Eq. (27), which we call $\mathcal{F}_m$, is approximately equal to the flux in the central cone of the m th harmonic of the one-electron pattern.

4.2. THE EFFECT OF A FINITE ELECTRON BEAM EMITTANCE

Let us now consider the case when the electron beam has a non-zero emittance. Suppose that the center of the undulator is a waist of the electron beam (implying a vertical phase-space ellipse) with horizontal (x) and vertical (y) rms beam widths (σ_x , σ_y) and angular widths (σ'_x , σ'_y) given by

$$\sigma_x = \sqrt{\varepsilon_x \beta_x}, \quad \sigma'_x = \sqrt{\frac{\varepsilon_x}{\beta_x}} \quad \text{and} \quad \sigma_y = \sqrt{\varepsilon_y \beta_y}, \quad \sigma'_y = \sqrt{\frac{\varepsilon_y}{\beta_y}}, \quad (28)$$

where ε_x , ε_y are the storage ring emittances and β_x , β_y are the electron beam amplitude functions at the waist. Suppose that an electron in the mid-plane of the undulator has phase-space coordinates (x , x' , y , y'), and that we regard the coordinates as representing a ray. Let the arrival point of the ray in a receiving plane distance D downstream be (ξ, η) . Then $\xi = x + x'D$ and $\eta = y + y'D$. If each phase-space coordinate is Gaussian-distributed, then the normalized probability that the arrival point will be (ξ, η) is

Figure 8. The function $F_m(K)$ [Eq. (26)].

$$p(\xi, \eta) = \frac{1}{2\pi\sigma_\xi\sigma_\eta} \left(\frac{-\xi^2}{2\sigma_\xi^2} \right) \exp\left(\frac{-\eta^2}{2\sigma_\eta^2} \right) , \quad (29)$$

where

$$\sigma_\xi^2 = \sigma_x^2 + D^2\sigma_x'^2 \quad \text{and} \quad \sigma_\eta^2 = \sigma_y^2 + D^2\sigma_y'^2.$$

In calculating the total intensity at (ξ, η) , we need to know the weighted average of $1/P_0 \partial^2 P / \partial \Omega \partial \omega$ over θ and ϕ . The weight corresponding to (θ, ϕ) is the probability, from Eq. (29), of the ray arrival point (uD, vD) , which is the one needed to send light at angles $(\theta \cos \phi, \theta \sin \phi)$ to the point (ξ, η) . Thus, the intensity at (ξ, η) per unit area per unit frequency interval is

$$\frac{\partial^2 I(\xi, \eta)}{\partial \omega \partial S} = \frac{1}{D^2} \int_0^\infty \int_0^{2\pi} G(K, \theta, \phi, \omega) p(u) p(v) \theta d\theta d\phi , \quad (30)$$

where G is essentially the right-hand side of Eq. (22) and $p(u)$ and $p(v)$ are normalized Gaussians like Eq. (29) with

$$\begin{aligned} u &= \frac{\xi}{D} - \theta \cos \phi & \sigma_u^2 &= \frac{\sigma_x^2}{D^2} + \sigma_x'^2 \\ v &= \frac{\eta}{D} - \theta \sin \phi & \sigma_v^2 &= \frac{\sigma_y^2}{D^2} + \sigma_y'^2 \end{aligned}$$

Although this treatment is based on the superposition of the intensities of the one-electron patterns according to the principles of geometrical optics, it remains valid in the far field even when the system is diffraction limited or partly so. However, there are regimes when both diffraction is important and the calculation is in the Fresnel region. In these cases, it is necessary to carry out a superposition of the fields rather than the intensities. This is covered by the so-called "brightness convolution theorem" (Kim, 1989), which requires use of the brightness function that we discuss in Section 5.

Since it is important to be able to model the behavior of undulators in real storage rings, it is necessary to evaluate large numbers of integrals like Eq. (30). In fact, such evaluations pose one of the principal difficulties in designing efficient codes for the frequent "production runs" involved in developing and using undulator x-ray sources. One approach to minimizing the processing time is to use Gaussian quadrature as proposed by Kincaid, 1993. There exist several fairly widely used computer codes capable of implementing the calculations discussed so far (Kim, 1989; Jacobsen and Rarback, 1985; Walker, 1992).

4.2. FLUX AND BRIGHTNESS ESTIMATES FOR REAL ELECTRON BEAMS

We now turn to assessing the effect of finite emittance on the flux per unit solid angle and on the brightness. The basic approach was worked out on geometrical optics principles by Green, 1977, for bending magnet radiation. To adapt Green's ideas to undulator radiation, we use Eq. (16) for the diffractive angular spread in place of the vertical opening angle of bending magnet radiation. This leads us to a new way to write Eq. (27) for the flux per unit solid angle:

$$\left. \frac{\partial \mathcal{F}_m}{\partial \Omega} \right|_{\theta=\phi=0} = \frac{\mathcal{F}_m}{2\pi \Sigma'_x \Sigma'_y}, \quad (31)$$

where

$$\Sigma'_x = \sqrt{\sigma_r'^2 + \sigma_x'^2} \quad \text{and} \quad \Sigma'_y = \sqrt{\sigma_r'^2 + \sigma_y'^2}. \quad (32)$$

To obtain a similar estimate of the brightness, we need to know the diffraction-limited source size σ_r corresponding to the diffraction-limited emission angle σ_r' , both of which can be calculated by approximating the one-electron undulator source as a Gaussian laser mode (Kim, 1986). At the wavelength of peak emission, which is slightly longer than λ_m (see Section 6.2), this results in the following description in terms of rms width and angular width of the radiation beam:

$$\sigma_r = \frac{\sqrt{\lambda_m L}}{4\pi}, \quad \sigma_r' = \sqrt{\frac{\lambda_m}{L}}, \quad \varepsilon = \sigma_r \sigma_r' = \frac{\lambda_m}{4\pi}. \quad (33)$$

The on-axis spectral brightness is then given by

$$B_m(0,0) = \frac{\mathcal{F}_m}{4\pi^2 \Sigma_x \Sigma'_x \Sigma_y \Sigma'_y}, \quad (34)$$

where

$$\Sigma_x = \sqrt{\sigma_x^2 + \sigma_r^2} \quad \text{and} \quad \Sigma_y = \sqrt{\sigma_y^2 + \sigma_r^2}.$$

To summarize the present section, we show in Fig. 9 the spectral flux per unit solid angle and the spectral brightness of a variety of synchrotron radiation sources as calculated by Hulbert and Weber, 1992.

5. Coherence of Undulator Radiation

5.1. SPATIAL AND TEMPORAL COHERENCE

We are interested in the possibility of interference experiments for which we must create two or more interfering beams with a definite phase relationship so as to allow interference fringes to be formed. There are two ways to do this, and each one challenges the degree of coherence of the x-ray beam in a different way. In the first method, we combine the beam with a delayed copy of itself formed by amplitude division as in the Michelson interferometer. If the delay is greater than the length of the wave train (the “coherence length” of the beam), then we will not see any interference fringes. Thus, for this method, we must have a sufficiently monochromatic beam, which is the same as having high *temporal* coherence. In the second method, we combine beams of x-rays taken from two different points on the wave front (wave front division) as in a Young’s slits experiment. If the distance between the two points is greater than the “coherence width” over which a sufficiently good phase relationship exists, then, again, we will not get the desired fringes. The requirement for this method is to have good collimation (a source subtending a sufficiently small angle at the experiment), which is the same as having high *spatial* coherence.

Figure 9. Flux (a) and brightness (b) for various synchrotron radiation sources from Hulbert and Weber, 1992.

5.2. DEFINITION OF A MODE OF THE UNDULATOR BEAM

The angle over which a source provides spatially coherent illumination is roughly the wavelength divided by the source size. If only this angle is filled with light in each of the horizontal and vertical directions, then the beam is said to comprise a single mode. Under such conditions, its size-angle product (emittance) is approximately equal to the wavelength. To make the concept of an undulator mode more precise, we represent the undulator radiation pattern in a phase space (x, x', y, y') , which is essentially the same as the phase space used to represent the electron beam. Calculations of the paraxial ray optics of the radiation beam can be carried out using matrix techniques to manipulate the vectors (x, x') and (y, y') as one would do for the electron trajectories. However, as we have seen, there are significant diffraction effects in undulator action that are not accounted for by a geometrical optics analysis nor by the computer ray-tracing techniques that have been so valuable up to now in modeling beamline optical systems. In physical optics, we are obliged to work with the fields, so we represent the electric field at distance z from the mid-plane as $E(x, y; z)$. We will also need the frequency-space representation of E , $\hat{E}(x', y', z)$, where we note that, for the small angles of interest to us, the angle variables (x', y') are proportional to the spatial frequencies $[(\sin x')/\lambda, (\sin y')/\lambda]$. E and $\hat{E}$ are thus related by a Fourier transform. We now define the rms spatial and angular extent of the fields as

$$\sqrt{\langle x^2 \rangle} = \frac{\int_{-\infty}^{+\infty} x^2 |E(x)|^2 dx}{\int_{-\infty}^{+\infty} |E(x)|^2 dx}, \quad \sqrt{\langle x'^2 \rangle} = \frac{\int_{-\infty}^{+\infty} x'^2 |\hat{E}(x')|^2 dx'}{\int_{-\infty}^{+\infty} |\hat{E}(x')|^2 dx'}. \quad (35)$$

As with any signal represented in the direct and frequency domains, the widths of the two representations are reciprocally related. In fact, the product of the widths has a minimum value that corresponds to a signal with minimum information content. Specifically, the rms widths that we have just defined are related (as shown, for example, by Bracewell, 1978) in the following way:

$$\sqrt{\langle x^2 \rangle} \sqrt{\langle x'^2 \rangle} \geq \frac{\lambda}{4\pi}. \quad (36)$$

The minimum information signal, corresponding to the equals sign in Eq. (36), can be shown to be a Gaussian wave packet. Physically, Eq. (36) represents the fact that, if the width is restricted, the angle (i.e., the frequency) will increase because of diffraction. The minimum allowed value of the width-angle product corresponds to the single-mode beam we are seeking to define, and this, therefore, has the emittance ε_c , characteristic of a spatially coherent beam, given by

$$\varepsilon_c = \sigma_r \sigma_r' = \frac{\lambda}{4\pi}. \quad (37)$$

Equation (37) is the same as Eq. (33), which was derived from the Gaussian-laser-mode representation. The rectangular function of equal area to a Gaussian has a width $\sqrt{2\pi} \sigma$, so, assuming we are dealing with Gaussian-distributed beams, we find that the phase-space area of a single-mode (spatially coherent) beam is given by

$$(xx')_c = \frac{\lambda}{2} . \quad (38)$$

The above results are derived from fundamental considerations and represent a physically correct measure of the size of the coherent phase space. However, in practical experiments, one usually needs to choose the amount of phase space to accept on the basis of a resolution-flux trade-off. Insufficient spatial coherence (accepting too much phase space) leads to a loss of resolution in a hologram, for example, while accepting too little phase space is equivalent to a loss of flux. A common compromise is exemplified by the case of illumination of a zone plate lens by a pinhole of diameter d at distance z . The complex coherence factor (Born and Wolf, 1980) of the pinhole source (taken to be incoherently illuminated) is a circular Airy function peaked at zero separation of the two test points. This function is of the same form as the amplitude distribution of the pinhole Faunhofer diffraction pattern that has a zero at a radius $1.22\lambda z/d$. The bright region inside the zero is known as the Airy disk. To maintain a high degree of spatial coherence over the whole zone plate, it would be necessary to accept light only within a region near the central peak of the complex coherence factor. However, a compromise that causes only slight loss of resolution is to set the *diameter* of the zone plate equal to the *radius* of the Airy disk. This choice maximizes the so-called “resolution-luminosity” product of the system and is equivalent to accepting phase-space areas in x and y of $(1.22\lambda)^2$ instead of $(\lambda/2)^2$, roughly a six-fold flux gain. As an example of the consequences of these ideas, we show in Fig. 10 a graph of the spatially coherent fraction of the light from ALS undulators for both the single-mode and the half-the-Airy-disk definitions of coherent phase space. The main point, of course, is that undulators are capable of delivering enough coherent flux to do many interesting coherence experiments.

5.3. THE DEGENERACY FACTOR

We traditionally characterize the usefulness of an undulator by quoting its time-averaged spectral brightness B , which is the number of photons per unit phase-space volume per unit fractional bandwidth per unit time. However, a more fundamental quantity would be its degeneracy parameter δ_w (Goodman, 1985). This dimensionless quantity is defined as the number of emitted photons per coherent phase-space volume per coherence time or the number of photons per mode. The coherent phase-space volume is $(\lambda/2)^2$ and the coherence time is $\lambda^2/(\Delta\lambda c)$, so δ_w is given by

$$\delta_w = DB \left(\frac{\lambda}{2} \right)^2 \left(\frac{\lambda^2}{c\Delta\lambda} \right) \left(\frac{\Delta\lambda}{\lambda} \right) = \frac{DB\lambda^3}{4c} , \quad (39)$$

where D is the duty cycle of the storage ring. In practical units, this is

$$\delta_w = 8.33 \times 10^{-25} DB(\text{ph/mm}^2/\text{mr}^2/0.1\%\text{BW/s})\lambda(\text{\AA})^3 . \quad (40)$$

It is significant that the bandwidth cancels out and we are left with a measure of the probability that two wave trains will overlap in the same wave mode. Since photons are bosons, δ_w is allowed to be greater than unity; however, it is only with the advent of undulators on modern storage rings that values greater than unity have been achieved in the XUV spectral region. As an example, the ALS undulators will achieve δ_w values greater than unity for wavelengths longer than about 50 Å.

Figure 10. Coherent fraction of the central cone radiation from ALS undulators for the two definitions of coherent phase space discussed in the text.

One of the phenomena that are understandable in terms of δ_w is the bunching of photoelectron counts due to the stochastic variations of the classical electromagnetic field. This is expected to be observable with thermal light for which the intensity fluctuates in a chaotic way, but not with light from a good-quality laser for which the intensity is stable. Bunching is a separate effect from shot noise, which affects all types of light beams equally. Undulator radiation is produced as a *coherent* sum of the fields radiated by one electron, but an *incoherent* sum of the wave trains emitted by the population of electrons. The resulting intensity, therefore, has chaotic fluctuations like thermal light, but does not have the black-body spectral distribution. Accordingly, an undulator beam should be described as *pseudo thermal light* with a high δ_w indicating a high effective temperature. This combination of qualities is more unique than one might suppose. Based on the Planck thermal distribution function for a black body, one can show that the degeneracy parameter for thermal sources, even very hot ones like the sun, is much less than unity (Goodman, 1985). Moreover, it can be shown that δ_w is equal to the ratio of the size of the photo count fluctuations due to the stochastic variations of the classical electric field to the size of those due to shot noise. Therefore, for sources with a very small value of δ_w , the shot noise dominates and bunching is essentially not observable. Thus, even in the visible region, neither

lasers nor thermal sources produce easily observable photo count bunching under normal conditions. The only way to imitate a pseudo thermal source with strong bunching is to pass laser light (which also has a very high δ_w) through a moving diffuser.

In view of the above conclusions, we expect the measured instantaneous and time-integrated intensity in an undulator beam to show chaotic behavior. Specifically, we expect that the probability-density function of the instantaneous intensity will be negative-exponential, while that of the intensity integrated over a finite time will be Gaussian. The time scale of these fluctuations would be on the order of the coherence time of the wave field, which is in the femtosecond region for cases of practical interest. These physical quantities would be constants for a well-stabilized laser beam. Thus, in spite of the practical similarities between undulator beams and laser beams based on their low phase-space volume, the physics of their emission processes and the statistical properties of their radiations are very different.

The degeneracy parameter has importance in other matters as well. For example, it determines the detectability of the intensity fluctuations of the classical field in an intensity-interferometer experiment (Gluskin *et al.*, 1992). This is a close parallel to its role in determining the degree of bunching. The conclusion appears to be that soft x-ray intensity-interferometer experiments will be quite feasible with undulator beams on third-generation storage rings, while only ultraviolet experiments could be considered at older facilities.

5.4. "DEPTH-OF-FIELD BROADENING" EFFECTS

Undulators and other sources of synchrotron radiation are essentially small transversely and very extended in the emission direction. With an intuition based on geometrical optics, one, therefore, expects that it will be impossible to make a perfect image of the source due to depth-of-field effects. This has been discussed by various authors, especially Green, 1977, and Coisson and Walker, 1985. As discussed by the latter, the effect can be described using the phase-space representation. An electron with coordinates (x, x') at $z = 0$ transforms to $(x + x'z, x')$ at $z = z$. If, at this point, it emits a photon at an angle x_e' to its trajectory, then the apparent emission point of the photon in the $z = 0$ plane is $x - x_e'z$. If the trajectory was steered by an angle x_s' in traveling to z , then the apparent emission point would be $x - (x_e' + x_s')z$. The point to note is that this expression is independent of x' . This implies that depth-of-field broadening is *not* caused by the electron beam angular spread. Rather, it results from the emission angular spread or from steering of the beam, as in a wiggler, and is still present even for a zero-emittance beam. The calculation of the form of the depth-of-field-broadened source is rather cumbersome. Even for the case of a zero-emittance beam (treated by Coisson and Walker), the expression must be written in terms of the exponential integral and is infinite at its center point. The more realistic case, including a finite emittance but still within the geometrical optics approximation, is treated by Green, who represents the source by a new function $ef(a, Y)$ (see Appendix 3). The function $ef(a, Y)$ has a finite peak at the origin and, for long sources, has large non-Gaussian tails extending out to many sigmas of the original unbroadened source.

For the case of an undulator, the amount of steering is negligible and the possibility for depth-of-field effects rests on the angular spread of the emission from a single electron. However, we have already noted that such spreading of the one-electron pattern is a diffraction effect and its counterpart is a broadening of the source (to $\sqrt{\lambda_m L / 4\pi}$). Both effects are included in the representation of the source as a Gaussian laser mode. The diffraction picture thus includes essentially the same broadening effects that we discussed in the previous paragraph. We conclude that the "depth-of-field broadening" is simply the geometrical optics approximation of the diffraction picture of the single-electron pattern and its convolution with a realistic source

with finite emittance. Therefore, diffraction and depth-of-field broadening represent the same thing and should not be added in calculations.

On this basis, we can get some idea of what will happen when we try to image the one-electron undulator source. It will behave like any other diffraction-limited source, and we will not see evidence that the source had a great depth. As a consistency check, we compute the transverse and longitudinal resolutions (Δ_t and Δ_l) to be expected from an imaging system at wavelength λ and numerical aperture $NA = \sqrt{\lambda / L}$. This yields

$$\begin{aligned}\Delta_t &= \frac{\lambda}{NA} = \sqrt{\lambda L} \\ \Delta_l &= \frac{\lambda}{NA^2} = L\end{aligned}\tag{41}$$

Thus, roughly speaking, the resolution of the optical system would be such that it could not tell the difference between a point and an object of the size and shape of the undulator. In summary, we expect no harmful depth effects in imaging the undulator source.

5.5. PARTIAL COHERENCE EFFECTS IN UNDULATOR BEAMS

We have already noted that geometrical ray tracing is not adequate to represent all behaviors of an undulator source because of diffraction. Nevertheless, it is very desirable to have a way to model the performance of undulator beamlines with significant partial coherence effects, and such modeling would, naturally, start with the source. The calculation would involve a knowledge of the partial coherence properties of the source itself and of how to propagate partially coherent fields through space and through the optical components used in the beamline. We discuss the source properties further below, but it is important to recognize that, although most of these calculations are, in principle, straightforward applications of conventional coherence theory (Born and Wolf, 1980; Goodman, 1985), there is not much current interest in this type of problem in the visible optics community. Therefore, there is not a large body of literature to help us with solutions to specific cases. For example, even for the rather simple problem of diffraction by an open aperture with partially coherent illumination, we have found published solutions only for circular and slit-shaped apertures and only for sources consisting of an incoherently illuminated aperture of similar shape to the diffracting aperture. Thus, there is no counterpart in these types of Fourier optics problems to the highly developed art of ray tracing in geometrical optics, nor is there anything as simple as a ray to which an exact system response can be calculated.

This is not to say that no progress has been made. One of the difficulties of coherence-theory calculations is that integration over a large number of variables and a high degree of complication is often encountered. A major simplification of the problem for cases where the small-angle approximation applies has been achieved by Kim, 1986, 1989. This author has developed an extension to the normal coherence theory based on the use of the frequency-space representation of the mutual intensity (see Appendix 2) rather than the usual direct-space representation. The Fourier transform of the mutual intensity (called the “brightness” by Kim) is shown to be invariant with respect to propagation through free space and simple lenses. This means that representation of such propagation is very simple and consists of linear operations on the phase-space coordinates. This allows the brightness to be calculated anywhere without multiple integrals. It would take us too far away from our main subject to give a full presentation of this, but we do consider in the next section the coherence properties of the source itself.

We first recall that the undulator source consists of an incoherent superposition of many one-electron patterns, each of which is to be represented as a Gaussian laser mode with rms width and

angular width σ_r and σ_r' as given by Eq. (33). Therefore, throughout the source area, there is an rms coherence width σ_r with a complex coherence factor $\mu(\Delta x, \Delta y)$ of Gaussian form. Thus, apart from the Gaussian intensity distribution of the source, its field correlations are spatially stationary. We, therefore, consider the undulator to be a *quasi homogeneous* source (Goodman, 1985). The latter is defined as one for which the mutual intensity can be written as

$$J_{12}\left(x + \frac{\Delta x}{2}, x - \frac{\Delta x}{2}\right) = \sqrt{I\left(x + \frac{\Delta x}{2}\right)} \sqrt{I\left(x - \frac{\Delta x}{2}\right)} \mu(\Delta x) . \quad (42)$$

The expressions we use in this section are all separable in x and y so, starting with Eq. (42), we give only the x part. Substituting the above Gaussian forms into this equation gives

$$J_{12}\left(x + \frac{\Delta x}{2}, x - \frac{\Delta x}{2}\right) = \exp\left[\frac{-x^2}{2\sigma_x^2} + \frac{-\Delta x^2}{2\sigma_{\Delta x}^2}\right] , \quad (43)$$

where

$$\frac{1}{\sigma_{\Delta x}^2} = \frac{1}{4\sigma_x^2} + \frac{1}{\sigma_r^2} ,$$

and J_{12} is a function of the spatial variables $(x, \Delta x)$. The propagation law for J_{12} is a standard result of coherence theory (Born and Wolf, 1980; Goodman, 1985) and involves a multiple integral over four variables altogether, including y and Δy . In general, this is difficult and can be avoided by using the brightness function defined by Kim, which is valid for many practically interesting cases. The brightness function is denoted by $B(x, x'; 0)$. It is a function of both position and angle coordinates and is defined by

$$B(x, x'; 0) = C \int_{-\infty}^{+\infty} J_{12}\left(x + \frac{\Delta x}{2}, x - \frac{\Delta x}{2}\right) e^{-ik\Delta x x'} d\Delta x , \quad (44)$$

where $k = 2\pi/\lambda$ and C is a constant. Using Eq. (43) in Eq. (44), we find

$$B(x, x'; 0) = \sqrt{2\pi} C \sigma_{\Delta x} \exp\left[\frac{-k^2 \sigma_{\Delta x}^2 x'^2}{2} + \frac{-x^2}{2\sigma_x^2}\right] . \quad (45)$$

This forms the starting point for the simplified propagation and optical calculations that are enabled by knowledge of the brightness function. It is noteworthy that the brightness function used by Kim is not a physically measurable quantity, although several such quantities can be obtained from it. It is, therefore, necessary to pay special attention to the meaning of the brightness function as described in the published accounts (Kim, 1986, 1989) before using the results derived from it.

As an example of the use of the brightness function, we calculate the mutual intensity at a plane distance z downstream of the source. We begin by propagating the brightness a distance z using the transform $(x \rightarrow x - x'z, x' \rightarrow x')$. This gives

$$B(x, x'; z) = \sqrt{2\pi} C \sigma_{\Delta x} \exp \left[\frac{-k^2 \sigma_{\Delta x}^2 x'^2}{2} + \frac{-(x - zx')^2}{2\sigma_x^2} \right], \quad (46)$$

from which we obtain J_{12} via the transform that is the inverse of Eq. (44);

$$J_{12} \left(x + \frac{\Delta x}{2}, x - \frac{\Delta x}{2} \right) = \frac{\sigma_{\Delta x}}{\Sigma_{\Delta x} C} \exp \left[\frac{-x^2}{2\sigma_x^2} + \frac{-\left(\Delta x + \frac{xz}{k\sigma_x^2} \right)^2}{2\Sigma_{\Delta x}^2} \right], \quad (47)$$

where

$$\Sigma_{\Delta x}^2 = 2\sigma_{\Delta x}^2 + \frac{z^2}{k^2 \sigma_x^2}.$$

It is noteworthy that J_{12} is no longer spatially stationary (Δx part separable). For the special case $x = 0$, meaning that the two test points are disposed symmetrically about the axis, we see that J_{12} is a Gaussian with a width consisting of the quadratic sum of two terms. The first term is equal to the van-Cittert-Zernike-theorem result for an incoherent Gaussian source of rms width σ_x . The second term is a constant width of $\sqrt{2}$ times σ_r . This shows that the van Cittert-Zernike theorem result is a good approximation when it predicts a large coherence width ($\gg \sqrt{2} \sigma_r$) such as in the far field of small sources (the ALS, for example). On the other hand, at shorter distances from larger sources, the van Cittert-Zernike theorem predicts a very small coherence width, and the constant term then dominates. The failure of the van Cittert-Zernike theorem should not be surprising since the strong directionality of the undulator beam shows that the incoherent representation must break down eventually.

Before leaving this subject, we should point out that, for designing coherence experiments, it is essential to know the shape and extent of the function J_{12} [or its normalized form, the complex coherence factor $\mu_{12} = J_{12}/(J_{11}J_{22})^{1/2}$] at the location of optical components, microscope samples, etc. This is usually calculated by an approximation, the main one being the van Cittert-Zernike theorem, in which (under suitable conditions) $\mu_{12}(\Delta x)$ is given by the Fourier transform of the source intensity distribution $I(x)$. We show in Table 1 the nature of the available approximations to help in judging when they can be safely used. The main point is that the coherence character of undulator sources varies, in practical cases, over the whole range from essentially coherent, to essentially incoherent, so that no simple approximation can cover every case.

6. Brightness: Compromises and Limitations

6.1. OPTIMUM CHOICE OF BETA FUNCTIONS

High brightness is one of the most desirable properties of undulators, and a great deal of effort is devoted to optimizing it. One question which arises is whether the β functions at the undulator location have a large effect on the brightness. When $\varepsilon \gg \lambda$, i.e., the source is far from diffraction-limited, the brightness is dominated by the electron beam emittance. Conversely, when $\varepsilon \ll \lambda$, the source is extremely diffraction-limited, and the brightness is dominated by

TABLE 1. Methods to find the complex coherence factor downstream of an undulator source.

Assumed Source Character	RMS Coherence Width at the Source*	Complex Coherence Factor Distance z Downstream	Method of Calculation
Coherent (diffraction-limited)	$\approx \sigma_s$	Constant	None
Quasi homogeneous	$< \sigma_s$ (general case)	$J_{12}/(J_{11}J_{22})^{1/2}$ from Eq. (47)	Brightness function
Almost incoherent	$\ll \sigma_s$	$\mathcal{F}[I(x)] \mathcal{F}[\mu_{12}(\Delta x)]/\lambda z^{**}$	Generalized van Cittert-Zernike theorem (Goodman, 1985)
Incoherent (electron-beam-limited)	$= 0$	$\mathcal{F}[I(x)]/I_0^{**}$	van Cittert-Zernike theorem

*The source is taken to have an rms width σ_s .

** I_0 is the integrated flux, $\mathcal{F}$ represents the Fourier transform.

diffraction. In both cases, the brightness is relatively insensitive to β , although there is a shallow minimum. On the other hand, when $\varepsilon \sim \lambda$, it is possible to suffer a major loss of brightness by a poor choice of β . To see the effect of the β functions, consider the dimensions of a diffraction-limited x-ray beam. Its phase-space ellipse has semiaxes σ_r, σ_r' while that of the electron beam has semiaxes (e.g.) σ_x, σ_x' , and the two would have similar area because $\varepsilon \sim \lambda$. The optimum value of the β function would match the two ellipses by having $\sigma_x' \sim \sigma_r'$ and $\sigma_x \sim \sigma_r$ while the worst choice would mismatch them in the manner of a cross. In the latter case, the resulting photon phase-space area would be approximately a *circle* with the crossed ellipses inside it! To find the optimum β , we set the ratio of the major to minor axes equal for the two ellipses

$$\frac{\sigma_r'}{\sigma_r} = \frac{\sigma_x'}{\sigma_x} \quad \text{or} \quad \frac{\sqrt{\frac{\lambda}{L}}}{\frac{\sqrt{\lambda L}}{4\pi}} = \frac{\sqrt{\frac{\varepsilon_x}{\beta_x}}}{\sqrt{\varepsilon_x \beta_x}}, \quad (48)$$

leading to

$$(\beta_x)_{opt} = \frac{L}{4\pi}. \quad (49)$$

In practice, this is a rather low but possible value for β .

6.2. INTENSITY DISTRIBUTION NEAR THE CENTRAL CONE

It comes as a slight surprise to learn that there is somewhat of a shortage of central-cone radiation at the exact frequency of a harmonic even in the one-electron pattern. The angle-integrated flux per unit fractional bandwidth is actually twice as high at a frequency $\omega_{peak} = m\omega_1(0)(1-1/mN)$ as it is at the exact harmonic frequency $m\omega_1(0)$. This arises because the exact harmonic intensity on-axis can only receive contributions from the sinc functions in Eq. (22) centered on directions

at higher angles, whereas, the hollow cone of frequency ω_{peak} can receive contributions from beams at both higher and lower angles. Thus, there is a peak of intensity on the axis at $m\omega_1(0)$ with an approximately Gaussian angular distribution, but a decidedly non-Gaussian, hollow-cone distribution at ω_{peak} . From a practical standpoint, ω_{peak} is better for flux while $m\omega_1(0)$ is better for brightness. This is illustrated quantitatively for an ALS 5-cm-period undulator in Fig. 11.

It is important to note that Eq. (33) is true for the frequency ω_{peak} . The corresponding equation at the exact harmonic frequency $m\omega_1(0)$ (Kim, 1993) is

$$\sigma_r = \frac{\sqrt{2\lambda_m L}}{4\pi} \quad , \quad \sigma'_r = \sqrt{\frac{\lambda_m}{2L}} \quad , \quad \varepsilon = \sigma_r \sigma'_r = \frac{\lambda_m}{4\pi} \quad . \quad (50)$$

6.3. FAILURE OF THE FAR-FIELD APPROXIMATION (WALKER, 1988)

The far-field approximation is widely used to simplify the calculation of undulator spectral and angular distributions, allowing, in particular, their expression in closed form. It consists essentially of assuming that the observation direction is constant as the electron traverses the undulator, or that all parts of the undulator are at the same distance from the observer. However, there are many practical cases, including some at the ALS (which has especially long undulators), where the far-field approximation is not satisfied. To evaluate the effect, consider the situation depicted in Fig. 12. The observer angle changes from θ_1 to θ_2 as the electron traverses the undulator, and so, according to Eq. (12), the emission wavelength changes. The result is a "chirped" spectrum as shown in the figure. From Eq. (12), the change in wavelength $\Delta\lambda$ is given by

$$\Delta\lambda = \frac{\lambda_u}{2} (\theta_2^2 - \theta_1^2) \quad . \quad (51)$$

From Fig. 12, we can also see that $\theta_1 = \theta/(1+L/2D)$ and $\theta_2 = \theta/(1-L/2D)$. Therefore, the spectral lines will be broadened by their own fractional width $1/mN$ when θ is given by

$$\frac{1}{mN} = \frac{\gamma^2 \theta^2 \left\{ \frac{1}{(1-L/2D)^2} - \frac{1}{(1+L/2D)^2} \right\}}{1 + K^2/2 + \gamma^2 \theta^2} \quad . \quad (52)$$

After some reduction, this leads to

$$\theta = \sigma'_r \sqrt{\frac{D}{L} \left(1 - \frac{L^2}{4D^2} \right)} \quad . \quad (53)$$

If we take $\theta = \sigma'_r$ as a reasonable collection half angle, then the conclusion is that the spectral lines will be broadened significantly.

6.4. LIMITATIONS ON TWO-PHOTON EXPERIMENTS

There are two kinds of two-photon experiments that one might consider suited to undulator radiation. The first is a two-color experiment involving two coaxial undulators giving two different photon energies. This experiment might be imagined as a way to probe a short-lived

U5 3rd harmonic, $E_0 = 284$ eV, $\Delta E = 0$

U5 3rd harmonic, $E_0 = 284$ eV, $\Delta E = -0.8$ eV

Figure 11. One-electron intensity distributions near the axis for the ALS 5-cm-period undulator in the third harmonic. Curve (a) is for the exact harmonic energy (E) and curve (b) is for an energy $E(1 - 1/mN)$, which is the energy of the peak of the angle-integrated spectrum. ΔE is the energy difference between (a) and (b). Note that the former has a peaked and the latter a hollow-cone shape.

Figure 12. Illustration of the effect of the change in observer angle from one end of the undulator to the other and the resulting chirped spectrum, which becomes important when the far-field assumption is not satisfied.

intermediate state, but is not promising for the following reason. Considering that, for a single mode, we would have $d\Omega = 2\pi\sigma^2$, $\Delta\omega/\omega = 1/mN$, and $\pi(1 + K^2/2)F_m(K)$ is approximately unity, then Eq. (27) shows that the number of radiated photons per incident electron is about $\alpha \approx 1/137$. Therefore, the probability of getting two photons from two undulators is proportional to $(1/137)^2$, which would give a very low rate.

In the second type of two-photon experiment, two nominally identical photons of energy E would do something that needed energy $2E$. This experiment is much more promising because the probability of getting two photons in the same mode at the same times (from a single undulator) is equal to the degeneracy factor δ_ω , which, as discussed earlier, can be much larger than unity for some conditions. This type of experiment can be considered for samples with sufficiently high interaction probability.

6.5. BENDING MAGNET BACKGROUND

An observer near an undulator axis will see radiation from both the upstream and downstream bending magnets. The nature of this radiation will vary from a spectrum characteristic of the bending magnet fringing fields at zero and small angles to that characteristic of the bending magnet full field at sufficiently large off-axis angles. As an example, we show in Fig. 13 the power density due to an ALS 3.65-cm undulator and that due to its upstream and downstream bending magnets as calculated by the POISSON magnetic field code. It is noteworthy that the two bending magnet beams are unequal and very much weaker than the undulator beam. This has important consequences for the operation of beam position monitors, although the situation is not as good as it seems because the monitors respond to photons in proportion to their photoelectron yield, not their energy. One can also see that the full bending magnet power density is not achieved until several milliradians off axis. Another feature with implications for beam position

Figure 13. The power density distribution near the axis of an ALS 3.65-cm undulator showing the undulator total-power and central-cone distributions and the power density from the fringing fields of the upstream and downstream bending magnets using magnetic fields from POISSON.

stabilization is that the central cone is a narrow and relatively weak beam buried in a much wider and stronger power-density distribution; however, it is the broad power distribution that will be sensed by the beam position monitors.

6.6. IMPERFECT UNDULATORS: MEASUREMENT AND ANALYSIS OF DEFECTS

Until now, we have assumed that we were dealing with a perfect undulator. We now turn to assessing the effects of the inevitable imperfections of real undulators. The consequences of departures of the undulator magnetic field from its nominal form are illustrated qualitatively in Fig. 14. This figure shows a calculated electron trajectory for a realistic imperfect undulator field. Obviously, if one wants to obtain near-theoretical performance from the undulator, one must pay careful attention to the size of the field errors and their effects. In seeking to maintain good field quality, it is worth considering the consequences of failure. Electrons traversing even the most imperfect undulator still radiate, and the power must go somewhere. In the worst case, all coherent superposition of the one-electron signals from successive periods of the undulator is lost and the coherent sum is replaced by an incoherent one. In this case, each half-period of the undulator acts like a small bending magnet, and the resulting power output is equal to $2N$ times the output from each half-period. The spectrum then loses the undulator peaks and becomes smooth like the spectrum of a wiggler.

Figure 14. Three sample orbits for a 50-period undulator with rms field errors of 0.5%. The orbit deviation is expressed in units of the amplitude of its ideal sinusoid.

The consequences of field errors fall into two main classes: (1) effects on the storage ring, and (2) effects on the radiated spectrum. We consider the first category in Section 6.7 and the second in Section 6.8. However, the prerequisite for any rational approach to these effects is an ability to measure the undulator fields accurately enough to compare the fields of real devices with their nominal values and the error tolerances derived from experience or calculation. The first two ALS undulators have been extensively measured, and the analysis of the measurements has been reported by Marks *et al.*, 1993B. We use the results of this work to illustrate the following material.

Like their counterparts in other laboratories, the ALS group has developed a magnet measurement facility for qualification of undulators (Marks *et al.*, 1993A). The measurement system consists of two primary elements. The first element is a moving stage with precise position measurement and control. This moving stage carries Hall probes capable of measuring B_x and B_y ; it can map B_x and B_y throughout the three-dimensional region between the undulator poles with an accuracy of ± 0.5 Gauss. Bearing in mind that the undulator gap varies from 14 mm to 210 mm and that a single scan of the 4.5-m length of the undulator generates 2500 data points, one can see that a great many scans and a large quantity of data are involved in fully characterizing the undulator at a reasonable range of gaps. The second measurement system element is an integral coil used to measure the field integrals $\int B_y dz$ and $\int B_x dz$, where the z axis is the undulator axis. The coil is 550×1 cm² in area and measures the field integrals with an accuracy of ± 20 Gauss-cm.

Figure 15 shows an example of a spline fit to a data set, derived from a scan of the Hall probe measuring B_y as a function of z . This type of data can be analyzed using a variety of processing

Figure 15. Measured B_y as a function of z for an ALS 5-cm-period undulator.

tools including tools to identify field peaks, truncate the data to eliminate end fields, least-squares fit the data to a set of harmonics, take the Fourier transform, half-period filter the data, calculate the optical phase errors, and calculate the expected radiation emission. We discuss some of these tools further below.

Given that the undulator structure is nominally a periodic function with a symmetry of the form $f(z + \lambda_u/2) = -f(z)$, its field (without the non-periodic parts at the ends) should fit a cosine Fourier series with only odd harmonics:

$$B_h(z) = \sum_m B_m \cos(mk_u z + \phi_m) \quad , \quad m = 1, 3, 5, \dots \quad , \quad (54)$$

where $k_u = 2\pi/\lambda_u$. A nonlinear least-squares fit routine is used to fit B_h to the measured data with B_m and ϕ_m as fitting parameters. The rms value σ_e of the residual $B_y - B_h$ between the fit and the measured data is then defined as the measure of the overall size of the field errors. It includes both local errors and global effects such as taper and sag.

Another interesting technique is the half-period filter, which is applied to the spline fit to the measured B_x or B_y data. This is defined, for example, by

$$F_h(z) = \frac{1}{2} \left[B_y \left(z + \frac{\lambda_u}{4} \right) + B_y \left(z - \frac{\lambda_u}{4} \right) \right] \quad . \quad (55)$$

It is implemented in the frequency domain by means of the convolution theorem. For any function that is exactly periodic with period λ_u and that has only odd harmonics, we can see that $F_h(z)$ will be zero. The output of the filter provides a measure of the field errors over a half-period range (i.e., local errors). Figure 16 shows the half-period-filtered output corresponding to half of a data set similar to the one in Fig. 15. One can see the small values representing local errors in the periodic part of the undulator and the large values representing the transition to a nonperiodic field at the end. Examination of the above equation also shows that the integral of $F_h(z)$ is equivalent to the integral over B_x or B_y , provided the limits of integration correspond to constant field regions. Therefore, this procedure also allows separation of the contributions to $\int B_x dz$, $\int B_y dz$ into portions corresponding to the periodic and nonperiodic parts, a capability which is useful in correcting the field integrals. Integrals like $\int B_y dz$ are important in considering the effect of the undulator on the electron beam as discussed in the following section.

6.7. IMPERFECT UNDULATORS: EFFECT ON THE STORAGE RING

An undulator is generally short compared to a betatron wavelength, so the primary effect of the undulator magnetic fields on the electron beam is via their line integral through the device and its variation with horizontal and vertical position. We first note that in free space, $\mathbf{B}(x, y, z)$ satisfies the three-dimensional Laplace equation, a fact which follows from Maxwell's equations. Therefore, $\mathbf{B}(x, y) = \int \mathbf{B}(x, y, z) dz$ satisfies the two-dimensional Laplace equation as do its components, B_x and B_y , separately. The values of the line integrals of B_x and B_y can, therefore, be expressed as general solutions of Laplace's equation in polar coordinates (r, θ) as follows (Jackson, 1975):

$$\int B_y dz = \sum_{m=0}^{m=\infty} a_m r^m P_m(\cos \theta) \quad \text{and} \quad \int B_x dz = \sum_{m=0}^{m=\infty} b_m r^m P_m(\cos \theta) \quad , \quad (56)$$

Figure 16. Half-period filter output corresponding to a curve like that of Fig. 15.

where we have imposed the condition that $\int B_y dz$ and $\int B_x dz$ are finite at the origin. These are essentially Taylor-series representations of the functions $\int B_y dz$, $\int B_x dz$ and are equivalent to two-dimensional multipole expansions of the integrated magnetic fields as shown in Table 2.

The radius of convergence of the series in Eq. (56) is equal to the magnetic half-gap. The area of validity includes the central region where the electron beam core is always located, but does not include some regions that lie outside the circle of convergence but still inside the dynamic aperture. The latter can contain scattered electrons that are not lost and are in the process of being returned back into the central region by radiation damping. If these particles get lost as a result of undulator magnetic field errors not represented by the multipole expansion, then the beam lifetime will be reduced. The field integral variations that *are* represented by multipoles are described by the coefficients a_m and b_m , which can be determined from the integral coil measurements. The size of the unwanted multipoles, as defined by these coefficients, can then be compared to a calculated tolerance value. Table 3 shows the tolerance values calculated for the ALS and the storage ring operational consequences expected for each type of unwanted multipole.

In general, it is difficult to correct the errors listed in Table 3 by means of adjustments to the accelerator optics because the errors change in value as the undulator gap is tuned. Consequently, the best strategy is to make the errors negligible for each undulator. Two exceptions to this are the horizontal and vertical dipole components for which there are both fixed corrections (by means of permanent magnet rotors) and tunable corrections (by means of the horizontal and vertical bump-coil systems). These correction mechanisms are already installed at the ALS and other third-generation storage rings to achieve beam stability.

TABLE 2. Field integral multipole terms.

m	Field Integral Term	Multipole Character
0	$\int B_y dz = a_0$	dipole
1	$\int B_y dz = a_1 x$	quadrupole
2	$\int B_y dz = \frac{a_2}{2} (2x^2 - y^2)$	sextupole
3	$\int B_y dz = \frac{a_3}{2} (2x^3 - 3xy^2)$	octupole
4	$\int B_y dz = \frac{a_4}{8} (5x^4 - 30x^2y^2 + 3y^4)$	decapole
0	$\int B_x dz = b_0$	skew dipole
1	$\int B_x dz = b_1 x$	skew quadrupole
2	$\int B_x dz = \frac{b_2}{2} (2x^2 - y^2)$	skew sextupole
3	$\int B_x dz = \frac{b_3}{2} (2x^3 - 3xy^2)$	skew octupole
4	$\int B_x dz = \frac{b_4}{8} (5x^4 - 30x^2y^2 + 3y^4)$	skew decapole

As an example of the magnitudes of the errors, we show in Table 3 the tolerances used at the ALS. The as-built undulators had values of the multipole terms about two to three times larger than those in Table 2, so a correction system comprising several small, individually adjustable,

TABLE 3. Storage ring effects of undulator magnetic field integral errors.

Integrated Multipole Term	Tolerance Values at ALS	Operational Consequences
Horizontal (vertical) dipole	100 Gauss · cm	Vertical (horizontal) steering
Quadrupole	100 Gauss	Tune shift
Skew quadrupole	100 Gauss	Horizontal-to-vertical coupling, beam rotation
Sextupole	50 Gauss / cm	Amplitude-dependent tune shift; loss of dynamic aperture
Skew sextupole	—	Amplitude-dependent tune shift; loss of dynamic aperture
Octupole	20 Gauss / cm ²	Higher-order tune resonances; loss of lifetime
Skew octupole	—	Higher-order tune resonances; loss of lifetime

permanent magnets (Hoyer, 1992) was installed at each end of the devices. By this means, the multipoles were brought within tolerance or within the range of adjustment in the case of the dipoles.

6.8. IMPERFECT UNDULATORS: EFFECT ON THE SPECTRUM

The main purpose of an undulator is to deliver a spectrum as close as possible to theoretical. Thus, there is a need for a theoretical analysis of the errors that impair its ability to do this. Such an analysis has been provided by Kincaid, 1985. A primary conclusion of this study was that the performance of the undulator source is degraded by random field errors and that the degradation increases like the square of the harmonic number. The peak value of the flux per unit solid angle (and hence also, via Eq. (27), the brightness) of the n th harmonic is degraded by a factor G_Δ or F_Δ as follows:

$$\begin{aligned} G_\Delta &\equiv e^{-30gp^2} & g &\leq 1 \\ F_\Delta \text{ varies like } (gp)^{-2} & & g &\geq 1 \end{aligned} \quad (57)$$

where

$$g = \sigma^2 N^3, \quad p = \frac{\frac{n}{N}}{1 + \frac{N}{K^2}},$$

and σ is the rms field error. The regime $g \leq 1$ corresponds to a small degree of wandering of the orbit (Fig. 14) while $g \geq 1$ corresponds to a large one. Some of the conclusions of Kincaid's paper are summarized in Fig. 17, which shows the contours $G_\Delta = 0.7$ and $F_\Delta = 0.7$ on a log-log plot of g against p . The circular plotted points represent harmonics of actual undulators for which p and g are known. The fact that the points lie to the left of the contours shows that the predicted losses of intensity are less than 0.7. Note that all these examples are in the regime of small walking of the orbit, which implies a Gaussian dependence of the degradation factor on the size of the field errors.

The ALS group set a goal of achieving at least 70% of theoretical flux in the 5th harmonic, which, according to the above equation for G_Δ , implies that σ must be less than 0.25%. There is some difficulty in finding a rigorous procedure for determining a value for σ from measured magnetic field data, but roughly speaking, we could identify it with σ_e . At the time the ALS undulators were started, the 0.25% value was about a factor of 2 beyond the state-of-the-art. Nevertheless, it was achieved, even at the minimum gap of 14 mm.

In view of the arguments following Eq. (16), it is also clear that another factor that can lead to degradation of the brightness is the electron beam angular spread resulting from its finite emittance. The emittance sets a limit to the quality of undulator fields beyond which further improvement to the undulator does not improve its performance. We show an example of the effect of emittance in the following paragraph.

Once an undulator has been built, there is no longer a need to study it by means of a general theory. One can simply calculate the radiation output using the actual measured field of the device. This can be accomplished more easily than hitherto using the simplified radiation equation derived by Wang, 1993B [Eq. (21)]. As an example of the procedure, we show in

Figure 17. Curves of constant G_Δ and F_Δ on a plot of p against g as explained in the text. The circles represent the harmonics of various real undulators as follows: TOK means the transverse optical klystron undulator at Brookhaven, BL X means the Beamline 10 wiggler at Stanford, BL VI means the 54-pole wiggler at Stanford, U10.0 means a putative 10-cm-period undulator at the ALS, and U5.0 means an actual 5-cm-period undulator at the ALS.

Fig. 18 the flux per unit solid angle of an ALS 5-cm-period undulator operated at a magnetic gap of 23 mm ($K = 2.13$) for three cases: (1) ideal field and zero emittance, (2) actual field and zero emittance, and (3) actual field and actual emittance. The spectra are taken from Wang, 1993A. It is noteworthy that all the harmonics are reduced by both field error and emittance effects and that the size of the reduction increases rapidly with harmonic number as predicted by the theory. The first, third, and fifth harmonics are all still large enough to be useful, consistent with the goals of the ALS undulator design and manufacturing program.

7. Undulator Performance Trade-Offs: Discussion and Conclusions

7.1. UNDULATOR DESIGN STRATEGIES

To give an overview of the material presented so far, we consider some of the scaling laws that prevail under various conditions. Equation (25) shows that the on-axis intensity scales like N^2 , while Eq. (27) shows that the central-cone flux scales like N . The brightness scaling, given by Eq. (33), requires a closer examination. The value and scaling of the Σ 's depend on whether the beam size and angle are dominated by diffraction or by the electron beam dimensions. Four cases can be distinguished (Kim, 1989):

- (1) $\sigma_x, \sigma_y \ll \sigma_r$ and $\sigma'_x, \sigma'_y \ll \sigma'_r$ (size and angle are both diffraction limited)

$$B_m(0,0) = \frac{\mathcal{F}_m}{4\pi^2 \sigma_r^2 \sigma_r'^2} = \frac{\mathcal{F}_m}{(\lambda/2)^2}, \quad (58)$$

- (2) $\sigma_x, \sigma_y \gg \sigma_r$ and $\sigma'_x, \sigma'_y \ll \sigma'_r$ (size is electron-beam limited and angle is diffraction limited)

$$B_m(0,0) = \frac{\mathcal{F}_m}{4\pi^2 \sigma_x \sigma_y \sigma_r'^2} = \frac{\mathcal{F}_m N \lambda_u}{4\pi^2 \sigma_x \sigma_y \lambda}, \quad (59)$$

- (3) $\sigma_x, \sigma_y \ll \sigma_r$ and $\sigma'_x, \sigma'_y \gg \sigma'_r$ (not realistic in cases of interest to us), and

- (4) $\sigma_x, \sigma_y \gg \sigma_r$ and $\sigma'_x, \sigma'_y \gg \sigma'_r$ (size and angle are both electron beam limited)

$$B_m(0,0) = \frac{\mathcal{F}_m}{4\pi^2 \sigma_x \sigma_y \sigma'_x \sigma'_y} = \frac{\mathcal{F}_m}{4\pi^2 \epsilon_x \epsilon_y}. \quad (60)$$

From these cases, we see that the brightness scales like $\mathcal{F}_m$ (which scales like N) when the size and angle are either both diffraction limited or both electron-beam limited. On the other hand, if the size is electron-beam limited and the angle diffraction limited, then the brightness scales like N^2 . The latter is a common case of which there are several examples at the ALS.

The conclusion of this discussion for the undulator designer is to use the largest possible N for a given L (i.e., the smallest possible λ_u) consistent with achieving enough field to get to the longest wavelength desired. This implies that the gap has been reduced to the minimum consistent with storage ring operation. This same philosophy of using the minimum possible λ_u also maximizes the required K , which increases the total power output.

Figure 18. On-axis flux per unit solid angle of an ALS 5-cm undulator at $K = 2.13$ (a) for the ideal field and zero emittance, (b) for the actual field and zero emittance, and (c) for the actual field and actual emittance.

Figure 18. (continued).

As a final example to illustrate these principles, we show in Table 4 three ALS undulator schemes that provide 50-eV photons. Table 4 illustrates two important points: (1) it is possible to gain flux by producing low-energy photons at high K , but there is a significant price in higher power output, and (2) such unfavorable trade-offs generally happen when trying to generate photons at an energy well below that for which the storage ring is optimized.

TABLE 4. Various designs to generate 50-eV photons using an ALS undulator.

Characteristic	Low- K Device	Existing 8-cm Device	Existing 5-cm Device	Bending Magnet for Comparison
Undulator period (cm)	36	8	5	
Number of poles	12	55	89	
K value at 50 eV	1.2	3.0	3.9	
Field at 50 eV (T)	0.036	0.40	0.83	
Useful flux (usual units)	4.5×10^{14}	3×10^{15}	5×10^{15}	9.2×10^{13} (per 10 mr)
Brightness (usual units)	5.5×10^{16}	5×10^{17}	9×10^{17}	2×10^{14}
Unwanted power	low	high	higher	
Wiggler E_{crit} (eV)	not a good measure	600	1250

Appendix 1

We want to prove that the K^2 that should be used in Eq. (12) is $\sum_m K_m^2$. We start with Eq. (10). To obtain β_z , we use Eq. (3) for β so $\beta_z = \sqrt{\beta^2 - \beta_x^2} = \sqrt{1 - 1/\gamma^2 - \beta_x^2}$ and Eq. (9) for β_x (including all the harmonics) so $\beta_x^2 = \frac{1}{\gamma^2} \left(\sum_m K_m \sin mk_u z \right)^2$. We then expand $\sin^2 mk_u z = (1 - \cos 2mk_u z)/2$ and take the average over z . All the cosine and cross terms of the Σ^2 then vanish, and we are left with $\bar{\beta}_x^2 = \frac{1}{2\gamma^2} \sum_m K_m^2$. Substituting this in the square root and expanding by the binomial theorem ($1/\gamma^2 \ll 1$), we finally get $\bar{\beta}_z = 1 - \frac{1}{2\gamma^2} \left(1 + \frac{1}{2} \sum_m K_m^2 \right)$. When this is inserted in Eq. (10), we obtain Eq. (12), provided that we define $K = \sqrt{\sum_m K_m^2}$, which completes the proof. The equation for B_{eff} follows from Eq. (13).

Appendix 2

The mutual intensity J_{12} is a measure of the spatial coherence of light at two transversely separated points, 1 and 2. It is assumed that the points are illuminated by quasi-monochromatic light and that the optical paths to the two points differ by an amount that is much less than the coherence length of the light. This implies that, in using J_{12} , it is understood that there is full temporal coherence and only spatial coherence is to be considered. The mutual intensity J_{12} is then equal to the correlation function of the optical fields at the points 1 and 2.

Appendix 3

In Green, 1977, the author represents the finite-emittance, depth-broadened source as a function $ef(a, Y)$, where $a = y/\sigma_y$ and $\tan Y = \frac{\sigma L/2}{\sigma_y}$, where L is the length of the source and σ is the rms opening angle of the radiation emission. The value of $ef(a, Y)$ is defined by $ef(a, Y) = \int_0^Y \exp\left\{-\frac{a^2}{2} \cos^2 t\right\} \frac{dt}{\cos t}$. It is normalized by $\int_{-\infty}^{+\infty} ef(a, Y) da = \sqrt{2\pi} \tan Y$, has the

value $\text{ef}(0, y) = \frac{1}{2} \ln \left(\frac{1 + \sin Y}{1 - \sin Y} \right)$ at $a = 0$, and asymptotically approaches $Y \exp(-a^2/2)$ for $Y < 0.1$. Graphs and numerical tables are provided by Green for a comprehensive range of values.
