Abstract

Long-term cap rock integrity represents the single most important constraint on the long-term isolation performance of natural and engineered CO₂ storage sites. CO₂ influx that forms natural accumulations and CO₂ injection for EOR/sequestration or saline-aquifer disposal both lead to concomitant geochemical alteration and geomechanical deformation of the cap rock, enhancing or degrading its seal integrity depending on the relative effectiveness of these interdependent processes. Using our reactive transport simulator (NUFT), supporting geochemical databases and software (GEMBOCHS, SUPCRT92), and distinct-element geomechanical model (LDEC), we have shown that influx-triggered mineral dissolution/precipitation reactions within typical shale cap rocks continuously reduce microfracture apertures, while pressure and effective-stress evolution first rapidly increase then slowly constrict them. For a given shale composition, the extent of geochemical enhancement is nearly independent of key reservoir properties (permeability and lateral continuity) that distinguish EOR/sequestration and saline-aquifer settings and CO₂ influx parameters (rate, focality, and duration) that distinguish engineered disposal sites and natural accumulations, because these characteristics and parameters have negligible (indirect) impact on mineral dissolution/precipitation rates. In contrast, the extent of geomechanical degradation is highly dependent on these reservoir properties and influx...
parameters because they effectively dictate magnitude of the pressure perturbation; specifically, initial geomechanical degradation has been shown inversely proportional to reservoir permeability and lateral continuity and proportional to influx rate. Hence, while the extent of geochemical alteration is nearly independent of filling mode, that of geomechanical deformation is significantly more pronounced during engineered injection. This distinction limits the extent to which naturally-occurring CO$_2$ reservoirs and engineered storage sites can be considered analogous. In addition, the pressure increase associated with CO$_2$ accumulation in any compartmentalized system invariably results in net geomechanical aperture widening of cap-rock microfractures. This suggests that ultimate restoration of pre-influx hydrodynamic seal integrity—in both EOR/sequestration and natural accumulation settings—hinges on ultimate geochemical counterbalancing of this geomechanical effect. To explore this hypothesis, we have introduced a new conceptual framework that depicts such counterbalancing as a function of effective diffusion distance and reaction progress. This framework reveals that ultimate counterbalancing of geochemical and geomechanical effects is feasible, which suggests that shale cap rocks may in fact evolve into effective seals in both natural and engineered storage sites.

**Introduction**

Sufficient curbing of projected anthropogenic CO$_2$ emissions to achieve a stabilized “safe” atmospheric concentration ranks high among the grand challenges of this century. In the near term, significant emissions reduction can only be achieved through innovative capture/isolation strategies applied to point-source waste streams. Among currently proposed isolation techniques, injection into confined geologic formations represents one of the most promising alternatives. Oil reservoirs, where CO$_2$ storage and EOR can be co-optimized, and saline aquifers, which feature immense storage capacity and widespread geographic distribution, represent particularly attractive geologic targets.
Successful engineered CO$_2$ storage in these environments hinges on our ability to identify optimal sites and forecast their long-term security. This ability, in turn, relies upon predictive models for assessing the relative effectiveness of CO$_2$ migration and sequestration processes (isolation performance) as a function of key target-formation and cap-rock properties (screening criteria). It also relies on detailed knowledge of naturally-occurring CO$_2$ reservoirs and clear understanding of the extent to which they represent natural analogs to engineered storage sites. Among key screening criteria, long-term cap rock integrity represents the single most important constraint on the long-term isolation performance of both natural and engineered CO$_2$ storage sites. And among predictive methodologies, the reactive transport modeling approach is uniquely well-suited to quantify this fundamental constraint.

In this study, we have extended and applied our computational toolbox to address this central issue of long-term hydrodynamic seal capacity. In the development phase, we first interfaced our existing reactive transport and geomechanical modeling capabilities to facilitate assessment of stress-strain evolution along and above the reservoir/cap-rock contact during and after CO$_2$ influx. We then constructed a new conceptual framework for evaluating the net impact on long-term cap rock integrity of influx-triggered geochemical alteration and geomechanical deformation processes.

In the application phase, we have used our modeling capabilities to address two fundamental questions. First, what is the evolution of cap-rock integrity during engineered CO$_2$ storage—and does this evolution vary significantly between EOR/sequestration and saline aquifer settings? This work builds directly upon our earlier modeling studies, which demonstrated enhanced hydrodynamic seal capacity of shale cap rocks as a function of injection-triggered geochemical processes during saline aquifer disposal [1-4]. Here, these earlier analyses have been extended to include explicit account of the concomitant geomechanical processes, and to assess
dependence of this coupled geochemical-geomechanical evolution on key reservoir properties (permeability and lateral continuity) that distinguish typical oil reservoirs and saline aquifers [5-6].

We then address a closely related key issue: is the predicted evolution of cap-rock integrity for engineered CO$_2$ disposal sites similar to or appreciably different from that of natural CO$_2$ accumulations; i.e., what is the dependence of this evolution on the rate, duration, and focality of CO$_2$ influx? The widely espoused natural analog concept implicitly assumes a dearth of such dependence; however, this assumption—upon which strict validity of the concept hinges—may be invalid in some cases. For example, a given reservoir/cap rock system that now holds a natural CO$_2$ accumulation may be incapable of doing so in the context of an engineered injection owing to significant differences in the magnitude and style of CO$_2$ influx. Further, the currently secure cap rock of a given natural accumulation may have evolved into an effective hydrodynamic seal following geochemical alteration that attended some degree of CO$_2$ migration through it. To address these issues, we have conducted and compared reactive transport simulations of a representative generic natural CO$_2$ reservoir for natural and engineered “filling” modes [7-8].

Because cap-rock integrity represents the ultimate constraint on the long-term isolation performance of geologic CO$_2$ storage sites, our reactive transport modeling analysis is linked to a number of additional CCP-funded studies presented in this volume [9-14]. There are potential direct links to three studies: the SAMCARDS analysis of Wildenborg et al. [9], into which our simulation results could be directly incorporated, and the natural analog and experimental studies of Stevens et al. [10] and Borm et al. [11], respectively, with which future coordinated efforts might provide field- and laboratory-scale “proof of concept” for our modeling capabilities. In addition, the reactive transport modeling approach used here could be employed to simulate the advective and diffusive migration of imposed anomalies in noble gas isotope ratios, as measured in the field by Nimz et al. [12]; to generate the fluid-phase pressures, saturations, densities, and viscosities required to predict dependent geophysical properties, as discussed by Hoversten et al.
CO$_2$ Capture Project

[13]; and to predict the migration paths of CO$_2$-charged fluids within magma-hydrothermal systems, as inferred from field measurements by Evans et al. [14].

**Methodology**

Reactive transport modeling is an advanced computational method for quantitatively predicting the long-term consequences of natural or engineered perturbations to the subsurface environment [15-16]. Because these predictions typically involve space, time, and system complexity scales that preclude development of direct analytical or experimental analogs, they often represent a unique forecasting tool. The necessary point of departure for predictive investigations of this kind is established by successful application of the method to simulate well-constrained laboratory experiments [17-18].

The method is based on mathematical models of the integrated thermal, hydrological, geochemical, and geomechanical processes that redistribute mass and energy in response to the disequilibrium state imposed by perturbation events such as magmatic intrusion or CO$_2$ influx (Figure 1). Traditionally, such models have been developed as separate entities and applied as such to address specific issues relevant their individual scope. The fundamental advance embodied in reactive transport modeling is its explicit integration of these conceptually distinct process models. In practice, however, present-day simulators address and couple various subsets of these models, while the ultimate simulation tool—one that implements and explicitly couples all of the relevant processes—remains on the horizon.

We have developed a unique computational capability that integrates a state-of-the-art reactive transport simulator (NUFT), comprehensive supporting geochemical software and databases (SUPCRT92, GEMBOCHS), and a versatile distinct-element geomechanical model (LDEC).

NUFT [19-20] is a software package that facilitates numerical simulation of non-isothermal
CO$_2$ Capture Project

multiphase/multicomponent flow and reactive transport within a wide range of subsurface environments characterized by multi-scale physical and compositional heterogeneity. The package implements an integrated finite-difference, spatial discretization to solve the flow and reactive-transport equations, using the Newton-Raphson method to solve the resulting nonlinear systems at each time step. Explicit account is taken of multiphase advection, diffusion, and dispersion; of relative permeability and capillary pressure, using an extended Van Genuchten formulation [21]; and of kinetically controlled fluid-mineral reactions, using rate laws from transition state theory [22]. Moreover, explicit account is also taken of coupling between these transport and geochemical processes through the dependence of permeability on porosity changes due to mineral precipitation/dissolution, using a normalized Kozeny equation [23], and through the dependence of fluid-phase volumetric saturations on gas (e.g., CO$_2$(g)) generated or consumed by fluid-mineral reactions.

The GEMBOCHS system [24-25] integrates a comprehensive relational thermodynamic/kinetic database and dedicated software library that together facilitate generation of application-specific thermodynamic/kinetic datafiles for use with a variety of geochemical modelling codes and reactive transport simulators. The thermodynamic database covers about 3200 distinct chemical species, spanning 86 elements of the periodic table; its core component is the current version of the SUPCRT92 database [26-27], which covers about 1550 species, spanning 82 elements. Custom datafiles are generated using Jewel [24], a GUI-driven software package that extrapolates reference-state properties to elevated P-T conditions using a number of standard algorithms, the core set of which are those encoded with the SUPCRT92 software package [26]. These include global- and critical-region equations of state and a dielectric formulation for H$_2$O [28] that are explicitly integrated with equations of state for both aqueous solutes [29-30] and minerals/gases [31].
LDEC [32-33] is a geomechanical model that implements the distinct element method, which facilitates representation of fractured rock mass using arbitrary polyhedra, detection of new contacts between blocks resulting from relative block motion using the “Common-Plane” approach [34], exact conservation of linear and angular momentum, and simplified tracking of material properties as blocks move. Use of an explicit integration scheme allows extreme flexibility with respect to joint constitutive models, which here include effects such as cohesion, joint dilation, and friction angle. Both rigid and deformable approximations to block response are implemented. The rigid block approximation assumes that the compliance of fractured rock mass is closely approximated by lumping all compliance at the joints alone; however, this formulation also includes an optional second joint stiffness term that approximates deformation of the rock matrix.

Current one-way coupling between NUFT and LDEC represents our integrated model’s key approximation to the “ultimate” simulation tool. Specifically, the NUFT-LDEC interface facilitates mapping pressure evolution into the corresponding stress-strain, fracture aperture, and permeability history; however, at present, this geomechanical-dependent permeability evolution (LDEC) is not back-coupled into the multiphase flow and reactive transport model (NUFT). In the present study, the NUFT-LDEC interface is used to translate CO₂ influx-triggered pressure perturbations along and above the reservoir/cap-rock contact into the corresponding evolution of effective stress and microfracture apertures, which permits first-order assessment of influx-induced geomechanical deformation.

In order to evaluate the net impact on long-term cap rock integrity of concomitant geochemical and geomechanical processes, we introduce a new conceptual model that depicts geochemical counterbalancing of geomechanical aperture evolution as a function of effective diffusion distance and reaction progress. This model provides a theoretical framework for assessing the extent to
which cap-rock integrity will ultimately be enhanced or degraded in specific reservoir/cap-rock systems in the context of specific injection scenarios.

Results and Discussion

Predicting long-term permeability evolution within the cap-rock environment of CO$_2$ storage sites requires first identifying, then quantifying its functional dependence on key system parameters and dynamic processes. The most important factors influencing this evolution are conveniently subdivided into three groups: intrinsic cap rock properties, chemical conditions at the reservoir/cap-rock interface, and the CO$_2$ influx-triggered pressure perturbation.

Relevant cap-rock properties include geomechanical parameters, such as fracture normal stiffness, and geochemical characteristics, such as bulk concentrations of carbonate-forming cations—principally Fe, Mg, Ca, Na, and Al. These cation concentrations represent the primary control on geochemical alteration processes, while chemical conditions at the reservoir/cap-rock interface, which are determined by reservoir compositions and CO$_2$ waste-stream impurities (e.g., CH$_4$, H$_2$S, SO$_4$, NO$_x$ concentrations), exert a secondary control. Magnitude, duration, and focality of the injection-induced pressure perturbation—which depend on these same characteristics of CO$_2$ influx as well as on reservoir permeability, lateral continuity, compartment height (for laterally confined settings), depth, and thickness—represent the fundamental controls on geomechanical deformation processes.

In the context of these dependencies, long-term enhancement or degradation of cap rock integrity hinges on the relative contributions of geochemical alteration, which tends to reduce microfracture apertures in shale, and geomechanical deformation, which—on balance—tends to widen them (Figure 2). As a result, long-term performance forecasting of potential CO$_2$ storage sites requires a predictive capability that quantifies this pivotal interplay of geochemical and geomechanical processes. Previously, we have modeled the geochemical contribution within a
CO₂ Capture Project

full system analysis of coupled hydrological and geochemical processes [1-4]. Here, we first assess the geomechanical contribution—through analysis of its dependence on hydrological processes, key reservoir properties, and CO₂ influx parameters—then evaluate the ultimate net effect of opposing geochemical and geomechanical contributions to cap-rock integrity for both natural and engineered storage scenarios.

In describing this work, we begin with a review of subsurface CO₂ migration and sequestration processes, which provides not only the geochemical contribution to long-term cap rock integrity, but also full-system context for the subsequent analysis, which focuses on the cap rock environment.

**Subsurface CO₂ migration and sequestration processes**

Our previous modeling studies [1-4] have been largely based on simulating CO₂ injection at Statoil’s North-Sea Sleipner facility—the world’s first commercial saline-aquifer storage site. Here, CO₂-rich natural gas is produced from 3500 m below the seabed. Excess CO₂ is removed by amine absorption on the platform, then stripped from the amine, and finally injected—at the rate of one million tons per year since 1996—into the Utsira formation 2500 m above the hydrocarbon reservoir [35]. The 200-m-thick Utsira is a highly permeable fluid-saturated sandstone capped by the Nordland Shale. Hydrologic and compositional properties of the Utsira are relatively well constrained [36], while those of the Nordland Shale are virtually unknown, and must be estimated [1,4].

All of our Sleipner simulations have been carried out within a common 600x250 m spatial domain, which represents the near-field disposal environment, and over a single 20-year time frame, which encompasses equal-duration prograde (active-injection) and retrograde (post-injection) phases. The domain includes a 200-m-thick saline aquifer (35% porosity, 3-darcy permeability),
CO₂ Capture Project

25-m-thick shale cap rock (5% porosity, 3-microdarcy permeability), and an overlying 25-m-thick saline aquifer. Its lateral boundaries are open to multiphase flow, while its top and bottom boundaries are not. During the prograde phase, pure CO₂ is injected at a rate of 10,000 tons/yr into the basal center of this domain (37°C, 111 bars), which therefore corresponds to a one-m-thick cross-section though the actual 100-m screen length at Sleipner.

Within the common domain, we have evaluated three distinct injection scenarios—models XSH, CSH, and DSH [1,4]. Model XSH examines CO₂ injection into a shale-capped homogeneous sandstone aquifer. Models CSH and DSH impose into XSH four thin (3-m thick) intra-aquifer shales, which are separated from the cap rock and each other by 25 m. Model CSH examines the effect of imposing laterally continuous microfractured shales having assigned permeability (3 md) that equates to a continuum representation of 100-µm fractures spaced roughly 30 m apart. Model DSH examines the effect of imposing laterally discontinuous shales, which are bridged by lateral facies change to sandstone. Assigned permeability of these shales (3 µd; same as the cap rock) reflects typical shale integrity.

Compositionally, the saline aquifers are represented as impure quartz sand (80% quartz, 10% K-feldspar, 5% plag-ab₈₀, 3% muscovite, 2% phlogopite), while the shale cap rock is represented as 60% clay minerals (50% muscovite, 10% Mg-chlorite), 35% quartz, and 5% K-feldspar). Mg end-member components are used to represent Fe/Mg solid solutions because in situ oxidation states are unknown. The saline aquifers and shale are all saturated with an aqueous phase of near-seawater composition.

Our Sleipner simulations suggest that the ultimate fate of CO₂ injected into saline aquifers is governed by three interdependent yet conceptually distinct processes: CO₂ migration as a buoyant immiscible fluid phase, direct chemical interaction of this rising plume with ambient saline waters, and its indirect chemical interaction with aquifer and cap-rock minerals through the
aqueous wetting phase. Each process is directly linked to a corresponding trapping mechanism: immiscible plume migration to hydrodynamic trapping, plume-water interaction to solubility trapping, and plume-mineral interaction to mineral trapping.

**Immiscible plume migration and hydrodynamic trapping**

Intra-aquifer permeability structure controls the path of prograde immiscible CO₂ migration, thereby establishing the spatial framework of plume-aquifer interaction and the potential effectiveness of solubility and mineral trapping. Actual efficacy of these trapping mechanisms is determined by compositional characteristics of the aquifer and cap rock. By retarding vertical and promoting lateral plume mobility, inter-bedded thin shales significantly expand this framework (i.e., CO₂ storage capacity), enhance this potential, and delay outward migration of the plume from the near-field environment (**Figure 3**). Seismic data strongly suggest that the Utsira formation combines elements of models CSH and DSH (1,3-4).

In all three models, steady-state configuration of the immiscible CO₂ plume is realized within one year. During the prograde phase, a residual saturation zone marks the wake of initial plume ascent to the cap rock or deepest inter-bedded shale (e.g., **Figure 3A**, left insets). During the retrograde phase, this zone encompasses virtually the entire prograde steady-state plume (e.g., **Figure 3A**, right inset)—effectively maintaining the prograde extent of solubility trapping and continually enhancing that of mineral trapping, as described below for model DSH. In the near-field environment of Sleipner-like settings, 80-85% by mass of injected CO₂ remains and migrates as an immiscible fluid phase ultimately subject to hydrodynamic trapping beneath the cap rock, which represents an effective seal in these models[1-4], where geomechanical processes are unaccounted for.

**Geochemical trapping mechanisms**
As the immiscible plume equilibrates with saline formation waters, intra-plume aqueous CO₂ concentrations (primarily as CO₂(aq) and HCO₃⁻) rapidly achieve their solubility limit, while pH decreases [1-4]:

\[
\text{CO}_2(g) + \text{H}_2\text{O} = \text{CO}_2(aq) + \text{H}_2\text{O} = \text{HCO}_3^- + \text{H}^+
\]

For the chemical system and P-T conditions that characterize the Utsira formation at Sleipner, equilibrium aqueous CO₂ solubility is 1.1-1.2 molal, accounting for 15-20% by mass of injected CO₂ (Figure 4A). Owing to residual saturation of immiscible CO₂, this degree of solubility trapping is virtually constant throughout the prograde and retrograde phases. The initial pH drop caused by solubility trapping—from 7.1 to 3.4—catalyzes silicate dissolution, which after 20 years has increased pH from 3.4 to 5.3. This dissolution hydrolyzes potential carbonate-forming cations (here, primarily Na, Al, and Mg) within the immiscible-plume source region, and thus represents the critical forerunner of all mineral-trapping mechanisms.

We have identified four distinct mechanisms whereby CO₂ precipitates as carbonate minerals. Intra-plume dawsonite cementation (Figure 4B) is catalyzed by high ambient Na⁺ concentration, CO₂ influx, and acid-induced K-feldspar dissolution [1-4].

\[
\begin{align*}
\text{KAlSi}_3\text{O}_8 + \text{Na}^+ + \text{CO}_2(aq) + \text{H}_2\text{O} & \leftrightarrow \text{NaAlCO}_3(\text{OH})_2 + 3 \text{SiO}_2 + \text{K}^+ \\
\text{K-feldspar} & \text{dawsonite} & \text{silica}
\end{align*}
\]

The volume of co-precipitating dawsonite and silica polymorphs slightly exceeds that of dissolving K-feldspar. Hence, this kinetic dissolution/precipitation reaction effectively maintains initial CO₂ injectivity; after 20 years, porosity has decreased by a factor of less than 0.1% (Figure 5A).

Pervasive dawsonite cementation will likely be characteristic of saline aquifer storage in any feldspathic sandstone. In fact, natural analogs for this process have been documented: widespread dawsonite cement in the Bowen-Gunnedah-Sydney Basin, Eastern Australia, which has been interpreted to reflect magmatic CO₂ seepage on a continental scale [37], and sporadic dawsonite cement in the clastic Springerville-St. Johns CO₂ reservoir [38].
Calcite-group carbonate rind (here, magnesite) forms along—and therefore effectively delineates—both lateral and upper plume boundaries (Figure 4C). Genetically distinct, these two processes can be described by [1-4]:

\[ Mg^{2+} + CO_2(aq) + H_2O \leftrightarrow MgCO_3 + 2 H^+ \text{ (magnesite)} \]  

(3)

As intra-plume formation waters, progressively enriched in Mg\(^{2+}\) from phlogopite dissolution, migrate outward across lateral plume boundaries, they traverse steep gradients in CO\(_2\)(aq) and pH; the net effect strongly promotes magnesite precipitation. Along upper plume boundaries, CO\(_2\)(aq) concentration and pH are nearly constant, but aqueous Mg\(^{2+}\) concentration increases most rapidly here because formation-water saturation is minimized; this leads to magnesite cementation from the reservoir/cap-rock interface downward.

However, magnesite precipitation is most extensive from this interface upwards (cf. Figures 4C and 4D), owing to the relatively high concentration of Mg in clay-rich shales. The coupled intra-shale mineral dissolution/precipitation reaction can be expressed as [1-4]:

\[
\begin{align*}
\text{KAlSi}_3\text{O}_8 + 2.5 \text{Mg}_2\text{Al}_3\text{Si}_3\text{O}_{10}(OH)_2 & \leftrightarrow 12.5 \text{CO}_2(aq) \\
\text{K-feldspar} & \quad \text{Mg-chlorite} \\
\text{KAl}_3\text{Si}_3\text{O}_{10}(OH)_2 + 1.5 \text{Al}_2\text{Si}_2\text{O}_5(OH)_4 & + 12.5 \text{MgCO}_3 + 4.5 \text{SiO}_2 + 6 \text{H}_2\text{O} \\
\text{muscovite} & \quad \text{kaolinite} & \quad \text{magnesite} & \quad \text{silica} \\
\end{align*}
\]

(4)

This kinetic reaction proceeds to the right with an increase in solid-phase volume of 18.5% (magnesite accounting for 47 vol.% of the product assemblage). After 20 years, porosity and permeability of the 5-m-thick cap-rock base have been reduced by 8% and 22%, respectively, by this process (Figure 5B), which upon hypothetical completion at 130 years would reduce initial porosity by half and initial permeability by an order of magnitude (Figure 5C), thereby significantly
improving cap-rock integrity. A natural analog to reaction (4) has recently been documented in the Ladbroke Grove natural gas field, where post-accumulation CO$_2$ influx has converted Fe-rich chlorite to Fe-rich dolomite (ankerite), kaolinite, and silica [39].

Although composite mineral trapping accounts for less than 1% by mass of injected CO$_2$ in the near-field disposal environment, it has enormous strategic significance: it maintains initial CO$_2$ injectivity (reaction 2), delineates and may partially self-seal plume boundaries (reaction 3), and—most importantly—reduces cap-rock permeability (reaction 4), thereby enhancing hydrodynamic containment of immiscible and solubility-trapped CO$_2$ [1-4].

The CO$_2$ migration and sequestration processes reviewed above in the context of engineered saline-aquifer storage are equally applicable to CO$_2$-flood EOR operations in shale-capped water-wet oil reservoirs, which are primarily distinguished by the presence of a hydrocarbon phase and lateral confinement, and the formation of natural CO$_2$ reservoirs, which are fundamentally distinguished by the rate, focality, and duration of CO$_2$ influx. However, in all of these settings the effect of geochemical alteration to improve shale cap-rock integrity may be counterbalanced or even overwhelmed by concomitant geomechanical deformation, which initially acts in opposition. Hence, in evaluating long-term hydrodynamic sealing capacity, explicit account must be taken of both processes.

**Pressure evolution and geomechanical deformation**

A first-order assessment of cap-rock geomechanical deformation can be obtained from evaluating the dependence of microfracture aperture evolution on the influx-triggered pressure perturbation at and above the reservoir/cap-rock interface. In a new series of NUFT simulations, we have assessed this dependence, first as a function of reservoir permeability and lateral continuity—two key parameters that typically distinguish saline-aquifer disposal sites and oil reservoirs, and second, as a function of CO$_2$ influx rate—the fundamental parameter that distinguishes
engineered and natural storage scenarios. Within these new models, the values adopted for other important parameters that influence geomechanical response to CO₂ injection (e.g., reservoir depth and thickness as well as influx duration) are those used in the Sleipner simulations described above.

In the Sleipner models, we addressed coupled hydrological and geochemical processes. In the following simulations, we explicitly address only the effect of hydrological (multiphase flow) processes. However, this approximation has negligible impact for impure sandstone reservoirs (such as the Utsira formation), where reservoir porosity and permeability—and thus the injection-induced pressure perturbation—are not modified appreciably by geochemical alteration, as demonstrated above (Figure 5A).

**Dependence on reservoir properties: saline aquifer versus EOR settings**

In this analysis, four distinct simulations have been carried within two spatial domains (Figure 6). Reservoir permeability and lateral continuity are varied from 3000 md and infinite in model UHP (laterally-Unconfined, High Permeability), which represents desirable saline-aquifer storage sites, to 300 md and 2000 m in model CLP (laterally-Confined, Low Permeability), which represents a typical compartmentalized EOR setting. Models ULP and CHP represent cross-combinations of these values, which facilitate evaluation of specific dependence on reservoir permeability and lateral confinement. In both laterally confined models, compartment height—itself a parameter that exerts second-order influence on the injection-induced pressure perturbation—is 150 m. In all four models, supercritical CO₂ is injected at the rate of 10,000 tons/yr during the prograde event.

Magnitude of the influx-triggered pressure perturbation at the reservoir/cap rock interface varies significantly with (and inversely proportional to) reservoir permeability and lateral continuity (Figures 7-10), although its general evolution during prograde and retrograde phases of the influx event does not (Figure 11). For highly permeable, laterally extensive reservoirs (model UHP),
this perturbation follows a characteristic three-stage evolution: (1) rapid increase to maximum pressure as the aqueous phase is displaced upwards during initial ascent of the immiscible CO₂ plume to the cap rock, (2) rapid asymptotic decrease to a near steady-state value intermediate to ambient and maximum pressures that is maintained thereafter during the prograde regime; and (3) a second rapid asymptotic decrease towards the ambient value, which is triggered by onset of the retrograde regime (Figure 7). This pressure evolution suggests that the potential for dependent geomechanical deformation events is maximized during three very brief, distinct episodes that occur during the earliest stages of prograde and retrograde storage. Note that for this Sleipner-like setting, the range of injection-induced pressure variation is small—on the order of 3 bars.

Decreasing reservoir permeability from 3000 to 300 md without imposing lateral confinement (i.e., model ULP) significantly increases magnitude of the pressure perturbation—from roughly 3 to nearly 22 bars—without altering the three-stage evolution described above (cf. Figures 7 and 8). Also noteworthy from this comparison is the inverse dependence of CO₂ storage capacity on reservoir permeability, which suggests that for pure-sequestration scenarios the additional energy cost of exploiting less permeable reservoirs—which require higher injection pressures—may be partially offset by the benefit of increased storage and delayed migration into the far-field environment, providing cap-rock performance is not significantly compromised.

The influence of reservoir compartmentalization on the influx-induced pressure perturbation at the reservoir/cap rock interface is examined in models CHP and CLP (Figures 9-10). Although the functional form of pressure evolution in these models is analogous to that described above for laterally unconfined reservoirs, three significant variations are introduced by compartmentalization. First, the magnitude of initial pressure increase during plume ascent to the cap rock is significantly enhanced—reaching 60 bars in model CLP—owing to the restricted lateral flow (increased flow resistance) of displaced formation water. Second, a permeability-
CO₂ Capture Project

dependent fourth stage of pressure evolution—one that bridges cap-rock and spillpoint plume arrival times—is introduced that either causes a secondary pressure increase (CHP) or slows prograde decrease (CLP) of the initial pressure anomaly. Third, owing to presence of the accumulated CO₂ column, during the retrograde phase pressure decays asymptotically toward a steady-state value that exceeds hydrostatic and whose magnitude is proportional to column height. This final variation is extremely significant because it imposes a long-term pressure perturbation upon the cap-rock interface, which does not occur in unconfined reservoirs.

Direct translation of the injection-induced pressure perturbation from the well to and above the reservoir/cap-rock interface in all four models controls CO₂ migration into the undeformed cap rock through changes in capillary pressure, and controls geomechanical deformation of the cap rock through changes in effective stress and dependent microfracture apertures. Hence, the magnitude and evolution of these migration and deformation processes directly reflect those of the injection-induced pressure perturbation. The capillary pressure effect can be modeled directly with NUFT, while assessment of deformation effects requires use of the NUFT/LDEC interface.

CO₂ migration into the undeformed 25-m-thick 3-µd cap rock through increased capillary pressure is minimized in model UHP, where penetration distance is only 5 m, and maximized in model CLP, where such migration actually breeches the overlying reservoir (Figure 12).

Pressure evolution at and above the cap rock can be mapped into a corresponding evolution of effective stress and dependent microfracture apertures, yielding a first-order estimate of injection-induced geomechanical deformation. Here, we use a simplified form of the constitutive relationship between effective stress (σₑ), total stress (σₜ), and pressure (Pᵢ):

\[ \sigma_e = \sigma_T - P_f, \]  

(5)
where $\sigma_T$ is assumed to be constant ($\Delta \sigma_E = -\Delta P_t$). By further neglecting the nonlinear aperture dependence of fracture normal stiffness ($K_N$), normal aperture displacement due to reduced effective normal stress ($\Delta a_N$) can be expressed as:

$$
\Delta a_N = (\frac{\Delta P_t}{K_N}).
$$

Using equations (5) and (6) together with an estimated normal stiffness for shale fractures at depth [40], we first translate the maximum injection-induced pressure perturbation for each of the four models (Figure 11) into the corresponding maximum aperture normal displacement in order to gauge relative scale (Figure 13). As can be seen, the potential maximum aperture increase due to reduced effective normal stress is 50-1100 $\mu$m. Because attainment of this pressure maximum coincides with arrival of the immiscible plume at the cap rock—after only 15-100 days in all four models—the potential for geomechanical deformation is maximized very early during the prograde phase.

Simulating long-term aperture evolution requires use of the NUFT-LDEC interface, which facilitates translation of pressure evolution within a given reservoir cap-rock system into the dependent evolution of effective stress and microfracture apertures—here cast within the simplifying context of eqns (5) and (6). In this application, the interface is applied to a representative sub-grid from our NUFT domains: a 60m-by-50m half-space that encompasses the uppermost 10 m of the lower reservoir (2 NUFT grid cells), the 25-m-thick shale cap rock (5 cells), and the 25-m-thick upper reservoir (5 cells).

The functional form of aperture evolution at the reservoir/cap rock interface is directly analogous to that described above for pressure, as exemplified by LDEC simulation of such evolution for model CLP (Figure 14). Here, during the prograde phase apertures rapidly increase by about 1100 $\mu$m during initial plume ascent, then asymptotically decrease to a steady-state value that reflects net widening of roughly 400 $\mu$m. During the retrograde phase, they first rapidly decrease
from this prograde steady state, then continue to decrease asymptotically towards a final steady state value that reflects net widening of about 75 µm per the approximate 5-bar net pressure increase associated with CO₂ accumulation. Hence, geomechanical deformation degrades cap-rock integrity only during the earliest stages of the prograde phase, after which it continuously mitigates this initial degradation event. However, unless counterbalanced by geochemical effects, this ultimate 75-µm net aperture widening could facilitate long-term CO₂ migration into the cap rock. Moreover, although maximum prograde and ultimate net aperture increases (roughly 1100 and 75 µm, respectively) occur at the reservoir interface, concomitant increases of 200-1100 and a few 10s of µm, respectively, are realized throughout the basal 20 m of the 25-m-thick shale cap rock (Figure 15). Such pervasiveness suggests the potential development of microfracture continuity sufficient to permit CO₂ migration into and perhaps completely through relatively thin shale cap rocks in certain influx settings.

*Dependence on influx parameters: saline aquifer versus EOR settings*

In this analysis, three distinct simulations have been carried within a single spatial domain (Figure 16) that represents a confined sandstone reservoir whose compartment width (10 km), height (100 m), and width:height aspect ratio (100:1) typify those of natural CO₂ reservoirs [41]. In all three models, reservoir and shale cap rock permeability are 300 md and 3 µd, respectively. The models are distinguished primarily by prograde CO₂ influx rate, which is varied from 10⁴ to 10³ to 10² tons/yr, representing engineered injection, “fast” natural accumulation, and “slow” natural accumulation, respectively. The engineered injection rate is that used in the earlier Sleipner simulations, while the two values adopted for natural accumulation rates—which are presently unknown [41]—are rough estimates. A secondary difference is duration of the prograde and retrograde events, both of which span 10 years for the engineered injection, but are extended to 40 and 20 years in both natural accumulation models.
CO₂ Capture Project

Because the engineered-injection model adopts the same injection rate used in the preceding set of simulations, it illustrates dependence of the pressure perturbation on compartment width and aspect ratio, while providing a baseline for evaluating its dependence on influx rate per comparison with the two natural accumulation models (Figure 17). Increasing compartment width from 2 to 10 km causes pressure to increase even after the plume has reached the cap rock, owing to the increased volume of formation water that must be displaced. Hence, while pressure increases from 90 to 150 during plume ascent in both models CLP and here (cf. Figures 10 and 17), in this case pressure ultimately reaches 250 bars before declining after the plume reaches the lateral boundary. Subsequent asymptotic pressure decline during the post-spillpoint prograde and retrograde phases is dampened by increased compartment width.

When influx rate is reduced by one and two orders of magnitude, migration of the plume is retarded and the pressure perturbation is reduced proportionately, while its functional form remains unchanged (Figures 18-19). In the “fast” natural accumulation model, the immiscible plume does not reach the lateral compartment boundary until just before termination of the 40-year prograde event, while the maximum pressure perturbation (about 22 bars) is a factor of 7-8 less than that for the engineered injection model. In the “slow” natural accumulation model, the plume has not quite advanced halfway to the compartment boundary after 60 years (which encompasses both the prograde and retrograde events), while the maximum pressure perturbation is less than 3 bars.

The extent of CO₂ migration into undeformed shale through increased capillary pressure is strongly dependent on influx rate. Such migration extends halfway through the 25-m-thick shale in the “slow” accumulation model (intra-shale saturations approaching 8%), completely through this shale and halfway through the overlying 25-m-thick reservoir in the “fast” accumulation model (upper reservoir saturations approaching 12%), and completely through this upper reservoir to form a laterally-restricted (see Figure 17) accumulation zone beneath the upper domain.
boundary (where saturations approach 25%) in the engineered injection model (Figure 20).

The extent of geomechanical cap-rock deformation through changes in effective stress and dependent aperture evolution is also strongly dependent on influx rate. As the maximum pressure perturbation realized at the reservoir/cap rock interface increases from 3 to 22 to 160 bars with a 10- to 100-fold increase in influx rate (Figures 17-19), the dependent aperture opening—evaluated in the context of eqns (5) and (6)—increases from approximately 50 to 350 to 2900 µm.

The three simulations described above address a fundamental question regarding natural CO$_2$ reservoirs: are they natural analogs to engineered CO$_2$ storage sites? The models suggest that geomechanical degradation of seal integrity will be characteristic of both natural and engineered CO$_2$ influx, but significantly more severe during the latter. This result implies that cap-rock isolation performance may vary considerably as a function of filling mode, which severely limits the extent to which natural CO$_2$ reservoirs can be considered directly analogous to engineered CO$_2$ storage sites.

**Geochemical counterbalancing of geomechanical effects**

Long-term enhancement or degradation of shale cap-rock integrity ultimately hinges on the relative effectiveness of concomitant geochemical alteration and geomechanical deformation. The analyses presented above offer an opportunity to evaluate an important aspect of this geochemical/geomechanical interplay: the extent to which these initially opposing processes may counterbalance one another.

This cross-comparison requires a common reference frame, the choices for which are changes in porosity or fracture aperture, which have been used above to represent the respective contributions of geochemical and geomechanical effects. Converting aperture change into the corresponding porosity change requires an initial aperture or fracture density (neither of which are
known here), while the aperture change associated with matrix expansion due to a specific mineral dissolution/precipitation reaction can be represented as a function of the dependent variables. Hence, we adopt the latter approach and translate the geochemical contribution into the aperture-change reference frame.

For a given dissolution/precipitation reaction within the matrix, the associated aperture change ($\Delta a$) depends on initial volume fraction of the reactant assemblage ($V_R/V_T$), standard molal volume change of the reaction ($\Delta V_r^o = V_p^o - V_R^o$), effective diffusion distance ($L_D$, how deep into matrix blocks the reaction occurs), and reaction progress ($C$, the extent to which the reaction proceeds to completion) [5]:

$$\Delta a = -2 \left[ \left( V_R / V_T \right) \left( \Delta V_r^o / V_R^o \right) L_D C \right]$$

(7)

All of these variables are typically known or can be closely estimated except for diffusion distance and reaction progress. Hence, it is both appropriate and convenient to plot $\Delta a$ isopleths as a function of these latter two parameters.

We have constructed such a diagram for reaction 4 (Figure 21), where the $\Delta a$-isopleths plotted span the range of maximum aperture widening due to geomechanical displacement that was predicted for models UHP, ULP, CHP, and CLP (Figure 11). Hence, they can be viewed as geochemical "counterbalance" isopleths; i.e., along any curve, departing to greater diffusion distances or reaction progress equates to net aperture closure (improved cap-rock integrity) as a function of combined geochemical and geomechanical effects, while departing to lesser values equates to net opening (degraded integrity).

This diagram reveals that geochemical counterbalancing of geomechanical deformation over this range of $\Delta a$ requires diffusion distances of only 3-6.5 cm for reaction progress of 30-60%. These ranges—both of which are commonly observed in natural systems—suggest that early-stage maximum geomechanical deformation may be eventually counterbalanced by geochemical
alteration. This raises the possibility that shale cap rocks in natural CO₂ reservoirs may have evolved into effective seals following some degree of CO₂ migration through them. Careful mineralogical and petrographic analyses of these shale cap rocks may shed light on this important concept.

Conclusions

Reactive transport and geomechanical models have been interfaced and a new conceptual framework developed to evaluate long-term cap rock integrity in natural and engineered CO₂ storage sites. For typical shales, influx-triggered geochemical alteration and geomechanical deformation act in opposition to enhance and degrade hydrodynamic seal capacity though aperture narrowing and widening of cap-rock microfractures; hence, net impact of these concomitant processes hinges on their relative effectiveness. The extent of geochemical enhancement is largely independent of reservoir characteristics that distinguish saline-aquifer from EOR/sequestration settings and influx parameters that distinguish engineered disposal sites from natural accumulations, because such characteristics and parameters have negligible (indirect) effect on mineral dissolution/precipitation rates. In contrast, the extent of geomechanical degredation is highly dependent on these reservoir characteristics and influx parameters, because they effectively dictate magnitude of the pressure perturbation; specifically, it is has been shown inversely proportional to reservoir permeability and lateral continuity and proportional to influx rate.

As a result, while the extent of geochemical alteration is nearly independent of filling mode, that of geomechanical deformation is significantly more pronounced during engineered injection. This distinction severely limits the extent to which naturally-occurring CO₂ reservoirs can be considered “natural analogs” to engineered CO₂ storage sites. In addition, the pressure increase associated with CO₂ accumulation in any compartmentalized system invariably results in net geomechanical aperture widening of cap-rock microfractures. This suggests that ultimate restoration of pre-influx
CO₂ Capture Project

hydrodynamic sealing capacity—in both EOR/sequestration and natural accumulation settings—hinges on ultimate geochemical counterbalancing of this geomechanical effect, which further suggests that the well documented leaky-to-secure character of fossil CO₂ reservoirs may reflect the incomplete-to-complete nature of such restoration.

To explore these hypotheses, a new conceptual framework has been introduced that depicts ultimate geochemical counterbalancing of geomechanical aperture evolution as a function of effective diffusion distance and reaction progress. This framework reveals diffusion length scales and reaction progress extents consistent with those observed in nature, which suggests ultimate counterbalancing of geochemical and geomechanical effects is feasible, and, therefore, that shale cap rocks may in fact evolve into effective seals—in both natural and engineered storage sites. Further, it provides a theoretical model for assessing the extent to which cap-rock integrity will ultimately be enhanced or degraded in specific reservoir/cap-rock systems in the context of specific engineered injection scenarios.

**Recommendations**

The present contribution can be viewed as a scoping study in which influx-triggered geochemical and geomechanical contributions to cap-rock integrity have been modeled, then merged within a new conceptual framework that facilitates assessment of their ultimate net effect for CO₂ storage sites whose compositional and influx parameters can be well characterized. As such, it provides a unique computational methodology for addressing two central issues for geologic storage—long-term prediction of isolation performance and the extent to which natural and engineered sites are analogous. A number of model development and application activities are immediately posed by this inaugural work.

In terms of important technological advances, there is a pressing need to develop a simulation capability that fully integrates reactive transport and geomechanical processes, which we have
merely interfaced here. There are many ways to accomplish this, ranging from, ideally, a global-implicit approach to, perhaps more realistically in the short-term, bi-directional coupling of distinct models. Equally pressing is the need for improved kinetic descriptions of mineral dissolution and (especially) precipitation processes as well as more accurate and comprehensive databases of the associated species-specific parameters. Also very important is the need to develop methodology for assessing the specific rates and time frames of geochemical counterbalancing that involves multiple dissolution/precipitation reactions; here, we have addressed this concept only in a time-integrated sense and for a single representative reaction.

In parallel with such development activities, several key applications could provide critical benchmarking, validation, and refinement for both the simulation capabilities and new hypotheses described above. For example, detailed reactive transport modeling of well-characterized fossil or active CO₂ reservoirs—ideally, a suite of leaky-to-secure systems for which cap-rock core is available—would provide a crucial field-scale test bed for the incomplete-to-complete geochemical counterbalancing concept. Similarly detailed modeling of carefully designed and precisely characterized batch and plug-flow reactor experiments would provide an analogous laboratory-scale test bed for this hypothesis—as well as the ideal means of benchmarking simulation capabilities for all mineral trapping mechanisms.

Finally, for a suite of well-characterized potential CO₂ disposal sites, reactive transport and geomechanical modeling could be used to identify and evaluate the volume change associated with key injection-triggered mineral dissolution/precipitation reactions, to assess concomitant pressure-dependent geomechanical deformation, and to determine net impact of these interdependent processes on long-term cap-rock integrity. It would be particularly instructive and useful to carry out this modeling study for a suite of prospective sites that spans the broad range of potential reservoir/cap-rock lithologies—well beyond the single sandstone/shale combination.
examined here. Such an analysis would provide a unique means of quantitatively ranking long-term isolation performance as a function of important lithologic and other dependent variations.
