NUCLEAR DATA AND MEASUREMENT SERIES

The Nuclear Data and Measurements Series presents results of studies in the field of microscopic nuclear data. The primary objective is the dissemination of information in the comprehensive form required for nuclear technology applications. This Series is devoted to: a) measured microscopic nuclear parameters, b) experimental techniques and facilities employed in data measurements, c) the evaluation of nuclear data. Contributions to this Series are reviewed to assure a high technical excellence and, unless otherwise stated, the contents can be formally referenced. This Series does not supplant formal journal publications but it does provide the more extensive information required for technological applications (e.g. tabulated numerical data) in a timely manner.

ABSTRACT

Energy-averaged total cross sections of elemental vanadium were measured from 1.5 to 5.5 MeV. Differential elastic and inelastic neutron scattering cross sections were measured from 1.8 to 4.0 MeV. Neutrons corresponding to the excitation of states in vanadium at 321 ± 10 , 938 ± 15 , 1603 ± 19 , 1811 ± 21 , 2409 ± 27 , ~ 2500 , 2706 ± 30 and 2773 ± 30 keV were observed. From these experimental results an energy-average model was deduced suitable for extrapolating and interpolating the measured values. These results and those reported elsewhere were used to construct a comprehensive Evaluated Neutronic File in the ENDF format with particular attention to higher-energy processes having an impact on FBR, CTR, dosimetry and gas production applications.

I. INTRODUCTION

Vanadium is a promising structural metal for use in high-temperature neutronic systems particularly where tritium containment is a concern (e.g., in fusion power systems). The element is essentially monoisotopic ($> 99\%$ ^{51}V), "magic" in neutron number, an odd nucleus near the peak of the s-wave strength function and the spectroscopic structure is relatively well known to excitations of several MeV (1). These unusual characteristics make the interaction of fast neutrons with vanadium of physical interest and, in some ways, simplify experimental studies of the associated fast-neutron interactions and their interpretation. At incident energies of ~ 1.0 MeV the respective neutron cross sections are known to fluctuate with energy and to have some aspects characteristic of intermediate structure (2). Between 1.0 and 5.0 MeV there is a transitional region where the character of the neutron interactions change from a discrete-resonance to an energy-averaged behavior. Compound-nucleus processes in this mass-energy region remain a matter of physical interest (3). Moreover, experimental information in the few-MeV region is useful in establishing nuclear models which subsequently can be applied to extrapolate and interpolate difficult to measure cross sections. This is particularly true for vanadium as a number of important $(n;X)$ cross sections are not well measured; and, as a consequence, model-based theory must be used to extrapolate the measured values over wide energy ranges in order to obtain

cross section values important to many applied calculations.

The primary objective of the present work is the provision of a good contemporary data base for applied use. It was an intent of the measurements to better define the fast neutron interaction with vanadium in the few-MeV range and thus provide a basis for the development of a realistic energy-average model for subsequent extrapolation and interpolation. The present results and those reported elsewhere in the literature were used to develop a comprehensive Evaluated Neutronic File in the ENDF format (4). Particular attention was given to the higher-energy processes of importance in FBR and CTR applications and to the dosimetry and gas-production aspects of the data file. Subsequent portions of this paper outline the present experimental and calculational results and the construction of the evaluated file. The complete numerical contents of the file are given in the Appendix.

II. EXPERIMENTAL METHODS

All samples used in the measurements consisted of natural metallic vanadium cylinders with 99+ percent chemical purity. The samples used in the neutron-total-cross-section measurements were cylinders approximately 2.5 cm in diameter with lengths adjusted to provide neutron transmissions of 50 percent or greater in the axial direction. Sample-thickness perturbations were assumed small. The scattering samples were solid cylinders 2 cm. in diameter and 2 cm. long; arranged so that neutrons were incident upon their lateral surfaces.

Both the neutron total and scattering cross section measurements employed the ${}^7\text{Li}(p,n){}^7\text{Be}$ source reaction (5). The incident neutron energy scale was determined relative to the threshold of this reaction. The incident neutron-energy resolution was determined by the thickness of the lithium-metal film used as the neutron producing target. Throughout the measurements the source was pulsed for a duration of approximately 1 nsec at a repetition rate of 2 MHz using the pulsing capabilities of the Argonne National Laboratory Tandem Dynamitron (6).

The neutron total cross sections were determined from the observed transmissions of approximately monoenergetic neutrons through the vanadium samples. A large collimator was placed about the neutron source so arranged as to provide an approximately monoenergetic neutron beam of about 1 cm diameter at a source-reaction angle of zero degrees. The collimator was approximately a meter thick and care was taken to assure that the aperture did not perturb the neutron-energy distribution. The samples were placed approximately 30 cm beyond the collimator with the beam passing through them in an axial direction. The samples were mounted on a wheel which changed the samples ~ 180 times a minute. In addition to the vanadium samples, the wheel contained a void and a carbon reference standard. A scintillation detector was placed upon the beam axis about 5 m from the neutron source. The time of flight of the neutrons from the source to the detector was determined using conventional electronic systems. The experimental time resolution was sufficient to control experimental perturbations such as back-

ground and to separate the second and minority neutron groups from the primary ${}^7\text{Li}(p,n){}^7\text{Be}$ source neutrons. Several BF_3 neutron detectors were arranged in moderating media to provide a monitoring of neutron-source intensity. The data acquisition and reduction to cross sections was done on-line using a digital computing system which automatically correlated sample position and detector count. The measurements were carried to predetermined statistical-cross-section accuracies, typically 1-3 percent. The details of the experimental apparatus and its application have been extensively described elsewhere (7).

The neutron scattering cross sections were determined using the pulsed-beam time-of-flight technique (8) and a ten-angle detection system. The incident neutron energy spread varied from 20 to 50 keV. Scattered-neutron flight paths were nominally five meters and scattered neutron velocity resolutions λ 0.4 nsec/m. The detection apparatus consisted of a massive shield with 10 well-collimated flight paths distributed over an arc of approximately 140 deg. The placement of individual detectors could be varied to yield scattering angles from +160 to -160 deg. The relative angular position of the detectors was determined to within ± 1.0 deg. using a precision optical transit. The reference zero of this angular system was determined to ± 1.0 deg. by observing the energy shift of neutrons scattered from hydrogen at a number of angles both left and right of the zero-deg. reaction angle. Measurements were made concurrently at 10 scattering

angles. Additional angular placements of the collimator system were used to obtain 20 or more differential scattering cross sections at a given incident neutron energy.

The scattered-neutron detectors were proton-recoil liquid scintillators. Electronic pulse-shape-selection circuitry was employed to reject most gamma-ray induced events. Data acquisition was by means of a digital computing system. These were programmed to select the detector sensitivities for optimum signal-to-background ratios and/or time resolutions. Generally, the detectors were sensitive to scattered neutron energies of $\gtrsim$ 500 keV.

The neutron source intensity was monitored using four long counters (9) and a special-purpose time-of-flight system. The monitors were arranged so as to be insensitive to the angular placement of the collimator system and to the presence of the scattering samples.

The relative energy-dependent sensitivities of each of the scattered-neutron detectors were experimentally determined by the observation of neutrons scattered from the hydrogen in a polyethylene sample. Subsequently, the normalization of these relative sensitivities was established by the observation of scattering from hydrogen at each incident energy (8). Thus all scattering cross sections were determined relative to the well known H(n,n) cross sections (10). These detector calibration procedures were not sensitive to the energy dependence of the monitors nor did they require an absolute flux determination or an exact knowledge of the

source reaction. The calibration procedures were repeated at each of approximately ten measurement periods. There was considerable redundancy in the measured cross section values. Thus the consistency of the results was a measure of the reliability of the techniques.

All of the experimental data were corrected for multiple scattering, incident beam attenuation and angular resolution effects using a combination of Monte-Carlo and analytical procedures (11). These correction procedures were applied to the vanadium samples and the polyethylene standard samples. At each incident energy, in addition to the polyethylene-standard and vanadium measurements, a carbon-reference measurement was made. The carbon cross sections are reasonably well known at the energies of the present experiments and their determination provided a verification of the experimental procedures (12).

The details of the scattering apparatus and the associated procedures have been described elsewhere (8,13).

III. EXPERIMENTAL RESULTS

A. Neutron Total Cross Sections

The total cross sections measurements were made in two separate sets, extending in energy from less than 1.0 MeV to 5.5 MeV. The energy resolution of one set was approximately 5 keV and that of the other approximately 25 keV. The primary objective was the accurate determination of the energy-averaged magnitudes of the total cross sections so as to: verify the results of previously reported higher-resolution measurements, provide a basis for the

development of energy-averaged models (e.g. optical model), and assure the consistency of the present scattering cross section results with the total cross section values. Considerable care was taken to avoid experimental distortions due to backgrounds, "in-scattering" and dead times. The resolution of details of the resonance structure was not emphasized. The individual data values fluctuated with energy depending upon the resolutions employed in the particular measurements and the exact incident neutron energies. The energy-averaged values were derived by averaging the individual measurements over energy intervals of 100 keV. These averaged results were relatively smooth functions of energy and reasonably comparable with the angle-integrated scattering values deduced from the present measurements. The statistical errors of the energy-averaged values were 1 to 4 percent and the systematic uncertainties were believed to be appreciably smaller. A possible exception is the sample size effect. It was assumed small (< 2 percent) due to the relatively large average transmissions of the samples. The energy-averaged results are illustrated in Fig. 1. At the lower energies (e.g., below 1.5 MeV) the present results compare favorably with those reported previously from this laboratory (2). More generally, the present results support the higher-resolution values of several authors as summarized in the evaluation described in Sec. V (e.g., Cierjacks et al. Ref. 14).

B. Elastic Neutron Scattering Cross Sections

The differential elastic neutron scattering cross sections

were measured at 20 or more scattering angles distributed in the range of 20 and 160 deg. and at incident neutron energy intervals of ≤ 0.2 MeV from 1.8 to 4.0 MeV. The experimental resolution was sufficient to resolve the elastically-scattered component from all known inelastically-scattered contributions. The accuracies of the individual differential data points were $\gtrsim 5$ percent or 2 to 3 mb/sr, whichever was larger. These uncertainty estimates were inclusive of experimental counting statistics ($\gtrsim 1$ percent), uncertainties in the reference $H(n;n)$ cross sections ($\gtrsim 1$ percent), uncertainties in the correction procedures (1 to 3 percent) and estimated systematic uncertainties associated with the determination of detector sensitivities and scattering angles (3 to 5 percent). The data were obtained from a number of measurement periods each with essentially independent calibration procedures. The incident neutron energy resolutions varied from 20 to 50 keV and the estimated uncertainty in the mean incident energy was ≈ 10 keV. Angular distributions obtained at different measurement periods were not always consistent, with discrepancies as large as several times the estimated uncertainties particularly at the lower extremity of the measured energy range (i.e., 1.8 to 2.0 MeV). These discrepancies were attributed to the large fluctuations in the cross sections evident in the results of high-resolution total cross section measurements (See Fig. 1). Small variations in the mean incident neutron energy and/or resolution employed in scattering measurements at nominally the same energy could easily lead to considerably different results, particularly since the fluctuations observed in the total cross are expected to be

accentuated in the individual elastic channel. These fluctuations make it very difficult to compare the results obtained at different times (or at different laboratories). In order to obtain a better representation of the energy-average of the differential cross sections, the present results obtained at nominally the same incident energies (though with somewhat varying incident resolutions and mean energies) were averaged using a Legendre Polynomial fit to the data to interpolate the scattering angles so as to provide a common angular scale. The resulting energy-averaged differential elastic distributions are shown in Fig. 2. Even with this averaging procedure it is evident from Fig. 2 that some fluctuation persists, particularly at lower (e.g., near 2.0 MeV) energies.

The differential elastic scattering cross sections were fitted by least-squares with Legendre Polynomial expansions. These were used to deduce the angle-integrated elastic scattering cross sections. There were no constraints on this fitting procedure other than the introduction of a few 180 deg. cross section values, deduced from the model described in Sec. IV, in order to assure a well-behaved distribution at scattering angles beyond the measured angular range. The zero degree cross sections derived from this fitting procedure were consistent with Wick's Limit (15). These angle-integrated elastic scattering cross sections are compared with the measured neutron total cross sections in Fig. 1. The estimated uncertainty in the angle-integrated elastic scattering values is $\lesssim 5$ percent and this is largely attributed to uncertainty in detector normaliza-

tion. The angle-integrated elastic scattering cross sections are consistent with the total and inelastic scattering cross sections as outlined in Sec. V.

The present elastic scattering results are in good agreement with those reported by Towle et al. (16) at 2135 MeV as illustrated in Fig. 3. There is similar good agreement with the 4.0 MeV results of Holmqvist et al. (17). The 3.5-MeV values of Holmqvist et al. are reasonably consistent with the present results but at 2.47 and 3.0 MeV their values are systematically smaller than those of the present work. In addition, the values reported by Becker et al. (18) at 3.2 MeV are smaller than those from the present work. Whether these discrepancies are real or the consequence of cross section fluctuations is not clear. However, if the lower elastic scattering values are accepted, there will tend to be an inconsistency with the total and inelastic scattering cross sections.

C. Inelastic Neutron Scattering Cross Sections

The observed energies of states excited by inelastic neutron scattering were determined from the measured transit times of the scattered neutrons over the known flight paths. The method was verified by the observation of well-known inelastically-scattered neutron groups, particularly that due to the excitation of the 846.7 keV state in ^{56}Fe . Simple averages of the measured excitation energies were obtained from a minimum of five and as many as fifty individual measurements distributed over a four-year period. The corresponding uncertainties were expressed as RME

deviations from the average values. Cross sections were determined for the excitation of the six "states" at 321 ± 10 , 938 ± 15 , 1603 ± 19 , 1811 ± 21 , 2409 ± 27 , and 2706 ± 30 keV. In addition, neutrons corresponding to "states" at 2773 ± 30 and approximately 2500 keV were observed in a few (less than 5) measurements. The observed values are compared with the evaluated quantities given in the Nuclear Data Sheets in Table 1 (1). The present results are consistent with those determined from a diversity of other measurements using a variety of techniques. However, it should be emphasized that the objective of the present energy determinations was limited to the correlation of the observed scattered neutron groups with known structures in ^{51}V which have been determined more precisely using other methods.

In addition to the above "primary states", neutrons were observed corresponding to excitation energies of 751 ± 20 , 1370 ± 30 , 2060 ± 30 , 2260 ± 30 , and 2862 ± 50 keV. These excitation energies and the corresponding cross sections were very consistent with the excitation of the primary states by the secondary neutron group from the $^7\text{Li}(p,n)^7\text{Be}^*$ source reaction. Therefore, these "states" were attributed to an artifact of the source reaction. Any true scattered neutron component underlying these satellite neutron groups would have been of low intensity and not in agreement with previous knowledge of excited states in ^{51}V .

Intensities of scattered neutron groups were observed over the incident neutron range 1.8 to 4.0 MeV at intervals of ≤ 0.2 MeV. Minimum-energy scattered neutron sensitivities were ~ 0.5

MeV. Prominent inelastic-neutron groups were observed at up to forty scattering angles at each incident energy. Less intense groups, particularly at higher excitation energies, were observed at fewer angles, but a minimum of four at a given incident energy was required for a cross section determination. Generally, the inelastic-neutron groups were nearly isotropically distributed in angle, and there was no significant deviation from symmetry about ninety degrees as illustrated in Fig. 4. Each observed angular distribution was fitted with a low-order (≤ 2) Legendre Polynomial series, using the method of least-squares, thereby providing angle-integrated values. The sharp resonance structure clearly evident in the high-resolution total cross section measurements, would be even more evident in isolated exit channels. Moreover, systematic inelastic-neutron gamma ray studies (e.g., those of Smith (19)) clearly display fluctuations that are generally consistent with the present experimental results. In view of these fluctuations, cross sections obtained at energies identical within the experimental incident-energy resolution were averaged to obtain a more representative sample of the true value. Even with this procedure, considerable variations over small incident energy changes (e.g., 50 keV) can be expected.

The accuracies of the differential inelastic cross sections varied depending upon the particular experimental conditions and inelastic component involved. Under optimum conditions (e.g., the excitation of the prominent 1603-keV state by ≈ 3.0 MeV neutrons) the cross-section uncertainties were ≈ 5 percent, ap-

proximately equally divided between contributions from the counting statistics, the relative detector response and the normalization to the $H(n,n)$ reference-standard reaction. These uncertainties were inclusive of contributions from data correction procedures such as multiple scattering corrections. The angle-integrated cross section values benefited from improved statistical accuracies and, in the best cases, were believed known to $\lesssim 5$ percent accuracies. Uncertainties associated with minor inelastic components, particularly those with relatively high excitation energies, were much larger than the above (e.g. in the worst cases, 30-50 percent uncertainties). Moreover, no appreciable effort was made to extend sensitivities below a level of ~ 1 mb/sr and this limit was a large fraction of some of the minor inelastic components. The cross section uncertainties increased as scattered neutron energies decreased below ~ 1.5 MeV due primarily to detector efficiencies that changed rapidly with energy and fewer detectors having a reliable response to neutrons with energies of $\lesssim 0.5$ -1.0 MeV.

The present cross sections for the neutron excitation of the above states are summarized and compared with previously reported values in Fig. 5.

The cross sections for the 321 keV state were large throughout the measured incident-neutron energy range. However, at incident energies above 3.4 MeV, the measurements were complicated by the presence of the nearby elastic component due to the second

neutron-source group from the ${}^7\text{Li}(p,n){}^7\text{Be}^*$ reaction. At these energies the secondary elastic and the primary inelastic groups could not be clearly resolved at all angles thus inelastic contributions were deduced by correcting the observed composite cross sections for the elastic contribution using the measured elastic scattering cross sections and the known relative intensities of the two source components (5). This correction procedure increased the uncertainties. The present results for the 321 keV state are in a very good agreement with those reported by Towle et al. (16) and generally consistent to within the respective uncertainties with those of Alman-Ramstrom (20) and of Holmqvist et al. (21). The lower-energy values extrapolate reasonably well to the work of Smith et al. (2). A number of cross section sets for the production of 321 keV gamma-rays by inelastic neutron scattering have been reported. These are not always easy to correlate with directly observed neutron values due to uncertain branching ratios. However, up to incident neutron energies of ~ 1.6 MeV the only restriction of that type is due to the excitation of the 929 keV state, and the reported gamma-ray data were corrected for that contribution before making comparisons with the present results. Here, and generally throughout the comparisons with gamma-ray production cross sections, attention was given to possible effects of gamma-ray anisotropy. Unfortunately, it was not always possible to interpret reported experimental values in the context of such angular-distribution effects. The corrected gamma-ray results of Porter et al. (22), Barrows

(23), and Smith (19) were reasonably consistent with the present and other reported neutron cross sections results. As expected the gamma-ray results are larger than the neutron values at higher energies (above ~ 1.6 MeV) due to uncorrected and uncertain branching-ratio affects. Some of the gamma-ray results provide more energy detail than the neutron measurements tending to confirm the presence of fluctuating structure. This is particularly so of the results of Smith (19).

The present cross sections for the excitation of the 938 keV state are in good agreement with those reported by Towle et al. (16) and by Cranberg and Levin (24). They are somewhat larger than the values given by Alman-Ramstrom (20) and Holmqvist et al. (21). The cross sections for the production of 938 keV gamma rays should reasonably correspond to the directly observed neutron cross sections due to the spin configurations of the first few excited states in ^{51}V . Indeed, the gamma-ray production cross sections reported by Barrows (23), and Smith (19) are consistent with the present values for the neutron cross sections. The gamma-ray cross section values of Porter et al. (22) tend to be somewhat lower.

Neutron cross sections for the excitation of the 1603- and the 1811-keV states obtained in the present work were in good agreement with those reported by Towle et al. (16), Alman-Ramstrom (20), Cranberg and Levin (24) and Holmqvist et al. (21). The present neutron cross sections were further supported by the re-

sults of the inelastic neutron gamma-ray studies of Porter et al. (22) and Barrows (23). Any difference between neutron and gamma-ray results could easily be attributed to uncertainties in gamma-ray branches and/or the angular distribution of emitted gamma-rays.

Neutrons corresponding to the excitation of a 2409 keV state were clearly evident in the present work. In addition, a neutron component corresponding to the excitation of a state at ~ 2500 keV was observed in a few measurements. The cross sections for the latter state were very small (of the order of a mb/sr) and qualitatively consistent with the small values reported by Alman-Ramstrom (20). However, since the present work was primarily oriented toward applied needs the cross sections for the excitation of the 2409 and 2500 keV were combined into a single value. Even these collective cross sections, were relatively small. They were in good agreement with the similar composite quantity derived from the work of Alman-Ramstrom (20) and reasonably extrapolated to the results of Perey and Kinney (25) at 4.19 MeV and above.

Neutrons corresponding to the excitation of a state at 2706 keV were attributed to the combined contributions from previously reported states at 2675 and 2699 keV. There were only a limited number of results at a given incident energy, and as a consequence, the uncertainties associated with these values were relatively large. However, the present results are consistent with those of Alman -Ramstrom (20) and with an extrapolation of the values of Perey and Kinney (25). At incident energies of 4.0 MeV there were

two occasions when a neutron group corresponding to a state of 2773 keV was observed. This energy was not well determined, but it was consistent with the state reported at 2790 keV. The corresponding cross sections were very small, similar to the few mb/sr values reported by Alman-Ramstrom (20), and quantitative values were not deduced due to their uncertainty and their dependence upon rapidly changing scattered-neutron detector sensitivities.

IV. CALCULATIONAL MODELS

Here the objective was the development of an energy-averaged calculational model suitable for extrapolating and interpolating measured values particularly as required for the construction of the evaluated data file. The interpretation was based upon the conventional spherical-optical and statistical models (26,27). Initial estimates of the optical-model parameters were obtained from χ^2 -square fitting of the differential elastic distributions determined in the present experiments. The fitting procedures were applied to all measured distributions from incident energies of 1.8 to 4.0 MeV. Compound-nucleus processes were calculated using the Hauser-Feshbach formula with width fluctuation corrections (28), and the previously reported spectroscopic properties of states to excitations of approximately 3.2 MeV as given in the Nuclear Data Sheets (1). At incident energies above approximately 3.0 MeV, the observed fluctuations in the elastic distributions became small and the energy-averaged model was appropriate. However, at these same

energies the knowledge of the contributing compound-nucleus channels was uncertain and as a consequence it was difficult to calculate quantitatively the still appreciable compound-elastic component. Therefore the model parameters were selected from fitting procedures at energies of 3.2 MeV or less where the calculations were more definitive. As the incident energy decreases from 3.0 MeV the fluctuations in the observed distributions increase with a consequent impact upon the deduced parameters. The fit to any isolated distribution can be good, as illustrated in Fig. 6, but the resulting potential parameters may differ from those obtained from a neighboring distribution by relatively large amounts. Parameters obtained from a single distribution may not be representative of the average, and even be deceptive. Thus the selected parameter set was obtained from a simple average of the parameters deduced from the fits to the individual distributions to incident energies of 3.2 MeV. The resulting selected parameter set is given in Table 2. The uncertainties associated with the respective parameters were derived from the RMS deviation of the individual values from the mean. In all, 15 individual distributions and fits were involved spanning nearly 1.5 MeV and thus the average parameters should be reasonably representative of the energy-averaged optical potential in the region 2.0 to 3.0 MeV.

Neutron total cross sections calculated with the above potential were reasonably descriptive of the measured values to 20.0 MeV as illustrated in Fig. 7. The largest discrepancy between

calculation and measurement was near 5.0 MeV, amounting to about 6 percent. The use of energy dependent real and imaginary potentials as indicated by wider-scope analysis, did not appreciably alter this discrepancy (29). The introduction of volume absorption with increasing energy as noted, for example, by Engelbrecht and Fiedelvey (29) may be an additional factor but could not be verified by the present measurements. Calculated elastic scattering distributions at approximately 8.0 MeV give a good description of the measured values reported by Holmqvist and Wiedling (17) and by Perey and Kinney (25). Moreover, the calculated ℓ_0 strength function was 4.5×10^{-4} , in good agreement with that reported from the analysis of low energy neutron resonances (30). Generally, the potential of Table 2 is very similar to that of Holmqvist and Wiedling (17), the main difference being a larger radius in the absorption term of the present potential. The present potential is different from that deduced by Moldauer (31) from lower energy phenomena. The latter has smaller real-potential strengths and larger radii than the potential of Table 2. There tends to be a characteristic difference between potentials in this mass region at energies of 1.0 to 2.0 MeV and, indeed, on occasion the present fitting procedures at the lower-energy extreme of the experimental range resulted in potential parameters very similar to those proposed by Moldauer and quite different from those obtained from the body of the measurements at somewhat higher energies.

The above potential and the Hauser-Feshbach formula, with and without width fluctuation corrections, were used to calculate the inelastic excitation cross sections (28,32). The potential was not adjusted to improve the description of the inelastic scattering processes. The spectroscopic character of states to excitations of 2.75 MeV is reasonably known with the additional identification of some states to excitations of 3.5 MeV and above (1). Thus the calculations should be reasonably reliable to about 3.5 MeV but less definitive at higher energies as the uncertainties associated with contributing channels increases. These calculational results are compared with the measured values in Fig. 5. From this figure it is clear that comparisons with the calculated results must be made in an energy-averaged context and not at isolated energy points. Both measured and calculated neutron inelastic scattering distributions are very nearly isotropic as illustrated in Fig. 4.

An average of the cross sections for excitation of the 321 keV state tends to lie approximately midway between results calculated with and without width fluctuation corrections. This suggests that there is a channel-channel correlation enhancement of this cross section and use of the "Q-parameter" of Moldauer resulted in better agreement with experiment. However, this parameter adjustment is a simple approximation of the complexity of effects contained in the "M-matrix" which are not readily calculable (28,3). Therefore the Q-parameter adjustment was not pursued. In view of these uncertainties, the well

established $5/2^-$ character of this state is consistent with the present measurements and calculations.

The calculated excitation of the 938 keV state tends to be 10 to 20 percent lower than the present experimental results. The $3/2^-$ character of this state appears to be well established thus this small discrepancy is probably due to the inappropriateness of the model and/or calculational methods. The width-fluctuation-corrected calculated result is in good agreement with the measured excitation of the 1603 keV state and reasonably descriptive of the measured values for the 1811 keV state. These results tend to support the tentative $J-\pi$ values of $11/2^-$ and $9/2^-$ given in Ref. 1. Alternate choices consistent with $(n;n',\gamma)$ measurements proved less suitable. The observed cross sections for the composite excitation of the 2409- and 2545 keV states were relatively small (less than 80 mb). Calculations based upon the tentative $J-\pi$ values of $3/2^-$ and $1/2^+$, respectively, were consistent with the measured values, but due to the small size of the measured quantities and the experimental uncertainties, a quantitative test of spectroscopic assignments was judged unreliable. Cross sections for the observed 2706 keV "state" were attributed to the composite contributions from the 2675($3/2^+$) and 2699($1/2^+$) states. The calculated results were consistent with experimental values but the latter were small and uncertain and thus precluded detailed analysis of spectroscopic properties. The remaining state at 2773 keV was observed in

the present work at only one incident energy, 4.0 MeV. The corresponding measured cross section was only qualitative. For completeness, the calculations assumed that this state was $3/2^-$ but this assumption was not justifiable from the present measurements. Alternate choices had little impact upon the results calculated for the excitation of lower-lying states.

V. EVALUATION

Experimental and calculational results were used to construct a comprehensive evaluated nuclear data file in the ENDF format (33). Primary emphasis was given to higher-energy cross sections extending to 20 MeV. The following data types were considered:

- A. Resonance region.
- B. Neutron total cross sections.
- C. Neutron elastic scattering.
- D. Neutron inelastic scattering.
- E. Radiative neutron capture.
- F. The $(n;2n')$ process.
- G. The $(n;p)$ process.
- H. The $(n;\alpha)$ process.
- I. The $(n;n',p)$ process.
- J. The $(n;n',\alpha)$ process.
- K. The $(n;d)$, $(n;t)$, $(n;^3\text{He})$ and $(n;2p)$ processes.
- L. Gamma-ray production processes.

The evaluation is based upon the present measured and calculated

results (above) and measured values reported in the literature, interpolated with theoretical estimates where necessary (34). Results were accepted for the evaluation process only when they could be reasonably documented. The literature search was inclusive of the major journals, the NNCSC files and reference materials cited in CINDA 76/77 (35). The file is elemental and primary attention is given to the predominant isotope ^{51}V (99.76% abundant). However, in some of the reaction-cross-sections, contributions from the minor isotope ^{50}V were a factor and were considered. Throughout, attention was given to conciseness and physical validity. Subsequent paragraphs of this Section address the various file components and the remarks are the reference documentation for the file.

A. Resonance Region

Some new measurements give better resolution of resonance structure in the ≤ 100 keV region. A preliminary evaluation was undertaken employing the Reich-Moore multi-level formalism. This approach was promising but in midstream the ENDF formats were changed deleting the Reich-Moore formalism. The Adler-Adler representation is an alternative but apparently no generalized conversion of Reich-Moore to Adler-Adler descriptions has been worked out. Other format options are not particularly suitable and have resulted in physically curious results when applied in other similar evaluations; e.g. large and fluctuating backgrounds. In view of this physical problem with ENDF formats and the

present emphasis on higher-energy processes the present evaluation describes the resonance region below 100 keV with a pointwise representation. This is considered an interim step until such time as the above format issues are resolved. The corresponding pointwise data as given in ENDF/B-IV (MAT-1196) at energies below 100 keV was explicitly used throughout. Some comparisons with newer data indicated some changes from that previous evaluation but not of sufficient impact to warrant a revision of the file in this region until the above format problems can be solved.

B. Neutron Total Cross Sections

Above 100 keV the evaluation represents the total cross sections with point values. The evaluation employs the data of Rohr et al. (36) over the energy range 100 to 220 keV. Considering the varying resolutions, the Rohr et al. cross section magnitudes are in reasonable agreement with the results of Rainwater et al. (37), of Whalen (38), and of Blair et al. (39). From 220 to 360 keV the evaluation is based upon the results of Whalen (38). That particular set of measurements did not have the resolution of the Rohr et al. (36) data (at the lower energy extreme) or of the data of Cierjacks et al. (40) (at the upper energy limit), but it apparently is the only set of reasonably good resolution data available in this energy region. The magnitudes of the Whalen cross sections are consistent with the broader resolution results of Blair et al. (39). However, the energy scale of the

Whalen results appears a few keV different from those of both Rohr et al. or Cierjacks et al. This discrepancy probably is not significant in most applications. The evaluation employs the results of Cierjacks et al. (40) throughout the energy range 0.36 to 20.0 MeV. Below 2.0 MeV their magnitudes are reasonably consistent with the lesser resolution results of Whalen (38), of Cabe (41), of Smith et al. (2) and of Blair et al. (39). Generally, the resolution of the Cierjacks et al. results appears superior. There are some differences in energy scales between the various results amounting to as much as 5 keV. These energy discrepancies appear to be rather random. From 2.0 to 4.0 MeV the Cierjacks et al. results are consistent with those of the present work, of Foster and Glasgow (42), of Kent et al. (43), of Manero (44), and of Sorriaux (45). There is similar agreement with the results of Galloway et al. (46) above 2.5 MeV, although the Galloway et al. values tend to be lower than the Cierjacks results in the range 2.0 to 2.5 MeV. The results of Bennett et al. (47) and of Thibault et al. (48) appear anomalous and were abandoned. From 4.0 to 20.0 MeV, the values of Cierjacks et al. are in good agreement with those of Galloway et al., of Foster and Glasgow, of Manero, and of the present work. An exception is the region from 8.0 to 10.0 MeV where the results of Refs. 42 and 46 tend to lie on alternate sides of the Cierjacks values. The differences are only a few percent. In addition, the 14.0 MeV values of Goodman (49) and Lasday (50) are consistent with the Cierjacks et al. results.

The evaluation was constructed from the above data base in two manners. Below 6.0 MeV the selected data sets were plotted on a large scale. From these graphical displays measured values were selected in sufficient detail to well describe the fluctuating structure. Above 6.0 MeV the data base is a relatively smooth function of energy. Therefore, energy-averages of the measured values were constructed starting with an increment of approximately 20 keV at 6.0 MeV, increasing to approximately 100 keV at 20.0 MeV. The final result is compared with that of ENDF/B, MAT-1196 in Fig. 8. The two evaluations do not appreciably differ. This is not surprising as both place considerable reliance upon the data of Ref. 40. The energy-average magnitude uncertainties in the present evaluation were estimated to be less than 5 percent. However, it is clear that the structure is not fully resolved and that, particularly at energies below approximately 360 keV, appreciable increases in the structure may be expected as the result of new and higher resolution measurements at some future date. In addition, it is not clear to what extent sample-size effects may have perturbed the various experimental values. These will be most prominent below ~ 2.0 MeV and in some cases it is suspected that rather thick samples have been used. If so, the magnitude of the average cross sections may have been underestimated.

C. Elastic Neutron Scattering

The relative elastic scattering distributions were derived from experimental results, interpolated using the above model

where necessary. Below 300 keV the energy-averaged model was used. This should give an average trend of the distributions although it obviously will not follow the resonance structure of the cross section. Experimental knowledge of these fluctuating distributions appears unknown. From 0.3 to 1.0 MeV the experimental results of Smith et al. (2) were used, averaged over $\sim$ 100 keV increments. Such an average should reasonably outline the intermediate resonance phenomena while at the same time avoiding the pronounced fluctuations due to one or several isolated distributions that may not be representative of the energy increment as a whole. From 1.0 to 1.5 MeV, a 200 keV average of the Smith et al. results was used. Between $\sim$ 1.5 and 1.8 MeV the 1.610 MeV value of Towle et al. was used (16). Over the range 1.8 to 4.0 MeV the present measurements were employed using a 200 keV average. Considering the fluctuations involved, they are in agreement with previous values and are the most comprehensive set of data in this region. From 4.5 through 8.5 MeV the measured values of Perey and Kinney and Holmqvist and Wiedling are used at $\sim$ 1-MeV intervals (e.g., 4.5, 5.5, 6.5, 7.5 and 8.5 MeV) (25,17). In interpreting these experimental values "Wick's Limit" was used at zero degrees and the model at 180 deg. as necessary to assure a good Legendre polynomial fit to the data at back angles. Above 8.5 MeV, the evaluation relies upon the above model. The results are consistent with the values measured at 14.7 by Western et al. (51). Throughout, consistency with

"Wick's Limit" was assured up to energies of 3.0 MeV. The magnitudes of the elastic scattering cross sections were set by the total cross section and non-elastic-channel contributions. Above 3.0 MeV the continuum inelastic scattering cross section increases and is uncertain. Thus the elastic-scattering cross section was set by the above distributions and the non-elastic cross section determined from this and the total cross section. The various particle-emission cross sections are not always certain (see below) but they can be reasonably determined or are relatively small. The continuum inelastic scattering was treated as a free parameter to assure consistency between the partial cross sections and the total cross section.

The above procedures introduced various energy-dependent-elastic-scattering-cross-section uncertainties. A "guideline" is ~ 5 percent uncertainty in the energy-average elastic scattering magnitude to ~ 8 MeV; increasing to ~ 10 percent at 20 MeV.

D. Inelastic Neutron Scattering

1. Discrete Inelastic Neutron Scattering Cross Sections

The evaluation considers the inelastic neutron excitation of the seven "states" defined in Table 3. The excitation energies are taken from Ref. 1. The first four and the seventh inelastic neutron groups are uniquely associated with individual excited states. The fifth and sixth groups are composites of the excitations of several states as noted in the Table.

These composites are consistent with the resolutions generally available in the determination of the respective scattering cross sections. The excitation of states above 3.08 MeV is included in the continuum component as the respective cross sections are poorly known.

The evaluated excitation cross sections are based upon the present and previously reported experimental measurements interpolated, particularly toward thresholds, using model calculations. The majority of the data base is illustrated in Fig. 5 and extends upward to 8.5 MeV primarily via the work of Percy and Kinney (25). The evaluated cross sections were subjectively constructed from the experimental data base attempting to portray the more qualitative features of the fluctuating structure where possible. The correlation between measured values and evaluation is indicated in Fig. 5. Above 8.5 MeV there is no experimental information and thus the evaluation is smoothly extrapolated to a 20 MeV value. This extrapolation qualitatively represents some of the relatively small direct-excitation cross sections that must be present. The emitted-neutron angular distributions are taken to be isotropic. This is a good assumption up to several MeV where the cross sections are large as illustrated in Fig. 4. Experimental values at 8.5 MeV remain reasonably isotropic but at higher energies the distributions doubtless become forward peaked. The omission of this latter effect will have little impact on many applications of the file.

The ENDF/B-IV file contains cross sections for the excitation of only the first four states. These are compared with the present evaluation in Fig. 9. The energy-averages of the two evaluations for these states are very similar. It is estimated that the present discrete-cross-section evaluation is known to within about 10 percent for the more prominent cross sections. This estimate is supported by the agreement between the energy-averaged results of the present work and those of ENDF/B-IV though the two evaluations were derived quite independently.

2. Continuum Inelastic Scattering Distributions

As noted above, this cross section is constructed from the non-elastic cross section and the sum of the other reaction cross sections in such a manner as to assure internal consistency of the file. The primary competition is from the $(n;2n)$ reaction which is an appreciable portion of the non-elastic cross section at higher energies. Competition from other channels is relatively minor until 20 MeV is approached.

The evaluation below 10 MeV is primarily based upon the measured values of Perey and Kinney (25). Spectra were observed for incident energies between 5.5 and 8.5 MeV. They are isotropically distributed and can generally be described by a Maxwellian temperature distribution with $T \sim 1.5$ MeV. The energy dependence of T is consistent with a $\sqrt{E}$ behavior although this is not well defined by the limited incident-energy range of the measurements. Superimposed upon the general temperature dependence is consider-

able structure. The evaluation generally describes the measured values with the temperature distribution upon which is qualitatively superimposed the gross features of the observed structure. Extrapolation from 5.5 MeV to threshold and from 8.5 to 10.0 MeV is via a simple-temperature distribution.

Above 10.0 MeV the evaluation is deduced from the experimental results of Hermsdorf et al. (52). These authors report detailed emission-spectrum measurements at an incident energy of approximately 14.5 MeV at a number of reaction angles extending from 40 to 150 deg. The spectra are characterized by a soft component that can be primarily attributed to the $(n;2n')$ process, an extensive intermediate component and a high energy very-hard component associated with pre-compound processes. The latter is very strongly angular dependent with anisotropies of more than an order of magnitude at some energies. The lower energy portions of the distribution become nearly isotropic. This type of energy-angle correlation of the spectrum appears to require file-6 representation (33). Unfortunately, that format is not recommended and compromises must be made in order to describe the information in the more acceptable file-4 and -5 formats. The compromise consisted of averaging the Hermsdorf et al. data over angle and assuming general isotropic emission. This is a reasonable approximation for emission energies of less than approximately 6 MeV but is very inappropriate at energies above 10 MeV. The consequences of these compromises on the calculation of deep-material penetration of high energy neutrons

may be very serious in some cases and the user is warned to beware. The problem seems unavoidable until such time as file-6 or equivalent formats come into general use. Using the above angle average of the 14-MeV results of Hermsdorf et al. the general distribution is reasonably represented by a Maxwellian temperature of $T \sim 2.5$ MeV with the addition of the hard pre-compound component. The softer temperature component was ignored as being due to the $(n;2n')$ process. The evaluation smoothly extrapolates this distribution to the 10 MeV value based upon the Perey and Kinney measurements (above) and upward to 20 MeV. The result is given as a set of pointwise distributions. In view of the above approximations, it is not clear that uncertainty estimates are warranted.

E. Radiative Neutron Capture

Despite the fact that measurements have been made at incident neutron energies above 0.1 MeV for nearly forty years these cross sections are not well known. The uncertainties may be attributed to the relatively small size of the cross sections. The present evaluation is based on the data of Refs. 53-64. Most of the measured values were obtained with activation techniques with a few additional sets of scintillation-tank results. Some of the results were available only from small journal figures. These were read with reasonable care but the corresponding numerical values remain somewhat qualitative. The data base is summarized in Fig. 10. One value, from Ref. 60, was widely discrepant and chronologically very early therefore it was omitted. There

are obvious variations in the measured values at lower energies. However, this is a region of sharply fluctuating cross sections where measured results can be very sensitive to the exact energy scale and experimental resolution, thus none of the lower energy values were rejected.

The evaluation was obtained subjectively via a graphical estimate of the energy-averaged behavior of the cross section with the results shown in Fig. 10. The data suggests cusps in the regions corresponding to the onset of prominent inelastic-scattering cross sections, and this feature was retained in the evaluation. The cross section calculated from the general reaction model was qualitatively consistent with the experimentally-based evaluation, thereby supporting the general validity of the calculational model. At lower energies, the present evaluation is pronouncedly higher than that of ENDF/B-IV. The latter is not particularly consistent with the energy-averaged trends of the experimental results in this region nor with the theoretical estimates. Above several MeV, the present evaluation is larger than that of ENDF/B-IV and more consistent with reported experimental values. In view of Fig. 10, there is considerable uncertainty associated with the present evaluation. Some energy-average guidelines are: 15-25 percent from 0.1-0.3 MeV, 10-20 percent from 0.3-3.0 MeV and more than 15 percent above 3.0 MeV.

F. The V(n;2n') Reaction, Q= -11.052 MeV

The product nucleus is stable prohibiting activation measurements. A scintillator measurement at 14.1 MeV by Ashby et al. (65) gives a result of 660 mb. The same authors give a Cu(n;2n) value considerably larger than that given in the ENDF/B-IV dosimetry file (66). Therefore the vanadium value of Ref. 65 was renormalized to the ENDF/B copper value to give a cross section of 523 mb. Recently Gaussig et al. (67) have reported measured values in the range 11.4 to 14.8 MeV. The results are relative to the ^{238}U fission cross section as given in AERE-R-7273 which is not greatly different from that of ENDF/B-IV. This limited data is the basis for the evaluation to 15 MeV as shown in Fig. 11. The relative energy dependence of the cross section is consistent with the results of calculations and the latter were used to guide the extrapolation to 20 MeV together with the analogous $^{59}\text{Co}(n;2n)$ and $^{55}\text{Mn}(n;2n)$ cross sections. The evaluation is qualitatively consistent with other theoretical estimates (68,69). The uncertainty associated with the evaluation is estimated to be ~ 10 percent below 16 MeV and larger at higher energies. The emission spectrum was assumed to be a temperature distribution with the temperature consistent with the results of 14 MeV neutron emission measurements (see Section V-D, above). The present evaluation is considerably smaller in cross section magnitude than that of ENDF/B-IV and the difference is probably significantly beyond the respective uncertainties.

G. The $V(n;p)$ Reaction, $Q(^{51}\text{V})=-1.675$ and $(^{50}\text{V})=+3.000$ MeV

The ^{51}V reaction is suitable for study by activation techniques although the combination of relatively small cross section and short product half-life (5.8 min.) makes the measurements difficult. Most experimental values were obtained near an incident energy of ~ 14 MeV as outlined in Refs. 70-85. For the evaluation these measured results were referenced to a consistent set of standards as defined in Ref. 66. All of the measured values are for the $^{51}\text{V}(n;p)$ reaction. Apparently, no experimental values are available for energies appreciably below 14 MeV except in-pile results which were not used. The measured values of Mitra and Ghose (75), Borman et al. (73), Crumpton (82) and Robertson et al. (85) were averaged to obtain the cross section at 14.5 MeV. The data of Paul and Clarke (70), Poularikas and Fink (71), Bramlitt and Fink (72), Allan (74), Dressler et al. (76), Levkovskii et al. (77), Khurana and Govil (79), Strain and Ross (80), Pai and Clarke (83) and Prasad and Sarkar (84) were also considered but were not used in the evaluation because of various problems or inconsistencies in the results. Above 14.5 MeV the evaluation follows the results of Borman et al. (73) as they are reasonably consistent with other values at 14.5 MeV and give a definition of shape to 20 MeV. Near 14 MeV the evaluation is qualitatively consistent with the calculational estimates of Brown and Muirhead (78), Gardner and Rosenblum (81) and Pai and Clarke (83). The evaluation below approximately 13 MeV is based

entirely upon the present theoretical calculations. These included contributions from the $^{50}\text{V}(n;p)$ process. The latter, although of small magnitude, extend to zero energy with a relatively large contribution to the "sub-threshold" cross section region. The calculated results also qualitatively show the effect of the competition from the $(n;n'p)$ process. The present evaluation is compared with that of ENDF/B-IV and with the data base in Fig. 12. The present evaluation is similar to that of ENDF/B-IV above approximately 14 MeV but at lower energies it is considerably smaller. The uncertainties in this low energy region are large (25-50 percent) but probably not as big as the differences between the two evaluations. At the experimentally-studied energies (above ~ 13 MeV) the uncertainty in the present evaluation is estimated to be 10-20 percent.

H. The $\text{V}(n;\alpha)$ Reaction, $Q = -2.055$ (^{51}V) and $+0.759$ (^{50}V) MeV

The primary residual reaction product has a well known decay thus this process is amenable to study via activation techniques. In spite of this the experimental data is not particularly comprehensive or consistent. The present evaluation gives consideration to the data and calculations of Refs. 86 to 103. Most of this data is concentrated near 14 MeV and there appears to be no experimental information below 12 MeV. Several isolated energy measurements appeared to be anomalous and were not accepted. The data of Ref. 88 is of wide energy scope but appears to be high by approximately a factor of two. The data of Ref.

103 is in good agreement with other results near 14 MeV but is much lower at higher energies. In view of this divergent experimental information reliance was placed upon theoretical calculations inclusive of the contributions from the ^{50}V isotope. The calculated result was then subjectively adjusted to agree with the experimental data near 14 MeV where the measured values are most consistent. The normalization factor was 0.8. The evaluation is compared with the experimental data base in Fig.13. The evaluation is qualitatively consistent with the theoretical results of Savelev et al. (101), Gardner and Yu-Wen Lu (98) and Facchini et al. (97). It is also very similar to that given in ENDF/B-IV though the uncertainties in both evaluations are probably ~ 20 percent.

I. The $V(n;n',p)$ Reaction, $Q = -8.052$ MeV

There appears to be no experimental information on this process therefore the evaluation relies entirely upon theoretical calculations. The emitted neutron spectrum is assumed to be an isotropic temperature distribution. This assumption is a qualitative approximation in view of the pre-compound components that must be a contributing factor at higher energies. The present evaluation is qualitatively consistent with the theoretical predictions of Brown and Muirhead (78). This evaluation is compared with that of ENDF/B-IV in Fig. 14. There are obviously large differences in both shape and magnitude well beyond a reasonable uncertainty in the present calculation.

J. The $V(n;n',\alpha)$ Reaction, $Q = -10.293$ MeV

There are several energy-isolated measurements of this cross section near 14 MeV (90,104,105) and a more comprehensive set of experimental results reported by Borman et al. (106). The measurements are relatively consistent with one another. The evaluation is subjectively constructed through these measured values with the results shown in Fig. 15. The shape of the evaluation is different than predicted by theoretical calculation, being considerably larger near threshold. Both the calculations and the evaluation are larger than the values given in ENDF/B-IV. The uncertainty is approximately 20 percent providing the data of Ref. 106 is reliable as assumed. For many applications the uncertainties are not a concern as the cross section is small at 14 MeV and below. The emitted neutron spectrum is assumed to be an isotropic temperature distribution.

K. The $V(n;d)$ Reaction, $Q = -5.827$ MeV

The primary product is the stable ^{50}Ti and the deuterons must be observed by direct particle detection. This is complicated by the angular distribution of the emitted particles and by difficulties associated with the detection of deuterons from transitions to states at higher excitations. Colli et al. (107, 108) have measured the 15 deg. cross section for the ground-state transition with the result of 0.48 mb/sr. Slaus et al. (109) have measured the angular distribution of the ground state transition. Combining these two measured results in a ground-state cross section of about 9 mb at 14 MeV. Ilakovac et al. (110)

have measured the cross sections for the ground and first three excited states with a 6 mb result at 14 MeV. These measured values suggest the total (n;d) reaction at 14 MeV is about 5-10 mb. The relative calculated excitation function was normalized by a factor of 6.6 to agree with this estimate and used for the evaluation. The present evaluation is much smaller than the comparable ENDF/B-IV cross sections below 18 MeV. There are large uncertainties in this evaluation but they will have little impact on most applications as the cross sections are very small below 14 MeV.

L. The V(n;t) Reaction, Q= -10.518 MeV

The primary product nucleus (^{49}Ti) is stable and there apparently have been no attempts to directly observe the emitted triton. A general survey by Khurana and Govil (111) suggests cross sections in the order of one milli barn at 14 MeV. The evaluated cross section relies upon a theoretically calculated shape renormalized by the same factor employed in the (n;d) reaction, above. The results are consistent with the Khurana and Govil estimate but considerably smaller than those of ENDF/B-IV. Both evaluations are only qualitative estimates and the cross sections in both cases are so small as to be of little concern in most applications.

M. The V(n; ^3He) Reaction, Q= -12.505 MeV

Kunabe et al. (112) and Bramlitt et al. (113) report measured cross sections at approximately 14 MeV of less than 1 mb. Theoretical calculations were consistent with these measured

values. These small cross sections combined with the large negative Q-value makes the reaction of little applied interest.

Therefore, it was ignored in the present evaluation.

N. The V(n;2p) Reaction, Q= -14.153 MeV

Measurements near 14 MeV by Bramlitt and Fink (90) and Lukic et al. (114) indicate cross sections of less than 30 and 60 micro-barns, respectively. These small values are qualitatively supported by theoretical estimates. The very small cross sections combined with the high threshold makes this reaction of little applied importance. Thus, this evaluation ignores this component.

O. Photon Production Cross Sections

1. Photon Production from the Neutron Capture Process

The multiplicity and photon spectra to be applied to the (n, γ) reaction are taken from Rasmussen et al. (115) for thermal neutron energy. It is assumed that the spectrum is energy independent for energies less than 3.0 MeV. The multiplicity is adjusted to conserve photon energy. For incident neutron energies greater than 3.0 MeV, photon production from the neutron capture process is subsumed into the total photon production process.

2. Photon Production by Inelastic Scattering of Neutrons from Specific Levels

Branching ratios for photon decay from the levels V^{51} are not known for several of the levels for which level excitation functions have been given in this evaluation. It was therefore necessary to assume branching ratios for V^{51} and this was done as follows:

<u>Level Energy</u>	<u>Transition</u>	<u>Probability</u>	<u>Photon Energy</u>
.3201	0	1.	.3201
.9290	.3201	.16	.609
.9290	0	.84	.929
1.609	0	1.0	1.609
1.813	.32	.22	1.493
1.813	0	.78	1.813
2.409	.32	1.0	2.089
2.675	0	1.0	2.675
3.080	0	1.0	3.080

To facilitate comparison with experimental data the cross sections for producing these photons were entered into the evaluation explicitly rather than using multiplicities that would be applied to the level excitation functions. Only a rough check can be made against the experimental data reported by Newman and Morgan (116) because of the relatively broad neutron and photon resolution of the experiment. The check that could be made shows reasonable agreement between evaluation and experiment.

3. Photon Production from Continuum Neutron Inelastic Scattering and Other Reactions

For incident neutron energies greater than or equal to 3.0 MeV the R-Parameter method of Perkins, Haight and Howerton (117) was used with the R-Parameter values determined from the experimental data of Newman and Morgan (115). This method provides a means for extrapolation to lesser photon energies than the 0.26 MeV experimental cut-off and also insures conservation of energy between the neutron

interaction and photon production portions of the evaluation. Comparison between evaluated and experimental values shows good agreement.

VI. CONCLUDING REMARKS

The present measurements improve the knowledge of neutron total and elastic and inelastic scattering cross sections of vanadium to incident energies of 4.0 MeV. The scope of the measurements is sufficient to assure a good representation of the energy-average behavior of the cross sections over a region of strong fluctuations. The measurements do not define that structure in detail. An energy-averaged model, based upon the present measured values, was descriptive of the general behavior of measured cross section results to 20.0 MeV. Primary uncertainties associated with the model are attributed to an inability to calculate channel-correlation properties of the compound-nucleus component from basic theory. This shortcoming has a detrimental impact on the quantitative calculational estimate of the compound-nucleus contributions to both elastic and inelastic scattering cross sections. Within these calculation uncertainties, the correlation of the present measured and calculated results is consistent with previously reported characteristics of excited states in vanadium to $E_x \sim 3.0$ MeV.

The present measured values, those reported elsewhere and calculations were used to construct a comprehensive evaluated nuclear data file in the ENDF format. The primary uncertainties in this evaluated file are associated with: 1) the resonance

parameters where experimental results and evaluated file formats have shortcomings, 2) high energy neutron emission spectra where both the data base and file formats are deficient and 3) some of the poorly known (n;x) reactions where primary reliance must be placed upon calculational estimates. Despite these shortcomings, it is believed that the present evaluated file provides a considerably improved data base for the applied user.

ACKNOWLEDGEMENTS

The authors are indebted to a number of people at Lawrence Livermore Laboratory, Hanford Engineering Development Laboratory and Argonne National Laboratory whose contributions made this work possible.

Table 1. Comparison of Present-Measured and Previously-Reported
Vanadium Excitation Energies.

<u>No. of State</u>	<u>Excitation Energies (keV)</u>	
	Exp.	NDS(1)
1	321±10	320.1(5/2-)
2	938±15	929.0(3/2-)
3	1603±19	1609.0(11/2-)
4	1811±21	1813.0(9/2-)
5	2409±27	2409.0(3/2-)
6	~ 2500± ?	2545.0(1/2+)
7	2706±30	2675.0(3/2+) 2699.0(-----)
8	2773±30	2790.0(-----)

Table 2. Optical Model Parameters^a

Real Potential^b

$V=50.76 \pm 1.21$ MeV, $R_0 = 1.188 \pm 0.016$ F, $A=0.663 \pm 0.047$ F.

Imaginary Potential^c

$W=8.95 \pm 0.62$ MeV, $R_0 = 1.270 \pm 0.045$ F, $A=0.467 \pm 0.064$ F.

- a. All uncertainties are RMS deviations from the average of the parameter values deduced from χ^2 -square fitting procedures as described in the text. A spin-orbit potential of the Thomas form with a 7.0 MeV magnitude was used throughout. All radii are expressed in the form $R=R_0 A^{1/3}$.
- b. Saxon form.
- c. Saxon-derivative form.

Table 3. Effective Inelastic Neutron Groups Used in this Evaluation

<u>No.</u>	<u>E_x (MeV)^a</u>	<u>Thres. (MeV)</u>
1	0.3201	0.3264
2	0.929	0.9472
3	1.609	1.641
4	1.813	1.849
5	2.409 2.545	2.456
6	2.675 2.699 2.790	2.727
7	3.080	3.140

a) All E_x values taken from the Nuclear Data Sheets (1).

FIGURE CAPTIONS

Fig. 1. Neutron total and elastic scattering cross sections of vanadium. 100 keV energy averages of the present total cross section results are represented by square data points. Circular data points indicate the angle-integrated elastic scattering cross sections deduced from the present measurements. The evaluated total neutron cross section, described in Sec. V of the text, is indicated by a curve.

(ANL Negative No. 116-76-54)

Fig. 2. Differential elastic scattering cross sections of vanadium. The values determined in the present measurements are indicated by the circular data points. The curves are the result of Legendre polynomial fits to the data as described in Sec. IV of the text.

(ANL Negative No. 116-76-52)

Fig. 3. Some comparisons of the present differential elastic scattering cross sections of vanadium with those previously reported in the literature. The results of the present work are indicated by circular data points, those of Ref. 16 by $\triangleleft$, of Ref. 17 by + and of Ref. 18 by X. Curves are the results of model calculations as discussed in the text.

(ANL Negative No. 116-76-53)

Fig. 4. Angular distributions of elastic- and inelastic-scattered neutrons at an incident energy of 3.0 MeV. Presently-measured values are noted by data points. Curves denote the results of calculation using the potential of Table 2 as described in the text. Results obtained with (WFC) and without (H-F) width fluctuation corrections to the compound-nucleus component are shown.

(ANL Negative No. 116-76-358)

Fig. 5. Comparison of measured and calculated inelastic neutron scattering excitation cross sections. The present results are noted by circular data points. Solid curves indicate calculated results as described in the text; lower indicates results with width fluctuation correction, the upper without. Measured values taken from the literature are noted by various symbols as per the following: $\dagger$ = Ref. 2, $\triangle$ = Ref. 25, $\diamond$ = Ref. 20, $\times$ = Ref. 16, $\uparrow$ = Ref. 17, $|||$ = Ref. 19, z = Ref. 23, γ = Ref. 22, and $\boxtimes$ = Ref. 24. The dashed curve is the present evaluation.

(ANL Negative No. 116-76-354)

Fig. 6. Measured and calculated elastic scattering distributions. Presently-measured values are indicated by data points. χ^2 -square optical model fits to the individual distributions are noted by curves.

(ANL Negative No. 116-77-17)

Fig. 7. Measured and calculated total neutron cross sections of vanadium.

Fig. 8. Comparison of the present evaluated total nuclear cross sections with those of ENDF/B-IV.

(ANL Negative No. 116-75-55)

Fig. 9. Comparison of the present evaluated discrete inelastic excitation cross sections with those of ENDF/B-IV.

(ANL Negative No. 116-76-178)

Fig. 10. Measured and evaluated radiative capture cross sections of vanadium. Experimental data values referenced as follows:

$\bigcirc$ = Ref. 53, $\diamond$ = Ref. 57, $\blacktriangle$ = Ref. 58, $\times$ = Ref. 59, $\mathbb{Z}$ = Ref. 60,
 γ = Ref. 61, $\boxminus$ = Ref. 62, $\boxtimes$ = Ref. 64, $\triangle$ = Ref. 54, $\times$ = Ref. 56,
 $+$ = Ref. 55 and $*$ = Ref. 63.

(ANL Negative No. 116-76-181)

Fig.11. Measured and evaluated $(n;2n')$ cross sections of vanadium. The solid notes the present evaluation and the dotted curve that of ENDF/B-IV.

Experimental values are referenced as follows:

$\square$ = Ref. 65 and $\bigcirc$ = Ref. 67. (ANL Negative No. 116-76-179)

Fig.12. Measured and evaluated $(n;p)$ cross sections of vanadium. Experimental values are referenced as follows: $\bigcirc$ = Ref. 70, $\triangle$ = Ref. 71, $+$ = Ref. 72, $\times$ = Ref. 73, $\diamond$ = Ref. 74, $\uparrow$ = Ref. 75, $\times$ = Ref. 76, $\mathbb{Z}$ = Ref. 77, γ = Ref. 79, $\boxminus$ = Ref. 80, $*$ = Ref. 82, $\boxtimes$ = Ref. 84 and $\star$ = Ref. 85. Solid curve indicates present evaluation, dashed curve that of ENDF/B-IV.

(ANL-Negative No. 116-77-29)

Fig.13. Measured and evaluated $(n;\alpha)$ cross sections of vanadium. Experimental values are referenced as follows: $\bigcirc$ = Ref. 103, $\uparrow$ = Ref. 86, $\times$ = Ref. 88, $\diamond$ = Ref. 89, $\uparrow$ = Ref. 90, $\times$ = Ref. 91, $\mathbb{Z}$ = Ref. 92, γ = Ref. 93, $\boxminus$ = Ref. 94, $*$ = Ref. 95, $\boxtimes$ = Ref. 96, $\star$ = Ref. 99, $\vee$ = Ref. 100 and $\%$ = Ref. 102. The solid curve denotes the present evaluation, the dashed that of ENDF/B-IV.

(ANL-Negative No. 116-77-30)

Fig.14. Comparison of evaluated $(n;n'p)$ cross sections. The solid curve indicates the present evaluation, the dashed that of ENDF/B-IV.

(ANL-Negative No. 116-77-32)

Fig.15. Comparison of measured and evaluated $(n;n',\alpha)$ cross sections.

The experimental values are referenced as follows:

$\times$ = Ref. 106, $\circ$ = Ref. 104, $\triangle$ = Ref. 105 and $+$ = Ref. 90.

The solid curve denotes the present evaluation, the dashed that of ENDF/B-IV.
