FOREWORD

This quarterly progress report of the Aircraft Nuclear Propulsion Project at ORNL records the technical progress of the research on circulating-fuel reactors and other ANP research at the Laboratory under its Contract W-7405-eng-26. The report is divided into five major parts: 1. Aircraft Reactor Engineering, 2. Chemistry, 3. Metallurgy, 4. Heat Transfer and Physical Properties, Radiation Damage, Fuel Recovery and Reprocessing, and Critical Experiments, and 5. Reactor Shielding.

The ANP Project is comprised of about 525 technical and scientific personnel engaged in many phases of research directed toward the achievement of nuclear propulsion of aircraft. A considerable portion of this research is performed in support of the work of other organizations participating in the national ANP effort. However, the bulk of the ANP research at ORNL is directed toward the development of a circulating-fuel type of reactor.

The design, construction, and operation of the Aircraft Reactor Test (ART), with the cooperation of the Pratt & Whitney Aircraft Division, are the specific objectives of the project. The ART is to be a power plant system that will include a 60-Mw circulating-fuel reflector-moderated reactor and adequate means for heat disposal. Operation of the system will be for the purpose of determining feasibility and for studying the problems associated with the design, construction, and operation of a high-power circulating-fuel reflector-moderated aircraft reactor system.

ACKNOWLEDGMENT

The material presented in this report was, in some instances, compiled and edited by persons not listed as authors or responsible group leaders. Those who contributed in this fashion are: D. Cuneo, Part 2; T. Hikido, Part 3; M. Gerrard, Chap. 4.3; L. S. Abbott, Chap. 4.4 and Part 5.

ANP PROJECT QUARTERLY PROGRESS REPORT

SUMMARY

PART 1. AIRCRAFT REACTOR ENGINEERING

1.1. Aircraft Reactor Test Design

Layouts on all the major subassemblies and a major portion of the detailed parts of the Aircraft Reactor Test (ART) have been completed. Preliminary layouts for the shield were modified to include provision for a substantial amount of instrumentation and special equipment. Models of reactor parts and auxiliary components are being used to study assembly and interference problems.

A stress analysis of the composite double-deck structure of the top of the reactor (referred to here as the "north head") was completed. An experimental check of the results is being made. The thermal stresses in the north head are now being evaluated, with estimates of the energy-deposition rates in this region being used as a basis.

A design analysis of the sodium expansion tank was completed. This analysis revealed the need for cooling of the roof of the expansion tank.

A full-size aluminum mockup of the fuel system components in the north head is being tested under simulated reactor operating conditions with water as the pumped fluid. Twin fuel pump operation was demonstrated up to 3000 rpm, although 2400 rpm produced approximately rated conditions of head and flow. Surging and instabilities in the pumps were resolved by the addition of straightening vanes to the pump inlet regions, and modifications to the xenon-removal system reduced pressure fluctuations to acceptable levels.

Studies of flow in the core were continued. Systematic relocation of the conical baffle plate resulted in the generation of a flow pattern containing no flow reversal along either the outer core shell or the island surfaces. This latest design is being evaluated in the half-scale ART volume-heat-source apparatus.

Performance requirements were established for pumps in the NaK systems of the ART. An intermediate pump speed was determined at which satisfactory warmup periods can be attained without excessive stresses. The design of the cooling system for the control rod was completed. Modifications were made in the sodium system as a result of pressure-drop calculations and stress analyses.

1.2. ART Physics

Calculations were made of the radiation heating to be expected on the ART equatorial plane in the vicinity of the fuel-to-NaK heat exchanger. Results are presented for the outer 3 cm of the beryllium reflector and for the Inconel and boron-containing shells on both sides of the fuel-to-NaK heat exchanger. The total gamma-ray heating is given in each region, as well as the heating from the sources which are the main contributors to the total heating in each shell.

Calculations of the radiation heating to be expected in various portions of the north head were also made. These calculations gave preliminary estimates of energy deposition rates for use in thermal-stress calculations.

The beta- and gamma-ray activities to be expected in the fuel expansion chamber and the off-gas system were determined. These results will also be used in calculations of radiation heating and thermal stresses. The total power and the power density in the gas space of the fuel expansion tank as a function of the volume of the gas and the helium flow rate were obtained, as was the power density in the off-gas line as a function of time and gas volume for helium flow rates of 1000 and 3000 liters/day (STP).

The activities in the ART of the various radioactive nuclides of niobium, molybdenum, and ruthenium, and their daughter products were determined for 100 and 300 days after shutdown and for reactor operating periods of 500 and 1000 hr. The gamma activity at 100 days after shutdown for 500 hr of operation at 60 Mw was found to be approximately 2×10^3 curies, and at 300 days after shutdown, for the same operating conditions, it was about 8×10^3 curies.

1.3. ART Instruments and Controls

The ART simulator was used for further study of the problem involved in closing the main heat-dump louvers to prevent the fuel from freezing as a result of fast control rod insertion. The control technique to be used will be that of closing the louvers to limit the minimum NaK temperature.

SECRET

DECLASSIFIED

ANP PROJECT PROGRESS REPORT

Specifications were prepared for the louver actuators, which will be hydraulic-actuated cylinders operated in conjunction with spring-loaded clamps arranged to grip the actuator-output shafts.

Specifications were also established for the actuator for the fuel enricher. The actuator will consist of a gear-motor drive equipped to provide a multiple-synchro indication of the position of the enricher piston.

The design of the control rod drive mechanism was completed. The drive mechanism is to be powered by two low-inertia servomotors, one bidirectional and the other unidirectional. The two motors will be connected through nonreversing worm gears on concentric shafts that will, in turn, supply power separately to the sun gear and to the arm of a differential gear box. A high-resolution potentiometer will feed a strip-chart recorder to make a permanent rod-position record. Two independently driven synchro transmitters will give the position indication. Two plunger-sealed limit switches will prevent rod overtravel at each end of the stroke.

Equipment suitable for transmitting 100 thermocouple signals on two conductors was assembled and tested. Fittings for reactor cell penetrations for heater wiring, control wiring, chamber leads, and thermocouples were specified. A helium-bubbler type of level indicator is being developed for level detection in the fuel expansion tank. High-temperature pressure transmitters submitted by vendors were tested, and orders were placed for units which utilize a diaphragm-isolated, NaK-filled tube system in which the NaK hydrostatically transmits the applied pressure to an external, low-temperature, displacement-type transducer. Development work is continuing on other types of transmitters. A high-temperature turbine-type flowmeter was developed for use in fused salt systems. This type of flowmeter does not require penetrations to the process fluid. Experimental models are being tested.

1.4. Component Development and Testing

Lubricants with a mineral-oil base have been found to be satisfactory for bearings and seals for the ART pumps under the proposed operating conditions, but an increase in the integrated radiation dose or the operating temperature could make such fluids unusable. Therefore efforts to find a liquid suitable for higher performance were con-

tinued. The important considerations are compatibility with materials of construction, radiation stability, thermal stability, and heat removal capacity. Since the loads in the bearings will be light the lubricating properties are of secondary interest. Tests of an organic-phosphate-based material, with the trade name "Cellulube," and Dowtherm A, which is a eutectic mixture of diphenyl and diphenyloxide, are under way. Excessive end play was found after long-duration runs with the originally designed spherical-roller type of antifriction upper pump bearing, and the design was modified to use a double-row angular-contact bearing having convergent angles of contact.

Seal leakage tests were continued, but test equipment redesign was found to be required before valid data can be obtained. An ART fuel pump (model MF) is being operated in an endurance test with the fuel mixture NaF-ZrF₄-UF₄. In the first 1488 hr of operation the temperature of the system was cycled 17 times between 1300 and 1100°F. The system has been functioning satisfactorily.

Water tests of a single ART fuel pump and centrifuge assembly have revealed pressure fluctuations similar to those found during twin-pump operation in the aluminum mockup tests. The pump suction inlet conditions will be modified to improve the pressure stability, and the xenon-removal system will be altered to study the effects of each of the various flow passages.

The ART sodium pump was modified by providing a pressure-breakdown labyrinth along the shaft and by removing the bypass vanes from the back face of the main impeller to prevent ingassing of the system.

Water tests on the primary NaK pump volute and impeller were completed. The tests indicated that the pump will meet the head and flow conditions required for the ART. A pump tank gas pressure of 10 psig should be sufficient to suppress cavitation at the design flow rate and up to a NaK temperature of about 1380°F. The design conditions are in the range of minimum volute hydraulic unbalance. Similar tests showed the auxiliary NaK pump design to be satisfactory. Endurance tests are to be run on complete pump assemblies.

Heat exchanger test stand operation was continued. York radiator No. 9 is currently being tested. The air pressure drop data being obtained agree substantially with those obtained for York

radiators Nos. 1 and 2, and the heat transfer data are in reasonable agreement with the data for Cambridge radiators Nos. 1 and 2. ORNL heat exchangers Nos. 1 and 2 were removed from the test stand and submitted for metallurgical examination. Test operations were resumed with two Black, Sivalis and Bryson heat exchangers. The failure of a heat exchanger in the small heat exchanger test stand was found to have been caused by overheating in the resistance-heated section.

Circulating cold traps are also being tested on heat exchanger test stands. The original design specified copper cooling coils, which necessitated maintaining the cold-trap temperatures below 700°F at all times to prevent excessive oxidation. A stainless steel cooling coil now being tested, which can be brought up to 1200°F with the rest of the system and then cooled, appears to offer many advantages. Various methods of cold-trap operation are being investigated under simulated ART operating conditions to establish an operating procedure for the ETU and ART cold traps.

Prototypes of the dump valve designed for use between the reactor and the fill-and-drain tank are being tested. Further work on the development of a trap for zirconium fluoride vapor included an investigation of high-temperature adsorbents for ZrF_4 , a determination of the plugging temperature of ZrF_4 in helium in equilibrium with the fuel as a function of the fuel temperature, and the testing of prototype traps.

The first thermal stability test of the one-quarter-scale model of the lower half of the outer core shell was terminated after the completion of 57 cycles because of a leak in the sodium circuit. A check of the dimensions revealed no significant changes, and no cracks or flaws were found on the inner surface. The test rig has been reassembled and is to be cycled a total of 300 cycles or to failure.

1.5. Procurement and Construction

Construction work is nearing completion on the contract portion of the ART facility in Building 7503. Design work on the process equipment, process piping, etc., to be installed by ORNL forces will probably be completed in July 1956.

Design work on the facility in Building 9201-3 for the Engineering Test Unit (ETU) is well under way. The lube-oil pumps, the NaK tanks, the ETU fuel dump tank, and miscellaneous Inconel ma-

terials were ordered. A decision to expedite assembly of the ART with respect to ETU completion resulted in procurement of additional items of equipment so that ART construction can proceed concurrently with ETU operation.

Methods for assembling the reactor are being studied, and a number of jigs and fixtures for use in assembly have been designed. Fabrication of the north head of the ETU has been started. Work is under way on the fabrication of the Inconel shells, and the beryllium reflector is being machined. Heat exchanger suppliers are studying fabrication techniques and assembly methods.

Orders have been placed for the boron carbide tiles and the copper-B₄C cermets. The fabricator has been selected for the lead shielding.

1.6. ART, ETU, and In-Pile Loop Operation

An Operations Committee was formed for the purpose of preparing an Operating Manual for both the ART and the ETU. The ART manual is being prepared first, and the ETU procedures will be adapted from those for the ART. Detailed considerations of procedures have prompted design modifications to assure smooth performance.

In-pile loop No. 4, which operated 501 hr in the MTR, was cut from the shielding plug, and the nose end is being sectioned for examination. As with loop No. 3, both the bearing-housing and the pump-sump purge outlets plugged during operation; otherwise, operation of the loop was satisfactory. In-pile loop No. 5 was inserted in the MTR, but could not be filled. Tests are being made on an improved horizontal-shaft sump pump for in-pile operation.

PART 2. CHEMISTRY

2.1. Phase Equilibrium Studies

A compilation has been made of phase diagrams of binary systems containing UF_4 or ZrF_4 with each of the alkali fluorides NaF, LiF, KF, RbF. Several of the diagrams are considered to be preliminary, and the systems described are still being studied. Major differences are apparent in comparing the diagrams, and it is evident that there is need for a detailed study of the complex crystal structures that characterize some of these materials.

Additional information was obtained on the RbF- ZrF_4 and RbF- UF_4 systems, which are of importance in the fuel system NaF-RbF- ZrF_4 - UF_4 .

ANP PROJECT PROGRESS REPORT

Several revisions were made in the tentative diagram presented previously for the RbF-ZrF_4 system, and it now appears that both these systems have been fairly well described. A phase diagram of the fuel solvent system NaF-RbF-ZrF_4 was also prepared. The solvent NaF-RbF-ZrF_4 (35-25-40 mole %) appears to dissolve up to 4 mole % UF_4 at liquidus temperatures below 480°C and up to 7 mole % UF_4 below 510°C , and therefore such mixtures are of interest as reactor fuels. Optical and x-ray data were obtained for the new compound found in this system, $3\text{NaF} \cdot 3\text{RbF} \cdot 4\text{ZrF}_4$.

Studies of beryllium-bearing systems were continued with investigations of the NaF-LiF-BeF_2 and NaF-RbF-BeF_2 systems. Extremely low melting points can be obtained in these systems, but it has not yet been established that these materials offer fuel mixtures that are substantially better than those in the ZrF_4 -containing systems. The lowest melting eutectic observed, to date, in the NaF-LiF-BeF_2 system melts at 318°C .

Further studies were made of the liquidus temperatures of mixtures formed by adding UF_4 to NaF-KF-LiF (11.5-42-46.5 mole %). It now appears that the liquidus temperatures of mixtures containing 0 to 10 mole % UF_4 are not as strongly dependent upon UF_4 concentration as previous data had indicated.

Studies of alkali fluoride- CeF_3 systems were continued. These systems are of interest because of concern over the behavior of fission-product fluorides in high-power long-duration reactor operation. In the LiF-CeF_3 system there is a eutectic with 19 mole % CeF_3 that melts at $755 \pm 5^\circ\text{C}$, and an extrapolation of available thermal data indicates a eutectic with 28 mole % CeF_3 in the NaF-CeF_3 system that melts at $725 \pm 10^\circ\text{C}$. The minimum liquidus temperature in the RbF-CeF_3 system is approximately 615°C , and it apparently occurs for a mixture with 42.5 to 50 mole % CeF_3 .

A re-examination of the LiF-CsF system was initiated because pure CsF became available. This system is of interest because a compound is formed that is similar to a compound formed in the LiF-RbF system. The binary compound in this system is believed to have the composition $\text{LiF} \cdot \text{CsF}$.

Cooling curves were obtained for mixtures in the $\text{MgF}_2\text{-CaF}_2$ system which covered the composition range 37.5 to 50 mole % CaF_2 . A eutectic was found with approximately 48.5 mole % CaF_2

which melted at $985 \pm 5^\circ\text{C}$. In studies of the RbF-CaF_2 system, thermal analysis data were obtained which indicated a eutectic with less than 10 mole % CaF_2 that melts at 765°C . Studies were continued of the LiF-NiF_2 and $\text{UF}_4\text{-UO}_2$ systems, and the melting point of pure ZnF_2 was found to be $940 \pm 5^\circ\text{C}$ rather than the value of $875 \pm 3^\circ\text{C}$ reported in the literature.

2.2. Chemical Reactions in Molten Salts

Studies of the activity of chromium in chromium-nickel alloys were continued. Electrode concentration cells were used that contained a eutectic mixture of sodium chloride and rubidium chloride with about 0.2 to 0.5 wt % chromous chloride added. Activity determinations were made for chromium-nickel alloys containing from 11.2 to 53.0 mole % chromium. The chromium activities found for alloys in the region near 15 mole % chromium were slightly below the ideal activity that would have been predicted for a perfect solid solution and considerably below that which might have been predicted from the chromium-nickel phase diagram. Thus the assumption of ideal activity for the chromium in Inconel is justified. This assumption is usually made in discussions regarding the chemical equilibria involved in the corrosion of Inconel by molten salts.

Data were obtained for the reduction of UF_4 by chromium in the reaction mediums KF-ZrF_4 and LiF-ZrF_4 (both 52-48 mole %) at 600 and 800°C . For the tests with LiF-ZrF_4 as the reaction medium both hydrogen-fired electrolytic chromium and iodide chromium were used at both temperatures. The equilibrium chromium concentrations were the same at both temperatures for the two types of chromium metal, and thus it appears that hydrogen treatment is effective in purifying electrolytic chromium. The data obtained on chromium activity indicate that the particular alkali fluoride used in combination with ZrF_4 influences the reaction markedly. The activity of the UF_4 is affected to various degrees, and the activity of the CrF_2 is also influenced through complexing of the CrF_2 by both the alkali fluoride and the ZrF_4 .

Studies of the reduction of UF_4 by iron at 600 and 800°C with the alkali fluoride- ZrF_4 mixtures as reaction mediums are also being made. In contrast to the results for the $\text{UF}_4\text{-Cr}^0$ reaction the $\text{UF}_4\text{-Fe}^0$ reaction is indifferent to changes in the reaction medium. No satisfactory explanation has

yet been found for these differences.

An analysis has been made, based on equilibrium data obtained for the chemical reactions involved, of the differences between the corrosion of Inconel by NaF-ZrF₄-UF₆ and by NaF-KF-LiF-UF₆ mixtures. The corrosion, as measured by depth of void formation in the hot region of a system with a temperature gradient, is much worse when the circulated fluid is the alkali fluoride mixture than when it is the ZrF₄-bearing fuel, but the depth of void formation increases with time in both systems. Also, discrete crystals of nearly pure chromium are found in the cold zones of Inconel loops in which the NaF-KF-LiF-UF₆ mixture has been circulated, but metallic deposits are not usually observed in loops which have circulated the NaF-ZrF₄-UF₆ preparations.

The equilibrium data show that Inconel exposed to the NaF-KF-LiF-UF₆ melt will support a higher concentration of CrF₂-CrF₃ in equilibrium at 800°C than pure Cr⁰ is able to support at 600°C. Chromium is therefore removed from Inconel in the hot zone of a loop and deposited as essentially pure chromium in the cold zone. The data also show that Inconel exposed to NaF-ZrF₄-UF₆ mixtures is in equilibrium with much lower CrF₂ concentrations than pure Cr⁰ is in equilibrium with when exposed to the fluoride mixture under the same conditions. It is not possible therefore for chromium to dissolve from 800°C Inconel and to deposit at 600°C as Cr⁰ when NaF-ZrF₄-UF₆ mixtures are circulated. These observations lead to an explanation of the mass transfer process that accounts for the fact that neither flow rate nor uranium concentration of the fuel mixture have important effects on corrosion attack and mass transfer in Inconel systems that circulate ZrF₄-bearing fuels. If it is assumed that most of the corrosion observed involves mass transfer to a dilute alloy, the lack of an effect of the surface-to-volume ratio becomes comprehensible. If the relative effect of diffusion rate vs driving force is noted, the reason for the poor correlation of corrosion with temperature drop can be understood.

An investigation of the equilibrium reduction of NiF₂ by H₂ in NaF-ZrF₄ (53-47 mole %) was initiated, and initial experiments were made to determine the solubility of NiF₂ in the solvent. Experimental values obtained at 625°C give activity coefficients of NiF₂ that are a factor of

10³ greater than those obtained for FeF₂. Experimental work is in progress at 575°C.

Studies of the solubility and stability of structural metal fluorides in molten NaF-ZrF₄ were continued. An examination of the data obtained thus far at 600°C shows that the solubility of CrF₂ increases quite rapidly as the zirconium-to-chromium ratio decreases. A less pronounced effect is noted for FeF₂, and for NiF₂ a slight increase is found for the higher ratios, but the solubility of NiF₂ is constant at the lower ratios.

Solubility studies of the structural metal fluorides and their complexes in molten NaF-ZrF₄ (53-47 mole %) were also continued through measurements of electromotive forces of concentration cells. As yet, no satisfactory explanation has been found for the discrepancies between the results obtained by this method and the results obtained by filtration methods.

Values for the free energies of formation of the complex metal fluorides MF₂·ZrF₄ were obtained by two different methods. The results obtained by calculations based on previously published data and from combining recently obtained solubility and activity coefficient measurements were in substantial agreement.

A special mixture containing LaF₃-BaF₂-RbF dissolved in a standard NaF-ZrF₄-UF₆ (50-46-4 mole %) fuel was prepared for studies of the effect of these simulated fission products on viscosity of the fuel. Solubility studies on the mixture indicate that the solubilities of the rare-earth fluorides in the NaF-ZrF₄-UF₆ may be sufficiently high to prevent precipitation upon their formation as fission products during ART operation.

A study was initiated of means for obtaining the transference numbers needed for correlating the electromotive forces of concentration cells with activities or other thermodynamic properties of solutions involved. The relative transference numbers that can be obtained from the Hittorf experiment are shown to be adequate for thermodynamic use, and a method is presented for obtaining useful correlations of the relative transference numbers with electric conductance.

2.3. Physical Properties of Molten Materials

The relationships of vapor pressure, composition, and temperature in the systems KF-ZrF₄ and RbF-ZrF₄ are being studied to obtain information on

which to base predictions regarding the changes in properties that will occur when one species of ion is substituted for another in an otherwise similar melt. The ability to make such predictions would be important in the search for improved fuel mixtures. Initially, measurements are being made of the vapor pressures as a function of composition in alkali fluoride-ZrF₄ systems. In both the KF-ZrF₄ and the RbF₄-ZrF₄ systems, the heat of vaporization shows a sharp minimum at 50 mole % ZrF₄ and increases linearly with composition in both directions from the minimum. Conclusive evidence has been obtained to show that in solutions of ZrF₄ and alkali fluorides, the vapor pressure of ZrF₄ decreases as the alkali ion size increases.

The vapor pressure of FeCl₂ in FeCl₂-KCl systems was measured in concentrations from 100 to 45 mole % FeCl₂ in the temperature range of 700 to 1050°C. A phase diagram was also prepared for the FeCl₂-KCl system on the basis of experimental data.

Preliminary values of the density and surface tension of NaF-ZrF₄ (53-47 mole %) were obtained by the maximum-bubble-pressure method. Experimental difficulties were resolved and additional measurements are to be made. Surface tension measurements were also made by the sessile-drop technique. Optimum experimental procedures were established for obtaining valid measurements by this method. Some data were obtained for the NaF-ZrF₄ (53-47 mole %) mixture.

Electrical conductance and density have been measured as a function of temperature for pure, fused lithium, potassium, and cesium fluorides. For these measurements a newly designed bridge was used in conjunction with a special cell fabricated from platinum-rhodium alloy. The data have been correlated with those obtained previously, and it is now possible to give satisfactory theoretical interpretations of the results in terms of the structure and transport properties of the liquid salts.

2.4. Production of Fuels

Additional quantities of structural metal fluorides were prepared for use in research programs. The CrF₃ requested was prepared by hydrofluorination of anhydrous CrCl₃, as well as by the thermal decomposition of (NH₄)₂CrF₆; NiF₂ was prepared by hydrofluorination of either hydrated NiF₂ or

hydrated NiCl₂; and AgF was prepared by hydrofluorination of Ag₂CO₃. Additional substantial quantities of CeF₃ and LaF₃ were prepared, and a batch of CuF₂ was prepared for use as a carrier in spectrographic boron analyses.

An attempt was made to remove oxide from a KF-ZrF₄ mixture by hydrofluorination, but runs at 600°C failed to remove the oxide completely. At 850°C the oxide was removed, but the loss of ZrF₄ was sufficient to alter the composition of the material significantly. A fuel mixture containing Li⁷ and U²³⁵ was prepared for radiation damage studies.

Several especially pure mixtures were prepared on a laboratory scale by using the standard hydrofluorination-hydrogenation process as appropriately modified. The new copper-lined stainless steel reactors and new facilities for transfer of small samples directly into apparatus were used successfully. Direct transfer has been found to significantly improve the purity of the test material. The use of the new copper-lined stainless steel reactors has also proved to be successful in preparing 5- and 250-lb batches of fluoride mixtures.

A survey is being made to determine the anticipated requirements for processed fluorides during the next six months. Indications are that, although the demands will not reach the production capacity of the large-scale facility, they will be sufficient to make continuous operation economically feasible. The remaining 7500 lb of hafnium-bearing zirconium fluoride ordered from an outside vendor was received and found to be satisfactory.

The batching and dispensing facility dispensed 148 batches totaling approximately 4900 lb of processed fluorides in batch sizes ranging from 1 to 250 lb. The facility for the conversion of hafnium-free ZrCl₄ to ZrF₄ now operates satisfactorily, and handling techniques are being developed to cut down raw-material and finished-product losses.

2.5. Compatibility of Materials at High Temperatures

The penetration of graphite by molten fluoride fuel mixtures is being investigated, since graphite seems to be the only reasonably effective reactor moderator material that will remain chemically stable upon direct exposure to molten fluoride fuel mixtures. If necessary, attempts will be made

to prevent penetration of the graphite by prior impregnation with high-melting-point materials such as NaF or CaF_2 .

Studies are also under way to determine the effect of atmosphere on anodic dissolution of nickel in molten sodium hydroxide. An apparatus has been constructed in which current density and temperature, as well as the atmosphere, can be varied. In measurements at a current density of 2 amp/cm², the dissolution efficiency was decreased slightly by substituting hydrogen for helium as the static cover gas and was reduced considerably by bubbling hydrogen through the molten electrolyte.

2.6. Analytical Chemistry

Methods were developed for the determination of rubidium, barium, and lanthanum in weight concentrations of 1 to 3% each in mixtures of fluoride salts. Barium was separated as the slightly soluble sulfate upon dissolution of the fluoride salts in sulfuric acid; lanthanum was precipitated from the sulfate solution as the oxalate. Rubidium was separated by anion exchange and then determined gravimetrically as the tetraphenylboron salt.

A method for the determination of copper in the range 1 to 25 ppm in fluoride fuels was evaluated that was based on the absorptancy of the cuprous-"cuproine" complex at 550 m μ . The complex is extracted with *n*-amyl alcohol. In order to reduce the solubility of the alcohol in the aqueous phase, 10 g of ammonium sulfate is added prior to extraction. The coefficient of variation is 2%.

The thiocyanate method was used for the determination of traces of niobium in NaF-ZrF₄-UF₆. The niobium complex is formed in a solution that is 4 M HCl and 0.5 M tartaric acid and then extracted into an ethyl ether-acetone medium. The tartaric acid eliminates the interference of uranium, and the interference of the iron(III)-thiocyanate complex is eliminated by reduction of the iron(III) to iron(II) with a solution of stannous chloride.

The method for the determination of traces of tantalum in NaF-KF-LiF-UF₆ was extended to include the determination of tantalum in samples of NaF-ZrF₄-UF₆. Tantalum was separated from zirconium and uranium by precipitation with tannin. The spectrophotometric pyrogallol procedure was then applied.

The design of an instrument for the photometric detection of microgram amounts of NaK in air was completed. The electronic components of the instrument were assembled and the optical system is being fabricated. Methods for providing an atmosphere with a known concentration of alkali metal are being investigated.

A procedure was established for using the modified Argonne distillation samples for the determination of sodium oxide in sodium and in NaK. Several cold traps which were removed from loops that had circulated NaK were examined chemically for sodium oxide content and corrosion products.

In brief experiments it was shown that metal connections and tubing should be used in the determination of water in helium with the dew-point meter. Spurious, high results were obtained when Tygon tubing was used. The latter is satisfactory, however, if sufficient helium is passed to purge the lines of volatile material.

Beryllium was shown to be compatible with such common degreasing agents as acetone, ethanol, trichloroethylene, and perchloroethylene.

PART 3. METALLURGY

3.1. Dynamic Corrosion Studies

An Inconel forced-circulation loop, in which the cold-leg surface area was larger than that in the standard loop but the volume was as nearly the same as possible, was operated to study the effect of cold-zone area on mass transfer in the fuel mixture NaF-ZrF₄-UF₆ (50-46-4 mole %). The maximum attack in the loop with the larger cold-zone area was to a depth of 4 mils in 1000 hr, whereas the attack in a standard loop operated at the same time under identical conditions was 4.5 mils. Thus the increase in cold-zone area produced no apparent effect.

A standard forced-circulation loop, operated to study the effect of the bulk fluoride temperature on the corrosion of Inconel, was examined. The maximum attack was found in the region of maximum wall temperature, both in this loop (which operated with a maximum wall temperature of 1700°F, a maximum fluid temperature of 1500°F, and a fluid temperature drop of 200°F) and in a loop operated previously with the same wall temperature and temperature drop but with a maximum fluid temperature of 1650°F. The depths of attack were also similar, being 9 mils in the loop operated

ANP PROJECT PROGRESS REPORT

with the fluid at 1500°F and 10 mils in the one operated with the fluid at 1650°F. The amounts of chromium in solution in the fluoride mixtures in both loops were also comparable. These results strengthen previous evidence that the wall temperature rather than the bulk fluid temperature is the important factor in corrosion of these Inconel-fluoride fuel systems.

Inconel forced-circulation loops were also operated with sodium and NaK under various conditions in efforts to reduce mass transfer. One loop was precleaned by operating it with sodium under isothermal conditions. This sodium was dumped and replaced with sodium especially treated to remove oxide contamination. Further, a circulatory cold trap was maintained at 300°F during the test. However, an evaluation of mass transfer in this loop showed the weight of deposit to be equivalent to that found in loops operated with normal sodium either with or without circulatory cold traps. A lower cold-trap operating temperature in an experiment with NaK rather than sodium was similarly ineffective in reducing the mass transfer.

Further compatibility studies of Inconel-beryllium-sodium systems were made to evaluate the effect of increasing the beryllium surface area with respect to the Inconel surface area and of including a cold trap in the system. Examinations of the two forced-circulation loops operated at a maximum hot-leg sodium temperature of 1250°F, one with and one without an oxide cold trap, showed no increase in mass transfer in comparison with the mass transfer found in similar loops with smaller beryllium inserts. The cold trap similarly had little effect.

Three standard Inconel thermal-convection loops were operated to evaluate Inconel castings in fluoride fuel and in sodium. The cast specimens exposed to fuel in the hot legs of two of the loops were severely attacked. The attack of the specimen exposed to sodium was similar to the attack of sodium on wrought Inconel. It is apparent that Inconel castings of the compositions tested are not suitable for use in contact with NaF-ZrF₄-UF₄ (50-46-4 mole %).

Thermal-convection loops were also operated to evaluate Hastelloys X and W in fuel mixtures and in sodium. Hastelloy X was unattacked by sodium, but it was attacked by NaF-ZrF₄-UF₄ (50-46-4 mole %) to a depth of 27 mils in the hot zone after 1000 hr. Hastelloy W showed no attack

of the hot leg by either the fuel mixture or sodium after 1000 hr; however, the loop operated with sodium had scattered metallic crystals in the cold leg. The significant difference in the attack on the two alloys, Hastelloys X and W, by the fuel mixture can undoubtedly be explained by the difference in the chromium content of the two alloys, 22 and 5%, respectively.

Efforts to operate metal thermal-convection loops have been relatively unsuccessful because of excessive oxidation of the outside surface and resultant leaks. One chromium-plated loop completed a scheduled 1000-hr operating period, but two chromium-plated loops scheduled to operate 1500 hr were terminated because of leaks at 1217 and 1339 hr. Examinations of these loops have not been completed. The fuel mixture NaF-LiF-KF-UF₄ (11.2-41-45.3-2.5 mole %) was circulated in these loops at a hot-leg temperature of 1500°F.

Additional thermal-convection loops were operated in the series of tests in which the alkali metal and the ZrF₄ content of the MF-ZrF₄-UF₄ fuel system are being varied. Lowering the ZrF₄ content from 46 to 40 mole %, but keeping the UF₄ content at 4 mole %, had no effect on attack by the NaF-containing mixtures, but the attack by the KF- and RbF-containing mixtures increased from 1 to 2 mils. The attack by the LiF-containing mixture decreased significantly with the decrease in ZrF₄ content, but this result is in doubt. Traces of metallic crystals were found in the cold legs of loops containing 56 mole % of the alkali-metal fluoride, except the loop containing KF.

3.2. General Corrosion Studies

Inconel thermal-convection loops containing inserts brazed with the 70% Ni-13% Ge-11% Cr-6% Si brazing alloy in the hot-leg section were operated at a hot-leg temperature of 1500°F for 500 hr with NaK (56-44 wt %) and with NaF-ZrF₄-UF₄ (53.5-40-6.5 mole %) as the circulated fluids. The brazing alloy was found to have been attacked to a depth of 1 to 1.5 mils by the NaK and to an average depth of approximately 5 mils by the fuel mixture. In a third thermal-convection loop the 82% Au-18% Ni brazing alloy was exposed in the hot leg to NaF-ZrF₄-UF₄ (50-46-4 mole %) for 500 hr at 1500°F. The attack on this brazing alloy averaged 8 mils.

Corrosion tests were conducted in seesaw apparatus on a series of Coast Metals No. 52 (89% Ni-

5% Si-4% B-2% Fe) brazing alloy buttons exposed to NaK and to NaF-ZrF₄-UF₄ (53.5-40-6.5 mole %) to obtain some information on the depleted region found at the edge of this alloy after exposure to liquid metals or to fused salts. It was found that the depth of the depleted region increased significantly with increased exposure time and that the boron content of the depleted region was very small after tests in both environments. It was also found that the silicon dropped to one-third its normal value in the depleted region.

Pure niobium was tested in static sodium for 1000 hr at 1500°F in type 304 stainless steel and in Inconel capsules to determine whether sodium would be a suitable protective environment for niobium during high-temperature mechanical property tests. The specimen tested in the stainless steel capsule showed more evidence of surface roughening and a greater thickness loss than did the specimen tested in the Inconel capsule. A brittle layer, as yet unidentified, formed on the surface of both specimens. The hardness of the specimen tested in the stainless steel capsule increased, while that of the specimen in the Inconel capsule decreased.

Samples of Thermanal (82% Fe-15% Al-3% Mo) were tested in static sodium for 100 hr at 1500°F in AISI 1035 steel and in type 430 stainless steel capsules. Small weight losses of the specimens were found, but the capsules were unattacked. The surfaces of the specimens were slightly roughened.

Specimens of Alfenal (84% Fe-16% Al) were corrosion tested in static NaF-ZrF₄-UF₄ (53.5-40-6.5 mole %), lead, lithium, and sodium. The specimens were found to have good resistance to attack by sodium and lead and very poor resistance to the fuel mixture and to lithium.

Several Inconel vs beryllium and chromium-plated Inconel vs beryllium couples were tested in contact under stress while immersed in sodium at 1300°F to determine the extent of reaction at the interfaces. Chromium plates of 1 and 2 mils on the Inconel greatly reduced the usual 10- to 24-mil reaction layer formed at the interfaces but did not eliminate it. The effectiveness of 4- and 6-mil plates will be evaluated.

Corrosion tests were made of Inconel castings in static NaF-ZrF₄-UF₄ (50-46-4 mole %) in wrought Inconel capsules to obtain further information on the effect of the composition of the cast material on its corrosion resistance. Three cast-

ings that differed primarily in silicon content were exposed to the fuel mixture for 1000 hr at 1500°F. The casting with the highest silicon content (1.93%) was the least attacked, while the casting with the lowest silicon content was the most severely attacked. In every case the wrought Inconel container was more corrosion resistant than was the cast specimen.

Static and tilting-furnace testing for 100 hr at 1500°F revealed little attack of Inconel and type 316 stainless steel by NaK with lithium additions. Thermal-convection loop testing for 1000 hr at 1500°F with NaK containing 5% lithium as the circulated fluid showed no change in attack on the Inconel, but the stainless steel was attacked to a depth of 6 mils in the cold leg.

Specimens of AISI 1043 steel were exposed to molten sodium in Armco iron and type 304 ELC stainless steel containers for 400 hr at 1830°F to determine the effect of exposure time on the extent of decarburization of the steel specimens. In comparison with previous 100-hr tests, the extent of decarburization was significantly greater. As before, the decarburization of the AISI 1043 steel specimens in the Armco iron container was more extensive than that of the specimens in the stainless steel container.

Relatively dense rare-earth-oxide bodies, one of Sm₂O₃ (5.88 g/cm³) and the other of 63.8% Sm₂O₃-26.3% Gd₂O₃-balance primarily other rare-earth oxides (6.58 g/cm³), were exposed to static sodium in Inconel capsules at 1500°F for 1000 hr. The specimens and the Inconel capsules showed good corrosion resistance to the sodium, but there was possibly a slight strength reduction of the rare-earth bodies. A porous body (63.8% Sm₂O₃-26.3% Gd₂O₃-balance primarily other rare-earth oxides) with a density of 3.53 g/cm³ which had an apparent porosity of 53.5% to water at room temperature was found to have an apparent porosity of 52% sodium after exposure to static molten sodium for 100 hr at 1300°F in a vacuum atmosphere. The weight loss of the low-density body was greater than that of the high-density body, and hardness tests showed the lower density body to have been weakened by the exposure to sodium.

In solid-phase-bonding screening tests in static NaF-ZrF₄-UF₄ (50-46-4 mole %) at 1500°F with a calculated contact pressure of 20,000 psi, molybdenum did not bond to tungsten or to K150A

ANP PROJECT PROGRESS REPORT

(80% TiC-10% NbTaTiC₃-10% Ni). It did, however, bond to itself and to K152B (64% TiC-6% NbTaTiC₃-30% Ni). The contact pressure had been reduced from the standard 50,000 to 20,000 psi in an effort to get below the yield strength of molybdenum at 1500°F. Even at 20,000 psi, however, the molybdenum deformed some in all the tests.

3.3. Fabrication Research

Conditions for the extrusion of nickel-molybdenum base alloys were established whereby tube blanks of these materials can be successfully fabricated on a laboratory scale. Slow extrusion rates and improved lubrication were found to be the most desirable conditions. This laboratory-established information was then successfully applied to the extrusion of Hastelloys B, W, and X on a commercial scale for the first time. It now appears to be feasible to produce seamless tubing of these alloys.

The search is continuing for a high-strength, corrosion-resistant nickel-molybdenum base alloy that will not be embrittled as a result of aging, such as is the case for Hastelloy-type alloys. Ternary alloys based on the 17% Mo alloy with additions of Ti, Al, W, Nb, Cr, Fe, V, and C are being fabricated into tubing for corrosion evaluation to establish the upper limit of the third element which will increase the strength of the alloy and yet not destroy its corrosion resistance. Various special nickel-molybdenum base alloys were received from the International Nickel Company and Battelle Memorial Institute for fabrication into tube blanks and subsequent corrosion evaluation.

The effect of consumable electrode arc melting on the strength and fabricability of nickel and several nickel-molybdenum base alloys is being investigated. It is hoped that the high arc temperatures will vaporize "tramp" elements and that the resulting melts will have improved mechanical properties. Electrodes of each composition of interest have been prepared for arc melting.

The oxidation of Hastelloy B in static air has been investigated at 1200, 1400, 1600, and 1800°F. The curves of weight gain vs time were parabolic at all test temperatures, and thus the oxide scale (NiMoO₄) that forms on the surface appears to be protective. Evidence has been found that the

formation of NiMoO₄ depends on the molybdenum content of the alloy, as well as on the temperature.

Billet configurations for the fabrication of two- and three-ply tube blanks have been developed. Tube blanks prepared from Inconel-type 316 stainless steel, monel-type 316 stainless steel, and nickel-type 316 stainless steel combinations were successfully drawn to small-diameter tubing that showed good thermal bonding at the metal interfaces. The thicknesses of the layers were about equal. A Hastelloy-B-type 316 stainless steel tube blank was rejected during processing because of longitudinal splitting.

Ceramic B₄C tiles of the type required for the ART neutron shield were received from two vendors for evaluation. Samples were irradiated for six weeks in the LITR, and no cracking or gas evolution was observed. Results of these examinations indicate that satisfactory material can be provided to meet ART specifications. Small plates of the stainless-steel-clad copper-B₄C cermet shield plates required for the ART have been successfully fabricated, and specimens have been prepared for irradiation. Dispersions of BN and CaB₂ particles in iron, nickel, and Inconel were also investigated as possible substitutes for copper-B₄C cermets. The most promising of these materials, BN-nickel and BN-Inconel, are being prepared for irradiation in the LITR.

Boron steels for use in a compression ring between the beryllium reflector and the support ring in the ART are being investigated, and specimens have been prepared for radiation-damage tests. The feasibility of using a duplex ring is also being investigated, because recent work by other investigators has revealed low ductility in boron-stainless steels after irradiation. The primary ring would be fabricated from Inconel and the secondary ring from clad copper-B₄C.

Studies were continued of methods for producing three-ply seamless tubular fuel elements and control rods and Inconel-clad niobium-UO₂ fuel elements. The search for a low-conductivity gamma-ray shielding material continued. Tungsten carbide appears to be the most promising base material, and constantan has been chosen as the binder. Work was also continued on the development of a 20% Li-80% Mg alloy for use as shielding material.

3.4. Welding and Brazing Investigations

Tests were conducted to determine procedures for minimizing distortion in the fabrication of Inconel pump volutes for the main NaK pumps of the ART. A welding procedure was developed whereby acceptable tolerances could be achieved, and it was shown that annealing of the volutes was required to remove residual stresses. Brazing experiments were also performed, and the results of dimensional measurements on the brazed volutes indicate that the brazing procedure gives a high degree of dimensional control.

Tests were also conducted to ascertain the possibility of welding an accurately machined and properly stress-relieved pump barrel to a thick-walled pressure shell without the need for finish machining or subsequent stress relieving. The results revealed that some distortion is inevitable and must be either accepted or removed by subsequent machining and that a stress-relief anneal will be necessary.

Weld shrinkage studies on cylindrical test specimens are also being conducted to provide data for use in the fabrication of the various ART shells. A program of welding Inconel plates under controlled conditions was carried out, and, based on the results obtained, the welding of large Inconel hoops was undertaken. It was found that in welding plates the effect of the welding variables could be minimized so that a welder could, essentially, duplicate his performance from test to test when welding manually. Also, a welder could nearly duplicate another welder's performance. The amount of tack-weld shrinkage in these tests was found to be inversely proportional to the length of the spacers used. The results of the hoop tests revealed greater shrinkage variations within a hoop than from hoop to hoop. Since each variation in the thickness of the Inconel plate to be welded creates new problems that are solvable only by more actual tests, additional tests will be made on each of the plate thicknesses of interest.

Examinations were completed on a 500-kw high-conductivity-fin NaK-to-air radiator, designated PWA HCF radiator No. 2, which failed as a result of a leak after operating for 1199 hr in the temperature range 1000 to 1600°F. For 546 hr of the operating period a temperature differential was imposed on the NaK flowing through the radiator by passing cold air across the fin surfaces. It was found that the radiator failed as the result

of the initiation of a fracture in a braze alloy fillet by shear forces and the propagation of this fracture through the tube wall by tensile forces or combinations of tensile and shear forces during periods of cyclic operation. Since the incidence of incipient fractures was associated exclusively with the presence of support members or plates, the design was modified to remove the transverse restraints.

Examinations are being made of a fuel-to-NaK heat exchanger, which failed as a result of a leak in a tube bundle after a total of 1794 hr of operation in the temperature range 1100 to 1500°F. There was a temperature differential imposed on the heat exchanger for 1015 hr of the operating time, and 21 thermal cycles were applied. Frequent and severe cracks were found in the rows of tubes with the shortest bends into the headers, where substantial degrees of strain occur. The cracks were most pronounced on the tension sides of the tubes. Metallographic examinations revealed that, at these locations, the corrosion and the stresses combined to form an abnormally unfavorable condition. Design modifications are being made to alleviate these problems.

3.5. Mechanical Properties Studies

Design data obtained from creep tests of solution-annealed Hastelloy B sheet stock in various environments at 1300, 1500, and 1650°F show that the times to 0.5, 1, 2, 5, and 10% total strain at each temperature in the various environments are the same, and that for stresses for which the rupture life is more than 300 hr the effect of environment is negligible. At 1500°F the better performance found in air than in the other environments at stresses for which the rupture life is less than 300 hr is caused by the ability of air to strengthen Hastelloy B during third-stage creep. At 1800°F, Hastelloy B tested in argon and in NaF-ZrF₄-UF₄ (50-46-4 mole %) did not age perceptibly, and the amount of third-stage creep was large at all stress levels. Of the environments tested only air and the fuel mixture affected the creep properties of the alloy, and at the normal structural stress levels even these environments had little effect.

Short-time tensile property tests of Hastelloy B in the temperature range 1000 to 1800°F showed a distinct decrease in the final elongation and in the ultimate strength at temperatures around

1200°F. The change in yield strength with temperature is relatively small.

Creep tests of Hastelloy W, which has 5% Cr, indicate that Hastelloy W has creep properties very similar to those of Hastelloy B. Hastelloy W has less of a tendency to age than Hastelloy B has, but a decrease in its ductility occurs at 1300°F.

The tensile properties of Inconel sheet were determined at temperatures from 78 to 2200°F. Fine-grained material was found to have better strength properties at temperatures up to 1700°F than coarse-grained material.

Creep tests were also made of several welded Inconel specimens in argon and in NaF-ZrF₄-UF₄ (50-46-4 mole %). The initial results indicated that the weld metal had greater creep strength and corrosion resistance than the parent metal.

3.6. Ceramic Research

A process was developed for the fabrication of the porous rare-earth-oxide compacts required for the ART control rods. The pores of the compacts are to be filled with metallic sodium, and the compacts are to be canned in Inconel. The compacts were prepared from Lindsay Chemical Co. material (Code 920) which contains 45 to 49.5% Sm₂O₃, 22.5 to 27% Gd₂O₃, and the balance primarily other rare-earth oxides (to a minimum of 90%). The final compacts were made oversize in all dimensions and then ground accurately to size.

3.7. Nondestructive Testing Studies

The study of the application of eddy-current testing to the inspection of small-diameter tubing was continued. The small defects of interest in reactor-grade tubing produce signals of amplitude comparable to the signals produced by the dimensional variations of interest in tube fabrication. Therefore the eddy-current test has real value as a rapid and continuous dimensional gaging method.

The inspection of pipe and tubing by the immersed ultrasonic method was continued. A reference notch of reproducible size is required on the inner and outer surfaces of the tubular object being inspected, and, since the problem of producing such a reference notch on the inside of small-diameter tubing has not been solved, this method is not being used for the inspection of small-diameter tubing.

PART 4. HEAT TRANSFER AND PHYSICAL PROPERTIES, RADIATION DAMAGE, FUEL RECOVERY AND REPROCESSING, CRITICAL EXPERIMENTS

4.1. Heat Transfer and Physical Properties

An experimental, compact heat exchanger with a triangular tube array was designed and is being constructed so that its heat and momentum characteristics can be determined and compared with those of a similar heat exchanger with a square tube array. The flow distribution to be expected in the ART reflector cooling system was studied experimentally for concentric spacing and for two types of annulus eccentricities.

Heat transfer tests were conducted on the half-scale model of the ART core with a volume heat source. A swirl entrance system and uniform volume heat source conditions were used. The mean, uncooled-wall temperature measurements obtained were compared with predicted values for idealized systems. Large temperature asymmetries and large temperature fluctuations, which stem from hydrodynamic asymmetries and flow instabilities, respectively, were recorded.

A thermal-cycling experiment was designed and constructed which is to be used to experimentally study the effect of the large cyclic thermal stresses that were calculated to exist in the Inconel core shells and in the tube bends at the fuel inlet end of the fuel-to-Nak heat exchanger as a result of temperature fluctuations. Additional calculations were made to determine the temperature structure in the region beyond the ART reflector.

The enthalpies and heat capacities of NaF-LiF-ZrF₄ (22-55-23 mole %) and LiF-NaF (60-40 mole %) were determined in the liquid and solid states. Additional information on the influence of the presence of fission products on the viscosities of fluoride fuels was obtained; no significant effects on viscosity were found. A new thermal-conductivity cell for molten salts was built which makes it possible to observe whether gas bubbles or films are present in the cell at the time measurements are being made. An electrical-conductivity cell was standardized at high temperatures with molten potassium chloride.

4.2. Radiation Damage

Disassembly of MTR in-pile loop No. 3 was completed. Samples of charcoal from two of the fission-gas adsorption traps, the black deposit found

around the inlet to one trap, and a thin brownish film that was around the inlet to a second trap were taken for analysis. It is thought that oil or decomposition products of oil entered the traps from the fuel-pump bearing housing and sump and caused a plug when they came in contact with the refrigerated trap inlet. The face and inside of the forward bellows of the pump contained a brittle, amber-colored, amorphous deposit; the pump slingers were coated with a black, shiny deposit. No evidences of fuel or ZrF_4 -vapor deposits were found in the pump.

The elongation of one Inconel tensile creep specimen stressed to 1500 psi in the MTR for 760 hr at 1500°F was found to be 1.7%. Tensile tests at high and low strain rates were conducted at 500 to 1400°F on Inconel and Nichrome V. The ductility minimum at 1000 to 1200°F, usually reported in the literature for Inconel, was not evident. Irradiation of the fuel mixture NaF-ZrF₄-UF₄ (63-25-12 mole %) planned for use in a creep and stress-corrosion test in HB-3 of the LITR resulted in only about one-third the heat production expected from previous measurements of the depressed thermal flux. More uranium will be added to the mixture, and the number of conductive fins on the apparatus will be reduced.

Irradiation of static corrosion capsules in the MTR has been continued. Two Inconel capsules filled with NaF-ZrF₄-UF₄ fuel mixtures were irradiated at 3.5 kw/cm³ and two at 6 kw/cm³ for six weeks each. Hastelloy B capsules are being prepared for MTR irradiation. They will be filled with NaF-KF-LiF-UF₄ fuel mixtures.

A vertical in-pile loop was inserted in the LITR, but it had to be withdrawn because of pump failure. Improved pumps are being tested. Corrections for the platinum-platinum-rhodium thermocouple and the fuel tube wall radial temperature difference were determined. The maximum correction was 35°C.

Further design calculations for the vertical in-pile fuel-circulating loop were made, based on the assumption of insertion to the bottom of the LITR lattice. It was found that, in spite of the greater length of irradiated loop in the "deep" position, the fuel temperature differential would be slightly less. The principal result of the change in position of the loop would be a substantial decrease in the dilution factor from about 11 in the "shallow" position to about 6 in the "deep" position.

Fast-neutron studies were begun on the energy spectrum in the ORNL Graphite Reactor and on the variation of radiation damage with energy. Calculations lead to reasonable agreement with experiments on germanium both in a reactor and with a fission spectrum from a uranium-converter plate.

Exploratory designs of a viscometer for measurements of irradiated fuel were studied.

It was demonstrated that the nonlinear, photo-sensitive conduction in commercial-wire insulation is a bulk- rather than a surface-leakage effect. Germanium diodes and transistors were irradiated in the ORNL Graphite Reactor and in a Co⁶⁰ gamma-ray source. Correlations were made between changes in diode and transistor properties. The displacement of germanium atoms by Co⁶⁰ gamma irradiation was observed, but the effect of this damage in diodes and transistors is different from the effect of neutron irradiation. Enhanced diffusion of interstitial atoms produced by fast-neutron irradiation has been observed in the barrier region of a germanium point-contact diode.

An evaluation was made of the radiation damage to be expected in the ART B₄C shield. Of the six bodies irradiated in the LITR for 800 hr at 200°C, the Norton Company high-density material is preferable, but only one material showed any serious radiation effects from a total dose of 6×10^{19} nvt (thermal). The ART copper-B₄C cermet layer and boron steel are to be irradiated in the MTR at 1600°F.

It has been decided to include some of the work on the radiation effects on polymers (which has heretofore been reported only in the Solid State Division Progress Reports) in the ANP Progress reports. Work is currently under way to study the reaction products of irradiated polymers by means of the infrared spectrometer. A summary of this work is presented.

4.3. Fuel Recovery and Reprocessing

The design of the volatility pilot plant for recovering fused-salt fuels was completed, except for minor auxiliary items. It is expected that the plant will be completed by June 30.

The behavior of NiF₂ in molten NaF-ZrF₄ and NaF-ZrF₄-UF₄ systems was studied to determine whether the presence of this corrosion product would cause the formation of sludges which would interfere with salt transfer in the fluoride-volatility process, since the addition of as much as 6 wt %

ANP PROJECT PROGRESS REPORT

NiF_2 to molten NaF-ZrF_4 (50-50 mole %) at 600°C resulted in the formation of a viscous dispersion. The initial sedimentation of such dispersions was rapid; however, the settling rate decreased with time as a result of a viscosity effect. In tests to determine the effect of the NiF_2 concentration on the sedimentation rate, it was found that NiF_2 concentrations of up to 2 wt %, a factor of 10 more than is expected in aircraft reactor fuel reprocessing, would not interfere with salt transfers unless the molten salt were permitted to stand unagitated for long periods of time. The presence of UF_4 in the molten salt mixtures was found to have very little effect on the sedimentation rate.

Some exploratory work was carried out on the decomposition of the $\text{UF}_6\text{-3NaF}$ complex at high temperatures in an effort to develop a UF_6 desorption procedure which avoids UF_6 decomposition, since the decomposition reaction would lead to uranium being held up on the NaF bed and would thus necessitate a subsequent recovery step. The results indicate that if a significant partial pressure of UF_6 is retained in the NaF bed because of a plugged line or cold trap during UF_6 desorption, excessive UF_6 decomposition will occur when the temperature reaches the 300 to 400°C range. Therefore precautions must be taken to ensure that full sweep-gas flow through the NaF bed is maintained during UF_6 desorption.

4.4. Critical Experiments

Experiments with the critical assembly of the sodium-cooled, reflector-moderated reactor with solid fuel elements proposed by the Nuclear Development Corporation of America (NDA) have been completed. The reactivity effect of the stainless steel shells that separated the fuel region was investigated by substituting aluminum shells of the same dimensions. The exchange of 4.4 kg of aluminum for 11.9 kg of stainless steel resulted in a gain in reactivity of 54.20, estimated to be equivalent to a 14% decrease in the critical mass.

Gamma-ray heating in the island and in the reflector was measured, and the results are reported as power dissipated as heat in a unit volume per unit reactor power. The leakage of fast neutrons at various points on the outer surface of the reflector was also measured. The thicknesses of the sides and top of the beryllium reflector were varied for these measurements.

PART 5. REACTOR SHIELDING

5.1. Shielding Theory

The joint ORNL and Wright Air Development Center (WADC) program to determine the contribution of air-scattered gamma rays to the dose rate in a cylindrical crew compartment has been separated into two parts. The first part, in which the flux at various points in air will be determined, has been programmed and coded for calculations on a type 1103 computing machine. In the second part the flux was considered to be the source at the outside surface of the crew compartment, and the dose at several arbitrary positions inside the crew compartment was determined. This part of the program has been completed.

A procedure for transforming flux, current, or dose rate from one density of an infinite homogeneous medium with anisotropic point sources to another density has been derived directly from the Boltzmann equation. This procedure provides a means of transforming Tower Shielding Facility (TSF) data from one altitude to another.

The code for a Monte Carlo calculation of energy deposition in a multiregion shield with slab geometry has been used to determine the percentage of the total energy from 1-Mev gamma rays that is reflected, absorbed, or transmitted in a fuel-Inconel-sodium-Inconel slab. The percentage of energy absorbed in various regions of the slab was also calculated.

Part 1

AIRCRAFT REACTOR ENGINEERING

S. J. Cromer

DECLASSIFIED

1.1. AIRCRAFT REACTOR TEST DESIGN

A. P. Fraas

STATUS OF ART DESIGN

Design work on the Aircraft Reactor Test (ART) reactor, heat-exchanger, pump, and pressure-shell assembly is nearing completion. Layouts on all the major subassemblies have been completed, along with the major portion of the drawings of the detailed parts. Drawings for the remaining parts should be completed during the coming quarter. The applied mechanics and stress analysis work is accompanying the design, with rough first approximations being completed, usually, shortly after completion of the layouts and with better, second approximations following closely, in most instances, upon completion of the detail drawings. In cases in which component tests have been deemed essential, the results are being analyzed and modifications in details made when essential. Of course the analyses have not been completed for many very complex situations, and many key component tests have not yet been run. It is believed that modifications that will be required as the results of this work become available will probably involve only relatively minor reworking of partially fabricated parts. Such a calculated risk is necessary and inherent in design work involving such exceptional extrapolations of available technology.

The preliminary layouts for the shield have been modified to include provision for a substantial amount of instrumentation and special equipment. A one-half-scale model of the top portion of the reactor (commonly referred to as the "north head"), including the NaK manifolding, has been completed, and models of the instrumentation components, the lead shielding, and associated parts are well under way. Such models are used to investigate assembly and interference problems. Preliminary layouts have also been prepared for the arrangement of the lube-oil, hydraulic-fluid, water, gas, electrical, and instrumentation lines in the reactor cell. A one-sixth-scale model of the entire ART assembly is being kept closely abreast of this work to ensure accessibility, freedom from interferences, etc. The fuel fill-and-drain tank design has been completed, preliminary layouts for the associated supports, shielding, plumbing and instrumentation have been prepared, and the consequent assembly, accessibility, etc. problems

are being studied in the one-sixth-scale model. The detail design of the plumbing and equipment installation outside the cell is well along and should be largely completed during the coming quarter.

APPLIED MECHANICS AND STRESS ANALYSIS

R. V. Meghreblian

North-Head Pressure Stresses

The stress analysis of the composite double-deck structure of the north head, mentioned in the previous report,¹ was completed. The analysis was based on the pressure loads to which the structure will be subjected during full-power operation. Since the actual design consists of two circular flat-plate decks joined by a complex pattern of vertical baffles and walls arranged both radially and circumferentially (Fig. 1.1.1), it was not possible to carry out an analysis of this composite structure which would yield an exact distribution of the elastic stresses. Moreover, this structure is to be exposed to various operating conditions at temperatures of 1200°F and above for about 1000 hr, and it is expected that thermal distortions and creep will cause redistributions of stresses which will differ markedly from any predicted elastic stresses. It is not entirely meaningful therefore to think in terms of an exact stress distribution, and, for this reason, precise analyses of this structure were not attempted. So long as the proposed design is capable of supporting the operating loads at relatively low stress levels, the details of the exact distribution are not important. From the viewpoint of creep limitations, it would suffice to know the general location and magnitude of the highest stresses in the system.

This information has been obtained from a series of calculations based on simplified geometric configurations of the north-head structure, and these results will eventually be checked by an experimental stress analysis of a full-size aluminum model. The calculations consisted of three parts: a very elementary analysis in which the various

¹R. V. Meghreblian, *ANP Quar. Prog. Rep.* March 10, 1956, ORNL-2061, p 22.

Fig. 1.1.1. Plastic Model of ART North-Head Structure.

deck and shell areas were treated as individual plate segments with assumed edge conditions, an analysis of two circular flat plates of annular shape joined by a continuous circumferential baffle (Fig. 1.1.2), and an analysis of a composite system of plates and shells to represent the primary structural members, which was based on the requirement that the deformations of adjoining members be matched along the various junction lines (welds). The first two analyses served to give a very crude estimate of the stress levels involved. The purpose of the third analysis was to determine the stresses produced in the north head due to compatibility requirements of the various segments of shells and plates subjected to a complex pattern

Fig. 1.1.2. Circular Plates with Baffle.

of pressure loads. The idealized model used in this calculation is shown in Fig. 1.1.3, and the net pressure loads at various points are indicated. This model represents approximately the cross section indicated in Fig. 1.1.4. It includes some of the longest spans which appear in the design, and the results obtained from this model are therefore conservative.

The configuration of Fig. 1.1.3 was analyzed by writing the deflection equation for each member in terms of its load and edge conditions and solving the resulting system of eleven simultaneous equations on the Oracle. The results were obtained in terms of the moments and reactions at the joints and edges of the members. The stresses due to these loads were then computed. The largest stress, as indicated on Fig. 1.1.3, was found to be 2100 psi. Since the highest temperature which will occur in the north-head structure during full-power operation will be approximately 1300°F, this 2100-psi stress value is to be compared to

the creep properties of Inconel in the fuel mixture at about 1300°F. Creep tests have indicated that the tensile stress required to produce rupture in 1000 hr at 1300°F is about 10,000 psi. The design criterion for creep which has been selected for the ART requires that the total deformation in any member not exceed 0.2% strain in 1000 hr. At 1300°F in the fuel mixture this corresponds to a tensile stress of about 2000 psi.

The experimental program, designed as a check on the calculations for the north-head structure, is under way at the University of Tennessee. It is believed that the combined results of the analytical studies and the model tests will reveal any defects in the proposed design.

North-Head Thermal Stress

With the completion of the analysis for the mechanical stresses in the north-head structure, attention is now being directed to the determination of the thermal stress distributions. For this

purpose, calculations have been undertaken to obtain preliminary estimates of the energy-deposition rates throughout this region (see Chap. 1.2, "Art Physics"). The locations in the north head at which these rates might lead to relatively large temperature rises are indicated in Fig. 1.1.5. The calculations of the associated temperature distributions and the thermal stresses are presently under way. If these calculations yield excessive temperature gradients, it is planned to review the initial energy-deposition estimates and, if necessary, perform more precise analyses.

Sodium Expansion Tank Design

The design analysis of the sodium expansion tank was completed, and the configuration which was found to be acceptable from both the pressure and thermal stress viewpoints is shown in Fig. 1.1.6. The proposed design consists of a vertical wall of more or less elliptical shape joined to an end cap of slightly cylindrical curvature. This cap (or roof) is welded to the control-rod thimble, which passes through the center of the ellipse. The stress analysis of this design was based on an idealized model consisting of a short, elliptical cylinder with a flat-plate cap subjected to an

internal pressure of 30 psi. The stresses in the cap were computed from the relations for an elliptical plate with various edge conditions. The stresses at the joint and in the vertical walls were computed from the relations for an equivalent circular cylinder with a flat head. These calculations indicate that the maximum stress (1000 psi) is due to the bending moment at the cylinder-cap junction.

During full-power operation the tank will be partially filled with sodium at 1270°F to an assumed depth of 2 in., and the upper portion of the side walls and the roof of the tank will be exposed to direct gamma radiation from the sodium (Fig. 1.1.7). The outer surfaces of the tank are to be surrounded by insulating material, and, if no cooling is provided for these surfaces, the metal temperature in the roof will rise to 1420°F. Since the side walls are to be welded to the pressure shell, which will be at 1250°F, there will be differential thermal growth between the roof and the shell, which will give rise to a thermal stress of 80,000 psi (based on an elastic analysis) at the roof-wall intersection. This stress is considered to be excessive; and therefore cooling is to be provided for the roof. Sodium at a temperature of 1250°F will be taken from the pressure-shell cooling circuit and fed into a system of tubes welded to the bottom surface of the roof. A total flow of 3 gpm will pass through this circuit at a pressure drop of 15 psi. The coolant sodium will leave the roof circuit at 1270°F and spill into the expansion tank volume. With this supply of coolant, the average roof temperature will be reduced to 1280°F. The temperature profiles in the roof in the vicinity of a cooling tube are shown in Fig. 1.1.8. The maximum thermal stress due to this temperature structure is 10,000 psi.

ALUMINUM NORTH-HEAD MOCKUP FLOW STUDIES

E. R. Dyrko²

circuits,³ and flow tests with water being pumped by the two fuel pumps under simulated reactor flow conditions are under way.

Twin fuel pump operation has been demonstrated up to 3000 rpm, although 2400 rpm produced approximately rated conditions of head and flow. Degassing of the system with pump speeds of 2400 rpm required less than 30 sec with the water level 1 in. or more above the bottom of the surge chamber. When the speeds of both pumps were lowered in unison from 2400 rpm, the first signs of ingassing

³D. R. Ward, ANP Quar. Prog. Rep. Dec. 10, 1955, ORNL-2012, p 65, Fig. 2.29.

occurred at 1200 rpm. The amount of gas entrained during operation with the pump speeds matched was believed to have reached a maximum, not exceeding 0.1 vol %, at 500 rpm. At speed levels above 1200 rpm, ingassing could not be detected with mismatching of up to 5%. Mismatching the speeds by 20% produced ingassing estimated to be 0.5 vol %. When the power to one of the hydraulically driven fuel pumps was cut off while both pumps were running uniformly at 2400 rpm, about 13 sec was required for the one pump to stop. This one-pump-stopped condition created ingassing of roughly 2 vol %.

Fig. 1.1.7. Energy Deposition in Sodium Expansion Tank Roof Due to Gamma Radiation.

Surging and instability were noted in pump speeds, flow rates, pumping power, and inlet and discharge pressures. It is believed that both the centrifuge hardware and the unfavorable pump inlet pipe configurations were contributing to the observed instability. The addition of straightening vanes to the pump inlet regions materially reduced the surging. This, coupled with some modifications to the xenon-removal system, appears to have reduced the pressure fluctuations to an acceptable level, that is, about 0.5 psi in the full-scale reactor.

Water bypassed into the surge chamber for simulated xenon removal was very turbulent, and splash-wetting of all surfaces and entrainment of fine bubbles resulted. Methods being considered for reducing the extreme turbulence in this region include the addition of baffles, a reduction in

bypass flow rates, and a redesign of the passages from the pumps to the surge chamber.

CORE FLOW STUDIES

W. T. Furgerson W. J. Stelzman
D. B. Trauger

Changes in design of both the center volute of the axial-flow type of header and the island expansion bellows located within the header of the proposed ART core resulted in an unsatisfactory core flow pattern being generated by the previously satisfactory inlet guide vane, designated GS-2, and the conical baffle plate, designated GS-2-P3 (ref. 4). Under the revised design, this particular guide vane and baffle plate combination generated flow reversal at the island surface in the region of the equator. Systematic relocation of the conical baffle plate only and analysis of the resulting core flow pattern yielded baffle plate GS-2-P10, which, in combination with guide vane GS-2, again generated a flow pattern containing no flow reversal along either the outer core shell or the island surfaces. Brief periods of minor flow reversals did occur at the equator; however, these occurred in midstream and seemed to be caused by the turbulent condition of the fluid mass in this region. In general, the flow generated in the upper half of the core by this combination was extremely unstable, but it exhibited excellent surface scrubbing, with very good transfer of fluid from the walls, and excellent fluid mixing. Below the equator, some improvements were noted in the fluid flow properties; however, the streamlines again tended to hug the inner and outer surfaces as they approached the core outlet. Attempts had previously been made with the original axial-flow header to improve the flow in the lower half of the core by means of turbulators on the island surface immediately below the guide vanes and again on the shell surface immediately below the equator; however, the improvement was only minor. This latest design is being evaluated in the half-scale ART volume-heat-source apparatus (see Chap. 4.1, "Heat Transfer and Physical Properties").

PERFORMANCE REQUIREMENTS FOR PUMPS IN THE NaK SYSTEMS

M. M. Yarosh

A study was completed to determine the speed and power range requirements for the main and auxiliary NaK pump motors. Because of unequal system lengths, the pressure drops in each of the four main NaK systems for an equal NaK flow are different, and thus a different pump speed is required for each system. In addition to the variations between systems, the individual system resistances will vary as a function of operating time and operating conditions. These variations will be attributable to the mass-transfer buildup anticipated in the colder sections of the NaK systems, principally in the radiator tubes.

Pump speed requirements were established from the pump performance curves. The NaK system curves (head vs flow) showing expected ranges of system resistance as a function of flow were plotted on the pump performance curves, and the operating speeds were established at design flow to be those speeds falling between the minimum

and maximum system resistance curves. Thus, a range of operating speeds was established for each individual NaK system. Power requirements were then computed for the corresponding speed, head, and flow requirements.

In order to reduce warmup time for the NaK systems, it will be desirable to operate the NaK pumps at, or near, full speed during the warmup period. Stress considerations, however, will prohibit operation at full NaK pump speed for extended periods of time when there is no fuel in the reactor. Therefore an intermediate pump speed was established at which reduced warmup periods can be attained at reduced stress. The operating speeds established and corresponding power requirements for the main and auxiliary NaK pumps are given in Table 1.1.1.

CONTROL-ROD COOLING SYSTEM

J. Foster

The ART control rod is designed to move vertically in a well containing static sodium, this sodium being deep enough to cover the control

TABLE 1.1.1. NaK PUMP SPEEDS AND HORSEPOWER REQUIREMENTS

Main System		Auxiliary System	
Pump Speed (rpm)	Power Required (hp)	Pump Speed (rpm)	Power Required (hp)
1900	27	1900	7
2300	42	2300	14
2650	61	2800	26
2800	72	2950	31
3000	87	3100	37
3200	102	3250	41
3400	118	3400	46
3500	127	3550	55

rod in its fully withdrawn position. This places the level of the sodium-free surface in the well just a few inches above the top of the reactor north head. The well extends up about 5 ft above this level so as to place the control-rod drive mechanism outside the reactor shield. The sodium at and near the free surface must be cooled to below 500°F to minimize the vapor pressure and hence the diffusion and deposition of sodium vapor on the components of the control-rod drive mechanism, where such deposits might create operating difficulties such as shorting of electrical circuits. Tests have shown that sodium vapor evolution and deposition are negligible at 500°F.

The lower portions of the sodium in the well will be exposed to temperatures of about 1200°F, and therefore the cooling system includes convection baffles to still the upper few inches of the sodium and a water jacket around this baffled sodium zone. As a precaution to ensure against any possibility of water entering the sodium chamber, the jacket will be a completely water-tight assembly. An Inconel sleeve will be shrunk over the outside of the control-rod well pipe to form a double wall. Water will be circulated at 220 to 240°F (sodium melts at 208°F) through the jacket and will serve to remove heat or supply

heat as required by the condition of the reactor system. No flow or pressure controls will be provided other than an orifice in the water line, designed to give a flow of 1 gpm.

The water-jacketed and baffled sodium zone will be separated from the hot sodium in the lower well by a solid Inconel plug inserted in the sodium as a heat dam to keep the thermal gradient along the Inconel well to a reasonable value from the thermal stress standpoint. This Inconel plug is a 4-in.-high cylinder with a central hole drilled along the cylindrical axis, through which the $\frac{3}{8}$ -in.-dia control-rod drive is free to move and position the rod as required.

The effluent hot water from the jacket will pass through an economizer, in which it will heat the entering water stream. This will reduce the water heating load and cool the effluent stream to prevent flashing in the drain.

SODIUM SYSTEM STUDIES

R. I. Gray

Recent tests showed that the flow resistance in the annuli around the core in which sodium will be circulated will be somewhat smaller than expected with the spacers in place. This will effect a slightly lower over-all pressure drop and more nearly balanced flow between the cooling holes and the core annuli. Pressure drop calculations indicated the need for increasing the thickness of the control-rod cooling annulus, in which sodium will circulate, from 0.080 in. to about 0.125 in.

Stress calculations indicate the need for cooling the top of the sodium expansion tank and for the addition of a flexible bellows to the island sodium inlet line (see previous section of this chapter on "Applied Mechanics and Stress Analysis"). An auxiliary sodium expansion tank of approximately 0.6 ft³ has been added to the system so that in the event of a major reactor shutdown sodium can be added as the sodium temperature is lowered from 1200°F to 300°F to avoid a loss of prime in the sodium pumps (which would otherwise occur at about 800°F).

1.2. ART PHYSICS

A. M. Perry

RADIATION HEATING ON THE ART
EQUATORIAL PLANE IN THE VICINITY
OF THE FUEL-TO-NAK HEAT EXCHANGER

H. W. Bertini

The results of calculations of the radiation heating on the ART equatorial plane in the outer 3 cm of the beryllium reflector and in the Inconel and the boron-containing shells on both sides of the fuel-to-NaK heat exchanger are presented in Figs. 1.2.1 and 1.2.2. The total gamma-ray heating in each region is given in Fig. 1.2.1, as well as the heating from the sources which are the main contributors to the total in each

shell. The encircled numbers on Fig. 1.2.1 refer to the sources described in Table 1.2.1.

The data on heating in the copper-boron layer by alpha particles from the $B^{10}(n,\alpha)Li^7$ reaction are plotted in Fig. 1.2.2. The heating goes to infinity at the face of the layer closest to the core because the heating at various points is governed by an E_1 function,

$$E_1(x) = \int_1^{\infty} e^{-x\lambda} \frac{d\lambda}{\lambda},$$

where λ is the mean free path. The integral under the curve will be finite.

TABLE 1.2.1. SOURCES OF RADIATION HEATING CONSIDERED IN CALCULATING
THE RESULTS PRESENTED IN FIG. 1.2.1

Source No.	Source	Source Strength
1*	Prompt gamma rays in the fuel region of the core of the reactor	28.3 w/cm ³
2	Decay gamma rays in the fuel region of the core of the reactor	6.84 w/cm ³
3	Gamma rays from inelastic scattering of neutrons in the fuel region of the core	10.1 w/cm ³
4	Capture gamma rays in the outer core shell	41.4 w/cm ²
5	Capture gamma rays in the reflector (average)	~0.5 w/cm ³
6	Capture gamma rays in first Inconel shell outside of beryllium reflector	22.5 w/cm ³
7	Boron capture gamma rays in copper-boron layer	1.8 w/cm ²
8	Alpha particles from the $B^{10}(n,\alpha)Li^7$ reaction in the copper-boron layer (average)	42 w/cm ³
9	Decay gamma radiation from the fuel in the heat exchanger	2.3 w/cm ³
10	Gamma rays from inelastic scattering of neutrons in first 9 cm of reflector (average)	0.7 w/cm ³

SECRET

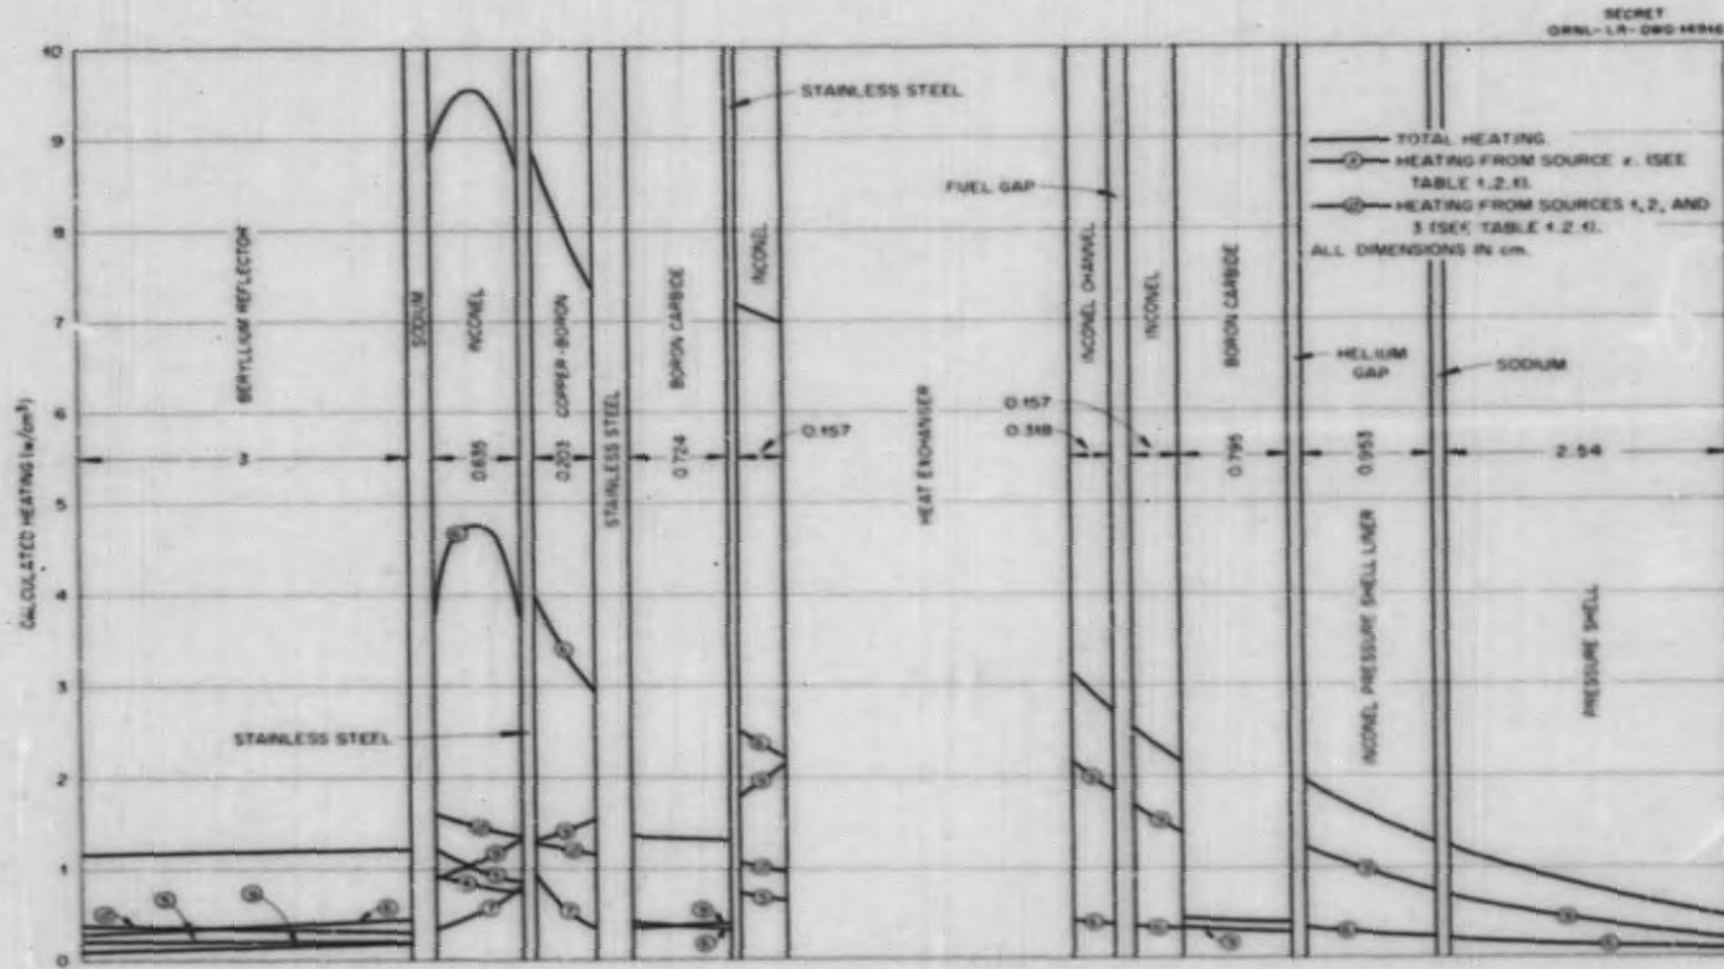

Fig. 1.2.1. Gamma-Ray Heating in the Vicinity of the Fuel-to-NaK Heat Exchanger on the Equatorial Plane of the ART.

Fig. 1.2.2. Heating in Copper-Boron Layer By Alpha Particles from the $B^{10}(n,\alpha)Li^7$ Reaction.

The heating from sources 10 to 14 was neglected. Their combined contributions to the heating in the region being considered was estimated to be about 5% of the total heating.

The fuel region of the core of the reactor was assumed to be a spherical shell 5.125 in. thick with an outside radius of 10.5 in.¹ This region was divided into 13 spherical shells of thicknesses varying from 0.27 cm to 2 cm. The source strength (in watts/cm²) of the prompt gamma rays in each shell was assumed to be proportional to the average fission power in each shell, which was calculated (from ref. 2) at the equatorial plane of

¹W. L. Scott, Jr., *Dimensional Data for ART*, ORNL CF-56-1-186 (March 13, 1956).

²A. M. Perry, *Fission Power Distribution in the ART*, ORNL CF-56-1-172 (Jan. 25, 1956).

the reactor. The source strength of the decay gamma rays was assumed to be the same for each fuel shell.³

The average source strength of gamma rays resulting from inelastic neutron scattering in the fuel was calculated⁴ by using the output of multigroup calculations⁵ performed by the Curtiss-Wright Corp. on ART-type reactors with spherical symmetry.⁶ The inelastic cross sections used for the fuel were those reported in ref. 3. This calculation had been performed before all the data in the latter reference had been accumulated, so it was assumed that, for each inelastic collision, one-half the average neutron energy in each energy group was given off as 1-Mev gamma radiation. Calculations made by using the more recent data indicate that the source strength used was too high by about 50%. The total heating values given in Fig. 1.2.1 may therefore be about 5% too high. This error is partially compensated for, however, by the neglect of sources 10 through 14.

The prompt and decay gamma-ray spectra⁷ were divided into four energy groups with average energies for each group of 0.5, 1, 2, and 4 Mev. The last four groups listed in ref. 3 were combined into one group with an average energy of 4 Mev. The heating at the various places described in Fig. 1.2.1 was calculated by summing the contributions from each energy group from every fuel shell.

It was assumed for the calculations that each fuel shell was replaced by an infinitely thin spherical-shell source embedded in an infinite homogeneous medium so that the standard transformation from a spherical-shell source to two infinite-plane sources would apply, that is, so that the heating at R , $H(R)$, would be given by

$$(1) \quad H(R) = \frac{r}{R} \left[H(R-r) - H(R+r) \right],$$

where

- r = radius of source (taken as the average radius of each fuel shell),
 R = distance from center of fuel shell to field point,
 $H(x)$ = heating at a field point due to an infinite plane source of monoenergetic gamma rays a distance x away from the field point.

The second term of Eq. 1 was dropped for these calculations because of the large radii involved.

The assumptions made were certainly not consistent with the geometry, inasmuch as the region between the source shells and the field point is not everywhere homogeneous. The justification for this approach was that it appeared to be as good as could be done without going to a much more detailed numerical integration over all source points for each energy group to calculate the heating at one field point.

In deriving H , it was assumed that the attenuating medium between the plane source and field point consisted of infinite slabs of materials whose thicknesses were determined by their thicknesses at the equatorial plane of the ART.¹

The buildup factor used was of the form

$$(2) \quad A \left(e^{\frac{\alpha \sum \mu_i t_i}{1}} - 1 \right) + 1,$$

where

- A, α = parameters of the equation,
 μ_i = linear total gamma-ray absorption cross section (cm^{-1}) for material i ,
 t_i = thickness of material i (cm).

Under these conditions,

$$(3) \quad H = \frac{S \mu_e}{2} \left\{ A E_1 \left[(1 - \alpha) \sum_i \mu_i t_i \right] + (1 - A) E_1 \left(\sum_i \mu_i t_i \right) \right\},$$

where

- H = heating (w/cm^2) at the field point,
 S = source strength (w/cm^2),
 μ_e = linear gamma-ray energy absorption cross section (cm^{-1}) for the field point,
 t_i = thickness of the i th slab (cm).

The S term was determined for each fuel shell and each energy group by multiplying the source strength for each group (in w/cm^2) by the thickness

of the shell. The buildup factor parameters, A and α , were taken to be those for beryllium. The μ 's, A 's, and α 's were evaluated at each energy group.³

The spectrum of prompt gamma rays reported in ref. 7, $8.8 e^{-1.01E}$ photons/Mev-fission, is different from that reported in ref. 3, $9.61 e^{-1.01E}$ photons/Mev-fission. The former value, which neglects the variation of $(\sigma_c/\sigma_f)_{\text{U}^{235}}$ with energy, was used in these calculations before the correction was pointed out. Use of the latter spectrum would change the results reported here by less than 2%.

The heating by the capture gamma rays in the outer core shell was calculated with the use of the same assumptions as those used for the calculations of the heating by the fuel-region sources, that is, a sphere-to-plane transformation was made and slab geometry was used for the intervening mediums between the plane source and field point. The absorption rate in the outer core shell was calculated from the output data of multigroup calculations.⁵

The spectrum of capture gamma rays in Inconel was divided into seven energy groups in ref. 3, but, for this calculation, the first three groups were combined into one group, and the average energy of this combined group was taken to be 2 Mev. The fourth and fifth groups in ref. 3 were taken as the second and third energy groups for this calculation, and the average energies were taken to be 4 and 6 Mev, respectively. The sixth and seventh energy groups in ref. 3 were combined into one group with an average energy of 8 Mev. Thus a total of four energy groups was used in this calculation. The buildup factor used was that for beryllium at each energy group. The outer core shell has an inside radius of 26 cm and a thickness of 0.381 cm.⁸

The capture gamma rays in the island core shell were neglected because of the shielding properties of the fuel. The heating by the capture gamma rays in the beryllium reflector was calculated by using the sphere-to-plane transformation and the other assumptions given above. The reflector region was divided into five spherical shells, that is, the same shells as those used by the Curtiss-Wright Corp. in their multigroup calculations of reactor No. 675.⁶ The capture gamma-ray source

⁸Calculations performed by C. M. Copenhaver, ORNL, private communication to H. Bertini.

DECLASSIFIED

strengths in each region were calculated⁸ from the output of the multigroup calculations. The spectrum of the capture gamma rays in beryllium is divided into two energy groups in ref. 3, and these groups were combined into one group with an average energy of 6 Mev, for this calculation. The buildup factor for beryllium at 6 Mev was used.

In calculating the gamma-ray sources in the first Inconel shell around the beryllium reflector, it was assumed that 32% of all neutrons born in the core escape from the reflector as thermal neutrons.⁶ It was further assumed that these neutrons escape with an isotropic angular distribution from the surface of the reflector. A source strength, S , in thermal neutrons/cm²-sec escaping from the surface of the reflector, was calculated by using a reflector radius of 55.04 cm (ref. 1). Because of the large radii of curvature in this

$$(6) \quad h_i = \frac{e^{\mu_i t}}{2\mu_i} \left(\frac{A}{1-\alpha} \left\{ E_2 \left[(1-\alpha) \sum_{i=2}^n t_i \mu_i \right] - E_2 \left[(1-\alpha) \sum_{i=1}^n t_i \mu_i \right] \right\} + (1-A) \left[E_2 \left(\sum_{i=2}^n t_i \mu_i \right) - E_2 \left(\sum_{i=1}^n t_i \mu_i \right) \right] \right),$$

region of the reactor, the neutron absorption rates were calculated on the basis of slab geometry.

Between the Inconel shell and the reflector there is a $\frac{1}{8}$ -in. layer of sodium coolant.¹ If it is assumed that a neutron leaving the surface source will be absorbed only on a first-flight absorption collision, the probability of absorption in the sodium, $P_a(\text{Na})$, is derived to be

$$(4) \quad P_a(\text{Na}) = 1 - E_2 \left[\Sigma_a(\text{Na}) t \right],$$

where

$$E_2(x) = \int_1^{\infty} e^{-x\lambda} \frac{d\lambda}{\lambda^2},$$

t = thickness of sodium layer (in cm),

$\Sigma_a(\text{Na})$ = macroscopic thermal-neutron absorption cross section for sodium
= $5.6 \times 10^{-3} \text{ cm}^{-1}$.

It was assumed that the angular distribution of the neutrons reaching the Inconel was still isotropic, and a similar expression was obtained for the Inconel, for which the macroscopic thermal-

neutron absorption cross section is 0.18 cm^{-1} . Then, for the Inconel,

$$(5) \quad \text{absorption rate in Inconel} = S[1 - P_a(\text{Na})] P_a(\text{Inconel}).$$

The capture gamma-ray source strength per unit volume was then calculated by using the dimensions given in ref. 1, the energy per capture given in ref. 3, and the assumptions given above. The macroscopic neutron absorption cross sections at average velocity at 700°C were calculated from values given in BNL-325.⁹

It was assumed that the gamma-ray source was constant in the Inconel. Also, because of the large radii involved, slab geometry was assumed for the source and for the mediums between the source and field points.

For a slab source and the buildup factor given in Eq. 2, the heating for monoenergetic gamma rays is given by

where

S = source strength (w/cm³),

μ_i = linear total gamma-ray cross section (cm⁻¹) for the i th slab,

t_i = thickness of i th slab (cm); $i=1$ designates the source region.

The spectrum of capture gamma rays from Inconel was divided into seven energy groups³ with average energies for each group of 0.5, 1, 2, 4, 6, 8, and 10 Mev. In calculating the heating in the shells adjacent to the Inconel source, the buildup factor for Inconel was used. Test calculations have shown¹⁰ that the heating is relatively insensitive to the type of buildup factor used for materials which have nearly the same equivalent Z . The heating in the beryllium reflector was calculated by using the buildup factor for beryllium. For the shells on the pressure shell side of the heat exchanger, the buildup factor for the

⁹D. J. Hughes and J. A. Harvey, *Neutron Cross Sections*, BNL-325 (July 1, 1955).

¹⁰H. W. Bertini, C. M. Copenhaver, and R. B. Stevenson, *ANP Quar. Prog. Rep.*, March 10, 1956, ORNL-2061, p 36.

heat exchanger was used. The heating at all field points was found by summing over the contributions of every energy group.

The self-heating of this Inconel shell for each energy group was calculated by using the expression

$$(7) H = \frac{q_{\mu_e}}{\mu} \left\{ 2 - \left(E_2(\mu t) + E_2 \left[\mu(t_0 - t) \right] \right) \right\},$$

where

- H = heating at t (w/cm^3),
- t = source strength of the shell (w/cm^3),
- μ_e = linear energy absorption cross section (cm^{-1}) of the Inconel shell,
- μ = linear total cross section (cm^{-1}) of the Inconel shell,
- t_0 = thickness of the Inconel shell (cm),
- t = distance from the surface of the Inconel shell (cm).

No buildup factor was used for this self-heating calculation.

Sample calculations were made in order to compare the heating from this shell when it was assumed to be a plane source with the heating when the shell was assumed to be a slab source; the results indicated a difference of 30% between the two values of the heating at a distance of 2.5 mean free paths from the source.¹⁰ Thus the approximation of a plane source was not used in this case.

The source strength of the gamma rays resulting from neutron captures in the boron of the copper-boron layer was calculated by assuming that all the neutrons leaving the reflector and escaping from the sodium and Inconel shell described above are absorbed at the front surface of the copper-boron layer. Actual calculations indicate that only 90% of the neutrons striking the layer are absorbed there, and they also indicate that the distribution of the sources of gamma rays would be the same as the distribution of heating by alpha particles, as illustrated in Fig. 1.2.2. The source strength of the gamma rays used for this calculation was therefore about 10% too high. It was assumed that there was a 0.48-Mev gamma ray associated with 93% of the absorptions.¹¹

¹¹F. Aizenberg and T. Lauritsen, *Rev. Mod. Phys.*, 24, 351 (1952).

The heating in the shells for this source was calculated by using Eq. 3. The buildup-factor parameters and the gamma-ray cross sections were evaluated at 0.5 Mev.³ The buildup factors used were the same as those used in the previous calculation of the sources in the Inconel shell outside the reflector.

The heating in the copper-boron layer by alpha particles from the $B^{10}(n,\alpha)Li^7$ reaction was calculated by using techniques similar to those used in estimating the neutron captures in Inconel. It was assumed that all neutrons escaping from the reflector, sodium, and Inconel were incident on the surface of the copper-boron layer with an isotropic angular distribution. By assuming slab geometry and by assuming that the neutrons make only first-flight absorption collisions, the probability of absorption at t per unit thickness in the i th constituent of the layer is given by the expression

$$(8) P_a = \sum_a^i E_1(\sum_a^T t),$$

where

- \sum_a^i = macroscopic thermal-neutron absorption cross section of the i th constituent,
- \sum_a^T = total macroscopic thermal-neutron absorption cross section of the copper-boron layer,
- t = distance from the front face of the slab (cm).

In this case the copper-boron layer was assumed to consist only of copper and B^{10} , and the atomic density of each was calculated for a matrix consisting of 16 vol % natural B_4C and 84 vol % copper.¹² The microscopic cross sections used were those for the average velocity at a temperature of 700°C, and they were calculated from the room-temperature cross sections given in BNL-325.⁹

The neutron absorption rate per cubic centimeter in B^{10} at t is given by

$$(9) S \sum_a^{B^{10}} E_1(\sum_a^T t),$$

where S is given in neutrons/cm²-sec impinging on the front face of the matrix. The heating resulting from neutron captures in B^{10} was calculated by assuming that in 93% of the absorptions in B^{10}

¹²A. M. Perry, ORNL, private communication to H. W. Bertini.

DECLASSIFIED

ANP PROJECT PROGRESS REPORT

a 2.32-Mev alpha particle is given off and that in the remaining 7% a 2.8-Mev alpha particle is given off.¹³ The heating from beta decay resulting from neutron captures in copper was calculated, and it was found to be negligible compared with the alpha-particle heating.

The gamma-ray heating resulting from the emission of decay gamma radiation in the heat exchanger was calculated on the basis of slab geometry by using Eq. 6 for each energy group. The spectrum of gamma rays was divided into the seven energy groups given in ref. 3, with average energies of 0.5, 1, 2, 4, 6, 8, and 10 Mev. The buildup factor for the heat exchanger was used for each energy group. The total heating at various points was calculated by summing over the contributions of each energy group.

The source strength of the gamma rays resulting from inelastic neutron scattering in the beryllium reflector was also calculated. These sources are appreciable only in the first 9 cm of beryllium. However, their contributions to the heating in the regions around the heat exchanger are small compared with those of the beryllium capture gamma-ray sources. The reason for this is that the gamma rays from inelastic scattering were taken to be 1-Mev gamma rays, which are attenuated much more strongly by the beryllium than are the 6-Mev capture gamma rays. In addition the total source strength of the gamma rays from inelastic neutron scattering is much smaller than that of the capture gamma rays because of the volumes of beryllium involved in each.

The source strength of the capture gamma rays resulting from delayed neutron captures was calculated by assuming that 50% of the delayed neutrons were given off in the heat exchanger and that all these neutrons were captured in the neighborhood of the heat exchanger. By assuming that an 8-Mev gamma ray was given off for each capture, the average source strength per unit volume was found to be small as compared with the other sources in this region.

The capture gamma-ray sources in the copper were calculated in the same general way that the alpha-particle heating in the copper was calculated, with the source converted to a surface source of gamma rays. In itself this is not an insignificant source, but the heating resulting from this source would be only about 2% of the total from all the sources considered here.

The gamma rays resulting from inelastic neutron scattering in the core shells were calculated by using the Curtiss-Wright multigroup fluxes⁵ and an inelastic microscopic cross section of 1.5 barns (ref. 13) for the constituents of Inconel. It was assumed that a 2-Mev gamma ray was given off for each inelastic collision. The results gave a source strength of about 10% of that resulting from the capture gamma rays in these shells.

As has already been remarked, the capture gamma rays in the island core shell were neglected because of the shielding properties of the fuel. Where it has not been stated otherwise, the dimensions used in these calculations were those from ref. 1 for the equatorial plane of the reactor.

RADIATION HEATING IN VARIOUS REGIONS OF THE NORTH HEAD

H. W. Bertini D. L. Platus¹⁴

Calculations of the radiation heating to be expected in various regions in the north head of the ART were undertaken in order to supply numbers from which thermal-stress calculations could be made. Because of the complexity and the time that would be involved in calculating accurately the heating in all the regions of the north head, it was decided to make preliminary estimates of the deposition rates. More accurate values calculated for other regions of the reactor were used as guides. In all cases the tendency was to overestimate the heating. These estimates can be used to identify the thermal-stress problems, and where the calculated thermal stresses are marginal, the heating will be recalculated.

Calculations were made of the heat-deposition rate in a slab of Inconel bounded on one side by an infinite fuel region containing the sources of radiation. This heat-generation rate was used in all regions in the north head which are bounded by finite fuel volumes.

The heat-deposition rates in a slab of Inconel bounded on one side by slabs of sodium of various thicknesses were calculated, and the results were extrapolated and interpolated to obtain the heat-generation rates in the Inconel regions of the north

¹³H. L. Taylor, O. Lönsjö, and T. W. Bonner, *Phys. Rev.* 100, 174 (1955).

¹⁴On assignment from USAF.

03729030

head which are bounded by various thicknesses of sodium.

Fairly accurate calculations have been made of the heat-deposition rates in the Inconel filler plates below the island and in the vicinity of the fuel-to-NaK heat exchanger on the equatorial plane of the reactor. These results were used as a guide in estimating the heating in some north-head regions, and new values were obtained by compensating (by simple exponential attenuation) for decreased beryllium thicknesses, penetrations through additional fuel layers, increased thermal-neutron leakage currents into the north head, etc.

A neutron current of 7×10^{13} neutrons/cm²-sec was assumed to be escaping uniformly from the upper portion of the core,¹⁵ and it was assumed that 1 Mw of fission power was being generated in the fuel regions of the north head by neutrons escaping into this region. The latter increased the gamma rays in the fuel by about 30%.

The sources of gamma radiation considered were those from the sodium and fuel in the north head, the heat exchangers, boron, the fuel in the core, core shells, beryllium, and Inconel shell capture gammas. The sources of beta particles considered were those from the gases in the fuel-expansion tank, and the sources of alpha particles were taken to be those from boron captures. The average values of heat generation obtained in these calculations are presented in Table 1.2.2. The configuration of the north head is shown in Fig. 1.1.5 of Chap. 1.1 of this report.

BETA- AND GAMMA-RAY ACTIVITY IN THE FUEL EXPANSION CHAMBER AND THE OFF-GAS SYSTEM

R. B. Stevenson¹⁶

The power-source distribution of the activity of the gases in the space above the fuel in the fuel expansion chamber and in the off-gas line has

¹⁵A. M. Perry, ORNL, private communication to H. W. Bertini.

¹⁶On assignment from Pratt & Whitney Aircraft.

¹⁷J. J. Newgard, *Fission Product Activity and Decay Heat Distribution in the Circulating Fuel Reactor with Fission Gas Stripping*, TMM-205 (Sept. 28, 1955).

been determined. The results obtained are to be used in the calculation of the radiation heating and the thermal stresses in this region of the reactor.

The radioactive constituents of the gas in this space are the gaseous fission products, xenon and krypton, and their daughter products. There is also a possibility that some volatile fission-product fluorides will be formed in the fuel and will escape into this area. However, it has been shown¹⁷ that if all the fission-product fluorides entered this space, they would add very little activity to that already caused by the gaseous fission products and their daughters. Thus, their effect has been neglected here. Also, there is some question as to whether the daughter products of the fission gases will actually be carried downstream by the off-gas system or whether they will be deposited on the enclosing walls as they are formed. In order to get a conservative estimate of the power-source distribution, it was decided to treat the daughter products of xenon and krypton as gases (except insofar as their purging from the fuel into the fuel expansion chamber is concerned).

The equilibrium amount of the gaseous fission products in the fuel expansion chamber is given by (approximately)

$$N_i = \frac{\gamma_i \lambda_p}{(\lambda_i + \lambda_p)(\lambda_i + \lambda_s)}$$

where N_i is the total number of atoms of type i in the gas volume per fission per second, γ_i is the saturation fission yield of the i th nuclide, λ_p is the "purging" constant, λ_s is the "sweeping" constant, and λ_i is the decay constant of the i th nuclide. The "purging" constant is determined by the volume flow rate of the fuel through the purging pumps and the total volume of fuel. This constant determines the amount of the gaseous fission products which are purged from the fuel into the expansion chamber. The "sweeping" constant is determined by the flow rate of helium through the expansion chamber and the volume of the gas space. This constant determines the dwell time of the radioactive nuclides in the gas space and thus the number of disintegrations they suffer there. The "purging" and "sweeping" constants are given by

$$\lambda_p = \frac{\text{volume flow rate of fuel through purging pumps}}{\text{total volume of fuel}}$$

$$\lambda_s = \frac{\text{volume flow rate of helium through expansion chamber}}{\text{volume of gas space}}$$

The power-source distribution of the radioactive nuclides is found by multiplying their equilibrium concentration by their decay constant λ_i and their average energy per disintegration.

The total power and the power density in the gas space of the fuel expansion tank as a function of the volume of the gas and the helium flow rate are given in Fig. 1.2.3. For these calculations, λ_p was taken to be 5.82×10^{-3} sec, which corresponds to a fuel flow rate of 22 gpm through the purging pumps. If the purging device is

assumed to be 100% efficient, this means that the reactivity effect of the xenon is reduced to about 0.1% at equilibrium.¹⁸ The sweeping constant, λ_p , is dependent on the helium flow rate and the gas volume, and thus it is different for each point on the curves. In converting the STP values of the helium flow rate, the temperature of the gas was assumed to be 1200°F, and the pressure in the expansion chamber and off-gas line was

¹⁸J. L. Meem, *The Xenon Problem in the ART*, ORNL CF-54-5-1 (May 3, 1954).

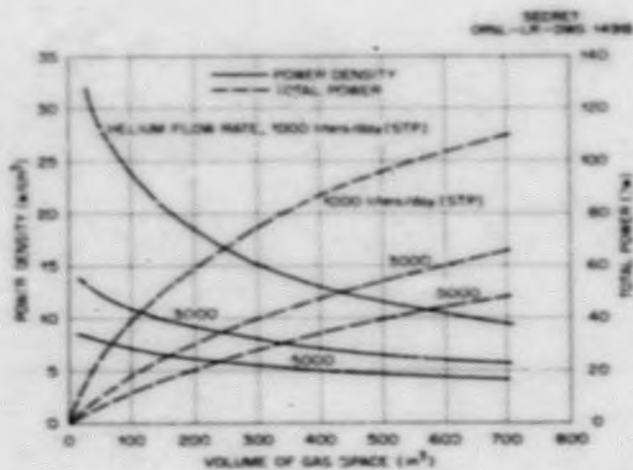

Fig. 1.2.3. Total Power and Power Density in the Gas Space of the ART as a Function of the Gas Volume and the Helium Flow Rate for a Fuel Flow Rate of 22 gpm.

taken to be 1.3 atm. The power of the reactor was assumed to be 60 Mw.

In the calculation of the curves, the very short- and very long-lived nuclides of xenon and krypton (along with their decay products) were neglected. Since the fuel circulation time in the ART is less than 3 sec, nuclides with half lives less than this value will decay mostly in the fuel before it reaches the purging pumps. Thus very few atoms with half lives less than about 3 sec would get into the gas space. Also, for nuclides with long half lives (greater than about 100 hr), the number of disintegrations taking place in the fuel expansion chamber and off-gas line would be small, since the dwell time at the assumed helium flow rates is very short. Thus, these nuclides may be neglected.

In this study, 32 nuclides were considered, 16 of these being isotopes of xenon and krypton and 16 being their daughter products. The main contributors to the power distribution are the daughter products and not the nuclides of xenon and krypton themselves. In all cases, the daughter products contribute about 50 to 60% of the total power distribution. Of the total power, about 90% is due to the beta-ray decays, with only 10% being due to gamma-ray decays. Thus, in determining the heating caused by these gases, it can be

assumed that the heat deposition will occur mainly in a small surface layer of the materials surrounding the gases in the fuel expansion chamber and the off-gas line.

The power density in the off-gas line as a function of time and gas volume for helium flow rates of 1000 and 3000 liters/day (STP) is given in Fig. 1.2.4. The time axis can be converted into lengths along the off-gas line by dividing the volume flow rate of the helium gas by the cross-sectional area of the off-gas pipe. Thus, Fig. 1.2.4 gives the power-source density of a cubic centimeter of the gas at any position in the off-gas line.

These plots were made by using the well-known equations of the decay of parent products and the buildup of their daughters as a function of time. The initial conditions at the beginning of the off-gas line were taken as the equilibrium conditions prevailing in the fuel expansion tank.

ACTIVITIES OF NIOBIUM, MOLYBDENUM, RUTHENIUM, AND THEIR DAUGHTER PRODUCTS AFTER SHUTDOWN

R. B. Stevenson

The activities of the materials which will plate-out on the walls surrounding the fuel channel in the ART during reactor operation will, along with other factors, determine how long a period must elapse before reactor disassembly can proceed. The activities of the various radioactive nuclides of niobium, molybdenum, and ruthenium, and their daughter products have been determined for 100 and 300 days after shutdown and for reactor operation periods of 500 and 1000 hr. These three fission products are expected to plate-out in large quantities, and therefore it has been assumed in this study that all the atoms of these elements created as fission products are plated-out. There is evidence that other fission products may plate-out; however, it is felt that the three taken into account here are the primary ones.

The only isotopes of these elements that need to be considered at times greater than 100 days after shutdown are Nb^{95} , Ru^{103} , and Ru^{106} . All the other isotopes have sufficiently short half lives that they will decay appreciably in this time, and thus they may be neglected. The only daughter products that will have large activities after shutdown for more than 100 days will be Rh^{103m} and Rh^{106} (daughters of Ru^{103} and Ru^{106} , respectively).

Fig. 1.2.4. Power Density in the Off-Gas Line as a Function of Time and Gas Volume in the Expansion Tank for a Fuel Flow Rate of 22 gpm.

The activities to be expected at shutdown and 100 and 300 days after shutdown for reactor operating periods of 500 and 1000 hr at 60 Mw are presented in Table 1.2.3, which also gives the average beta-ray energies, the gamma-ray energies, and the gamma-ray yields in photons per 100 disintegrations. It has been assumed that, at shutdown, the fuel is dumped instantaneously so that no more plating takes place. Also, the activities of Rh^{103m} and Rh^{106} are zero at shut-

down, since these nuclides are carried away with the fuel and have a chance to build up only when their precursors decay.

The gamma activity at 100 days after shutdown for 500 hr of operation at 60 Mw is approximately 2×10^5 curies, and at 300 days after shutdown, for the same operating conditions, it is about 8×10^3 curies. These high activities at times long after shutdown must be contended with in any disassembly procedure suggested for the ART.

TABLE 1.2.3. ACTIVITY OF PLATED-OUT MATERIALS IN THE ART AFTER 500 AND 1000 hr OF OPERATION AT 60 MW

Nuclide	Average Beta-Ray Energy (Mev)	Average Gamma-Ray Energy (MeV)	Gamma-Ray Yield (photons per 100 disintegrations)	Activity at Shutdown (curies)		Activity 100 Days After Shutdown (curies)		Activity 300 Days After Shutdown (curies)

1.3. ART INSTRUMENTS AND CONTROLS

E. R. Mann

C. S. Walker

LOUVER CONTROL SIMULATION

J. M. Eastman¹

F. P. Green

E. R. Mann

The ART simulator was used for further study of the problem involved in closing the main heat-dump louvers to prevent the fuel from freezing as the result of a fast insertion of the control rod. Improved transport-lag simulators were incorporated in the system. The control technique to be used will be that of closing the louvers to limit the minimum NaK temperature.

Two louver-closing speeds have been found to be necessary to keep the temperature of the NaK returning from the radiator from dropping below the fuel freezing temperature. One speed will automatically close the louvers from the open position to the 10% open position in 9 sec after a fast control-rod insertion. With the louvers at the 10% open position and with the four main blowers at design point speeds, 15 Mw of power will be removed.

The slow-speed louver actuators will operate on a temperature signal from the radiator outlets. When this temperature drops below 1070°F, the slow actuator will start to close the louvers. The slow actuator will be capable of closing the 10% open louvers in 3 sec.

For the simulation study it was assumed that all four blowers remained in operation, two being supplied from the TVA circuit and two from the diesel circuit. With the four blowers operating, a fast control-rod insertion will automatically shut off the power to one of the blowers on the TVA circuit and one on the diesel circuit. A power failure of either the TVA circuit or the diesel circuit would then leave only one blower in operation. The NaK-temperature undershoots would then be somewhat less, the overshoots somewhat more, and the ultimate cooling rate lower. Although this NaK-temperature limit system seems to be functionally acceptable, the system will be further explored on the simulator. The fail-safe characteristics are being studied, and modifications may be made which will require further simulator work for evaluation.

¹On assignment from Bendix Products Division.

LOUVER ACTUATOR

J. M. Eastman

Specifications for the louver actuators were established that are based on the following safety considerations: first, if the actuators should fail, the louvers must lock into the position they are in at the time of failure; second, the components which are not considered to be of first-order reliability must be located in an area accessible for repair without the NaK systems having to be cooled or drained; and, third, the over-all system reliability and dependability must be high. Since the actuators and any locally mounted associated equipment will not be accessible during the test, these components must be of first-order reliability. Hydraulic-actuator cylinders were selected. They will be operated in conjunction with spring-loaded clamps arranged to grip the actuator-output shafts. For steady-state louver conditions, both ends of the actuator cylinder will be vented to the hydraulic return, or drain. The louvers will be moved by valving hydraulic pressure to either end of the hydraulic cylinder. This pressure will be simultaneously vented to a piston which will release the spring-loaded clamp. The rate of louver movement will then be controlled by an orifice in the line through which return hydraulic fluid will flow from the cylinder to the drain.

The fast louver-closing rate will be obtained by opening an orifice in parallel with the one used for slow closing. The hydraulic pressure supply unit is to be located in an area accessible for repair work. Two pumps will be used that will operate in parallel and be driven from different electric power sources. They will be arranged so that one can be repaired or replaced without interrupting the fluid-pressure supply. Solenoid valves will be used for control of the hydraulic fluid. When not energized, these valves will hold the louvers fixed, and they will be energized to move the louvers. Low-viscosity hydraulic fluid and thin-plate orifices will be used so that the flow rates and the corresponding louver-actuation rates will be relatively insensitive to fluid temperature. Valves and orifices will be located near the hydraulic-power-supply unit in an area accessible for repair work.

ENRICHER ACTUATOR

J. M. Eastman

Specifications were also established for the actuator for the fuel enricher. The actuator is to consist of a gear-motor drive equipped to provide a multiple-synchro indication of the position of the enricher piston. Enrichment is to be at the rate of 1 lb of U^{235} in approximately 22.5 sec. Three synchros will be used to indicate 1, 10, and 150 lb of U^{235} per revolution. Thus the synchro dials will be read in gas-meter fashion to note the pounds of U^{235} displaced (equivalent volumetric measurement of enriched fuel mixture, Na_2UF_6) in terms of piston position.

Data obtained from calibration tests of the enricher during operation of the high-temperature critical assembly have been adjusted for changes in the geometry of the ART. The data indicate that the enriching uncertainty which will result from a fuel-meniscus effect at the spillover weir will be equivalent to approximately 4% of 1 lb of U^{235} . The enricher will be able to deliver about 130 lb.

FLUX SERVO SIMULATION

F. P. Green

E. R. Mann

C. S. Walker

The ARE micromicroammeter and servo amplifier were used in the preliminary simulation of the ART flux servo, but the system is unstable because of the faster reactor response that results from the lower delayed-neutron contribution. The latter effect is caused by the differences between the ART and the ARE in core-residence time of the fuel and in ratio of core-residence time to loop-flow time. The system is being studied to ascertain methods for correcting the instability.

CONTROL ROD AND DRIVE MECHANISM

S. C. Shuford²

The design of the control-rod drive mechanism was completed, and 95% of the parts to be supplied by vendors have been obtained. A mechanical shakedown test of the mechanism at operating temperature is planned. Ruggedness, reliability, and ease of servicing were the prime objectives in the design of the mechanism. A single rod that will operate in a thimble passage through the north head and down the center line of the island to

10 in. below the mid-plane is to be employed to furnish normal shim control for changing the fuel mean temperature and to provide for emergency reactor shutdown.

The neutron-absorbing section of the rod will consist of twenty-three 1-in.-long, 1.275-in.-OD, 0.775-in.-ID, rare-earth oxide (Lindsay Code 920) hollow cylinders. (The composition of these rare-earth oxide compacts and the fabrication methods used in producing them are presented in Chap. 3.6, "Ceramic Research.")

The cylinders are to be retained by Inconel inner and outer tubes with holes at the top and bottom to permit sodium permeation and communication with the stagnant sodium in the thimble. Heat generated in the rod will thereby be conducted to the cooled thimble wall.

The drive mechanism is to be powered by two, Diehl, 6-pole, 200-w, 2-phase, low-inertia servomotors. One motor will be bidirectional and is to be used for servo and manual control. It will give a rod speed of 0.01% ($\Delta k/k$)/sec. The other motor will be unidirectional and is to be used for fast insertion. It will give a rod speed of 0.125% ($\Delta k/k$)/sec. The fast-insertion motor will be energized through the safety circuit by the following emergency-condition signals:

1. any power outage,
2. fuel- or sodium-pump stoppage,
3. flux level above normal,
4. drop in fuel or sodium level,
5. a 3-sec reactor period.

The two motors will be connected through non-reversing worm gears on concentric shafts that will, in turn, supply power separately to the sun gear and to the arm of a differential gear box. This arrangement precludes the necessity for clutches or gear shifts. Both motors will be continuously capable of inserting the rod when either circuit or both circuits are energized.

A high-resolution potentiometer (0.1% linearity) will feed a strip-chart recorder to make a permanent rod-position record. A spare potentiometer and means for external switchover will be provided. It will be possible to read the rod position to 0.10 in. and to estimate it to 0.05 in. on the recorder chart.

Two independently driven synchro transmitters will be used for position indication. One will rotate 300 deg for full-rod stroke and the other will rotate one revolution per inch of stroke. Resolution from the two-synchro system will be approximately

²On assignment from Pratt & Whitney Aircraft.

DECLASSIFIED

ANP PROJECT PROGRESS REPORT

0.020 in. To minimize backlash and to prevent instrument pinion run-off (with attendant loss of synchronization), both the synchros and the potentiometers will be driven by a fine-pitch rack 1 in. longer than the power-transmitting rack.

Two plunger-sealed limit switches, which will operate through the motor control circuits, will be used to prevent rod overtravel at each end of the stroke, and one limit switch will be used for giving a 1% $\Delta k/k$ reserve indication for filling operations.

The drive mechanism, which will be coned, will be operated under a 15-psi helium pressure. The helium consumption will be limited to that lost in periodic venting of the container.

INSTRUMENT DEVELOPMENT

R. G. Affel

Thermocouple Data Reduction

J. T. DeLorenzo

W. R. Miller

Equipment suitable for transmitting 100 thermocouple signals on two conductors has been assembled and tested. As the simplified block diagram shows (Fig. 1.3.1), the input signals are

scanned by a high-speed mercury-jet switch. This switch is actually a centrifugal pump, driven by a motor, which directs a fine stream of mercury at adjacent pins to complete a circuit. Synchronization between the two switches is assured by driving them with synchronous motors that operate from the same power source. Such a system offers several advantages. For example, a large number of temperatures may be scanned, visually, on one large, 17-in.-screen oscilloscope; alarm or monitoring systems that scan several hundred readings a second are possible (available systems are limited to 1 point/sec or slower); temperature gradients or profiles on equipment may be directly displayed; essentially all time lag in the system lies in the sensor, and therefore transient studies are limited only by the sensors; commercial null-balance potentiometric recorders can be used with such a system.

The equipment being tested scans data at the rate of 2500 points/sec. Conventional, Brown, multipoint, strip-chart recorders have been modified to operate on the switch output, which is 30 pulses/sec, with each pulse 200 μ sec in duration.

UNCLASSIFIED
SARL-LR-DWG 1487

Fig. 1.3.1. Thermocouple Data Transmitting and Recording Apparatus.

Thus, even with an input signal only 0.006% of the time, the available, conventional equipment may be used in an integrated alarm or monitoring system.

Cell Bulkhead Penetrations

J. T. DeLorenzo

Fittings suitable for reactor cell penetrations for heater wiring, control wiring, chamber leads, and thermocouples have been examined. Preliminary specifications and drawings have been prepared for review, and a contract is to be negotiated with a vendor.

Fuel-Expansion-Tank Level Indicator

R. F. Hyland

Tests are under way to determine the practicability of using a helium bubbler to obtain a continuous fuel-level indication in the ART fuel-expansion tank in the temperature range 1100 to 1500°F with a varying pressure above the fuel. The tests were designed so that information could be obtained on whether the bubbler tubes would become clogged with fuel or ZrF_4 vapor deposits, to determine the minimum helium flow that would provide an accurate level measurement, to study the effect of changes in bubbling rate on the accuracy of measurement, to learn the response of the system to pressure surges, and to ascertain the accuracy of measurement.

The test apparatus consists of a conventional purge system that utilizes a constant-differential relay and purgometer to obtain constant flow and a pneumatic differential-pressure transmitter. One side of the pressure transmitter is tapped off the purge line, and the other side is connected to a gas-pressure tap above the fuel. The output of the transmitter is fed into a pneumatic recorder. The bottom of the bubbler tube is located exactly 5 in. from the surface of the fuel, and a spark plug is installed to provide a level reference when the rig is being filled. A reasonably accurate level indication is assured during filling by the spark-plug probe giving off a flickering light when the helium bubbles ripple the surface of the fuel. The vessel is maintained at a static pressure of 5 psig by venting off excess helium.

The accuracy and reproducibility of the level indications, as obtained by water calibration of the apparatus, was $\pm 2\%$ in the level range being measured. However, on fuel runs, errors of as

large as 0.43 in. of fuel in 5 in. (8.6%) and as small as 0.12 in. in 5 in. (2.4%) were noted. The average error appears to be of the order of $\pm 5\%$. This error can probably be accounted for by the fuel-density change with temperature, which is known to an accuracy of only $\pm 5\%$, difficulties in the precise placement of the bubbler tube and the spark plug, and the slight inaccuracy resulting from the use of a spark-plug probe to indicate the fuel level in the vessel.

It was found that a purge flow rate as small as 0.2 scfh of helium would yield consistent flow measurements, but the system response to pressure surges at this purge rate was sluggish. Purge rates of the order of 1.5 scfh (~ 1000 liters/day) of helium gave both consistent level measurements and fairly rapid system response to pressure surges. There is no observable change in level indication for any purge flow rate between 0.2 and 1.5 scfh.

On the basis of 1850 hr of operation of the apparatus in one run, it appears to be practical to measure fuel level at a fuel temperature of 1150°F by the helium-bubble method on a static system. There has not yet been a sufficient number of hours of a 1500°F test to evaluate the results of level indication at this higher temperature.

High-Temperature Pressure Transmitters

W. R. Miller

Pressure transmitters manufactured by four different vendors have been evaluated in tests in the temperature range 1000 to 1400°F. Three of the four units tested operated similarly. They were of the force-balance type that requires an external gas supply to maintain a zero pressure differential across a bellows or diaphragm. The fourth unit utilizes a diaphragm-isolated, NaK-filled tube system in which the NaK hydrostatically transmits the applied pressure to an external, low-temperature, displacement-type transducer. The tube-system units were found to have 0.6%, or better, average accuracy. Accordingly, orders have been placed for 81 of these units. Development work is continuing on other types of pressure transmitters, including electrically operated devices.

High-Temperature Turbine-Type Flowmeter

G. H. Burger

A high-temperature turbine-type flowmeter has been developed for measuring flow in fused-salt

ANP PROJECT PROGRESS REPORT

and in NaK systems at high temperatures. This type of flowmeter does not require penetrations to the process fluid, and it gives very accurate flow-rate data.

The flow-sensing unit, shown in Fig. 1.3.2, consists of an Inconel turbine, or rotor, supported by titanium carbide bearings, and flow-straightening vanes of Inconel, which, in turn, support the turbine bearings. The fluid enters the vanes and then impinges on the turbine blades and causes the turbine to rotate. The turbine contains, within its body, a small cobalt vane, which has the unique property of retaining its magnetic characteristics at temperatures up to 2100°F. A permanent magnet assembly is used outside the piping to establish a uniform magnetic field perpendicular to the axis of rotation of the turbine and the cobalt vane contained therein. A pickup coil, with a large number of turns, is mounted so that it intercepts the magnetic lines of flux of the magnet. When the

turbine is rotated by the fluid, the cobalt vane rotates and cuts the lines of flux of the magnet; this changing flux generates a voltage in the pickup coil. Thus, the number of pulses per unit time is a direct measure of the turbine speed, which, in turn, is a linear measure of the flow rate. The speed of the turbine (in counts, or pulses, per second) can be measured quite readily by using appropriate standard electronic equipment, such as a linear rate meter or scaler. Since the turbine speed is a linear function of the flow, the flow rate (in gpm) can be plotted against counts (pulses) per second. This device is not dependent upon pressure, temperature, or specific gravity but is dependent upon viscosity. The viscosity effect, which causes turbine "drag," is not appreciable, however, at viscosities below 5 cp. A water-calibration curve of turbine speed vs flow rate is presented in Fig. 1.3.3. Calibration of this type of flowmeter with water is valid for the fused-salt fuel mixtures.

UNCLASSIFIED
PHOTO 36144

Fig. 1.3.2. ORNL-Designed Turbine-Type Flowmeter for Flow Measurements in the Range 2.5 to 50 gpm at Temperatures Up to 1600°F.

Fig. 1.3.3. Water-Calibration Curve for a Turbine-Type Flowmeter.

Experimental models of the turbine-type flowmeter are being tested in gas-fired forced-circulation loops. The flowmeter is welded into the pump-discharge section of the loop, and the magnet assembly is cooled with plant air to keep the pickup coil at a low temperature. The experimental results obtained thus far indicate that the principle of operation of the turbine-type flowmeter is sound and valid for high-temperature operation. The cobalt vane has been satisfactory at temperatures up to 1400°F and should be satisfactory at 1600°F. Information is to be obtained in further tests on bearing corrosion and self-welding and on bearing tolerances at various temperatures. It is felt that after sufficient operating data are obtained, a satisfactory design can be worked out for scaling the flowmeter to any desired size. It is further believed that this method of flow measurement can be made accurate to within 1%, which is much better accuracy than is attainable with the conventional magnetic flowmeters used on liquid-metals systems. The magnetic flowmeters specified for use on the 3.5-in., sched-40 pipe in the ART NaK system must be calibrated individually to achieve 4% accuracy at a flow rate of 1200 gpm. In the larger, 10-in. pipe, the magnetic flowmeters can give accuracies of only about 12% at 8000 gpm.

1.4. COMPONENT DEVELOPMENT AND TESTING

H. W. Savage

PUMP DEVELOPMENT

E. R. Dytko¹

A. G. Grindell

Bearing-and-Seal Development

W. L. Snapp¹W. K. Stair²

The maximum operating temperature expected in the lubricating and cooling fluid used in the ART reactor pumps is approximately 220°F. For an operating period of 500 hr, with an oil dilution factor of approximately 0.03, the integrated radiation dose absorbed by this pump lubricant is calculated to be 3×10^8 rep. Therefore it will be possible to use a lubricant with a mineral-oil base for the ART pumps.

Since a petroleum product could not be used if the operating conditions given above became more severe, tests were continued³ in an effort to find a liquid more suitable for higher performance. Important factors affecting the choice of liquid are compatibility with the materials of construction (that is, elastomers) and process fluids, radiation stability, thermal stability, heat removal capacity, and lubricating properties. The loads that will be imposed on the pump bearings will be light, and therefore the lubricating properties are of only secondary importance. The other considerations listed are all of primary interest and are closely interrelated.

After the failure of the UCON fluids to perform satisfactorily,³ the next synthetic liquid investigated was an organic-phosphate-based material manufactured under the trade name "Cellulube" by the Celanese Corp. of America. Cellulube 150 was the particular grade selected for evaluation testing, since it most nearly approximated the operating properties of the liquids previously tested.

The initial test of Cellulube was made at a temperature of 210 to 220°F in a fuel pump (model MF) rotary element in a mechanical shakedown test stand. Over the entire operating period of 636 hr, the leakage of the lower seal was too small to be measured. The total leakage of the upper seal was

430 cm³. The unit was disassembled after this 636-hr period of satisfactory operation, and inspection revealed fully developed uniform wear patterns on both seals. However, the wear path on the upper seal rotor exhibited a ring, which, upon examination, proved to be a copper deposit. Although it was known that Cellulube would attack copper at high temperatures, attack was not expected at the operating temperature of this test.

With the exception of the upper seal, which was replaced entirely, the unit was reassembled, installed in the same stand, and operated under the same conditions for an additional 480 hr. During this period the operation was, again, completely satisfactory, with the total leakage of the upper seal being 70 cm³. Since all the leakage occurred during the first 24 hr of operation, it may be considered as "run-in" leakage. The lower seal leakage totaled 40 cm³ for the 480-hr period. This low leakage rate is particularly significant because, when seals tested with other fluids were disassembled, inspected, reassembled, and tested again, with the same fluid, the retest leakage rates were always higher than those measured initially. Inspection of both seals after the test revealed a very light reflective film of copper on all surfaces exposed to the Cellulube.

A second test of Cellulube, again at a temperature of 210 to 220°F, was conducted on a model MF fuel pump rotary element mounted in a bearing-and-seal test stand which permitted the application of transverse shaft loads. The total operating time was 595 hr, with an equivalent journal bearing load of 150 lb being applied for the last 504 hr. The journal bearing, which was designed for a load of only 70 lb, suffered no measurable wear, and seal performance throughout the test was satisfactory. Both the upper and the lower seals had well-developed wear patterns, with a very slight trace of copper plating visible on all sealing surfaces. It should be noted that all the copper plating experienced during the testing of Cellulube was far less than that resulting from operation with the UCON fluids,³ and it did not appear to have a marked effect on seal performance.

All the elastomer O-ring seals used in the Cellulube tests had a Buna-N base. Such compounds have a tendency to swell, become tacky,

¹On assignment from Pratt & Whitney Aircraft.

²Consultant, affiliated with the University of Tennessee.

³W. L. Snapp and W. K. Stair, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 43.

ORNL-2061

and lose their hardness in the presence of Cellulube. These particular problems could be solved by using O-rings made from butyl rubber, but, unfortunately, butyl rubber suffers severe radiation damage. Tests to determine the radiation stability of Cellulube are planned for the near future.

Dowtherm A, which is a good heat transfer medium but which has poor lubricating properties, was also selected for study because it is relatively stable upon exposure to radiation. Dowtherm A is a eutectic mixture containing 26.5% diphenyl and 73.5% diphenyloxide that is manufactured by the Dow Chemical Co. of Midland, Michigan. The only test run to date was terminated after 575 hr due to a motor failure. There was no transverse load applied during the test. The Dowtherm A operating temperature was 210 to 220°F. Both seals had well-developed wear patterns. The upper seal showed no leakage after the first 4 hr. The lower seal had no leakage for the first 150 hr, at which time it began to leak at a nearly uniform rate of 20 cm³/day. Upon examination, the lower seal rotor was found to have a light copper deposit. This is contrary to the information provided by Dow. The system used for this test had previously been operating with Cellulube, and, although it was carefully and thoroughly cleaned, it is possible that some Cellulube may have remained and caused the plating. This problem will be investigated in future tests.

The process side of the seal nose had a black, gummy deposit, which proved to be virtually all carbon. Since there was no evidence of physical damage to the Graphitar seal nose, it is probable that this deposit was the residue from Dowtherm A which thermally decomposed in leaking across the seal interface. Again, all the elastomer O-ring seals used had a Buna-N base, and they were not compatible with Dowtherm A. This difficulty can be overcome by using natural rubber, which should be adequate from a radiation standpoint. The only difficulty with the natural rubber may be its thermal stability, which will be determined in future testing.

A test stand is now available for testing the elastomeric compounds recommended for O-rings in a thermally hot environment in contact with various lubricants. These tests are now under way and results should be forthcoming soon.

As originally designed the reactor pumps utilized, as the upper bearing, a spherical roller type of

antifriction bearing. In addition to providing ample thrust and radial load-carrying capacities, this type of bearing permitted shaft alignment with respect to the journal bearing without attendant shaft deflections. This design appeared to be adequate until tests of long duration on pump rotary elements revealed that the initial bearing end play of 0.0045 in. (maximum) had increased by a factor of 2 to 3. Such excessive end play is not conducive to good dynamic seal performance and it also interferes with the close axial tolerances required in these pumps. The easiest solution to this problem, with respect to minimizing pump redesign, was to change to a double-row angular-contact bearing having convergent angles of contact. This has been done and, to date, all performance has been satisfactory. However, more operating time will be necessary to prove the reliability of the redesigned bearing arrangement.

A temporary impasse has been reached in the development of seals for the NaK (primary and auxiliary) pumps. All the seals purchased for comparative testing have failed in operation. The seal obtained from the Sealol Corporation failed because the unhardened stainless steel wear ring rotor and the mating carbon ring wore out in less than 20 hr. The ceramic rotor of the seal obtained from the Durametall Corporation disintegrated upon application of a 70°F temperature differential to the lubricating oil. An attempt to correct this condition will be made by utilizing a thin ceramic facing on a steel-bodied rotor. The Byron Jackson Co. seals never developed full wear patterns, even after runs in excess of 300 hr. This condition apparently resulted from distortion of the relatively thin rotor. At no time during test operation with any of these seals was a satisfactory leakage rate established. Therefore efforts are being made to adapt a seal configuration similar to that being used on the fuel and sodium pumps. In addition, other promising types of commercially available seals will be investigated.

Pump Lube-Oil System Gas-Attenuation Tests

S. M. DeCamp

The leakage tests of the seals on the model MF-2 fuel pump, started previously,⁴ were continued with Gulfspin 60 oil being used as the lubricant. For these tests the temperature of the

⁴S. M. DeCamp, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p. 48.

DECLASSIFIED

system was 1000°F, the temperature of the lubricant was 160°F (max), the pump speed was 2400 rpm, and the gas pressure in the system was 5 psig. There was no liquid in the main pump loop. The seal leakage data were obtained by bleeding 550 liters of helium through the pump into the loop system each day and at the same time bleeding 500 liters of argon into the loop system directly. Fifty liters of gas was bled from the pump catch-basin drain each day and 1000 liters of gas was bled from the pump loop system. Gas samples were taken by evacuating a glass container and then filling it through a line connected to a sample joint. The sample joints were at the catch-basin drain, the off-gas line from the loop system, and the gas space over the lube-oil reservoir. The samples were analyzed spectrographically for argon, helium, oxygen, and nitrogen. The appearance of argon in a sample taken at the catch-basin drain was an indication that the argon had back-diffused up the annulus between the pump shaft and shield-barrier plug. The appearance of argon in the sample taken at the lube-oil reservoir gas space was an indication that the argon was leaking across the lower pump seal. The data obtained from this test are presented in Table 1.4.1.

During the tests it became apparent that the control of the small gas flow rates and low pressures was more difficult than had been anticipated and that the adequacy of the method of gas sampling was questionable. Therefore the data presented in Table 1.4.1 give only qualitative indications of the leakage. Future seal leakage tests will be made by bleeding argon down the pump shaft and using helium as the trace gas. This should improve the accuracy of the data obtained spectrographically. The masking effect of air will also be less. The sampling technique will be improved by continuously bleeding gas through the sample bottles to eliminate the possibility of drawing gas from regions other than the sampling points.

Fuel Pump Endurance Tests

S. M. DeCamp

An endurance test of an ART fuel pump (model MF) was started on April 10, 1956 with the fuel mixture (No. 30) NaF-ZrF₄-UF₆ (50-46-4 mole %) as the pump fluid. The first 1488 hr of operation of the system is described here. The operating conditions are indicated on Fig. 1.4.1, which gives the system temperatures, oil flow rates, and seal

ANP PROJECT PROGRESS REPORT

leakage as a function of operating time. The speed of the pump was maintained at 2400 rpm during the period described by Fig. 1.4.1. In addition to the temperature fluctuations shown on the graph, the temperature of the system was cycled 17 times between 1300 and 1100°F. It takes approximately 1½ hr to lower the temperature to 1100°F and 2½ to 3 hr to increase it to 1300°F. The lubricating oil being used in the system is Gulfspin 60. Helium is being bled down the pump barrel at a rate of 550 liters/day, and 50 liters/day is bled off through the catch-basin drain. Present indications are that low leakage rates and satisfactory removal of seal oil leakage from the catch basin can be obtained.

Thus far very little trouble has been experienced in the operation of this pump. The hydraulic-drive equipment has functioned satisfactorily, except for some trouble with the hydraulic pressure indicator.

Fuel Pump Development Tests

J. J. W. Simon⁵

The two loops designed⁶ for high-temperature performance testing of the ART fuel pump and centrifuge assembly were completed and are being used for development tests. Water performance data were taken on these loops to determine whether the addition of the xenon-removal system would have an effect on pump performance.

The head and flow curves obtained for these loops substantiated the original water-test data.⁷ During the tests it became apparent, however, that the system pressures were not stable. The fluctuations in system pressure appeared to be a function of the water level in the fuel expansion tank and the loop resistance. In some instances these fluctuations appeared to be large enough to be detrimental to reactor operation.

Two types of modification will be made to the system in an attempt to locate and remove these fluctuations. First, the pump suction inlet conditions will be improved, and, second, the xenon-removal system will be altered to study the effects of each of the various flow passages.

Sodium Pump Endurance Tests

S. M. DeCamp

Preliminary water tests of a sodium pump that had been installed in a test stand for endurance

testing indicated that leakage, or bypass flow, around the impeller was causing ingassing of the system. The pump and the loop were therefore modified, as described in the following section, by providing a pressure-breakdown labyrinth along the shaft and by removing the bypass vanes from the back face of the main impeller. The system is now being prepared for high-temperature operation. As in the fuel pump endurance tests, described above, seal leakage tests will be run before the system is filled with the test fluid.

Sodium Pump Development Tests

S. M. DeCamp

The original design of the ART sodium pump (model MN) called for the bypass flow around the main impeller to be from the expansion tank to the pump discharge. This was to be accomplished with the aid of vanes on the back side of the main impeller. During the first series of tests of this pump, however, it became evident that the system was ingassing. In an effort to correct this situation the bypass flow was reduced by reducing the vane diameter on the back of the impeller, but ingassing still occurred. It was decided then to reverse the direction of bypass flow, that is, to allow the flow to be from the pump discharge to the expansion tank. This flow condition allows the gas bled down the pump shaft to flow to the expansion tank in the same direction and through the same opening as that through which the bypass liquid flows. This reversal of flow was accomplished by completely removing the bypass vanes from the back of the sodium impeller. The amount of reversed bypass flow was restricted by adding a pressure-breakdown labyrinth around the shaft. Tests of the modified pump indicate satisfactory operation. Tests are now under way to determine whether the expansion tank and the bypass flow lines can handle reactor bypass flow requirements without ingassing of the system fluid. The best sodium pump performance data obtained to date are presented in Fig. 1.4.2.

Primary NaK Pump Development Tests

H. C. Young⁸

J. G. Teague⁹

M. E. Lockey

Water tests on the primary NaK pump (model PK-P) volute and impeller, initiated previously,⁷ were completed. The final performance curves which show head vs flow, efficiency, and the volute pressure balance line at several constant speeds from 1225 to 3550 rpm are presented in Fig. 1.4.3, and a plot of pump shaft horsepower vs flow for the same head and flow conditions is shown in Fig. 1.4.4. The original test design point of 1220-gpm flow and a 340-ft head has been changed to 1220-gpm flow over the head range indicated by the vertical line on Fig. 1.4.3. The volute hydraulic balance line crosses this head range at approximately the mid-point, and thus the normal operating conditions appear to be in the range of acceptable hydraulic balance.

Tests were run at speeds above 2900 rpm by using a 200-hp wound-rotor motor, which was replaced with a 60-hp d-c motor in order to obtain

⁸On assignment from Pratt & Whitney Aircraft.

⁹H. C. Young and M. E. Lockey, ANP Quaterly Progress Report, March 10, 1956, ORNL-2061, p 4B.

data at the lower speeds required for reactor startup operation.

In order to determine the correct volute-tongue angle, a directional probe was installed in the volute at the periphery of the impeller to measure the angle at which fluid left the impeller. The data obtained indicated that the original tongue angle was correct.

A weir was installed in the pump pot to measure leakage flow through the labyrinth seal around the impeller hub. Some leakage flow is needed to remove gas from the system fluid; however, excessive leakage, particularly at low liquid levels, would cause agitation of the liquid level in the pump pot and possibly result in ingassing through the pump suction. A series of three tests was conducted in which the radial clearance between the impeller hub and the top labyrinth seal and the axial clearance between the dynamic seal vanes on the back of the impeller hub and the stationary element were varied. Bypass flow was measured during these tests, and the pumped fluid was observed through Plexiglas parts in the loop. There was no visible indication of ingassing. The tests showed the optimum axial clearance to be

DECLASSIFIED

Fig. 1.4.3. ART Primary NaK Pump (Model PK-P) Performance Curves of Head vs Flow Showing Efficiency and Volute Pressure Balance Lines.

0.030 in. and the optimum radial clearance to be 0.015 in. These clearances will result in a bypass flow rate of 3 to 6 gpm at 1220-gpm pump-discharge flow.

Static deflection tests were made on the pump shaft used in the water test rig and on the Inconel pump shaft to be used in the final pumps. The information obtained, along with the calculated deflection of the Inconel pump shaft during high-temperature operation, indicated that a top labyrinth

seal radial clearance of 0.015 in. should be sufficient to prevent rubbing of the impeller hub against the top labyrinth seal.

These water tests of the primary NaK pump indicate that the pump will meet the head and flow conditions required for the ART. A pump tank gas pressure of 10 psig should be sufficient to suppress cavitation at the design flow rate and up to a NaK temperature of approximately 1380°F. The design conditions are in the range of minimum volute hydraulic unbalance.

SECRET

Fig. 1.4.4. ART Primary NaK Pump (Model PK-F) Performance Curves Showing Shaft Horsepower vs Flow.

Auxiliary NaK Pump Development Tests

H. C. Young J. G. Teague
M. E. Lackey

Water tests were conducted on the auxiliary NaK pump (model PK-A). The volute used for these tests consisted of two brass volute halves bolted together. The volute flow passage was accurately milled in each volute half. The test impeller was fabricated of brass, with vanes silver-soldered to the hub and soft-soldered to the inlet shroud.

The pump assembly was tested in the test loop used for the water tests of the primary NaK pump.⁹ A 60-hp d-c drive motor was used. No changes were necessary in the instrumentation, except that a new orifice was installed to measure the lower flow rates.

Performance and cavitation data were obtained for as wide a flow range as possible within the practical limits of volute hydraulic unbalance, and the final head vs flow curves are presented in Fig. 1.4.5. A plot of pump shaft horsepower versus flow for some head and flow conditions is shown in Fig. 1.4.6. The volute hydraulic unbalance over the design range was found to be quite satisfactory,

Fig. 1.4.5. ART Auxiliary NaK Pump (Model PK-A) Performance Curves of Head vs Flow Showing Efficiency and Volute Pressure Balance Lines.

and therefore this pump will be satisfactory for use as the special NaK pump for cooling the ART fuel fill-and-drain tank. This pump requires 300-gpm flow at a 275-ft head. The impeller diameter, the dynamic seal vanes, and the top labyrinth seal are the same as those for the primary NaK pump, and the speed ranges of both pumps are the same. Therefore the radial and axial clearances determined by the primary pump tests were used for the auxiliary pump. The pump showed satisfactory degassing characteristics with these clearances.

After the initial performance tests were completed, a 0.023-in. spacer was installed between the volute halves, and tests were conducted to determine whether the addition of the spacer would change the volute hydraulic unbalance. The purpose of these tests was to ascertain the allowable tolerances for use in welding the Inconel volute halves together.

The volute hydraulic unbalance was measured during these tests by eight static pressure taps equally spaced in the volute near the periphery of the impeller. The static pressure readings at any of the eight taps, for a given discharge head and a set flow rate, did not change over 1 psi from the measurements taken without the spacer.

In general, the water tests indicate that the pump will meet the head and flow conditions required for use in the ART, both for the auxiliary and the special NaK pumps. The design conditions are in the range of minimum volute hydraulic unbalance. Cavitation characteristics of the pump, based on extrapolations from water to NaK, indicate that a pump tank gas pressure of 14.4 psia, or -0.3 psig, should be sufficient to suppress cavitation at design flow for a NaK temperature of 1282°F, as compared with a required pressure of 6 psig for the primary NaK pump at the same NaK temperature.

Primary and Auxiliary NaK Pump Test Stands

H. C. Young J. G. Teague

Fabrication of all parts for two primary and two auxiliary NaK pump high-temperature test loops is under way. At present, the pump volutes are the most critical delivery item. A method of profile-machining the volute halves from a pattern is being used. Several primary pump volute halves have been received, and the vendor is now setting up for profile-machining of the first auxiliary pump volute halves.

A series of welding tests were conducted to determine the joint preparation and the welding

SECRET

Fig. 1.4.6. ART Auxiliary NaK Pump (Model PK-A) Performance Curves Showing Shaft Horsepower vs Flow.

ANP PROJECT PROGRESS REPORT

techniques required to control weld shrinkage so that final volute dimensions would be within acceptable tolerances (see Chap. 3.4, "Welding and Brazing Investigations"). The first set of primary pump volute halves has been welded.

In the first tests in the new loops the pumps will be operated with water in order to check the pump assembly, test-stand vibration, loop resistance, and operation of the system throttle valve, and, of primary importance, to correlate performance and cavitation data with the data previously obtained on the water-test rig.

Some engineering changes are being made in order to lengthen the piping on the primary NaK pump endurance-testing loop and also on the auxiliary NaK pump endurance-testing loop and to relocate these loops for use in calibrating electromagnetic flowmeters.

HEAT EXCHANGER DEVELOPMENT

E. R. Dytko

R. E. MacPherson

J. C. Amos

Intermediate Heat Exchanger Tests

J. W. Cooke

H. C. Hopkins

The information obtained from intermediate heat exchanger (IHE) test stand operation during the quarter is summarized in Table 1.4.2. York radiator No. 9, which is being tested in intermediate heat exchanger test stand A, is currently undergoing a thermal-cycling program consisting of 16 hr of power operation followed by 8 hr of isothermal operation. During the power phase of the cycle, the radiator NaK inlet and outlet temperatures are 1500 and 1100°F, respectively. Isothermal operation is at 1500°F. Transition from isothermal to power operation is accomplished by dropping the NaK outlet temperature at a rate of 20°F/sec for

TABLE 1.4.2. SUMMARY OF INTERMEDIATE HEAT EXCHANGER TEST STAND OPERATION

Test Unit ^a	Hours of Nonisothermal Operation	Total Hours ^b of Operation	Number of Thermal Cycles	Reason for Termination
Test Stand A

Circulating cold trap No. 5 (4 in. in diameter)		715		Test continuing

^aIncludes only units tested during this report period.

^bFor tests in progress the total operating time is shown as of May 15, 1956.

^cThis type of cold trap was previously referred to as 80-gal system.

the first 200°F and 8°F/sec for the next 100°F. The final 100°F drop is at a slower rate in order to allow the outlet temperature to level out properly. The transition from power to isothermal operation is accomplished at a rate of 10°F/sec for the first 100°F, 5°F/sec for the final 100°F. The radiator has been cycled 20 times, and the cycling program is continuing.

The air pressure drop data¹⁰ obtained for York radiator No. 9 substantially agree with the data for York radiators Nos. 1 and 2, and the heat transfer data substantially agree with the data¹⁰ for Cambridge radiators Nos. 1 and 2. Thus far the NaK pressure drop has increased 119% above the initial level (219% of the initial value). This radiator is the first 500-kw radiator of the revised design¹¹ to be tested, and it is identical to York radiator No. 7 illustrated in Fig. 1.4.8 of the subsequent section, "Small Heat Exchanger Tests," of this chapter.

ORNL heat exchangers Nos. 1 and 2, type IHE-3 (ref. 12), were removed from intermediate heat exchanger test stand B and are undergoing metallurgical inspection. Preliminary results of this inspection reveal that heat exchanger No. 1 (NaK-to-fuel heat exchanger) failed in the hot end between the header weld and tube bends (see Chap. 3.4, "Welding and Brazing Investigations"). Severe corrosion was evident on the fuel side of the tubes. Five tubes had obvious cracks in the tension side. The frequency and severity of the cracks were most pronounced in the end row of tubes where the distance between the tube bends and header was the shortest. A maximum of 15 mils of mass-transferred deposit was measured on the NaK side of this heat exchanger (Fig. 1.4.7). No evidence of mass transfer was detected in heat exchanger No. 2 (fuel-to-NaK heat exchanger). Mass transfer buildup would account for the NaK pressure drop increase experienced during nonisothermal operation. Pressure drop was not measured in the individual heat exchangers. However, if it is assumed, on the basis of the mass-transfer evidence, that all the pressure-drop increase occurred in heat exchanger No. 1, the total pressure drop

increase for this heat exchanger was approximately 180%.

Black, Sivalis and Bryson Nos. 1 and 2 heat exchangers, type IHE-3, were installed in test stand B, and test operations were resumed. The stand is currently operating on a constant-power endurance run to provide corrosion information for comparison with the data for ORNL heat exchangers Nos. 1 and 2. During shutdown of the test stand, instrumentation was added to allow separate measurements of heat exchanger pressure drop. After 362 hr of power operation, the NaK pressure drop has increased 140% in heat exchanger No. 1 (NaK-to-fuel). No increase has occurred in heat exchanger No. 2. Cambridge radiators Nos. 1 and 2, which have operated for 820 hr under nonisothermal conditions, have experienced a NaK pressure drop increase of 84%. A tabulation of the NaK pressure drop variations that have occurred in the various heat exchanger tests is presented in Table 1.4.3.

Construction work on stand C, to be used as an ART prototype radiator test stand, is continuing.

^cThis type of cold trap previously referred to as 80-gal system.

and York radiator No. 4 were removed from the stand for metallurgical examination.

Heat transfer data, fuel pressure drop data, and NaK pressure drop data for the heat exchanger were in substantial agreement with data previously reported¹⁰ and did not change throughout the test. The radiator heat transfer data substantially agreed with the data for ORNL radiator No. 3, and the air pressure drop data substantially agreed with the data for Cambridge radiators Nos. 1 and 2, all previously reported.¹⁰ The radiator NaK pressure drop increased approximately 30% during the test operation. Much of the test program on these

units consisted of thermal cycling operations. A complete cycle consisted of 16 hr of power operation, with maximum and minimum NaK temperatures of 1275 and 1005°F, respectively, and 8 hr of isothermal operation at 1285°F. The rate of NaK temperature change during the transition from one condition to the other was approximately 7°F/sec. The heat exchanger log-mean temperature difference changed from 0°F during isothermal operation to 74°F during power operation.

York radiator No. 7 (Fig. 1.4.8) and Process Engineering Co. heat exchanger No. 1, type SHE-2, were installed in stand B, and test operations were

Fig. 1.4.8. York Radiator No. 7 (Revised Design).

resumed. A new, 4-in.-dia cold trap was installed in this loop. This cold trap is identical to the previously used cold traps except that the copper cooling coil has been replaced by a stainless steel coil and additional thermocouple wells have been provided to determine the temperature profile in the cold trap. Operation thus far has been devoted to cold-trap evaluation under simulated ART operating conditions.

Operation of small heat exchanger test stand C was terminated after 634 hr when ORNL heat exchanger No. 2, type SHE-2, developed a high resistance to fuel flow during power operation. This heat exchanger was replaced by Struthers-Wells Corp. heat exchanger No. 1, type SHE-2, and test operations were resumed. When heat transfer conditions were initially established, this heat exchanger also began to develop a high resistance to fuel flow, similar to that experienced by ORNL heat exchanger No. 2. At this time, a leak developed in the resistance heater and the stand was

shut down. The resistance heated section was removed for metallurgical examination.

Examination of ORNL heat exchanger No. 2 disclosed extensive buildup of metal particles throughout the fuel side of the heat exchanger that would account for the marked increase in resistance to fuel flow. It is felt that examination of Struthers-Wells heat exchanger No. 1 will reveal the same condition but to a lesser degree. Evidence of mass transfer and self-welding in certain areas of the resistance heater indicated that extreme hot spots had occurred in the heater. This would account for the buildup of metal particles in the heat exchanger. A section of the resistance heater at which severe overheating occurred is shown in Fig. 1.4.9. The metal particles which built up on one of the heat exchanger tubes are shown in Fig. 1.4.10.

A new heater design has been completed, and a heater is being fabricated. The test stand is currently being operated as a NaK loop to obtain

Fig. 1.4.9. Section of Resistance Heater Removed from Small Heat Exchanger Test Stand C Showing Effects of Overheating.

cold-trap-evaluation data. Upon receipt of a new 25-tube small heat exchanger (type SHE-7),¹⁴ the Struthers-Wells heater exchanger No. 1 will be replaced, and the test stand will be put back into full operation.

Cold-Trap Evaluation in Heat Exchanger Test Stands

J. C. Amos

Six similar 4-in.-dia circulating cold traps have been operated in the various heat exchanger test stands. These cold traps were previously referred to as 80-gal-system circulating cold traps.¹⁵ It

has been found that care must be exercised during initial cold-trap operation to prevent oxide plugging during main system heatup. The original design specified copper cooling coils which necessitated maintaining the cold-trap temperatures below 700°F at all times to prevent excessive oxidation of the copper. This meant that at system temperatures above 800°F, with high contaminant saturation levels (800 to 1100°F), it was possible to precipitate material in the economizer which tended to settle out and plug the cold-trap inlet line.

One cold trap with a stainless steel cooling coil has been tested. This trap was brought up to 1200°F with the main system. The temperature of the trap was then gradually reduced by supplying maximum air cooling and reducing the cold-trap NaK flow. By using this method of startup, no indication of serious plugging was observed. No

¹⁴J. C. Amos, L. H. Devlin, and J. G. Turner, *ANP Quar. Prog. Rep. Dec. 10, 1955*, ORNL-2012, p. 49.

¹⁵F. A. Anderson and J. J. Milich, *ANP Quar. Prog. Rep. Sept. 10, 1955*, ORNL-1947, p. 54.

Fig. 1.4.10. Fuel-Side Wall of Tube Removed from ORNL Fuel-to-NaK Heat Exchanger ORNL No. 2, Type SHE-3, Showing Mass-Transferred Metal Particles. (Secret with caption)

difficulty with cold-trap circuit plugging has been encountered with any of these cold traps during routine loop operation after initial heatup by the procedure described here.

In all cases, the cold traps have been capable of reducing the NaK contamination level of a 77-gal NaK system to less than 100 ppm and, in several instances, to below 50 ppm, as determined by a plugging indicator. All cold traps tested on 18-gal NaK systems have been capable of reducing the contamination to below 50 ppm and, in most cases, to below the sensitivity of the plugging indicator (<30 ppm).

A longer period of time is required to clean up a 77-gal system than an 18-gal system. The cleanup time appears to be related to the surface area in the system, and it is appreciably reduced when a large percentage of the system surface area has previously been cleaned at maximum system temperature. The rate of cleanup appears to increase with an increase of flow through the cold trap. The available cold-trap cooling limits the NaK flow through the cold traps to approximately 1.5 gpm while maintaining a 300°F cold-trap outlet temperature with a system temperature of 1500°F. Therefore, the effects of cold-trap flow rates of above 1.5 gpm have not been studied. The minimum attainable contamination level has been found to be dependent on the minimum attainable cold-trap temperature.

However, these two variables are not necessarily closely related. In some instances the equilibrium plugging temperature of the plugging indicator may be as much as 400°F above the minimum cold-trap temperature, while, in other instances, this difference may be less than 100°F.

At operating temperatures above 1350°F the contamination level has been found to increase rapidly when the system temperature is increased to beyond the temperature at which the system was previously cleaned. Sudden variations in system operating conditions, such as flow stoppage or abrupt flow changes, also appear to increase the contamination level. After a system has been cleaned at the maximum system temperature, there is slow contamination buildup if the cold trap is turned off. However, this increase appears to become slower with system age.

Cold-trap evaluation tests are continuing on the heat exchanger stands in an attempt to obtain quantitative data regarding the effects of cold-trap NaK flow, cold-trap temperature, rate of cooling, etc. Various methods of cold-trap operations are being investigated under simulated ART operating conditions to establish an operating procedure for the ETU and ART cold traps.

AUXILIARY COMPONENT DEVELOPMENT

D. B. Trauger

J. J. Keyes

Dump Valve

L. P. Carpenter

Prototype dump valve No. 2 was tested to determine its adequacy for use as the dump valve between the reactor and the fuel fill-and-drain tank in the ART. The variables investigated were seat leakage, self-welding of seat materials, and galling of the stem on the stem guides. Seat leakage requirements are less than 2 cm³/hr with a 90-psig differential pressure across the valve. The valve temperature during power operation is expected to be 1250°F.

The seat materials were the same as those for prototype valve¹⁶ No. 1, that is, Kennametal 152B (64% TiC-30% Ni-6% NbTaTiC₂) for the plug and Kennametal 162B (64% TiC-25% Ni-5% Mo-6% NbTaTiC₂) for the seat ring. Prototype valve No. 2 differed from valve No. 1 in that the stem-to-stem-guide clearance was increased from 0.001 to

¹⁶L. P. Carpenter, J. W. Kingsley, and J. J. Milich, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 40.

0.005 in. on the diameter and a 30-deg conical bevel was ground on the seat ring.

The valve was tested for seat leakage at 1200°F in the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %). The minimum leakage rate obtained was 2.13 cm³/hr, with a 5-psig differential pressure across the seat and a valve stem thrust of 1200-lb force, which gave an estimated seating pressure of 12,000 psi. Failure of the seat ring braze occurred when the valve was opened after having been closed for 72 hr with the above mentioned force applied to the stem. Examination of the seat ring and plug revealed that self-welding had occurred, and the seat ring had pulled from the valve at the brazed joint. The brazing technique has been revised for future valve fabrication. There was no evidence of galling of the stem guides, such as that which occurred in the tests of prototype valve No. 1.

Prototype valve No. 3 has been received from the manufacturer for testing. The flame plating on the stem cracked during a stress-relief operation, and the leakage past the seat, as measured with helium, increased. The valve will be accepted, however, for seat material testing.

Cold Trap and Plugging Indicator

R. D. Peak¹⁷

The cold-trap evaluation test stand, previously described,¹⁸ has been operated only intermittently because of continual equipment difficulties. Two different types of plugging indicators were tested, and the results correlated poorly with the data obtained with the Argonne sampler, described previously.¹⁹ Two methods have been tested for cooling the cold trap with air, but it is apparent that air cooling alone is insufficient. A combination of air with water injection and, finally, full water flow should achieve the low-temperature cold-trap operation desired for the ART systems. Other methods of cooling are being investigated.

The second cold-trap evaluation test stand was completed, and will be placed in operation soon. This test stand is much more versatile than the first stand, in that several means have been provided for sampling and for recontaminating the NaK with the various impurities of interest.

Zirconium Fluoride Vapor Trap

M. H. Cooper²⁰

The program for the development of a trap for zirconium fluoride vapor has included an investigation of high-temperature adsorbents for ZrF₄, a determination of the plugging temperature of ZrF₄ in helium in equilibrium with the fuel as a function of the fuel temperature, and the testing of prototype traps. High-temperature adsorbents were tested by passing helium partially saturated with ZrF₄ through a 1-in.-dia pipe packed for 24 in. with the test material. The temperature of the test section was controlled by clamshell heaters. From the trap, the helium flowed first through water bottles to collect any residual ZrF₄, through wet-test gas meters, and then to the atmosphere. The results of these tests are summarized in Table 1.4.5. Alumina is the most promising adsorbent tested, while UF₄, which has not yet been tested, may also prove satisfactory, since ZrF₄ and UF₄ form a solid solution with a high melting point. Charcoal, when used in a trap, enhanced the formation of ZrF₄ nuclei, which grew into large individual crystals. Charcoal thus may be a suitable packing for a thermal trap, since the formation of individual crystals does not plug the trap. Suitable operating conditions have not yet been established for charcoal traps.

The saturation temperature of ZrF₄ in helium in equilibrium must be known in order to design the fuel off-gas system of the ART for temperatures which will prevent the precipitation of ZrF₄. A schematic drawing of apparatus for determining the plugging temperature of ZrF₄ in helium passing through 1/2-in. tubing is shown in Fig. 1.4.11. In each run, helium was bubbled through the molten fuel mixture at a measured temperature, and the helium became saturated with ZrF₄. The helium and ZrF₄ vapor then passed through a section of 1/2-in.-dia tubing extending through a hole in the center of a stainless steel block which was 6 in. in diameter and 10 in. long. The entrance face of the stainless jacket was heated by a Calrod heater and the rest of the trap, except the exit face, was insulated to provide a linear thermal gradient. The temperature of the tube at the point where the ZrF₄ first precipitated was assumed to be the plugging temperature of ZrF₄ corresponding to the fuel temperature. The

experimental plugging temperatures obtained as a function of fuel temperature, as well as the saturation temperatures predicted from both ORNL and Battelle Memorial Institute vapor pressure data, are given in Fig. 1.4.12. The experimental plugging temperatures agree to within 5% with the temperatures predicted from the vapor-pressure data. The experimental plugging temperatures and the predicted temperatures differ because the helium was not actually saturated with ZrF₄ in the experiments.

Two prototype vapor traps, of the type described previously,²¹ have been tested. Prototype trap No. 2, which was connected to the fuel pump of intermediate heat exchanger test stand B and was cooled by natural convection and radiation, plugged

²¹J. J. Milich and J. W. Kingsley, ANP Quart. Prog. Rep. Dec. 10, 1955, ORNL-2012, p. 66.

with entrained fuel after 12 hr of operation. The pump off-gas line had been installed to closely approximate one designed for the ART. The fuel entrainment indicated the need for redesign of the off-gas line. Prototype trap No. 3, which is water cooled and mounted on a fuel sump through which helium is bubbled, was placed in operation on April 27. The pressure required to maintain the helium flow at 3.0 liters/min increased from 3.0 psi to 5.0 psi in 50 hr. There was no further rise in the pressure required to maintain the flow until the test was terminated after 420 hr. Two layers of ZrF₄ were found in the trap entrance just upstream of the tube header. The first layer was rather dense and amorphous, and the second layer was more porous and crystalline. A total of 984 g of ZrF₄ was found in the layers, which totaled

2 3/4 in. in thickness. The weight of ZrF_4 was only 30% of the amount that would have vaporized if the helium had been saturated with ZrF_4 . The dense deposit found in this trap near the inlet renders the design unsuitable for the ART.

OUTER CORE SHELL THERMAL STABILITY TEST

R. Curry²²

A. M. Smith

The first test of the one-quarter-scale model of the lower half of the outer core shell²³ was terminated after the completion of 57 thermal cycles, because a sodium leak developed in the loop piping near the test piece. It was decided to partially examine the shell before continuing the test. The center island was cut loose and lifted out of the housing assembly to expose the inner surface of the shell for inspection. A dye check of the inner

²²On assignment from Pratt & Whitney Aircraft.
²³D. W. Bell, ANP Quater. Prog. Rep. Sept. 10, 1955, ORNL-1947, p 51.

surface revealed no cracks or other flaws. X-ray photographs taken through the shell wall and the thick outer housing wall likewise did not indicate cracks or flaws, but it is judged that this inspection technique was not sufficiently sensitive to reveal hairline cracks, if such existed, on the exterior surface of the core shell.

The internal contour of the shell was mapped by centering the shell on a lathe and measuring 264 radii. For these measurements, 15 axial stations $\frac{1}{2}$ in. apart were designated. The radius was then measured for each 30 deg of rotation from an assigned zero position at the eight stations nearest the small-diameter end. At the seven stations nearest the large-diameter end, the radius was measured for each 15 deg of rotation from the zero position. The measurements obtained were compared with measurements taken after the initial machining of the model. It was found that the average radius at each station in no case differed from the original radius by more than 0.012 in. At no station did the spread from minimum to maximum radius exceed 0.021 in., and the average spread for the 15 stations was 0.014 in. The "crests" and "valleys" in a plot of radius vs rotation indicated that the basic deformation at each axial station was from circular to elliptical or pear shaped. This comparison between final and initial shape is invalid to some degree, because the initial measurements were taken before the shell was welded at each end and installed into the outer housing.

The shell is now back in the test rig and it is to be cycled a total of 300 cycles or to failure. Parts are being fabricated for a second 300-cycle test on another core-shell model.

FORCED-CIRCULATION CORROSION AND MASS-TRANSFER TESTS

W. B. McDonald

Fused Salts in Inconel and Hastelloy B

J. W. Kingsley P. G. Smith
A. G. Smith²⁴

Nine forced-circulation loops, seven fabricated of Inconel and two of Hastelloy B, were operated with fused salts as the circulated fluids during

²⁴On assignment from Pratt & Whitney Aircraft.

this quarter. The operational data for these loops are summarized in Table 1.4.6. Eight of these loops were electrically heated and one (loop 4935-6) was heated with a natural-gas furnace. Two of the Inconel loops circulated a new fuel mixture (No. 70) NaF-ZrF₄-UF₄ (56-39-5 mole %), and the Hastelloy B loops circulated the fuel mixture (No. 107) NaF-KF-LiF-UF₄ (11.2-41-45.3-2.5 mole %). All other tests were made with the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %). Other parameters investigated were operating temperature of the fluid, surface-area-to-volume ratio, temperature differential, and Reynolds number. When completed, the results of metallurgical examinations of the loops are reported in Chap. 3.1, "Dynamic Corrosion Studies."

The first Hastelloy B loop failed during attempts to put it into operation. Therefore no corrosion data were obtained, but valuable information pertaining to the engineering, fabrication, and operation of Hastelloy B loops was obtained. As a consequence, the second Hastelloy B loop operated satisfactorily for the scheduled 1000 hr.

The one gas-fired loop was terminated at 8319 hr as a result of a leak in the cooled section. This leak occurred while the cooled section was being thawed out after a freezeup which occurred when the pump-drive unit failed.

Liquid Metals in Inconel and Stainless Steel

J. W. Kingsley P. G. Smith
A. G. Smith

Twelve forced-circulation loops were operated with sodium or NaK as the circulated fluid, and one was operated with water. Ten of these loops were electrically heated and three were heated by natural-gas furnaces. The operational data for these loops are summarized in Table 1.4.7. The three loops that are heated by gas furnaces are being operated as life tests. Small centrifugal pumps (model LFB) are used on the gas-heated loops; the other loops that circulate liquid metals have electromagnetic pumps. The model LFB centrifugal pump was used on the loop that circulated water.

When completed, the results of metallurgical examinations of the loops are reported in Chap. 3.1, "Dynamic Corrosion Studies."

SECRET

1.5. PROCUREMENT AND CONSTRUCTION

W. F. Boudreau

ART FACILITY

F. R. McQuilkin

Construction work is nearing completion on the contract portion of the Aircraft Reactor Test (ART) facility in Building 7503. Package 1 work on the building additions, building alterations, and cell installation was approximately 7% behind schedule at the 92.5% completion point on June 1, 1956. About one-half the deficiency may be accounted for by lack of breakers and reactors for the electrical switchgear. During the quarter the principal work accomplished included final erection of the cell tanks; erection of the stack; placement of concrete for the main air duct, the penthouse, the radiator pit, the blower house floor and equipment bases, the cell encasement, and the main building floor at an elevation of 852 ft; painting; grading; fencing; and general job and site cleanup.

Package 2 work on the installation of diesel generators and facility, electrical control centers, and spectrometer-room electrical and air-conditioning equipment progressed to the 79% completion point during the quarter. The installation of the electrical control centers and the diesel generators will complete this work. The estimated date for shipment of the diesel generators is June 25, 1956.

The contract for Package A work on the installation of auxiliary piping was negotiated with the V. L. Nicholson Company at a contract price of \$50,351.62, with completion scheduled for June 15, 1956, unless material delivery schedules interfere.

Some of the Package 1 and Package 2 work may be seen in Fig. 1.5.1, which is a view from a location southwest of the building. The dark-sided portion of the main building is the addition which will house the reactor cell, the heat dumps, and the spectrometer tunnel. The appurtenances to the main building shown in this view are, from left to right, the generator house, blower house, vent house, and stack. In front of the vent house can be seen the top portion of the 10-ft-dia and 23-ft-deep concrete tank that will contain the water-submerged off-gas piping.

The west and north faces of the main building and the generator house may be seen in Fig. 1.5.2. On the left may be seen the newly installed 32-ft-

wide door that is required in order that the reactor and the tops of the cell tanks may pass into the building. The cylinder bank in the left foreground, which served as helium storage for the Aircraft Reactor Experiment (ARE) will be used for storage of nitrogen for the ART. In the foreground, in front of the truck, may be seen the 1500-kva transformer and substation that will serve the purchased power (TVA) portion of the power service to the facility. The openings in the generator house, on the right, will receive the radiators for the five diesel generators that will have 300-kw continuous ratings and will supply the locally generated power service to the facility. In Fig. 1.5.3 may be seen the pressure vessel and water tank that make up the containment cell. The 24-ft-dia, 36-ft-high pressure vessel is within the 30-ft-dia water tank. The top portion of the water tank had been removed and was sitting on the main floor when the photograph was taken. Although the pressure vessel manhole is 5 ft in diameter and will pass most of the items to be installed within the vessel, the contractor will remove the top head to provide the required access for the reactor. The pressure vessel was field stress-relieved and hydrostatically tested at 300 psi during the quarter. Inspection of the welded joints between the 24-in.-dia junction panel sleeves and the 4-in.-thick shell walls revealed a failure of a joint in the heat-affected zone of the sleeve base metal. Therefore all eight of the one-piece sleeves were replaced with two-piece units and a revised joint design and welding procedure was used. The field stress-relief procedure and the hydrostatic pressure tests will be repeated.

The concrete penthouse adjacent to the cell is shown in Fig. 1.5.4. This structure will house the NaK pumps, pump motors, and the mechanisms for supporting these units and the radiators, and will also house the NaK piping to the main air duct and to the radiator pit below. The special equipment room is directly below and covered by the roof plugs shown in the open doorway.

Design work continued on Package 3, which comprises the process equipment, process piping, etc. to be installed by ORNL. The design will probably be completed in July 1956.

for assembling other parts of the reactor. Of particular concern in these studies are the problems caused by weld shrinkage during assembly. Recent data obtained from test weldments (see Chap. 3.4, "Welding and Brazing Investigations") have shown the need to modify some assembly techniques originally considered for the reactor in order to control the dimensions of the final assembly. Stress problems which will occur in handling components during assembly have also imposed restrictions on assembly methods and are now being evaluated with respect to their effect on the techniques.

Virtually all of the long-delivery materials for the reactor assemblies have been ordered, but actual fabrication of most items has been delayed by lack of firm drawings.

A review of the design indicated the need for flow tests on the reflector-moderator and island

assemblies. While the extent of this test program has not been clearly defined, it is expected to cause a significant delay in the completion of the reactor assembly.

As stated above, construction of the ART is being accelerated with respect to construction of the ETU. A calculated risk is being taken that the ETU will not show a need for correction of the ART reactor, and thus the ART reactor will be assembled as soon as possible after the ETU assembly is completed. Parts for a third reactor are being procured as insurance against excessive time loss if the risk fails.

Fabrication of the north head of the ETU has been started. Some delay has occurred because of redesign, and welding progress appears to be slower than anticipated. Delays in the receipt of the sodium-to-NaK heat exchanger and some forged parts may hold up work on this item. All

ANP PROJECT PROGRESS REPORT

the necessary information for two of the six Inconel shells is available, and Lycoming is expediting work on these two shells. Additional design information is still needed for the remaining shells, but mandrels are being rough machined for producing them.

The beryllium reflector for the ETU is being machined by The Brush Beryllium Co., but some information on this item is still lacking because of design modifications. The island holes are now being drilled at ORNL and the island will be sent to The Brush Beryllium Co. for contouring when this operation is completed.

The heat exchanger suppliers are still studying assembly methods and techniques for fabricating the channel sections of the fuel-to-NaK heat exchangers. Potentially, this equipment still appears to be one of the controlling factors in the assembly schedule.

Orders for the boron carbide tiles and boron-copper cermets have been placed with the Norton Company and the Allegheny Ludlum Steel Corp., respectively. A fabricator has not yet been selected to form the boron-copper cermets into the desired shapes.

Fabrication of the heavy 1-in.-thick pressure shells, which must be specially formed, will re-

quire equipment that is not widely available. Because of the special dies which will be required, the delivery of these heavy shells may also affect the reactor completion date.

Knapp Mills, Inc., has been selected as the supplier of the lead shielding, which will be preformed and bolted to the reactor. It is proposed that only the side pieces be mounted on the ETU because of space and time considerations. No design drawings are available to describe the water shield, but it is anticipated that this, too, will be prefabricated.

A number of jigs and fixtures for use in assembly have been designed and are being procured. These include fixtures for assembling the reflector-moderator, assembly and checking fixtures for the main heat exchangers, templates and a gage for checking the shells, and several handling devices.

An area in Building 9201-3 is now being modified for use as a reactor assembly area. The area will be enclosed and air-conditioned, and it will be serviced by an overhead crane. It is anticipated that the area will be ready for use when the first reactor parts arrive in August.

1.6. ART, ETU, AND IN-PILE LOOP OPERATION

ART OPERATING MANUAL

W. B. Cottrell

An Operations Committee, consisting of representatives of the physics, design, control, engineering, construction, and operating groups, was formed for the purpose of preparing an Operating Manual for both the ART and the ETU. Thus far, the efforts of the committee have been directed toward the preparation of the ART operating procedures, which, in first rough-draft form, is about 20% complete. Since the ETU is to serve as a proving ground for the ART, the ETU operating procedures will subsequently be adopted from the ART operating procedures and will include other tests which may be desired.

The bases for the operating procedures are the experimental objectives of the ART, the reactor design, the reactor characteristics, as determined from simulator data, and the flow diagrams and instrumentation lists for the various systems. The information being used in the formulation of the procedures is presently available in the form of design memorandums and data sheets, reports prepared by staff members, and minutes of design and Operations Committee meetings.

The manual is to provide detailed procedures, including check lists, for all operations beginning after the installation of the ART equipment and terminating with the orderly shutdown of the reactor. As presently outlined the manual will include a check list of equipment and detailed procedures for cleaning the ART, for loading the NaK systems, for heating the reactor, for loading the sodium and fuel systems, for shakedown checking the fluid systems, for enriching the fuel, for operating at low power (10 to 100 w), for operating at intermediate power (2 to 20 Mw), for operating at high power, and for terminating the test.

By detailed consideration of procedures, the Committee has found incompatibilities in the performance of some system components and limitations in the design of others which would impair operation during unscheduled shutdowns. These difficulties fall into two categories: those which will require design changes to permit operation and those which will not require changes but which will restrict the method of operation. Pro-

posed design modifications for resolving these difficulties are currently being evaluated.

IN-PILE LOOP DEVELOPMENT AND TESTS

D. B. Trauger

Operation of Loop No. 4

C. C. Bolta ¹	R. A. Dreisbach ¹
J. A. Conlin	W. T. Ferguson
C. W. Cunningham	D. M. Haines ¹
W. L. Scott	

In-pile loop No. 4, which was described in the previous report,² was cut from the shielding plug, and the nose end is being sectioned for metallographic examination. This loop was operated for a total of 501 hr, including 316 hr at the maximum design temperature differential of 200°F and 80 hr at lower temperature differences. The high-temperature point in the loop was maintained at 1500°F throughout the periods of operation with a temperature differential imposed on the system. The loop was operated under isothermal conditions at lower temperatures during the remaining 105 hr, while the reactor was shut down for refueling and for other maintenance. The power density in the loop was 778 w/cm³ during operation with the maximum temperature differential, as determined from the heat removal through the heat exchanger and the total volume of fuel in the nose from the heat exchanger outlet to inlet.

Functionally, the loop operation was good. The heater circuits, which had better insulation than the insulation used for the heater circuits of loops tested previously, were free of failure. The pump operated smoothly throughout the test, and controls for the heat exchanger and other components were satisfactory. However, 7 of the 14 nose thermocouples failed in operation, either by the junction coming off the pipe or by breakage of one of the wires (usually the Chromel wire). These failures are now believed to have been caused by poor installation techniques. Six of the seven

¹On assignment from Pratt & Whitney Aircraft.

²C. C. Bolta et al., ANP Quin. Prog. Rep. March 10, 1956, ORNL-2061, p 41.

thermocouple lead wires which failed had, inadvertently, been clamped rigidly to the end of the outer wall of the double-walled heat exchanger. This could have resulted in strains on the thermocouple wire from the thermal expansion of the pipes. The loop design has been modified to correct this condition.

As with loop No. 3, both the bearing-housing and the pump-sump purge outlets plugged. The bearing purge outlet plugged five days after startup, and the sump purge outlet plugged four days later. The cause of this plugging is still being investigated. The fission-gas absorption traps from loop No. 3 have been sectioned. An extensive black deposit was found in the inlet of one and a brownish film was found in the other. This black deposit, believed to have come from the pump lubricating oil in the bearing housing, is to be given radioassay and spectrographic analysis to determine its composition (see Chap. 4.2, "Radiation Damage"). It is planned to operate future loops with little or no purging of the bearing housing and reduced purging of the pump sump to minimize the probability of plugging. Previously, the higher purging rates were considered necessary to minimize hydraulic-motor-oil contamination. Experience indicates that, although some contamination results from operating with the purges plugged, such contamination is not a serious problem during disassembly.

Other major difficulties encountered were a leak in the pump bulkhead, probably through a glass heater or thermocouple-wire seal, and an excessive radiation level in the cubicle after shutdown. A new type of electrical seal for the pump bulkhead is being investigated. The excessive activity of the cubicle after shutdown was caused by the deposition of material on the purge-outlet-tube walls during operation. Radiation levels as high as 50 r/hr were measured on the $\frac{1}{2}$ -in. pump-purge-outlet tube. This caused considerable difficulty in loop removal because it necessitated a relatively large amount of preparatory work. The design has

now been modified so that all tubes may be pinched leak-tight, cut, and removed remotely to make possible the removal of the activity prior to the entry of personnel into the cubicle. The only work which will require entry to the cubicle will be the removal of the air and water lines.

Loop No. 5

D. M. Haines

In-pile loop No. 5 was completed and inserted in the MTR, but could not be filled. This loop was to have operated for the duration of two MTR operating cycles with a maximum fuel temperature of 1600°F and a temperature differential of 200°F. The improved thermocouple installation mentioned above was used in the fabrication of this loop, and the rear section was modified to simplify removal and to provide a second hermetic seal to back up the seal at the intermediate bulkhead to prevent fission-gas leakage. The loop is being returned to ORNL for salvage.

Horizontal-Shaft Sump Pump for In-Pile Loops

W. S. Karn³

An improved prototype (Mark II) of the horizontal-shaft sump pump designed for in-pile loop operation completed 1000 hr of a 2000-hr endurance test at 4500 rpm and 1500°F. The test was terminated by shaft seizure, and disassembly showed that the seizure was caused by the buildup of zirconium fluoride on the shaft slinger. This was the first pump operated at 1500°F, the previous pumps being operated at 1400°F. The vapor pressure of zirconium fluoride in the fuel mixture (No. 44) NaF-ZrF₄-UF₆ (53.5-40-6.5 mole %) used in this test is 2 mm Hg at 1400°F and 4.5 mm Hg at 1500°F. The increase in vapor pressure is considered to have been the cause of the buildup of zirconium fluoride on the slinger. A new pump is to be built with increased clearances at the slinger.

2.1. PHASE EQUILIBRIUM STUDIES¹

C. J. Barton

R. E. Moore

R. E. Thoma

H. Insley, Consultant

The several methods described in previous reports of this series were used for further phase equilibrium studies of a variety of binary, ternary, and quaternary systems. Although the phase diagrams are not considered to be final in every respect, a compilation of the diagrams of binary systems consisting of UF_4 or ZrF_4 with each of the alkali fluorides is presented here. The striking differences observed in the diagrams for these systems indicate a need for detailed study of some of the complex crystal structures that characterize certain of these materials.

The $RbF-ZrF_4$ and $RbF-UF_4$ systems now appear to be moderately well described. A thermal effect in the $RbF-ZrF_4$ system at $375^\circ C$ that was previously reported to be a eutectic temperature has been shown to be a lowered inversion temperature of the $2RbF-ZrF_4$ compound; the eutectic contains 42 mole % ZrF_4 and melts at $410^\circ C$.

Solvents with compositions near 35 mole % NaF , 25 mole % RbF , and 40 mole % ZrF_4 apparently dissolve up to 4 mole % UF_4 at liquidus temperatures below $480^\circ C$ and up to 7 mole % UF_4 below $510^\circ C$. Such mixtures are of interest as reactor fuels.

Detailed examinations of some ternary systems containing BeF_2 are being made. While extremely low melting points can be obtained (the lowest eutectic observed to date in the $NaF-LiF-BeF_2$ system melts at $318^\circ C$), it is not yet apparent that these materials offer fuel mixtures that are substantially better than those available in the ZrF_4 -containing systems.

Studies of the phase behavior of CeF_3 in binary systems with alkali fluorides have been continued. These systems are of interest because of concern over the behavior of fission-product fluorides in high-power long-duration reactor operation.

GENERAL COMPARISONS OF THE BINARY SYSTEMS $MF-ZrF_4$ AND $MF-UF_4$

R. E. Thoma

The two parallel families consisting of binary systems of UF_4 and of ZrF_4 with each of the alkali metal fluorides have been under investi-

gation here for several years, and the characteristics of these systems are relatively well known. In the course of this research many people have contributed to an understanding of these phase relationships, and the information on phase behavior is scattered throughout a large number of reports in this series. Accordingly it has seemed worth while to prepare a brief summary of the differences and similarities in these several phase systems. No attempt has been made in this concise compilation to give credit to those who did the work.

Both these families of binary systems are much more complex than a cursory examination would indicate.² It is obvious that fundamental studies of the structures of the complex compounds involved would be of general value. The large number and wide variety of complex compounds observed in these systems are indicated in Table 2.1.1. (The ratios shown are the ratios of the alkali fluoride component to the ZrF_4 or the UF_4 component.) Comparisons of the phase diagrams presented in Figs. 2.1.1, 2.1.2, and 2.1.3 display several of the striking characteristics of these materials.

A stable, congruent, high-melting-point compound (Fig. 2.1.1) with the formula $3MF-ZrF_4$ or $3MF-UF_4$ characterizes all the diagrams, except those for $LiF-UF_4$ and $NaF-UF_4$. For the $LiF-UF_4$ system, which represents the lowest ratio of radius of M^+ ion to radius of M^{4+} ion, the 3:1 compound does not exist; for this system, and this system alone, an incongruent compound $4LiF-UF_4$ is observed. In the $NaF-UF_4$ system the compound $3NaF-UF_4$ is congruent but relatively low melting, and it is unstable at temperatures below about $530^\circ C$.

¹The petrographic examinations reported here were performed by G. D. White, Metallurgy Division, and T. N. McVay and H. Insley, consultants. The x-ray examinations were performed by R. E. Thoma and B. A. Soderberg, Materials Chemistry Division.

²The case of the related system $KF-ThF_4$ is similar. The early concept of the system reported by E. P. Dergunov, *Doklady Akad. Nauk S.S.S.R.* 60, 1185-1188 (1948), was a simple one, but a more recent report by W. J. Asker, E. R. Segnit, and A. W. Yllie, *J. Chem. Soc.* 1952, 4470, shows the system to be relatively complex.

- * (c) Congruent compound.
 (l) incongruent compound.
 (M) Metastable compound.
 (S) Subsolidus compound.

A series of incongruent compounds, $2MF \cdot ZrF_4$ and $2MF \cdot UF_4$, are observed in all the diagrams, except those containing LiF. The compound $2LiF \cdot UF_4$ does not exist, and $2LiF \cdot ZrF_4$ has a relatively low melting point but is congruent. All the incongruent $2MF \cdot ZrF_4$ and $2MF \cdot UF_4$ compounds, except the $2NaF \cdot UF_4$ material, melt to form the compounds $3MF \cdot ZrF_4$ or $3MF \cdot UF_4$ and liquid.

The low-melting-point central portion of the binary mixtures, that is, the mixtures with 35 to 55 mole % ZrF_4 or UF_4 , as shown in Fig. 2.1.2, exhibits many variations in compound types. The occurrence of the unusual compound $7MF \cdot 6ZrF_4$ or $7MF \cdot 6UF_4$ is remarkable. The compound has

the same crystal system wherever it occurs, and it displays no polymorphism. One member, the compound $7NaF \cdot 6ZrF_4$, forms an extensive interstitial solid solution series with the next lower ZrF_4 compound.

Compounds formed from mixtures with high concentrations of ZrF_4 or UF_4 are invariably incongruent, but they display wide variations in degree of incongruency. These compounds, as shown in Fig. 2.1.3, occur at widely varying compositions in the range 55 to 95 mole % ZrF_4 or UF_4 . Several of the diagrams in this series are considered to be preliminary, and the systems those diagrams depict are still being studied.

THE SYSTEM RbF-UF₄

H. A. Friedman R. E. Moore

The system RbF-UF₄ has been investigated recently because of its importance in the quaternary fuel system NaF-RbF-ZrF₄-UF₄. The earlier work of Blakely *et al.*³ has been largely confirmed by thermal analyses of slowly cooled melts. In addition to the compounds originally reported, however, there is an incongruent compound 7RbF·6UF₄.

Quenching experiments on the system are now under way, but the work is not yet far enough advanced to warrant presenting a phase diagram of the system. Petrographic examinations of a series of quenched samples containing 33.3 mole % UF₄ indicated that a rapid inversion of the compound 2RbF·UF₄ occurs at some temperature below 572°C. The congruent melting point of RbF·UF₄ (727°C) was confirmed by petrographic examination of a series of gradient-quenched samples containing 50 mole % UF₄. The composition of an incongruent compound previously thought to be RbF·4UF₄ has now been established as RbF·3UF₄ by the observation of single-phase material in a series of equilibrated and quenched samples containing 75 mole % UF₄. This phase is not stable above 714°C. In mixtures containing between 50 and 100 mole % UF₄, two phases, in addition to RbF·3UF₄, have been observed in both slowly cooled and quenched samples. One phase contains more than 80 mole % UF₄, while the other phase contains between 50 and 66.7 mole % UF₄.

THE SYSTEM RbF-ZrF₄

R. E. Moore

Several revisions have been made in the tentative diagram presented previously for the RbF-ZrF₄ system.⁴ The revised diagram is given in Fig. 2.1.4.

Visual observation experiments have shown that the eutectic between 2RbF·ZrF₄ and 5RbF·4ZrF₄ contains about 42 mole % ZrF₄ and melts at about 410°C. Results of quenching experiments had indicated previously that the eutectic contained

³J. P. Blakely *et al.*, ANP Quar. Prog. Rep. June 10, 1951, ANP-65, p 87, Fig. 4.1.

⁴H. A. Friedman and R. J. Shell, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 72, Fig. 4.1.

38 mole % ZrF₄ and melted at 375°C. It is now apparent that 375°C is the lowered rapid inversion temperature of 2RbF·ZrF₄ rather than the eutectic temperature. In the region between 37 and 44.5 mole % ZrF₄, 2RbF·ZrF₄ appears optically to be like quench growth at all temperatures above the lowered inversion temperature. This accounts for the misinterpretation of the quenching data.

Petrographic examination of a series of samples containing 48.3 mole % ZrF₄ established that 5RbF·4ZrF₄ is the primary phase; the liquidus temperature is about 396°C, and the solidus temperature is 390°C. Thus, the eutectic between 5RbF·4ZrF₄ and RbF·ZrF₄ contains about 48.5 mole % ZrF₄ and melts at 390°C.

Examinations of slowly cooled preparations have shown the existence of a compound containing more than 50 mole % ZrF₄. This compound has been tentatively identified as RbF·2ZrF₄ by the observation of nearly single-phase material in a series of equilibrated and quenched samples containing 66.7 mole % ZrF₄. This compound melts incongruently to ZrF₄ and liquid at 447°C.

THE SYSTEM NaF-RbF-ZrF₄R. E. Cleary⁵ H. A. Friedman

A phase diagram of the fuel solvent system NaF-RbF-ZrF₄, based on thermal analysis of slowly cooled melts, differential thermal analysis, and quenching experiments, is shown in Fig. 2.1.5. Some of the compatibility triangles and quasi-binary mixtures were reported previously.⁶ The present status of the information on the compatibility triangles, eutectics, peritectics, and boundary curves is shown in Fig. 2.1.5. The locations of the eutectics and the exact paths of the boundary curves are not considered to be final in this diagram; they are contingent on confirmation by quenching experiments.

The phase relationships of the recently discovered compound RbF·2ZrF₄ in the ternary system have not yet been determined. The ternary compounds of the solvent system are: NaF·RbF·ZrF₄, which melts congruently at 615°C; 3NaF·3RbF·4ZrF₄, which melts incongruently at 450°C; and NaF·RbF·2ZrF₄, which melts congruently at 460°C. A fourth ternary compound with

⁵On assignment from Pratt & Whitney Aircraft.

the approximate composition 3NaF·3RbF·2ZrF₄ may exist at high temperatures. Quenching studies have not yet established temperature limits on its stability. Preliminary quenching studies show that the compound 3NaF·3RbF·4ZrF₄ melts incongruently to NaF·RbF·ZrF₄ and liquid. The optical and x-ray data for the compound are presented in the following section.

OPTICAL PROPERTIES AND X-RAY PATTERNS FOR 3NaF·3RbF·4ZrF₄

R. E. Thoma H. Insley

Listed below are the identifying characteristics of 3NaF·3RbF·4ZrF₄, a new compound encountered in the phase studies described above. The symbol $d(\text{\AA})$ means the distance between reflecting planes measured in angstroms. The term I/I_1 refers to the relative intensity of the lines as compared with an arbitrary value of 100 for the strongest

line. Under optical properties, N_O and N_E refer to the ordinary and extraordinary indices of refraction of uniaxial crystals. The compound is believed to form an incomplete solid solution with the compound NaF·RbF·2ZrF₄.

THE SYSTEM NaF-RbF-ZrF₄-UF₄H. A. Friedman H. Davis⁷

Two areas of the quaternary system NaF-RbF-ZrF₄-UF₄ offer mixtures which may be suitable fuels for circulating-fuel reactors. Solvents with approximately 10 mole % NaF, 52 mole % RbF, and 38 mole % ZrF₄ with the addition of 4 mole % UF₄ give a fuel with a liquidus temperature of approximately 500°C. With the addition of 7 mole % UF₄ a fuel with a liquidus temperature of approximately 545°C is obtained. These fuel mixtures have RbF-UF₄ or RbF-3UF₄ as the primary phase. No serious segregation of the uranium phase has been evident in the experimental work. These mixtures are not optimal choices for the fuel mixture because the uranium phase contains a high concentration of UF₄ and there is a large difference between the temperatures at which the uranium phase and the primary phase of the solvent separate.

Solvents with approximately 35 mole % NaF, 25 mole % RbF, and 40 mole % ZrF₄ with the addition of 4 mole % UF₄ give a fuel with a liquidus temperature of approximately 480°C. With the addition of 7 mole % UF₄ a fuel with a liquidus temperature of approximately 510°C is obtained. At both UF₄ levels the uranium is contained entirely in the solid solution 7NaF-6Zr(U)F₄. Mixtures of this general type should have physical properties and corrosion characteristics that would make them of definite interest as fuels.

THE SYSTEM NaF-LiF-BeF₂

R. E. Meadows

Quenching studies of the system NaF-LiF-BeF₂ were continued, and it is now possible to present a diagram (Fig. 2.1.6) of the triangle having LiF, NaF, and NaF-BeF₂ at the apexes. Work on the other portion of the system is under way. Petrographic identification of phases in this system is very difficult, because several of the compounds have nearly the same indices of refraction and are isotropic, or nearly so. As a result reliance was placed on identification by means of x-ray diffraction patterns; even this identification is

⁷On assignment from Pratt & Whitney Aircraft.

Fig. 2.1.5. The System NaF-RbF-ZrF₄.

difficult in some cases, since the standard patterns were obtained from samples which are not single-phase materials.

The diagram shows the following compatibility triangles: LiF-2NaF-LiF-2BeF₂-2NaF-BeF₂, LiF-2NaF-BeF₂-NaF, and 2NaF-LiF-2BeF₂-NaF-BeF₂-2NaF-BeF₂. In addition to the congruently melting compounds which form the apexes of these compatibility triangles, the data show a subsolidus compound, NaF-LiF-BeF₂, which decomposes to LiF and 2NaF-LiF-2BeF₂ above about 240°C (ref. 8), and another subsolidus compound, probably

5NaF-LiF-3BeF₂, which decomposes above about 320°C to 2NaF-LiF-2BeF₂, 2NaF-BeF₂, and LiF. Below 320°C, LiF, 2NaF-LiF-2BeF₂, and 5NaF-LiF-3BeF₂ are the apexes of a compatibility triangle. No other subsolidus relationships have been definitely established. In the diagram (Fig. 2.1.6) the binary and quasi-binary eutectics are indicated, and the dotted lines are the approximate primary-phase boundaries which meet at the

⁸W. Jahn, *Z. anorg. u. allgem. Chem.* 276, 112-127 (1954).

Fig. 2.1.6. The System NaF-LiF-NaF-BeF₂.

ternary eutectics shown in each of the three compatibility triangles. There is a limited solid solution region in the ternary system for a high-temperature modification of 2NaF-BeF₂, which is not indicated on the diagram. It is not likely that the limits of this region can be accurately determined with the experimental methods now being used.

The phase which was previously⁹ believed to be a ternary compound and which was tentatively assigned the formula LiF-7NaF-4BeF₃ was identified by G. D. White through the use of high-temperature x-ray diffraction as a polymorph of 2NaF-BeF₂. This phase, which is stable above 320°C, had not been reported in previous investigations of the NaF-BeF₂ system^{10,11} and had not been found in quenched samples of NaF-BeF₂ mixtures examined in this laboratory because its inversion is too rapid for it to be quenched in the

binary system. It is, however, stabilized by the addition of LiF, with which it undoubtedly forms a limited solid solution.

Quenching experiments with compositions on the LiF-2NaF-LiF-2BeF₂ join on both sides of the mixture NaF-LiF-BeF₂ (37-26-37 mole %) show this mixture to have approximately the composition of the eutectic which melts at about 340°C. Petrographic and x-ray diffraction examinations of quenched samples and slowly cooled preparations show that the 2NaF-LiF-2BeF₂-2NaF-BeF₂ join is a quasi-binary system with a eutectic that contains 45 mole % NaF, 16.5 mole % LiF, and 38.5 mole % BeF₂ and melts at about 343°C.

A phase that appeared at a temperature below about 320°C in quenched samples was assigned the formula 5NaF-LiF-3BeF₂ because the x-ray diffraction pattern of a quenched sample of this composition was not found to contain lines that could be assigned to any other known phase in the system. The conclusion that this compound exists only below the solidus temperature is based on the following evidence. First, slowly cooled preparations within the 2NaF-LiF-2BeF₂-

⁹L. M. Bratcher, R. E. Meadows, and R. J. Shell, ANP Quen. Prog. Rep. March 10, 1956, ORNL-2061, p. 75.

¹⁰E. Thilo and F. Liebou, Z. physik. Chem. 199, 125-141 (1952).

¹¹D. M. Roy, R. Ray, and E. F. Osborn, J. Am. Ceram. Soc. 36(6) 185 (1953).

$\text{NaF}\cdot\text{BeF}_2\text{-}2\text{NaF}\cdot\text{BeF}_2$ triangle contained only the three phases at the apexes, since the reaction rate in the solid state is too slow to permit equilibrium to be obtained. Second, examination of quenched samples in the $\text{LiF}\cdot 2\text{NaF}\cdot\text{LiF}\cdot 2\text{BeF}_2\text{-}2\text{NaF}\cdot\text{BeF}_2$ triangle showed that the ternary eutectic (mp, 328°C) is above the upper limit of stability of the compound and that the phases just below the solidus temperature are those at the apexes of the triangle.

The x-ray diffraction pattern of $5\text{NaF}\cdot\text{LiF}\cdot 3\text{BeF}_2$ is related to that given by John¹² for low-temperature $3\text{NaF}\cdot\text{LiF}\cdot 2\text{BeF}_2$. Quenched compositions corresponding to $3\text{NaF}\cdot\text{LiF}\cdot 2\text{BeF}_2$ contained $2\text{NaF}\cdot\text{LiF}\cdot 2\text{BeF}_2$, $2\text{NaF}\cdot\text{BeF}_2$, and LiF just below the solidus temperature and $5\text{NaF}\cdot\text{LiF}\cdot 3\text{BeF}_2$, $2\text{NaF}\cdot\text{LiF}\cdot 2\text{BeF}_2$, and LiF below 320°C . No evidence has been found in this laboratory to suggest that $3\text{NaF}\cdot\text{LiF}\cdot 2\text{BeF}_2$ exists.

The locations of the phase boundaries and ternary eutectics were deduced from the primary and secondary phases observed in quenched samples of the compositions within the compatibility triangles and the temperatures at which the phases appeared, as well as from previously obtained thermal analysis data.

THE SYSTEM $\text{NaF}\cdot\text{RbF}\cdot\text{BeF}_2$

L. M. Bratcher

Thermal analysis data were obtained for a number of compositions in the $\text{NaF}\cdot\text{RbF}\cdot\text{BeF}_2$ system containing 50 mole % BeF_2 , and some of the slowly cooled melts were examined petrographically and by x-ray diffraction. The available data show that the $\text{NaF}\cdot 3\text{RbF}\cdot\text{BeF}_2$ join is a quasi-binary system which has a eutectic with the approximate composition $\text{NaF}\cdot\text{RbF}\cdot\text{BeF}_2$ (45-41-14 mole %) that melts at $640 \pm 5^\circ\text{C}$. The join $\text{NaF}\cdot 2\text{RbF}\cdot\text{BeF}_2$ is likewise believed to be a quasi-binary system which has a eutectic with the composition $\text{NaF}\cdot\text{RbF}\cdot\text{BeF}_2$ (43-38-19 mole %) that melts at $655 \pm 5^\circ\text{C}$. The $\text{NaF}\cdot\text{RbF}\cdot\text{BeF}_2$ join is complicated because one or more ternary compounds exist on or near the join and $\text{RbF}\cdot\text{BeF}_2$ melts incongruently. Thermal analysis data indicate that the addition of NaF lowers the incongruent melting point of $\text{RbF}\cdot\text{BeF}_2$. None of the slowly cooled melts was completely homo-

geneous, but the mixtures containing 45 and 50 mole % NaF were predominantly one phase, and therefore there may be a compound with the composition $2\text{NaF}\cdot\text{RbF}\cdot\text{BeF}_2$.

THE SYSTEM $\text{NaF}\cdot\text{KF}\cdot\text{LiF}\cdot\text{UF}_4$

R. J. Shell

Data reported previously on the liquidus temperatures of mixtures formed by adding UF_4 to $\text{NaF}\cdot\text{KF}\cdot\text{LiF}$ (11.5-42.0-46.5 mole %) indicated that the liquidus temperature varied quite rapidly with changing UF_4 concentration, at least with mixtures containing approximately 4 mole % UF_4 (ref. 13). Visual observations of liquidus temperatures in this system during this quarter gave values of 550, 570, and 595°C for mixtures containing 5.0, 7.5, and 10 mole % UF_4 , respectively. The values obtained by this method for the mixture containing 10 mole % UF_4 agreed quite well with earlier thermal analysis data. It now appears that the liquidus temperatures of mixtures in this system containing 0 to 10 mole % UF_4 are not so strongly dependent upon UF_4 concentrations as the earlier data¹³ had indicated.

ALKALI FLUORIDE- CeF_3 SYSTEMS

L. M. Bratcher

Preliminary data on the $\text{NaF}\cdot\text{CeF}_3$ and $\text{RbF}\cdot\text{CeF}_3$ systems were given in the previous report.¹⁴ Study of the $\text{LiF}\cdot\text{CeF}_3$ system was initiated recently, and thermal analysis data obtained with five compositions in this system showed that there is a eutectic containing approximately 19 mole % CeF_3 that melts at $755 \pm 5^\circ\text{C}$. For the $\text{NaF}\cdot\text{CeF}_3$ system, extrapolation of thermal data obtained with mixtures containing 10, 15, and 20 mole % CeF_3 indicates that the eutectic which melts at $725 \pm 10^\circ\text{C}$ contains approximately 28 mole % CeF_3 . A compound reported to be present in this system has not yet been identified. The $\text{RbF}\cdot\text{CeF}_3$ system has been studied more than the other two systems mentioned, but thermal analysis data and studies of slowly cooled melts have so far failed to give a clear picture of phase relations. It appears that at least two compounds are formed that possibly have the formulas $3\text{RbF}\cdot\text{CeF}_3$ and

ANP PROJECT PROGRESS REPORT

RbF-CeF₃. In addition to liquidus and solidus thermal effects on cooling curves, solid transitions were noted at about 425 to 450°C with mixtures in the 10 to 35 mole % CeF₃ range and at temperatures ranging from about 500 to 580°C with mixtures containing 33 to 60 mole % CeF₃. These transitions probably account for the fact that particle sizes of crystalline phases are so small that microscopic identification is difficult and some phases even give poor x-ray diffraction patterns. The minimum liquidus temperature of approximately 615°C apparently occurs between 42.5 and 50 mole % CeF₃. Study of all three systems mentioned is continuing.

THE SYSTEM LiF-CsF

L. M. Bratcher

The recent availability of pure CsF prompted a re-examination of the LiF-CsF system which is of interest because a compound is formed such as that formed in the LiF-RbF system.¹⁵ The results of the earlier studies were not published because of the scatter in the thermal analysis data. While

the existence of other alkali-halide binary compounds is well established, no mention of alkali-fluoride binary compounds has been found in the literature. The freezing point of the CsF used in the recent investigation was found to be 700 ± 5°C, which agrees with recently published values of 705°C (ref. 16) and 703°C (ref. 17). The thermal analysis data shown in Fig. 2.1.7 include some data from the earlier studies. The binary compound, believed to have the composition LiF-CsF, was easily recognized under the microscope because it is birefringent, whereas both LiF and CsF are isotropic. However, for reasons that are not well understood at present, the mixtures examined to date gave rather poor x-ray diffraction patterns for the compound. The large number of lines observed suggests that the compound is either monoclinic or rhombohedral.

Fig. 2.1.7. The System LiF-CsF.

THE SYSTEM MgF_2-CaF_2

L. M. Bratcher

In the course of an investigation of the system $NaF-MgF_2-CaF_2$, thermal data were obtained with two MgF_2-CaF_2 mixtures which indicated that the literature value for the melting point of the eutectic mixture in this system might be too low.¹⁸ Therefore six additional mixtures were prepared which covered the composition range 37.5 to 50 mole % CaF_2 . Cooling curves obtained with these mixtures showed that the eutectic mixture contained approximately 48.5 mole % CaF_2 and melted at $985 \pm 5^\circ C$, as compared with the literature value of $940^\circ C$.

THE SYSTEM $RbF-CaF_2$

L. M. Bratcher

Preliminary thermal analysis data indicate that there is a eutectic between RbF and a binary compound (probably $RbF \cdot CaF_2$) that contains less than 10 mole % CaF_2 and has a melting point of $765^\circ C$. Cooling curves with mixtures containing 10 to 45 mole % CaF_2 did not show reproducible liquidus thermal effects, but the thermal effect at $765^\circ C$ became less marked with increasing CaF_2 concentration in this range. Petrographic examination of samples containing 10 to 20% CaF_2 showed increasing amounts of a cubic compound having a refractive index of approximately 1.410. A 1:1 compound (molar ratio) has been reported¹⁹ to be present in the similar system $KF-CaF_2$.

THE SYSTEM $LiF-NiF_2$

L. M. Bratcher

Data obtained with three mixtures in the $LiF-NiF_2$ system covering the composition range 10 to 30 mole % NiF_2 were given in the previous report.²⁰ The compound found in this system was tentatively assigned the formula $3LiF \cdot NiF_2$, mainly on the basis of petrographic and x-ray diffraction studies of slowly cooled melts. The thermal analysis data obtained to date are difficult to interpret, but it appears likely that the compound melts incongruently to NiF_2 and liquid at a temperature only slightly above the

minimum liquidus temperature. Well-crystallized NiF_2 was found in slowly cooled mixtures containing 30 mole % NiF_2 or more. The first attempt to determine the melting point of NiF_2 was unsuccessful, but the melting point was evidently below $1200^\circ C$, the maximum temperature to which the material was heated.

THE SYSTEM UF_4-UO_2

R. J. Sheil

Preliminary thermal analysis data and the results of studies of a few slowly cooled mixtures in the UF_4-UO_2 system were reported previously.²¹ Thermal analysis data obtained during this quarter were not very satisfactory because of the previously mentioned undercooling difficulty and a container problem. The use of graphite containers for the UF_4-UO_2 mixtures was abandoned when it was discovered that mixtures containing 4 wt % UO_2 or more penetrated both ordinary (C-18) and high-density graphite when heated to a maximum temperature of $1100^\circ C$. Mixtures containing 2 wt % UO_2 or less did not penetrate ordinary graphite to a noticeable extent when heated to the same temperature. Surface tension measurements of UF_4-UO_2 mixtures will be made in an effort to account for this interesting phenomenon. The recent thermal analysis studies were conducted in sealed nickel capsules to minimize changes in oxide content of the mixtures while the thermal analysis data were being obtained. This closed apparatus does not permit the use of seeding, which apparently will be required in order to obtain reliable liquidus values in this system. Heating curves and some cooling curves obtained with mixtures containing 4, 6, 8, and 10 wt % UO_2 show evidence of a eutectic which melts at approximately $910^\circ C$. Extrapolation of available liquidus temperature data for these mixtures involves considerable uncertainty, but it appears that the eutectic probably contains 9 to 11 % UO_2 (10.3 to 12.6 mole % UO_2).

THE SYSTEM ZnF_2-ZnO

ANP PROJECT PROGRESS REPORT

liquidus temperatures was noted in attempts to determine the melting point of pure ZnF_2 . Cooling curves showed liquidus effects ranging from 885 to 940°C and a second break at or near 845°C. Since ZnO was found in all the samples that were examined subsequent to the melting-point determinations, it seemed probable that the liquidus temperature was affected by the amount of ZnO present. Confirmation of this postulate was obtained when a cooling curve obtained with oxide-free ZnF_2 , prepared by NH_4F -HF treatment of ZnF_2 previously dried in an HF atmosphere, showed a thermal effect only at $940 \pm 5^\circ C$. Because of the large discrepancies between this value for the melting point of ZnF_2 and those reported in the literature (872°C by Puschin and Baskow,²³ and $875 \pm 3^\circ C$ by Haendler, Patterson,

²³H. Puschin and A. Baskow, *Z. anorg. Chem.* 81, 359 (1913).

and Bernard²⁴), the slowly cooled ZnF_2 was analyzed chemically and spectrographically. It was also carefully examined petrographically and by x-ray diffraction, along with a highly precise determination of cell parameters. Since no evidence was found of the presence of impurities in more than trace amounts, the melting points for ZnF_2 reported in the literature are believed to be erroneous, possibly because of oxide contamination. Thermal analysis data obtained with mixtures formed by adding 5, 10, 15, and 20 mole % ZnO to purified ZnF_2 show that the eutectic which melts at $850 \pm 5^\circ C$ contains approximately 21.5 mole % ZnO. Only the pure components were found in the slowly cooled mixtures, and thus it appears that solid solutions do not occur, at least at room temperature.

ACTIVITY OF CHROMIUM IN CHROMIUM-NICKEL ALLOYS

M. B. Panish

Further measurements were made of the electromotive forces of electrode concentration cells in order to determine the activity of chromium-nickel alloys. The cells used were the same as those described previously,¹ and they contained as an electrolyte a eutectic mixture of sodium chloride and rubidium chloride with about 0.2 to 0.5 wt % chromous chloride added.

Activity determinations were made for alloys containing from 11.2 to 53.0 mole % chromium. It was found that there was a marked tendency for the electromotive forces of the cells to drift downward because of the reaction

This effect was reduced markedly by packing the lower end of the cell with crushed quartz in order to prevent the transfer of nickel by convection and diffusion. For several cells in which the quartz packing was not used, the equilibrium electromotive force was approximated by extrapolating the steadily drifting electromotive force to zero time.

With cells in which the alloy electrode contained over 35 mole % chromium, erratic results were obtained after raising and lowering the cell temperature, whereas the electromotive forces obtained should be reproducible. The reasons for this behavior have not yet been ascertained, but it is highly probable that the diffusion rate in these electrodes is very low and that surface effects play a very important role. It should also be noted that activity values for the high-activity region will be approximations because of the low electromotive force produced by cells containing these electrodes vs a pure chromium electrode. If the activity of the chromium in the alloy electrode of such a cell is 0.90, then the electromotive force will be about 0.004. The nonreproducibility of the cells in this region is of the same order of magnitude as the electromotive forces measured.

¹M. B. Panish, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 92.

The activities obtained for various chromium-nickel alloys at 750°C are shown in Fig. 2.2.1, along with the curve obtained by Grube and Flad² at 1100°C. The two curves are not inconsistent, in that it is quite possible that the differences are due entirely to the difference in the temperatures at which the measurements were made.

Fig. 2.2.1. Activity of Chromium in Nickel-Chromium Alloys at 750 and 1100°C.

It should be noted that the chromium activity in the region near 15% chromium is slightly below the ideal activity which would have been predicted for a perfect solid solution. This is considerably lower than the activity which might have been expected from an inspection of the chromium-nickel phase diagram, and it justifies the assumption of near "ideal" activity for chromium in Inconel. This assumption is usually made in discussions regarding the chemical equilibria involved in the corrosion of Inconel by molten salts.

ANP PROJECT PROGRESS REPORT

REDUCTION OF UF₄ BY STRUCTURAL METALS

J. D. Redman

Further studies were made, by use of the filtration method, of the reduction of UF₄ by chromium and by iron in reaction mediums that differed from those used previously. In the earlier studies, the reaction mediums used were NaF-ZrF₄ (50-50 mole %, ³ 53-47 mole %, ⁴ 59-41 mole %⁵), NaF-LiF-ZrF₄ (22-55-23 mole %),⁶ and NaF-LiF-KF (11.5-46.5-42 mole %).⁷ Other alkali fluoride mixtures containing ZrF₄ have been employed as reaction mediums in the recent studies in order to determine the effects of various alkali fluorides on the interaction of UF₄ with chromium or iron. The results obtained by using KF-ZrF₄ or LiF-ZrF₄ (both 52-48 mole %) as reaction mediums are presented in Tables 2.2.1 and 2.2.2.

*Blank of 290 ppm of Cr at 800°C.

Data for the reaction of UF₄ with chromium at 600 and 800°C in the reaction medium KF-ZrF₄ (52-48 mole %) are given in Table 2.2.1. In these runs approximately 2 g of chromium was reacted with UF₄ (10.6 wt %, 4.0 mole %) dissolved in approximately 40 g of the KF-ZrF₄ mixture contained in nickel. Similar studies were made with LiF-ZrF₄ (52-48 mole %) as the reaction medium at a UF₄ concentration of 12.0 wt % (3.9 mole %). In these studies chromium from two different sources was employed; the results are given in Table 2.2.2.

As seen from the data in Table 2.2.2 the equilibrium chromium concentrations are the same at both temperatures for the two different chromium metals used - hydrogen-fired electrolytic chromium

*Blank of 250 ppm of Cr at 800°C. Electrolytic chromium hydrogen-fired at 1200°C was used in all runs except those noted.

**Blank of 190 ppm of Cr at 800°C. Very pure iodide chromium, not hydrogen-fired, was used in these runs.

and iodide chromium. The iodide chromium was obtained from Battelle Memorial Institute and contained 10 ppm or less of oxygen. This pure chromium was not hydrogen-fired, and therefore a comparison of the blanks obtained for this metal with those found for the electrolytic chromium (used in all previous studies), which was hydrogen-fired under the usual conditions, should demonstrate the effectiveness of the hydrogen treatment. The chromium values of 190 and 250 ppm obtained for the unfired iodide chromium and the hydrogen-fired electrolytic chromium, respectively, suggest that the hydrogen-firing is successful (unfired electrolytic chromium gave a blank of 900 ppm). Evidently the major portion of the blank arises from oxidizing materials (H_2O and HF) present in the $LiF-ZrF_4$ mixture.

The equilibrium chromium concentrations and the equilibrium constants calculated from mole fractions for the reaction of UF_4 with chromium in the various solvents are presented in Table 2.2.3 for comparison. The effect of varying the NaF -to- ZrF_4 ratio in the various $NaF-ZrF_4$ mixtures on the chromium concentration has been shown and discussed previously.⁵ The values are included in Table 2.2.3 for comparison with the $KF-ZrF_4$ and $LiF-ZrF_4$ data. It is evident from the values

given in Table 2.2.3 that the particular alkali fluoride used in combination with ZrF_4 influences the reaction markedly. The different alkali fluorides affect the activity of the UF_4 to varying degrees. The activity of the CrF_2 is also influenced through complexing of the CrF_2 by both the alkali fluoride and the ZrF_4 . Studies will be made shortly with an $RbF-ZrF_4$ mixture as reaction medium to complete the alkali fluoride series.

Studies of the reduction of UF_4 by iron at 600 and 800°C with $LiF-ZrF_4$ and $KF-ZrF_4$ (both 52-48 mole %) as reaction mediums were made at UF_4 concentrations of 12.0 wt % (3.9 mole %) for the $LiF-ZrF_4$ mixture and 10.6 wt % (4.0 mole %) for the $KF-ZrF_4$ mixture. The data are presented in Table 2.2.4. As may be seen from the data the equilibrium iron concentrations are not significantly changed by replacing LiF with KF . It may be noted that somewhat smaller values result at 800°C than at 600°C for both solvents. These values also are in good agreement with those found when $NaF-ZrF_4$ (50-50 mole %), $NaF-ZrF_4$ (53-47 mole %), and $NaF-ZrF_4$ (59-41 mole %) were used as the reaction mediums. The iron values obtained by using $NaF-LiF-ZrF_4$ (22-55-23 mole %) as the solvent fell in the same range, but in this case the values were slightly larger at 800°C than at 600°C.

*Blanks of 100 and 40 ppm of Fe at 800°C for $LiF-ZrF_4$ and $KF-ZrF_4$, respectively.

The indifference exhibited by the UF_4-Fe^0 reaction to changes in the reaction medium is in marked contrast to the behavior noted for the UF_4-Cr reaction. No satisfactory explanation can be offered at this time for these differences.

SOME OBSERVATIONS ON MASS TRANSFER OF CHROMIUM BY MOLTEN SALTS

W. R. Grimes

When the corrosion of Inconel by $NaF-ZrF_4-UF_4$ mixtures and by $NaF-KF-LiF-UF_4$ mixtures is compared, some striking differences are observed. The corrosion, as measured by depth of void forma-

tion in the hot region of a system with a temperature gradient, is much worse when the circulated fluid is the alkali fluoride mixture than when it is the ZrF_4 -bearing fuel. In addition, discrete crystals of nearly pure chromium are found in the cold zones of Inconel loops in which the $NaF-KF-LiF-UF_4$ mixture has been circulated. Metallic deposits are not usually observed in loops which have circulated the $NaF-ZrF_4-UF_4$ preparations. Depth of void formation does increase with time, however, for both classes of systems, even though the concentration of chromium compounds in solution reaches an equilibrium concentration early in the corrosion test and remains essentially constant thereafter. The amount of chromium removed from the loop walls, as estimated from the volume of voids in the hot zone, is considerably larger than can be explained by the amount of chromium compound in solution in the melt after the test. Moreover, the corrosion seems to be nearly independent of the ratio of the surface area of the loop to the volume of the melt and not strongly dependent on the concentration of uranium in the melt.

The processes that occur are undoubtedly very complex, and it is not possible to explain in quantitative fashion all the effects observed. However, by the use of equilibrium data obtained for the chemical reactions and by making some reasonable assumptions it is possible to rationalize much of the available data and to indicate a possible explanation for the observed similarities and differences in these two fuel classes. For ZrF_4 -bearing mixtures, of which the mixture with 50 mole % NaF , 46 mole % ZrF_4 , and 4 mole % UF_4 is typical, the important corrosion reaction is known to be

The equilibrium constant for this reaction is given by

$$K'_{(a)} = \frac{(CrF_2)(UF_3)^2}{(UF_4)^2(Cr)}$$

where the quantities in parentheses represent the activities of the materials involved. The equilibrium constant, $K'_{(a)}$, cannot be determined by experiment, but the equilibrium concentration,

$K'_{(Cr)}$ which is defined by the equation

$$K'_{(Cr)} = \frac{C_{(CrF_2)} C_{(UF_3)}^2}{C_{(UF_4)}^2 C_{(Cr)}}$$

where $C_{(i)}$ represents the equilibrium concentration of the designated component in mole fraction, can be evaluated for pure chromium and has been shown to be constant at a given temperature.

For cases in which the CrF_2 and UF_3 present are formed only by the reaction described above,

$$C_{(UF_3)} = 2C_{(CrF_2)}$$

and

$$K'_{(Cr)} = \frac{4C_{(CrF_2)}^3}{C_{(UF_4)}^2 C_{(Cr)}}$$

If the amount of UF_4 added initially is always the same and if the fraction of this UF_4 reduced to UF_3 is small, then

$$C_{(UF_4)}^2 = A'$$

$$K'_{(Cr)} = \frac{4C_{(CrF_2)}^3}{A' C_{(Cr)}}$$

and

$$C_{(CrF_2)} = \left[\frac{K'_{(Cr)} A' C_{(Cr)}}{4} \right]^{1/3}$$

Accordingly, the CrF_2 concentration at equilibrium, if all other factors are constant, depends on the cube root of the mole fraction of chromium in the alloy. Therefore it should be possible to calculate, from experimental data for pure chromium, the equilibrium concentrations to be expected from Inconel.

The corrosion reaction for the NaF-KF-LiF- UF_4 mixtures is considerably more complex. In this case two consecutive reactions apparently proceed:

As a result of these reactions about 80% of the

chromium compound in solution is trivalent. The net reaction is (approximately)

and

$$K''_{(Cr)} = \frac{(CrF_2)(CrF_3)^4(UF_3)^{14}}{(UF_4)^{14}(Cr)^5}$$

$$K''_{(Cr)} = \frac{C_{(CrF_2)} C_{(CrF_3)}^4 C_{(UF_3)}^{14}}{C_{(UF_4)}^{14} C_{(Cr)}^5}$$

If CrF_2 , CrF_3 , and UF_3 all arise solely from this reaction and if $C_{(UF_4)}$ is constant, then

$$C_{(CrF_3)} = 4C_{(CrF_2)}$$

$$C_{(UF_3)} = 14C_{(CrF_2)}$$

$$K''_{(Cr)} = \frac{C_{(CrF_2)} 4^4 C_{(CrF_2)}^4 14^{14} C_{(CrF_2)}^{14}}{A'' C_{(Cr)}^5}$$

$$C_{(CrF_2)} = \left[\frac{K''_{(Cr)} A'' C_{(Cr)}^5}{1 \times 4^4 \times 14^{14}} \right]^{1/19}$$

Accordingly, with all other variables held constant, the concentration of $CrF_2 + CrF_3$ is a function of the 5/19 power of the mole fraction of chromium in the alloy. Therefore, from equilibrium data for pure chromium, corresponding concentrations can be calculated for Inconel.⁸

⁸It should be emphasized that accuracy of the complicated equation

is not an essential part of the argument. The same qualitative conclusions are apparent whether one uses as the corrosion reaction

or

In reaction 1, as shown for the ZrF_4 -bearing fuel, the CrF_2 concentration varies as $(Cr)^{1/3}$, and in reaction 2, the CrF_3 concentration varies as $(Cr)^{1/4}$.

AMP PROJECT PROGRESS REPORT

Inconel contains 15 wt % Cr or a chromium mole fraction of about 0.16. The assumption that the activity of chromium in Inconel is roughly equal to its mole fraction appears to be rather good. The compounds in the melts, which were treated with pure chromium at 600 and 800°C, are shown in Table 2.2.5, along with corresponding values calculated for equilibration with Inconel. Experimental values obtained from corrosion experiments with Inconel and these melts are usually slightly lower than these calculated values, presumably because in the experiments equilibrium is attained with an Inconel surface layer significantly depleted in chromium. When Inconel powder is used in experimental equilibration apparatus, side reactions that involve oxides of the metals complicate the situation; equilibrium concentrations of chromium compounds higher than those calculated are often observed. In general, it appears that the calculations are good only for the idealized case described.

From the data in Table 2.2.5 it is obvious that Inconel exposed to the NaF-KF-LiF-UF₄ melt will support a higher concentration of CrF₂-CrF₃ in equilibrium at 800°C than pure Cr⁰ is able to support at 600°C. Accordingly, chromium is removed from Inconel in the hot zone of a loop and deposited as essentially pure chromium in the cold zone. Since no diffusion process is necessary in the cold zone (the chromium can deposit at the surface of the Cr⁰ crystals), the rate of attack is controlled simply by the rate of diffusion of chromium to the metal-salt interface in the hot zone.

The data in Table 2.2.5 also reveal, however, that Inconel exposed to NaF-ZrF₄-UF₄ mixtures is in equilibrium with much lower CrF₂ concentrations than pure Cr⁰ is in equilibrium with when exposed to the fluoride mixture under the same conditions. Accordingly, it is not possible for chromium to dissolve from 800°C Inconel and to deposit at 600°C as Cr⁰ when NaF-ZrF₄-UF₄ mixtures of this general composition are circulated. Loops of pure Cr⁰ would, of course, mass-transfer in this medium; moreover, mass transfer can occur if a sufficiently dilute alloy of chromium can be formed in the cold zone. This suggests that the mass-transfer process takes place in the following general way.

The molten salt in the hot zone reaches equilibrium with the 800°C Inconel and passes with the dissolved CrF₂ to the cold zone. In the cold zone, equilibrium is established by deposition of a small amount of the chromium (by reversal of the reaction) in the surface layer of the metal to form an alloy containing slightly more chromium than is normally present in Inconel. If no diffusion of chromium were possible, a true equilibrium would be reached shortly, with the hot surfaces slightly depleted and the colder surfaces slightly enriched in chromium. The process would then stop (except for the exchange process which has no net effect), with negligible corrosion of the metal. Since diffusion does take place, however, the process continues. In the hot zone the concentration gradient causes a flow of chromium to

TABLE 2.2.5. EQUILIBRIUM CONCENTRATIONS OF CHROMIUM FLUORIDES WITH ALKALI FLUORIDE AND ZrF₄-BEARING FUEL MIXTURES

the salt-metal interface, and the activity of chromium at the surface is maintained at some level appreciably less than 0.16. In the colder zones the diffusion gradient is away from the salt-metal interface, and the chromium activity is maintained at some activity slightly higher than 0.16. Since diffusion at the lower temperature is slower than that at the higher temperature, the rate-controlling step is presumably the low-temperature diffusion process. It may be that the intermediate-temperature regions, in which the chemical driving force is less but the diffusion rate is faster, are the most important regions; there is no a priori way of telling.

If the dynamic-corrosion and mass-transfer phenomena are examined in this light, it is obvious why neither flow rate nor uranium concentration of the fuel mixture is an important factor affecting corrosion attack and mass transfer in Inconel systems. If it is assumed that most of the corrosion observed involves mass transfer to a dilute alloy, the lack of an effect of the surface-to-volume ratio becomes comprehensible. If the relative effect of diffusion rate vs driving force is noted, the reason for the poor correlation of corrosion with temperature drop can be understood; with a ZrF_4 -bearing fuel, corrosion may be worse with a top temperature of 1500°F and a 200°F drop than with a top temperature of 1500°F and a 400°F drop.

The argument points up the fact that, if the low temperature were made sufficiently low, deposition of Cr^0 might be possible in ZrF_4 -bearing systems; the temperature coefficient of the reaction is not known below 600°C. It is possible that the light frosting of chromium often observed in the cold dead-leg sump of old-style thermal-convection loops may have been due to such an effect. It would also be possible to have alloys sufficiently high in chromium concentration (and activity) to cause chromium deposition to occur. These considerations point to the considerable superiority of alloys over pure metals for containment of molten salts.

EQUILIBRIUM REDUCTION OF NiF_2 BY H_2 IN $NaF-ZrF_4$ C. M. Blood

Investigation of the equilibrium

when the mixture $NaF-ZrF_4$ (53-47 mole %) is used as the solvent was initiated. The equipment and experimental techniques for this study were very similar to those described previously for the study

of the reduction of FeF_2 by H_2 in $NaF-ZrF_4$.⁹⁻¹¹ Equipment changes included the substitution of nickel as the container material in place of the mild steel used in the previous study. Operational changes consisted in the use of hydrogen-helium mixtures of known composition instead of pure hydrogen in the preparation of the equilibrating gaseous streams. This was found to be necessary after the results of preliminary experiments indicated the necessity for using small partial pressures of hydrogen and high partial pressures of HF in order to maintain measurable quantities of NiF_2 in solution.

The initial experiments were made in order to ascertain the solubility of NiF_2 in the solvent mixture $NaF-ZrF_4$ (53-47 mole %). The values obtained by filtration of the saturated solution and chemical analysis of the filtrate when a total of 0.17 wt % Ni was added as NiF_2 are summarized in the following tabulation:

Temperature (°C)	Solubility of NiF_2 (ppm)
550	400
575	600
600	980
625	1450

Solubility values were also obtained by filtration by Redman (see following section on "Solubility and Stability of Structural Metal Fluorides in Molten $NaF-ZrF_4$ "), who showed that the solubility is a function of the quantity of NiF_2 added. Topol¹² also obtained solubility values by measuring the electromotive forces of electrolytic cells. The values for the solubility at 600°C that were obtained in the different investigations are shown in Fig. 2.2.2. There appears to be satisfactory correlation of these solubility values with those obtained by filtration methods. The change in solubility at 600°C with total quantity of NiF_2 added may be ascribed to the saturating phase being a complex compound rather than NiF_2 . The complex

compound is probably, though not necessarily, identical with the substance NiF₂·ZrF₄ previously synthesized by Sturm.¹³

Thermodynamic calculations performed prior to the experimental work indicated that if NiF₂ exhibited activity coefficients similar in magnitude to those previously determined for FeF₂, equilibration at 600°C with H₂-HF mixtures containing about 3% HF would allow sufficient NiF₂ to remain in solution for satisfactory analysis. Only traces of NiF₂ (<10 ppm) were found after repeated and prolonged equilibration under these conditions and even after the reactor temperature had been reduced to 550°C and the H₂-HF equilibrating mixture had been changed to contain 30% HF. Attempts to increase the NiF₂ concentration in solution by simply raising the HF concentration of the equilibrating gas were unsuccessful beyond NiF₂ concentrations of about 20 ppm Ni.

Nickel fluoride concentrations of sufficient magnitude for an acceptable degree of precision in the analytical determinations were finally obtained by lowering the partial pressure of hydrogen, in addition to maintaining a high HF concentration in the equilibrating gas mixtures. This was accomplished by the use of hydrogen-helium mixtures rather than pure hydrogen. The mixtures were prepared by injecting helium gas into a partially empty hydrogen

cylinder. The compositions of the mixtures thus prepared were determined by the proper adaptation of the hydrogen combustion analysis technique to the existing experimental assembly. The experimental results are summarized in Table 2.2.6.

As is customary, equilibrium was approached from both directions in obtaining the series of measurements described. It is of interest to note that the calculated values of the equilibrium constants for the reaction range from 11 to 45 atm at 625°C when the solid and the supercooled liquid, respectively, are used as standard states. The experimental values denote activity coefficients of NiF₂ a thousand times greater than those obtained for FeF₂. Detailed numerical calculations

of this reaction will be made at the conclusion of the experimental work.

Experimental work is now in progress at 575°C. Efforts will be made to extend the NiF_2 concentration ranges and to obtain the temperature dependence of the equilibrium. Particular attention will be given to the determination of the activity of NiF_2 in the saturating phase.

SOLUBILITY AND STABILITY OF STRUCTURAL METAL FLUORIDES IN MOLTEN NaF-ZrF_4

J. D. Redman

The results of studies of the stability and solubility of CrF_2 in NaF-ZrF_4 (53-47 mole %) at 600°C were presented previously.¹⁴ From these experiments it was concluded that the solubility of CrF_2 increased as the zirconium-to-chromium ratio decreased, and, accordingly, the solubility of CrF_2 in this solvent was a function of the amount of CrF_2 added. It was postulated that the change in solubility was due to the separation of $\text{CrF}_2\text{-ZrF}_4$ as the solid phase, with a resultant increase in the NaF concentration in the melt. Some of these experiments have been rerun in order to obtain more precise values at the larger zirconium-to-chromium ratios, and the values thus obtained, along with some of the earlier ones, are given in Table 2.2.7.

¹⁴J. D. Redman, *ANP Quar. Prog. Rep. Dec. 10, 1955*, ORNL-2012, p. 88.

Similar studies have been carried out on the solubility of FeF_2 and NiF_2 in this solvent, and the data are presented in Tables 2.2.8 and 2.2.9, respectively. The data for these three structural metal fluorides also are plotted on Fig. 2.2.3.

An examination of the data presented for 600°C shows that the solubility of CrF_2 increases quite rapidly as the zirconium-to-chromium ratio decreases over the entire range studied. A less pronounced effect is noted for FeF_2 , and in the case of NiF_2 a slight increase is observed for the higher zirconium-to-nickel ratios. At the lower zirconium-to-nickel ratios the solubility is constant. These differences in behavior are shown quite clearly in Fig. 2.2.3. It appears that the solid phases present for the CrF_2 and FeF_2 systems contain ZrF_4 , probably as $\text{MF}_2\text{-ZrF}_4$, whereas the solid phase in the NiF_2 system appears to tie up only very small amounts of ZrF_4 . It may be noted that at 800°C the solubility of NiF_2 is independent of the zirconium-to-nickel ratio, which suggests that the solid phase present is NiF_2 .

There is some question regarding the reliability of the data given in the zirconium-to-sodium ratio columns in the tables, but for CrF_2 and for FeF_2 at 600°C it is believed that the decrease in the ratio as the excess of metal fluoride added was increased is real. The ratio of zirconium to sodium is 0.88 in the starting material, and the considerably lower values found for the large additions of

metal fluoride are additional evidence for the belief that ZrF₄ is combined with the metal fluoride in the solid phase.

mole %) were continued through the use of the concentration cells discussed previously.¹⁵ Cells of the type

A comparison of values given for Fe⁺⁺ and total iron shows that Fe⁺⁺ is stable under these conditions. The slight deviations noted are attributable to experimental errors. The agreement between Cr⁺⁺ and total chromium is not so satisfactory, but it is evident that more than 90% of the chromium is present as Cr⁺⁺. Since the starting material does not contain over 95% of the chromium as Cr⁺⁺, it is evident that no appreciable disproportionation of CrF₂ occurs under the conditions employed.

SOLUBILITY DETERMINATIONS BY MEASUREMENT OF ELECTROMOTIVE FORCES OF CONCENTRATION CELLS

L. E. Topol

Solubility studies of structural metal fluorides and their complexes in molten NaF-ZrF₄ (53-47

where M was Fe, Ni, or Cr, and x = 0 or 1, were measured at 525 to 750°C in a helium atmosphere. The containers were alumina, platinum, or the metal M when M was iron and nickel; a ZrO₂ bridge impregnated with NaF-ZrF₄ (53-47 mole %) served as the electrical contact between the two half cells. When the electromotive force was measured as a function of temperature, the saturation points were apparent from the points of discontinuity in the plot of voltage vs temperature.

In the cell assembly employed it was not feasible to measure the temperature of either of the half cells directly. The temperature recorded by a thermocouple placed in a well that was permanently

¹⁵L. E. Topol, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 89.

fixed midway between the two half cells was formerly used as the cell temperature. In order to refine the temperature measurements, a calibrated thermocouple, enclosed in a nickel tube, was substituted for an electrode in a dummy cell. In the temperature range of interest (550 to 750°C) the melt temperatures found were $10 \pm 2^\circ\text{C}$ higher than the melt temperatures at the center between the two crucibles. Thus all the temperatures reported in connection with previous potential measurements should be revised upward by 10°C . Only the solubility data are sufficiently temperature sensitive to be appreciably affected.

Application of the temperature correction to the solubility data previously reported¹⁵ gave the following new expressions for the solubility of $\text{MF}_2 \cdot \text{ZrF}_4$ in $\text{NaF} \cdot \text{ZrF}_4$ (53-47 mole %):

$$\log N = -\frac{36.0 \times 10^3}{4.576 T} + 6.87, \quad \text{for } \text{FeF}_2 \cdot \text{ZrF}_4$$

$$\log N = -\frac{40.1 \times 10^3}{4.576 T} + 8.36, \quad \text{for } \text{CrF}_2 \cdot \text{ZrF}_4$$

$$\log N = -\frac{28.8 \times 10^3}{4.576 T} + 4.72, \quad \text{for } \text{NiF}_2 \cdot \text{ZrF}_4^{16}$$

where N is the mole fraction of $\text{MF}_2 \cdot \text{ZrF}_4$ and T is temperature in $^\circ\text{K}$. The corrected heats of solution and "ideal" melting points are now 36.0, 40.1, and 28.8 kcal/mole $\text{MF}_2 \cdot \text{ZrF}_4$ and 875, 775, and 1060°C for the Fe, Cr, and Ni compounds, respectively. Solubility data obtained by analyses of filtrates from saturated solutions, as described in the preceding sections of this chapter ("Equilibrium Reduction of NiF_2 by H_2 in $\text{NaF} \cdot \text{ZrF}_4$ " and "Solubility and Stability of Structural Metal Fluorides in Molten $\text{NaF} \cdot \text{ZrF}_4$ "), did not agree with the electrometrically determined solubilities, particularly in the case of NiF_2 . Since the filtration measurements were carried out by adding NiF_2 rather than $\text{NiF}_2 \cdot \text{ZrF}_4$ as solute (and similarly with FeF_2 and CrF_2), the electrometric determinations were repeated with NiF_2 as solute so that the data could

¹⁶From this investigation and x-ray and petrographic examinations of quenches of $\text{NaF} \cdot \text{ZrF}_4$ melts, NiF_2 is now believed to exist in a ternary compound, rather than as $\text{NiF}_2 \cdot \text{ZrF}_4$, in saturated solutions. The equation for the solubility was revised to include additional measurements, as well as the temperature correction.

be compared. X-ray and petrographic examinations of the solidified melt from the half cells should have sufficed to identify either or both of the joins as quasi-binary; in practice, however, both $\text{NiF}_2 \cdot \text{ZrF}_4$ and a new phase were found in the slowly cooled half cells. The new phase is thought to be a ternary compound, since it has never been found in the binary systems.

Gradient quenches (510 to 540°C) along the two joins revealed only the new phase, with no $\text{NiF}_2 \cdot \text{ZrF}_4$. Such ambiguous results were disappointing, since on a quasi-binary join the solubility does not vary with the amount of solute added, as it does along a random join.

Cells containing MF_2 in $\text{NaF} \cdot \text{ZrF}_4$ (53-47 mole %), with no addition of ZrF_4 , gave the solubilities of the structural metal salts shown in Table 2.2.10 and Fig. 2.2.4 for NiF_2 and Table 2.2.11 for FeF_2 . The solubilities of the nickel salts along the joins $\text{NiF}_2 \cdot \text{ZrF}_4 \cdot 7\text{NaF} \cdot 6\text{ZrF}_4$ and $\text{NiF}_2 \cdot 7\text{NaF} \cdot 6\text{ZrF}_4$, as well as the values for NiF_2 obtained by filtration methods, are plotted in Fig. 2.2.4. The discrepancy between the results of the various experiments has not been explained. The electrometrically determined solubilities appear to be virtually the same whether the solute is added as NiF_2 or as $\text{NiF}_2 \cdot \text{ZrF}_4$, and the same seems to be true for

FeF₂. The FeF₂ saturation points were not so well defined or reproducible, however, as those for FeF₂·ZrF₄, especially at temperatures above 650°C. The potentials of many of the cells fluctuated greatly and were much lower than the values predicted from the Nernst equation (where complete

solution in both half cells was expected). X-ray and petrographic examinations revealed a better-defined ternary complex in low-temperature (535°C) quenches of FeF₂ melts than in high-temperature (672°C) quenches; the FeF₂ ternary complex gives the same x-ray pattern as that given by the NiF₂ ternary complex.

FREE ENERGIES OF FORMATION OF COMPLEX METAL FLUORIDES MF₂·ZrF₄

L. E. Topol

For a saturated solution of MF₂·ZrF₄ in a molten electrolyte, the following equilibrium holds:

In NaF-ZrF₄ (53-47 mole %) as the solvent, the activities of MF_{2(soln)} and ZrF_{4(soln)} are known, at least approximately, in a few cases, and, since the activity of solid MF₂·ZrF₄ is unity, the free energy of formation of MF₂·ZrF₄ is the only unknown in the following relations as applied to the saturation equilibrium:

$$\begin{aligned} \Delta F = 0 &= \Delta F^\circ + RT \ln \frac{a_{MF_2} \cdot a_{ZrF_4}}{a_{MF_2 \cdot ZrF_4}} \\ &= \Delta F^\circ_{MF_2} + \Delta F^\circ_{ZrF_4} - \Delta F^\circ_{MF_2 \cdot ZrF_4} \\ &\quad + 2.3 RT \log \gamma_{MF_2} N_{MF_2} \cdot a_{ZrF_4} \end{aligned}$$

where N is mole fraction and a and γ are, respectively, the activity and the activity coefficient based on the pure solid as the standard state. The free energy of complexing of MF₂·ZrF₄ from solid MF₂ and solid ZrF₄ is:

$$\begin{aligned} \Delta F_{comp} &= \Delta F^\circ_{MF_2 \cdot ZrF_4} - \Delta F^\circ_{MF_2} - \Delta F^\circ_{ZrF_4} \\ &= 2.3 RT \log \gamma_{MF_2} N_{MF_2} \cdot a_{ZrF_4} \end{aligned}$$

Hence a knowledge of the activity of the dissolved MF₂ and ZrF₄ suffices to yield the free energy of complexing, ΔF_{comp}; this quantity has been calculated for the proposed family of complexes CrF₂·ZrF₄, FeF₂·ZrF₄, and NiF₂·ZrF₄, as shown in Table 2.2.12. Since for NiF₂·ZrF₄ ΔF_{comp} is positive, there is additional evidence that this

TABLE 2.2.12. FREE ENERGY OF FORMATION OF $MF_2 \cdot ZrF_4$

$MF_2 \cdot ZrF_4$	Temperature (°C)	Saturation Solubility, N (mole fraction)	Activity Coefficient, γ	Free Energy of Complexing, ΔF_{comp} (kcal/mole)	Free Energy of Formation, ΔF^0 (kcal/mole)
$FeF_2 \cdot ZrF_4$	600	0.0071	3.28	-8.8	-530
	700	0.0550	2.20	-8.3	-520
$NiF_2 \cdot ZrF_4$	600	0.00331	1900	+0.9	-510
	700	0.0180	1100	+1.6	-500
$CrF_2 \cdot ZrF_4$	600	0.0210	1.15	-8.8	-545
	700	0.183	0.67	-7.8	-535

solid complex is not stable with respect to solid NiF_2 and ZrF_4 .

The activities of MF_2 in the saturated solution were obtained by combining solubility and activity coefficient measurements. Henry's law is expected to hold quite well for dilute solutions in molten electrolytes because the environment of a solute ion is not significantly influenced by the presence of other solute ions unless appreciable concentrations are present. This has been demonstrated for FeF_2 in $NaF \cdot ZrF_4$ (53-47 mole %) over a range of concentrations from 0.03 to 0.06 mole % by measurements of the activity coefficient based on equilibrium studies at 600 to 800°C.¹⁷ The values of the activity coefficients for FeF_2 (γ at 600°C is 3.28; γ at 700°C is 2.20) were combined with electrometrically determined activity coefficient ratios¹⁸ (from bimetallic couples) to give the activity coefficients of CrF_2 and NiF_2 shown in Table 2.2.12. Previously published measurements¹⁵ showing a twofold change in γ_{FeF_2} with concentration in the range 0.06 to 1.5 mole % FeF_2 are tentatively regarded as in need of reinterpretation.

The saturation concentrations listed in Table 2.2.12 were obtained from the equations presented in the preceding section on "Solubility Determinations by Measurement of Electromotive Forces of Concentration Cells."

The activities of ZrF_4 were computed from vapor pressures by using the expression

$$a_{ZrF_4} = \frac{p}{p_0}$$

where p is the vapor pressure of ZrF_4 in $NaF \cdot ZrF_4$ (53-47 mole %) and p_0 is the vapor pressure of solid ZrF_4 . Since

$$\log p = 9.243 - \frac{9.252 \times 10^3}{T}$$

and

$$\log p_0 = 13.400 - \frac{12.376 \times 10^3}{T}$$

$$\log \frac{p}{p_0} = -4.157 + \frac{3.124 \times 10^3}{T}$$

where T is temperature in °K, which gives

$$\log \frac{p}{p_0} = -0.578 \text{ at } 600^\circ\text{C}$$

$$= -0.945 \text{ at } 700^\circ\text{C}$$

The equation for p_0 was obtained from the work of Sense *et al.*,¹⁹ The activity of ZrF_4 in the saturated solution was assumed to be the same as the activity in the pure solvent $NaF \cdot ZrF_4$ (53-47 mole %). This assumption is probably valid in all cases except that of CrF_2 at 700°C; here the solution is too concentrated for much reliance to be placed on the calculation. If the saturating phase were simple NiF_2 in the NiF_2 experiments, then

$a_{NiF_2} = \gamma_N$ should be unity (a pure solid has unit activity). The apparent activity is 9 at 600°C and 20 at 700°C, however, which indicates that the saturating phase is something less soluble than NiF_2 . The discrepancy amounts to a factor of 10 in the activity coefficient or the solubility and to about 5 kcal/mole in the value of $\Delta F_{NiF_2}^0$. In computing the ΔF^0 for the formation of the complex compound from the elements, the free energy estimates given in Table 2.2.13 were employed.²⁰

TABLE 2.2.14. COMPARISON OF FREE ENERGIES OF FORMATION OF $MF_2 \cdot ZrF_4$ OBTAINED BY TWO METHODS

	Difference Between $\Delta F_{MF_2 \cdot ZrF_4}$ and $\Delta F_{M'F_2 \cdot ZrF_4}$ (kcal/mole)	
	At 600°C	At 700°C
	$FeF_2 \cdot ZrF_4 - CrF_2 \cdot ZrF_4$ - $En\bar{3}$	15.5
ΔF_{calc}	15	15
$FeF_2 \cdot ZrF_4 - NiF_2 \cdot ZrF_4$ - $En\bar{3}$	-19.5	-20.0
ΔF_{calc}	-20	-20
$CrF_2 \cdot ZrF_4 - NiF_2 \cdot ZrF_4$ - $En\bar{3}$	-35.1	-36.3
ΔF_{calc}	-35	-35

An independent check on the differences in the standard free energies of formation of the $MF_2 \cdot ZrF_4$ complex from the elements is afforded by previously published data obtained for bimetallic couples in saturated half cells.²¹ To a first approximation, the cell reaction was

This reaction neglects transport and junction potentials, which are small if the saturated solutions are sufficiently dilute. From the relation

$$En\bar{3} = -\Delta F$$

for the cell reaction, where E is the electromotive force, n is the number of equivalents transferred, and $\bar{3}$ is the number of Faradays passed, an approximate value of the difference in the free energy of formation from the elements is found. The comparison is shown in Table 2.2.14.

The values of ΔF_{calc} in Table 2.2.14 were obtained by subtracting the values of ΔF^0 given for these complexes in the last column of Table 2.2.12. While the agreement is good, the effect of the high solubility of CrF_2 at 700°C is probably responsible for the larger of the discrepancies.

PREPARATION OF SOLUTIONS OF LaF_3 ,
 BaF_2 , AND RbF IN $\text{NaF-ZrF}_4\text{-UF}_4$

F. L. Daley

W. T. Ward

A special preparation containing LaF_3 - BaF_2 - RbF (2.8-1.0-1.1 mole %) dissolved in a standard $\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %) mixture was requested for use in determining whether the introduction of the simulated fission products would produce significant viscosity changes. The usual methods of purification and filtration were used, and the equipment was modified so that small filtered samples could be dispensed directly into the tubes used for the viscosity measurements. The resulting preparation was studied to obtain some indication of the solubilities of the fission products at 800°C in this solvent. It is believed that the solubility of LaF_3 may be typical of the solubilities of the rare-earth fluorides, since LaF_3 presumably forms solid solutions with other rare-earth fluorides.

Two filtered samples of the $\text{NaF-ZrF}_4\text{-UF}_4$ mixture without the additive were obtained, and two more samples were obtained after the fission-product mixture was added. A small portion of solution which remained unfiltered in the reactor after withdrawal of all the samples was also recovered for analysis. All filtrations were performed

at approximately $800 \pm 10^\circ\text{C}$. During the course of the viscosity measurements, the presence of a finely divided solid material was detected in the molten mixture, and a small sample of the solid was obtained by decantation. The solid was tentatively identified by x-ray diffraction analysis as free LaF_3 , with occluded solvent. The results of chemical analyses of all the samples taken are presented in Table 2.2.15.

The results indicate no greater concentration of additives in the unfiltered portion (reactor heel) than in the filtered samples, and consequently it appears that the additives were completely dissolved at 800°C . From visual observations, however, the solution seemed to be essentially saturated at this temperature. The saturating phase appeared to be free LaF_3 , and the probable solubility value for this compound at 800°C seems to be about 2.5 wt %. During the preparation of this material no particular effort was made to control the filtration temperature at exactly 800°C , and visual observations could not be made conveniently enough to fix a liquidus temperature; however, the order of magnitude of the solubility of LaF_3 in $\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %) appears to be about 2 mole % at 800°C .

Although it appears that the solubilities of the rare earth fluorides in the NaF-ZrF₄-UF₄ mixture are sufficiently high to prevent precipitation upon their formation as fission products during ART operation, some studies of solubility of individual rare earths and rare-earth mixtures are currently under way. One possible development from such a study might be the demonstration of a simple means for removal of the rare-earth fluorides from the fuel mixture if the magnitudes and temperature dependences of the solubilities are adequate.

PRELIMINARY SOLUBILITY VALUES OF CeF₃
IN NaF-ZrF₄-UF₄

C. M. Blood

As a start of a systematic determination of solubilities of the rare-earth fluorides in ART-type fuels, such as NaF-ZrF₄-UF₄ (55-40-5 mole %), one experiment was performed to determine the approximate solubility of CeF₃ in a typical solvent. A previously purified mixture of the NaF-ZrF₄-UF₄ solvent and approximately 2.5 mole % CeF₃ were enclosed in a nickel container and heated to 850°C. The mixture was continuously stirred by bubbling hydrogen and helium, alternately, through a dip leg. Two hours prior to filtration, the temperature of the solution was lowered to 800°C. Samples of liquid were then withdrawn through a nickel filter tube at 800, 700, and 600°C. A second set of filtrates was obtained in the same manner at 700 and at 600°C after the mixture had been given an additional hydrofluorination and hydrogenation treatment. The results are summarized in Table 2.2.16.

Since the CeF₃ used in these experiments was not especially pure and certain difficulties were

TABLE 2.2.16. APPROXIMATE SOLUBILITY OF
CeF₃ IN NaF-ZrF₄-UF₄ (55-40-5 MOLE %)

Temperature (°C)	CeF ₃ Solubility	
	Wt % Ce	Mole % Ce
800	1.62	1.2
700	0.79	0.6
	0.82	
600	0.65	0.5
	0.59	

apparent in analysis of the filtrates obtained, these data should be considered as preliminary. It is anticipated that more reliable values will be available within the next quarter.

CONCENTRATION CELLS AND TRANSFERENCE
NUMBERS IN FUSED SALTS

R. F. Newton

It is well known that transference numbers are needed for correlating the electromotive forces of concentration cells with activities or other thermodynamic properties of the solutions involved. While measurements have been and are being made of the transfer of ions of fused salts across porous diaphragms, some investigators doubt that these data can be properly interpreted as the "true" transference numbers of the ions, since the diaphragm itself may cause a flow of salt across the boundary. It is of interest to note, however, that relative transference numbers, which are the values of thermodynamic interest, can be measured in an ordinary Hittorf experiment.

It is well known that the transport of water as part of a hydrated ion in aqueous systems cannot be determined without some rather questionable assumptions, but standard transference numbers of aqueous ions are given relative to the water. For example, in a mixture of two salts, such as AgCl and NaCl, the transference number of Ag⁺ may be defined relative to the NaCl. The fictitious of the ideal transference numbers, t_{Na}^* , t_{Ag}^* , and t_{Cl}^* are useful in this analysis. In an ordinary Hittorf transference experiment in which silver electrodes are used and the mixture of salts contains m moles of AgCl per mole of NaCl, N faradays of electricity are passed, and the "idealized" anode compartment gains N moles of Ag⁺ by electrode reaction and Nt_{Cl}^* moles of Cl⁻ by transfer and loses Nt_{Na}^* moles of Na⁺ and Nt_{Ag}^* moles of Ag by transfer. This may be summarized as a gain of N moles of AgCl by electrode reaction and a loss of Nt_{Ag}^* moles of AgCl and of Nt_{Na}^* moles of NaCl by transfer. The best that can be done experimentally, however, is to compare the AgCl in a given quantity of NaCl at the end with that in the same amount of NaCl at the start. If, for example, the anode portion taken for analysis at the end of the experiment contains one mole of NaCl, and the "idealized" anode compartment has lost Nt_{Na}^* moles of NaCl, this represents $1 + Nt_{Na}^*$ moles of NaCl at the start. The AgCl at the start was $m + mNt_{Na}^*$ and

the AgCl at the end was

$$(1) \quad N + m + mNt'_{Na} - Nt'_{Ag}$$

where m is the AgCl in one mole at the start and N is the AgCl from the electrode reaction. If m and N are subtracted from expression 1 and the remainder is divided by N , the relative transference of Ag^+ is seen to be

$$(2) \quad t'_{Ag} = t'_{Ag} - mt'_{Na}$$

By a similar argument it may be seen that

$$(3) \quad t'_{Cl} = 1 - t'_{Ag}$$

These relative transference numbers are all that can be obtained unambiguously from the Hittorf experiment, in which N faradays of electricity are passed, the electrode compartments are analyzed, and the AgCl content of the electrode compartment is compared with that initially present in the same amount of NaCl. They are also the only numbers needed for thermodynamic use.

Useful correlations of the relative transference numbers with electric conductance may also be made. For these correlations, λ (the ionic conductance) is defined so that, for pure NaCl, $\lambda_{Na} + \lambda_{Cl} = \kappa/C$, where κ is the specific conductance and C is the concentration in equivalents per cubic centimeter. For the NaCl-AgCl mixture,

$$\begin{aligned} \kappa &= C_{Na}\lambda_{Na} + C_{Ag}\lambda_{Ag} + C_{Cl}\lambda_{Cl} \\ t'_{Na} &= \frac{C_{Na}\lambda_{Na}}{\kappa} \\ t'_{Ag} &= \frac{C_{Ag}\lambda_{Ag}}{\kappa} \\ t'_{Cl} &= \frac{C_{Cl}\lambda_{Cl}}{\kappa} \end{aligned}$$

and, when these values are substituted in Eq. 2, it may be seen that

$$(4) \quad t'_{Ag} = t'_{Ag} - \frac{C_{Ag}}{C_{Na}} t'_{Na}$$

$$\begin{aligned} &= C_{Ag} \frac{\lambda_{Ag} - \lambda_{Na}}{\kappa} \\ &= \frac{\lambda_{Ag} - \lambda_{Na}}{\kappa/C_{Na}} \end{aligned}$$

From Eq. 4 it is evident that the relative transfer of the silver ion is proportional to the concentration of the silver ion and to the difference in the mobilities of Ag^+ and of Na^+ , and hence the relative transfer may be either positive or negative. If it is negative, t'_{Cl} will be greater than unity.

For application to a concentration cell with transference, consider the cell

At the anode, for each faraday passed,

$t'_{Ag} m^A$ mole $Ag^+(m^A)$ is lost by transfer, and

$(1 - t'_{Ag})$ mole Cl^- is gained.

At the cathode the opposite processes occur, with each A replaced by B . In the section with a concentration gradient between A and B , in each element, such as between the dotted lines, the gain of AgCl is t'_{Ag} and the loss is $t'_{Ag} + dt'_{Ag}$, which gives a net loss of dt'_{Ag} mole AgCl in the element, and

$$\begin{aligned} \Delta F &= (1 - t'_{Ag}^A) \bar{F}^A - (1 - t'_{Ag}^B) \bar{F}^B - \int_A^B \bar{F} dt'_{Ag} \\ &= \bar{F}^A - \bar{F}^B + \int_A^B t'_{Ag} d\bar{F} \end{aligned}$$

If t' is constant this simplifies to

$$\Delta F = (1 - t'_{Ag}) (\bar{F}^A - \bar{F}^B);$$

however, as shown in Eq. 4, t' is not expected to be constant.

2.3. PHYSICAL PROPERTIES OF MOLTEN MATERIALS

F. F. Blankenship G. M. Watson
E. R. Van Artsdalen

PRESSURE-COMPOSITION-TEMPERATURE
RELATIONS FOR THE SYSTEMS
KF-ZrF₄ AND RbF-ZrF₄

S. Cantor

Among the important guiding principles in the search for improved or modified fuel mixtures are predictions regarding the changes in properties that will occur as a result of the substitution of one species of ion for another in an otherwise similar melt. To a very considerable extent these predictions can be based on a determination of how the activity coefficients of the constituents change with composition. One of the easiest activities to measure, and a fairly important one to know, is the activity of ZrF₄ in mixtures with alkali fluorides at compositions such that the vapor is essentially pure ZrF₄. Mixtures containing 45 mole % or more ZrF₄ produce a vapor which, for practical purposes, is pure ZrF₄, and the activity of ZrF₄ is readily obtained from the total vapor pressure. Accordingly, measurements are being made of the pertinent vapor pressures in alkali fluoride-ZrF₄ systems. It has been found that the volatility of the ZrF₄ varies inversely with the size of the alkali cation. This is a consequence of the more pronounced complexing of ZrF₄ in the presence of the alkali cations, which have less attraction for fluoride ions. Lithium fluoride represents the case of an outstandingly strong attraction of a cation for fluoride ions because of the large charge-to-radius ratio of the lithium ion. Correspondingly, the vapor pressures from the LiF-ZrF₄ mixture are the highest; this system is currently being measured at the Battelle Memorial Institute. The NaF-ZrF₄ mixtures have been measured at ORNL¹⁻³ and at Battelle.⁴ Vapor pressures for KF-ZrF₄ and RbF-ZrF₄ are currently being de-

termined by the Rodebush-Dixon method that has been used for other ZrF₄ mixtures at ORNL. This method depends on the "valve" action of the salt vapor above a liquid held at constant temperature; the valve action is manifested by a differential manometer which registers the resistance to flow of inert gas through a region occupied by the refluxing salt vapor. The "valve" becomes suddenly much more definite in effect when the inert gas pressure is lowered to a value corresponding to the salt vapor pressure. An absolute manometer is used to measure the pressure at which this occurs.

The System KF-ZrF₄

The vapor pressure experiments initiated previously on the system KF-ZrF₄ were continued.⁵ The Rodebush-Dixon method,⁴ previously described,^{5,7} was employed.

In the present study the temperature determinations were carried out potentiometrically by using calibrated platinum-platinum-rhodium thermocouples. Pure ZrF₄ was prepared by subliming hafnium-free ZrF₄ at 720°C under a vacuum. Translucent crystals were then hand-picked from the sublimate. Spectrochemical analyses for ten possible metallic contaminants showed, in every case, less of the impurity than of the available standard. Potassium fluoride was purified by heating the reagent-grade product to 50°C above the melting point, cooling it slowly, and selecting clear fragments of the fused salt.

In the KF-ZrF₄ compositions studied, the assumption that the ZrF₄ is responsible for the vapor pressure was justified by chemical analyses and x-ray and petrographic studies of sublimed material obtained from the apparatus after a run was completed. The vapor pressures obtained for the various mixtures are summarized in Table 2.3.1. The constants A and B are those expressed

750-900	59.6	40.4	9.142	8,321	38.1
775-900	55.0	45.0	8.403	7,778	35.6
825-950	49.9	50.1	7.722	7,363	33.7
875-950	47.3	52.4	7.679	7,467	34.2
950-1000	45.3	54.7	7.649	7,721	35.3
975-1100	40.4	59.6	7.612	8,465	38.8
1125-1300	34.9	65.1	7.387	9,020	41.3

in the relation

$$\log P \text{ (mm Hg)} = A - \frac{B}{T}$$

where T is in °K. These constants are obtained by treating the data by the method of least squares. The heat of vaporization, ΔH_v , of ZrF₄ is obtained by multiplying the constant B by 2.303 (°R) or 4.576. The values listed in Table 2.3.1 are considered to be more reliable than those previously published.⁵ Apparently there was some free ZrF₄ present in some of the earlier experiments, and for the compositions containing 65.9 to 49.9 mole % ZrF₄ a reanalysis by least squares gave the new constants. A plot of the data from which the equation for each mixture was obtained is shown in Fig. 2.3.1.

A very odd phenomenon is observed when the apparent heat of vaporization, ΔH_v , is plotted against composition (Fig. 2.3.2). A sharp minimum occurs at 50 mole % ZrF₄, and the heat of vaporization increases linearly with composition in both directions from the minimum. The change below 50 mole % ZrF₄ is in the expected direction, since ZrF₄ becomes more tightly complexed by fluoride ions. The change above 50 mole % was not expected; qualitatively it can be explained by assuming that ZrF₄ exhibits positive deviations from Raoult's law when dissolved in KZrF₅. (This version of Raoult's law calls for a "two-particle" depression at the ZrF₄ end of the composition range and for zero pressure at the KZrF₅ end.) In practice, the vapor pressure of supercooled liquid ZrF₄ is not sufficiently well

known for a numerically reliable Raoult law to be established for ZrF₄ systems at 600 to 800°C.

The System RbF-ZrF₄

The vapor pressures of various mixtures in the system RbF-ZrF₄ were determined in the same manner as in the KF-ZrF₄ system. Reasonably pure RbF was obtained by selecting clear crystals from a slowly cooled melt. Analyses showed that the other alkali metal ions were present in the following weight percentages: Li, 0.023; Na, 0.005; K, 0.16; Cs, 0.24.

The data for various mixtures are compiled in Table 2.3.2 and shown graphically in Fig. 2.3.3. The constants A and B are from the relation

$$\log P \text{ (mm Hg)} = A - \frac{B}{T}$$

where T is in °K.

As in the case of the KF-ZrF₄ system, the heat of vaporization goes through a minimum at 50 mole % ZrF₄ (Fig. 2.3.4). The linearity with mole fraction is also similar to that of the KF-ZrF₄ system. Thus the effect seems to be a real one in spite of its unnatural appearance.

A comparison of the effects of the various alkali fluorides is given in Fig. 2.3.5, in which pressure is plotted as a function of composition at 912°C, the melting point of pure ZrF₄. Moore⁶ has studied two compositions for the system LiF-ZrF₄, and Sense *et al.*⁴ of Battelle Memorial Institute and Moore¹⁻³ have studied the NaF-ZrF₄ system.

⁶R. E. Moore, ANP Quar. Prog. Rep. June 10, 1955, ORNL-1896, p 81.

CONFIDENTIAL
ORNL-LR-DWG 14637

Fig. 2.3.1. Vapor Pressures of KF-ZrF₄ Mixtures.

The value of 905 mm Hg for ZrF₄ at the melting point was obtained from the sublimation vapor pressure equation

$$\log P \text{ (mm Hg)} = 12.5417 - \frac{11,360.4}{T}$$

This equation represents a least-squares treatment of 33 experimental points obtained with the present apparatus. The results conclusively show that in solutions of ZrF₄ and alkali fluorides the vapor

pressure of ZrF₄ decreases as the alkali ion size increases.

VAPOR PRESSURES AND PHASE EQUILIBRIUM DATA IN THE FeCl₂-KCl SYSTEM

C. C. Beusman⁹

The vapor pressure of FeCl₂ in FeCl₂-KCl systems was measured by the Rodenbush-Dixon

⁹On assignment from the Oak Ridge Institute of Nuclear Studies.

Fig. 2.3.2. Effect of Composition on Heat of Vaporization of ZrF_4 in $KF-ZrF_4$ Mixtures.

method in concentrations from 100 to 45 mole % $FeCl_2$ in KCl . Pressure vs composition curves obtained at 850 and 900°C are shown in Fig. 2.3.6; these are typical of the curves obtained at temperatures from 700 to 1050°C. The strong deviation from ideality suggests that the $FeCl_2$ is complexed in the liquid at these temperatures. Since the experimental evidence was obtained in phase equilibrium studies of the compound K_2FeCl_4 in the solid state, it is interesting that the same stoichiometry may apply to the complex in the liquid. The strong depression of the vapor pressure below 45 mole % precludes further experimental efforts with the Rodenbush-Dixon technique. The transpiration method will be used to complete the experimental curve on the KCl -rich side of the graph.

The phase diagram for the $FeCl_2-KCl$ system, shown in Fig. 2.3.7, was determined by two experimental techniques. First, both conventional cooling and differential cooling curves were obtained on small melts, and, second, quenched samples were prepared by the gradient-quenching techniques used in this laboratory. Petrographic examination of the quenched and slowly cooled samples revealed two well-defined compounds in the solid state, K_2FeCl_4 and $KFeCl_3$. Both compounds appear to have solid-state transformations, and K_2FeCl_4 melts incongruently.

TABLE 2.3.2. SUMMARY OF VAPOR PRESSURES FOR THE SYSTEM $RbF-ZrF_4$

**SURFACE TENSION AND DENSITY
OF $NaF-ZrF_4$
F. W. Miles**

Preliminary values of the density and surface tension of $NaF-ZrF_4$ (53-47 mole %) were obtained by the maximum-bubble-pressure method previously described.¹⁰ The results are summarized in Table 2.3.3. Difficulties were encountered as a result of plugging of the nickel tube above the capillary tip. In every case the concentration of oxides and oxyfluorides in the plug material appeared to be quite high, and thus it is thought that there was air contamination of the helium stream. The assembly is being examined in an attempt to locate and eliminate the source of

0.0513	9	700	2.916	120

contamination, and changes have been made in the design of the capillary tips.

The four measurements listed in Table 2.3.3 were obtained on the same batch of material. Although the melt was re-purified, in place, after each determination, the formation of plugs indicated contamination during measurement. Furthermore, the batch was kept at high temperatures for several weeks. When the reactor was opened, it was observed that some ZrF_4 had sublimed out of the solution. These factors indicate that the values given in Table 2.3.3 must be considered to be only of a very preliminary nature. It is encouraging, however, to note that values of the same order of magnitude were obtained with capillary tubes of different wall thicknesses. This behavior seems to indicate contact angles of less than 90 deg. Consequently, the inside radius of the capillary controls the bubble size, and no particular uncertainty exists as to whether the value of the inside or of the outside radius should be used in the calculations.

Additional measurements will be made on a fresh batch of similar composition. When more reliable values are obtained, the measurements will be extended to other mixtures of interest.

SURFACE TENSIONS OF MOLTEN SALTS

S. Langer

The sessile-drop technique for measuring surface tension, briefly discussed in the previous report,¹¹ was applied to a number of samples of an $NaF-ZrF_4$ (53-47 mole %) mixture to establish the importance of a number of experimental variables. Since it has been demonstrated that $NaF-ZrF_4$ mixtures of this general composition do not wet C-18 graphite, all the experiments described here were conducted with this material as the supporting plaque.

A schematic drawing of the sessile-drop apparatus is shown in Fig. 2.3.8. The sample on its

supporting plaque is loaded into the tube through the sample-loading flange. The central portion of the tube is then baked out under high vacuum to remove volatile materials which might contaminate the surface of the sample. After the furnace is adjusted to the operating temperature, the sample is pushed to the center of the constant-temperature block with the solenoid-operated sample-manipulating rods. Photographs are taken of the sample as a function of time to ensure the establishment of an equilibrium droplet. A photograph of the sessile drop of NaF at 1025°C, taken during calibration work, is shown in Fig. 2.3.9.

Fig. 2.3.9. Photograph of Reference Scale and Sessile Drop of NaF at 1025°C on Graphite Plaque.

The dimensions¹¹ of the sessile drop (the maximum diameter, $2x$, and the distance from the line of the maximum diameter to the apex, z) are measured directly from the photographic negative by using a toolmaker's microscope. Corrections for anisotropic shrinkage of the film are obtained by using the reference scale which surrounds the drop. The surface tension is cal-

culated by using the tables of Bashforth and Adams¹² and the densities obtained by Miles.¹³

The initial experiments indicated no change in surface tension when an atmosphere of helium was admitted to the apparatus in which tests had been made under vacuum. When tests were conducted in vacuum, however, volatilization of ZrF_4 caused large changes in composition of the drop; helium atmospheres have been adopted as standard for future tests.

Data typical of those obtained to date for NaF-ZrF₄ melts whose initial composition was 53 mole % NaF and 47 mole % ZrF₄ are shown in Table 2.3.4. While the data of the earlier experiments are viewed with some uncertainty, the relative agreement of the surface tension values obtained from droplets of widely varying sizes (as evidenced by the spread of sample weights and x/z ratios) is gratifying.

SPECIFIC CONDUCTANCE AND DENSITY OF FUSED LITHIUM, POTASSIUM, AND CESIUM FLUORIDES¹⁴

E. R. Van Artsdalen

Electrical conductance and density have been measured as a function of temperature for pure, fused lithium, potassium, and cesium fluorides. A newly designed bridge, in conjunction with a special cell fabricated from platinum-rhodium alloy, was used in the measurements. The results of the measurements are expressed by the equations listed in Tables 2.3.5 and 2.3.6. Similar data were also obtained for several rare-earth halides.

These data have been correlated with those reported previously. It is now possible to give satisfactory theoretical interpretations of the results in terms of the structure and transport properties of the liquid salts.

2.4. PRODUCTION OF FUELS

G. J. Nessle G. M. Watson
L. G. OverholzerEXPERIMENTAL PREPARATION OF
VARIOUS FLUORIDES

B. J. Sturm

Continued use of structural metal fluorides for research necessitated the preparation of additional quantities of these materials by the several methods developed previously. As in the past, use was made of chemical, x-ray, and petrographic examinations to establish the identity and purity of the materials.

Additional CrF_3 was prepared by hydrofluorination of anhydrous CrCl_3 , as well as by the thermal decomposition of $(\text{NH}_4)_2\text{CrF}_6$. The latter is prepared by the interaction of hydrated CrF_3 with $\text{NH}_4\text{F}\cdot\text{HF}$, and it may also be reduced by hydrogen to yield CrF_2 . Several batches of NiF_2 were prepared by the hydrofluorination of either hydrated NiF_2 or hydrated NiCl_2 . One batch of AgF was prepared by hydrofluorination of Ag_2CO_3 . Methods described previously¹ were used for the preparation of additional quantities of CeF_3 and of LaF_3 .

An attempt to remove oxide from a $\text{KF}\cdot\text{ZrF}_4$ mixture by hydrofluorination was unsuccessful. Runs at 600°C failed to remove the oxide completely and, while this could be accomplished at 850°C , the loss of ZrF_4 was sufficient to alter the composition to the point where the material was unsatisfactory for its intended purpose.

A batch of CuF_2 was prepared for use as a carrier in certain spectrographic boron analyses. Material low in boron and silicon was requested for this purpose. Anhydrous CuF_2 was hydrofluorinated for 4 hr at 400°C , but this short period of treatment failed to reduce the boron content to a sufficiently low level. However, extending the period of hydrofluorination to 20 hr yielded a material that was acceptable.

A fuel mixture containing Li^7 and enriched uranium was prepared for radiation damage studies. Since Li^7 was available only as the carbonate, a preliminary run was made with normal Li_2CO_3 , UF_4 , KF , NaF , and excess $\text{NH}_4\text{F}\cdot\text{HF}$ to establish whether fusion of this mixture would yield an oxide-free product. After the preliminary run proved successful the procedure was applied to the mixture containing Li^7 and U^{235} . The material was

oxide free, but a sulfur content of 170 ppm was reported, most of which came from the $\text{Li}_2^{23}\text{CO}_3$. The fuel was subjected to 5 cycles, each of which entailed a 10- to 15-hr hydrogen treatment and 1 hr of hydrofluorination at 800°C . The product then contained 45 ppm of sulfur and a trace of oxide. Hydrofluorination at 700°C for 6 hr then produced an oxide-free product.

LABORATORY-SCALE PURIFICATION
OPERATIONS

F. L. Daley W. T. Ward

With appropriate modifications, the standard hydrofluorination-hydrogenation process was used to prepare a number of especially pure materials requested for various purposes. Of these only an $\text{NaF}\cdot\text{ZrF}_4\cdot\text{UF}_4$ mixture containing additives of BaF_2 , LaF_3 , and RbF had not previously been prepared by the standard procedure. Operational facilities to transfer and dispense small samples (200 to 500 g), especially into apparatus for accurate evaluation of physical properties of materials, were constructed and used successfully during this quarter. There is evidence that direct transfer of the purified melt into the apparatus has significantly improved the purity of the test material and, accordingly, increased confidence in the test results.

Copper-lined stainless steel reactors were used successfully in the purification operations.

PILOT-SCALE PURIFICATION OPERATIONS

J. P. Blakely C. R. Croft
J. Truitt

The pilot-scale purification facility processed 68 batches totaling approximately 1300 lb of various fluoride compositions for use in small-scale corrosion testing, phase equilibrium studies, and physical property studies. The bulk of the material was produced during February when the facility was operating on a three-shift, 24-hr-day basis. As a result, the backlog reported last quarter was eliminated and normal operations were resumed.

¹B. J. Sturm, ANP Quan. Prog. Rep. March 10, 1956, ORNL-2061, p. 100.

ANP PROJECT PROGRESS REPORT

The use of copper-lined stainless steel reactors in the 5-lb units has proved successful. Therefore, when the nickel reactors now on hand wear out and are discarded, they will be replaced with copper-lined stainless steel vessels. The new copper-lined vessels, in addition to showing promise of having longer lives, are more versatile than the nickel reactors in that they can be used in the preparation of $B\text{eF}_2$ -containing mixtures.

Although the supply of 50-lb nickel reactor vessels is at present sufficient, these will also be replaced with copper-lined stainless steel vessels as they are discarded.

PRODUCTION-SCALE OPERATIONS

J. E. Eorgan J. P. Blakely

Seventeen batches totaling approximately 4230 lb of fluoride compositions were processed by the production-scale facility. Two new copper-lined stainless steel reactors were received about the first of March and were put into production operation immediately. To date, nine batches have been processed in one reactor and eight in the other with no apparent difficulties. Recent external examination of these reactors show no deterioration or faults, and it may be that the life service of these reactors will be much better than expected.

In spite of the temporary shutdown of this facility, the processed fluorides inventory has remained high. Operations were slowed down during the last three weeks of this quarter because of a shortage of storage containers. A survey is now being made to determine the anticipated requirements for processed fluorides during the next six months. A recent communication from Pratt & Whitney Aircraft

gave fairly firm commitments for approximately 1700 lb of processed fluorides per month for the remainder of the calendar year. The ORNL Aircraft Reactor Engineering Division has been using an average of about 1000 lb of fluorides per month. Although the new survey is not complete, indications are that Aircraft Reactor Engineering Division usage will range around 1000 to 1500 lb per month for the remainder of 1956. The demands will not reach the production capacity of the facility, but at least they will make it economically feasible to maintain continuous operation.

The remaining 7500 lb of hafnium-bearing zirconium fluoride ordered from an outside vendor was received and all the material was accepted as satisfactory.

BATCHING AND DISPENSING OPERATIONS

J. P. Blakely F. A. Dass

The batching and dispensing facility dispensed 148 batches totaling approximately 4900 lb of processed fluorides in batch sizes ranging from 1 to 250 lb. The total amount dispensed was about 1000 lb less than was dispensed the previous quarter. Therefore there was another gain in stock inventory in spite of decreased production. A material balance for the quarter is given in Table 2.4.1.

The production and use of special compositions is decreasing steadily, but periodic increases can be expected as new materials are developed for testing and investigations. The use of NaF-ZrF_4 (50-50 mole %) and $\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %) or closely related compositions is expected to increase to about 3000 lb per month during the first

TABLE 2.4.1. MATERIAL BALANCE

	Material (lb)			Total
	$\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %)	NaF-ZrF_4 (50-50 mole %)	Special	
On hand at beginning of quarter	6,235	1,875	591	8,701
Produced during quarter	3,543	198	1,789	5,530
Total	9,778	2,073	2,380	14,231
Dispensed during quarter	3,828	0	1,078	4,906
On hand at end of quarter	5,950	2,073	1,302	9,325

half of fiscal year 1957. This estimate includes Pratt & Whitney requirements. At this rate, full production should still be able to maintain a high stock inventory and to allow for any necessary shutdown of the production-scale facility. The efficient handling, maintenance, and dispensing of some 200 storage cans has made it possible to fill all sizes of orders with a minimum of delay to operating sections of the ANP program.

PREPARATION OF ZrF_4 FROM $ZrCl_4$
J. E. Eorgan J. P. Blakely

The facility for the conversion of hafnium-free $ZrCl_4$ to ZrF_4 was operated three times during this quarter. The mechanical operation of the unit is now satisfactory. Handling techniques need to be improved to cut down on raw-material and finished-product losses. Also, the finely divided nature of the product ZrF_4 has presented a dust-loss problem of considerable magnitude. Steps are being taken to eliminate or greatly improve this situation. Large quantities of ZrF_4 dust were carried into the process gas exit lines and caused major line-plugging difficulties. A change in piping arrangement improved this situation somewhat in the last run.

Rough material balances of the three operations indicated a total loss of about 22% of product in the first two runs and 11% in the last run. Approximately 75% of this loss was accounted for in material removed from the exit gas lines. A new dust filter has been ordered for installation on the unit which should cut down the dust loss considerably. Operation of this facility will be postponed until this new filter arrives or there is an urgent need for more hafnium-free ZrF_4 .

Analytically, the product material was as good or better than material previously or presently being used. Four samples were taken from each batch as it was being discharged from the unit, each sample representing roughly one-fourth of each batch so that uniformity could be tested. The analytical results are given in Table 2.4.2. Although the first batch was not so good as the last two, either in uniformity or quality, it was considered to be usable.

SPECIAL SERVICES

J. P. Blakely F. A. Doss

Requests for service in filling, draining, and sampling operations were at a normal and steady level. The greatly accelerated pace set in the

*The hafnium content of the material was less than 100 ppm, the baron content was less than 1 ppm, the sulfur content was about 30 ppm, and the carbon content was 300 ppm.

previous quarter was not maintained. Past experience indicates that filling and draining operations will be requested in cycles, depending upon the rate at which tests are started or terminated. Present indications are that another accelerating cycle will occur in the next quarter.

Approximately 3000 lb of processed fluorides and 1500 lb of liquid metals were used to charge test equipment during the quarter in charge sizes ranging from 5 to 500 lb. Since the liquid metal (NaK) inventory had run below 1500 lb, another 5000 lb of noneutectic NaK (56% Na-44% K) was ordered and received. It is estimated that this supply should last six to eight months unless consumption is sharply increased.

A serious complication arose in the disposal of NaK during the cold months of this winter. This material, which is normally molten at room temperatures, could not be disposed of by underwater injection because it froze in the transfer lines. It was fortunate that sufficient storage cans were available to contain the NaK drained from equipment until warmer weather arrived and that a comparatively small amount of NaK was drained from

ANP PROJECT PROGRESS REPORT

equipment during this quarter. It has been requested that electric power be supplied at the disposal quarry so that disposal of both sodium and NaK can proceed regardless of atmospheric temperature. Present rough estimates of the cost of such an installation range from \$250 to \$1000. Firmer figures are to be obtained, and, if the range above is correct, adequate power is to be installed for liquid metal disposal.

In-pile loop No. 5 was filled with enriched NaF-

ZrF₄-UF₄ (53.5-40-6.5 mole %). Two new batches for in-pile loops were processed. Dates for filling loops with these batches have not yet been set.

Two other small batches of special enriched mixtures were also processed this quarter. One batch, NaF-ZrF₄-UF₄ (62.5-12.5-25.0 mole %), was to be used at CRNL for special radiation tests. The other batch, NaF-UF₄ (66.7-33.3 mole %), was ordered by Battelle Memorial Institute.

2.5. COMPATIBILITY OF MATERIALS AT HIGH TEMPERATURES

F. Kertesz

PENETRATION OF GRAPHITE
BY MOLTEN FLUORIDESH. J. Buttram G. F. Schenck¹

It appears very likely that graphite is the only reasonably effective reactor moderator material that will remain chemically stable upon direct exposure to molten fluoride fuel mixtures. The use of graphite to contain such fuel mixtures has been known for a long time to be practical for simple laboratory-scale experimental equipment. The graphite most commonly used for this purpose has the commercial designation C-18. However, little information is available concerning the rate of penetration of reactor-grade graphite by molten fluoride fuel mixtures, and accordingly an investigation of this phenomenon has been initiated.

Specimens of APC² graphite $\frac{1}{4} \times \frac{1}{4} \times \frac{1}{2}$ in. were soaked at 600°C for various periods in sealed capsules of Inconel containing molten NaF-ZrF₄ or NaF-ZrF₄-UF₄ mixtures under helium atmospheres. The specimens were then sectioned and examined under the petrographic microscope. Preliminary observations indicate that the APC graphite was completely penetrated by NaF-ZrF₄ (53-47 mole %) in 1 hr at 600°C but that NaF-ZrF₄-UF₄ (53.5-40.0-6.5 mole %) had not detectably penetrated the graphite in 10 hr at 600°C. The rapid penetration of the graphite by the NaF-ZrF₄ melt is considered to be surprising, since such penetration is in contrast to the stability of C-18 graphite in this and similar fluoride mixtures. Other graphites of higher density will be examined in these and other fluoride mixtures. If necessary, attempts will be made to prevent penetration of the graphite by prior impregnation with high-melting-point materials such as NaF or CaF₂.

EFFECT OF ATMOSPHERE ON ANODIC
DISSOLUTION OF NICKEL IN
MOLTEN NaOH

F. A. Knox

An attempt has been made to study the efficiency of anodic dissolution of nickel in NaOH under various atmospheres and various conditions of cur-

rent density and temperature. The apparatus consisted of a crucible of Morganite (recrystallized alumina) containing molten sodium hydroxide into which a nickel anode and a cathode, as well as a nickel thermocouple well, were inserted. This electrolytic cell and its furnace were placed in a large chamber which could be evacuated or filled with the desired atmosphere. A lead storage battery served as the power supply; the circuit also contained a voltmeter, ammeter, and ampere-hour meter, as well as rheostats to control the current density applied.

When the assembled electrolytic cell was maintained at the desired temperature without an applied voltage, attack on the electrodes was negligible. Passage of current resulted in erosion of the anode and subsequent deposition of crystalline nickel on the cathode. The weight gain of the cathode did not correspond precisely to the weight loss of the anode, since the crystalline deposit was not perfectly adherent; in addition some sodium aluminate, formed by the reaction of NaOH with the Al₂O₃ of the crucible, apparently contaminated the cathode deposit. Loss in weight of the anode was accordingly used to evaluate the efficiency of the cell.

The data shown in Table 2.5.1 were obtained at a current density of 2 amp/cm². At this current density the cell efficiency is very poor under all conditions. The dissolution efficiency is decreased slightly by substituting hydrogen for helium as the static cover gas and is reduced considerably by bubbling hydrogen through the molten electrolyte.

2.6. ANALYTICAL CHEMISTRY

J. C. White

DETERMINATION OF BARIUM, LANTHANUM,
AND RUBIDIUM IN FLUORIDE FUELS

A. S. Meyer, Jr.

B. L. McDowell

Methods were developed for the determination of barium, lanthanum, and rubidium in NaF-ZrF₄-UF₄ as part of a program for determining the effect of typical fission products on the physical properties of molten mixtures of fluoride salts. For the barium determination the fluoride salt mixture is dissolved in fuming sulfuric acid, and the barium remains in the insoluble residue, as the sulfate. After dilution of the sulfuric acid solution with water, the barium sulfate, which is contaminated with uranium and zirconium, is separated by filtration and purified by dissolving it in a hot ammoniacal solution of ethylenediaminetetraacetic acid. It is then reprecipitated by acidification of the solution with hydrochloric acid. The reprecipitated barium sulfate is filtered off. The filter paper is charred, and the barium sulfate is then ignited to constant weight at 600°C.

Lanthanum is separated from the filtrate from the barium determination by precipitation, as the oxalate, from a neutral solution of ammonium oxalate. Coprecipitated zirconium and uranium are separated from the original oxalate precipitate by dissolving the precipitate in concentrated nitric acid and carrying out a second oxalate precipitation from a neutral solution of ammonium oxalate. The purified oxalate precipitate is converted to the nitrate by digestion with concentrated nitric acid and evaporation to dryness. The residue is taken up in a small amount of water or very dilute nitric acid. Lanthanum is finally precipitated by the addition of solid oxalic acid to the hot, slightly acid solution. The lanthanum oxalate is ignited at 900°C and weighed as La₂O₃.

Ammonium salts in the filtrate from the lanthanum determination are destroyed by digesting the solution with aqua regia. The alkali metals are separated and converted to the hydroxides by passing the solution through an anion exchange column in the hydroxide form. After all traces of ammonia are removed by evaporating the alkaline solution to dryness, the rubidium is precipitated and weighed as the sparingly soluble tetraphenylboron salt. Potassium, which is present as a trace contaminant

in the base fuel, is also precipitated as the tetraphenylboron salt. The potassium in the tetraphenylboron precipitate is determined by flame photometry, and the weight of the precipitate is corrected accordingly.

Good precision has been obtained in analyses of replicate samples of fluoride mixtures which contained 1 to 3% of each of the above-mentioned elements. These methods are also being tested for the determination of cerium and the proximate determination of the cerium group of the rare-earth elements in fluoride fuels.

DETERMINATION OF NIOBIUM IN FUSED
MIXTURES OF FLUORIDE SALTS BY
THE THIOCYANATE METHOD

A. S. Meyer, Jr.

B. L. McDowell

R. F. Apple

A method for the spectrophotometric determination of niobium as the thiocyanate complex, reported by Ward and Marranzino,¹ was applied to the determination of niobium in NaF-ZrF₄-UF₄. The method is based upon the reaction of niobium(V) with thiocyanate in a mixed solution of 4 M hydrochloric acid and 0.5 M tartaric acid to produce a complex which exhibits an absorption maximum at 387 mμ in an ethyl ether-acetone medium. The addition of acetone to the extract of ethyl ether containing the complex inhibits the polymerization of the thiocyanate ion and stabilizes the solution for at least 20 hr.

Tartaric acid eliminates the interference of uranium, which also forms a complex with thiocyanate. The interference of the red color of the iron(III)-thiocyanate complex is eliminated by shaking the ether extract with a solution of stannous chloride for 30 sec to reduce the iron(III) to iron(II).

The concentration of the reagents in the aqueous phase must be held within rigid limits if reproducible absorbance values are to be obtained. In order to maintain fixed concentrations, the fluoride sample is dissolved by fusing it with potassium pyrosulfate and dissolving the melt in 1 M tartaric acid. A 1- to 10-ml aliquot of the resulting solution is combined with a sufficient

¹F. N. Ward and A. P. Marranzino, *Anal. Chem.* 27, 1325 (1955).

volume of 1 M tartaric acid solution to yield a total volume of 10 ml. Then 15 ml of the hydrochloric acid-tartaric acid reagent (9 M HCl and 0.5 M tartaric acid) and 15 ml of 20% (w/v) ammonium thiocyanate solution is added, following which the aqueous phase is extracted with 5 ml of ethyl ether.

Tests of this method have revealed that a linear relationship exists between the absorbance and the concentration of the niobium in the range 0.2 to 2.0 $\mu\text{g}/\text{ml}$. The coefficient of variation for this method, based on standards, is 2%.

DETERMINATION OF TRACES OF COPPER IN FLUORIDE FUEL MIXTURES

A. S. Meyer, Jr.

B. L. McDowell

Since copper is considered to be compatible with molten fluoride salts containing sulfur impurities, the nickel reactors used for the production of fluoride fuel mixtures have been equipped with copper liners to prolong their useful lifetimes. This modification in production technique necessitated the development of a sensitive method for the determination of copper in mixtures of fluoride salts. The spectrophotometric method in which "cuproine" (2,2'-biquinoline) is used as the chromogenic reagent, reported by Guest² to be specific for copper, was adapted for this determination.

Copper is determined as the copper(I)-cuproine complex formed by equilibrating an aqueous sulfate solution of the sample containing copper(I) with a solution of 0.02% (w/v) cuproine in *n*-amyl alcohol at pH 6. The copper complex is extracted in the organic phase. The complex exhibits its maximum absorbance at 550 $\text{m}\mu$. Hydroxylamine hydrochloride was used to reduce the copper to the monovalent state, and tartaric acid was used to complex iron and uranium.

The extraction procedure recommended by Guest² was modified for application to the determination of traces of copper in solutions of high ionic strength. The volume of the aqueous phase was increased from 30 to 100 ml in order to ensure an optimum amount of copper in the aliquot. The extraction period was increased from 1 to 30 min, and 10 ml of an alcoholic solution of the reagent was used. Since the aqueous-organic ratio was so large, 10 g of ammonium sulfate was added to reduce the solubility of the alcohol in the

²R. J. Guest, *Anal. Chem.* 25, 1484 (1953).

aqueous volume. The ammonium sulfate served to mask the mass-action effect of ionic constituents in the sample; however, it reduced the effective pH range for quantitative extraction from a range of 4.5 to 7.5 to a range of 6.0 to 6.5.

The absorbance of the organic extract is a linear function of the concentration of copper up to 7.5 $\mu\text{g}/\text{ml}$. The coefficient of variation of the method, as derived from standard samples, is 2%. Samples of NaF-ZrF₄-UF₄ prepared in the copper-lined nickel reactors have been analyzed for copper by this method. The range of the copper concentration was 1 to 25 ppm.

DETERMINATION OF TANTALUM IN NaF-ZrF₄-UF₄

J. P. Young

J. R. French

The determination³ of trace amounts of tantalum in NaF-LiF-KF has been extended to include the determination of tantalum in NaF-ZrF₄-UF₄. Since zirconium and uranium interfere with the determination of tantalum by the pyrogallol method,⁴ it was necessary to develop some means of removing these interferences. The separation of tantalum from uranium in NaF-LiF-KF-UF₄, which was described previously,³ was accomplished by a precipitation of the tantalum with cupferron. Zirconium, however, is also precipitated with cupferron. According to Hillebrand *et al.*,⁵ tantalum can be separated quantitatively from uranium and zirconium by precipitation with tannin in a slightly acidic solution of oxalate which is half-saturated with ammonium chloride. Since the samples contained alkali fluorides, it was necessary to dissolve them carefully to prevent the loss of TaF₅ by volatilization. This was accomplished by a careful digestion of the fluoride sample in dilute sulfuric acid in order to hydrolyze TaF₅ to Ta₂O₅. The solution was then evaporated to dryness, and the residue from this evaporation was fused with potassium pyrosulfate. The product of the fusion was dissolved in ammonium oxalate and then precipitated with tannin at a pH of 5 in a hot solution. The precipitate, after its removal and ignition to

ANP PROJECT PROGRESS REPORT

Ta₂O₅, was fused with potassium pyrosulfate, and the tantalum-pyrogallol color was developed, as described in the earlier report.³

The coefficient of variation was 5% for the determination of tantalum in NaF-ZrF₄-UF₄. In the separation of tantalum from uranium and zirconium, a sample which contained at least 0.5 mg of tantalum was taken.

DETECTION OF TRACES OF NaK IN AIR

A. S. Meyer, Jr.

J. P. Young

The design of an instrument for the photometric detection of NaK in air was completed. A functional description and the operational requirements of the apparatus were given previously.⁶ The electronic components of the instrument have been assembled, and the optical system is now being fabricated.

Preliminary engineering drawings of the instrument for the detection of submicrogram quantities of NaK in air by observation of the sodium resonance radiation have been prepared. Experiments are being carried out to devise a method for the introduction of reproducible concentrations of alkali metal oxides into air streams in order to provide synthetic samples for testing these instruments. The alkali metal is injected into the air stream in a jet of helium which is saturated with alkali metal by contact with the molten alkali metal. The temperature dependence of the vapor pressure of the molten metals provides the method for the control of the concentration of the metal in the helium. An apparatus has been assembled to test the stability of sodium aerosols that have been prepared at various mixing temperatures and various flow ratios of helium to air and to determine a quantitative method for transferring the samples of air to the detection instruments.

DETERMINATION OF OXYGEN IN NaK

A. S. Meyer, Jr.

G. Goldberg

Since it has been established that reasonable precision can be obtained in making the determination of oxygen in alkali metals with the modified Argonne distillation sampler, the sampler was connected to a loop in which NaK was being circulated. The loop operates at a temperature of

1200°F, with a cold trap differential of about 600°F. Since no inherent difficulties were encountered in the operation of the sampler in the loop, a detailed, step-wise procedure⁷ was written which covers the use of the sampler with both sodium and NaK loops. The analyses made over a five-day period while the cold trap was in operation gave the following concentrations of oxygen, in ppm: 1330, 1265, 575, 310, 265.

Since the results obtained with the sampler appear to be satisfactory, additional tests will be conducted in which the results from a plugging indicator will be compared with the results from the sampler. Plans are also being formulated to add a known amount of oxygen to the NaK to make further comparisons of the sampler and the plugging indicator. In the sampler now being constructed a sight tube is being placed in the distillation chamber so that the operations of sampling and distillation may be observed.

EXAMINATION OF COLD TRAPS FROM ALKALI-METAL SYSTEMS

A. S. Meyer, Jr.

G. Goldberg

A program was initiated to carry out the chemical examination of cold traps removed from systems circulating alkali metals, such as heat-exchanger test stands and corrosion-testing loops containing sodium or NaK. A typical request for analysis calls for the determination of oxygen, iron, chromium, nickel, and, in the case of NaK, a sodium-potassium ratio. Other constituents which are sometimes requested are uranium, zirconium, and beryllium. The cold traps range from 3 to 5 in. in diameter and from 2 to 6 ft in length.

In order to carry out the determination of oxygen successfully, the trap is drained as completely as possible. The residual sodium, or NaK, on the Demister packing within the trap is then reacted with butyl bromide to form the neutral bromide salts of sodium and potassium; oxides of these elements do not react with butyl bromide. When the reaction is completed, the organic material is drained, and the trap is cut into two parts. Until the trap is cut open, a blanket of helium is maintained in it.

⁶A. S. Meyer et al., ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 207.

⁷J. C. White, Procedure for the Determination of Oxygen in Sodium and NaK by the Distillation Method, ORNL CF-56-4-31 (April 5, 1956).

After the trap has been opened, both sections are washed carefully to dissolve the bromides and oxides, and the washings are combined and filtered. A portion of the filtrate is titrated with hydrochloric acid, and the concentration of oxygen is calculated from this titration. Both the filtrate and the residue are also analyzed for the corrosion products and any other constituents that were called for in the request for the analysis. The results of a typical analysis are presented in Table 2.6.1.

DETERMINATION OF WATER IN HELIUM

A. S. Meyer, Jr.

G. Goldberg

Traces of moisture in the helium used as a blanket gas in engineering studies can be conveniently determined by measuring the dew point of the gas. However, high and erratic dew-point temperatures are occasionally measured. It was observed that when copper tubing was used for the connections from the helium to the dew-point meter, dew-point temperatures below -145°F , corresponding to about 1 ppm H₂O, were obtained almost immediately. Conversely, periods of flushing of as long as 15 min at a rate of about 10 ft³/hr were required before comparable readings were obtained when the gases were passed through a 2-ft length of Tygon tubing. It is therefore recommended that, when possible, connections to the

meter be made with metal rather than plastic tubing when dew points below -40°F are to be measured. If plastic tubing is used, the tubing should be adequately purged with test gas before measurements are taken.

COMPATIBILITY OF BERYLLIUM WITH SOME TYPICAL ORGANIC DEGREASING AGENTS

A. S. Meyer, Jr.

W. J. Ross

Tests have been carried out to determine the compatibility of beryllium with the organic solvents being considered as possible agents for degreasing the machined reactor components. Suggested degreasing procedures include 30-min flushing periods with acetone and ethanol at room temperature and trichloroethylene and perchloroethylene at their boiling points. No detectable attack on beryllium was observed even after a 24-hr period of dynamic contact with these reagents.

ANP SERVICE LABORATORY

W. F. Vaughan

Analyses of ten samples were performed for the Wright Air Development Center (WADC). The determinations made on the WADC fused-fluoride-salt samples included total uranium, trivalent uranium, iron, nickel, and chromium. The hydrogen content of zirconium hydride liners, which had been encased in Inconel tubing, was also determined.

The bulk of the work of the service laboratory was the analysis of fused-fluoride-salt mixtures and alkali metals for the Reactor Chemistry and Experimental Engineering Groups. A total of 1164 samples was analyzed, which involved 4168 reported results, an average of 3.6 per sample. The backlog consists of 48 samples. A breakdown of the work follows:

	Number of Samples	Number of Reported Results
Reactor Chemistry	734	2601
Experimental Engineering	337	1375
WADC	10	50

J. H. DeVan

FLUORIDE FUEL MIXTURES IN INCONEL FORCED-CIRCULATION LOOPS

J. H. DeVan R. S. Crouse

An Inconel forced-circulation loop, 7425-8, in which the cold-leg surface area was larger than that in the standard loop, was operated to study the effect of the cold-zone area on mass transfer in the fuel mixture (No. 30) $\text{NaF-ZrF}_4\text{-UF}_6$ (50-46-4 mole %). A tube bundle with a top and a bottom header and five connecting coils of $\frac{1}{4}$ -in.-dia tubing was used in place of a standard-sized cooling coil of $\frac{1}{2}$ -in.-dia tubing.¹ With this arrangement the cold-zone area was twice that of a standard loop. The volume of the cold zone was held as nearly as possible the same as that for a standard loop so that the total loop volume would be unchanged. The standard loop (7425-10) operated concurrently with this loop was designed

as a control loop for this experiment and for several previously run experiments in which variables such as wall temperature, temperature gradient, and surface-area-to-volume ratio were studied. Both the loops, 7425-8 and 7425-10, were to operate at a maximum wall temperature of 1600°F and with the other conditions given in Table 3.1.1. However, it was found after operation that both loops had identical discrepancies in the recorders used to measure maximum wall temperature, and thus they actually operated at a maximum wall temperature of 1580°F. While good comparisons can be made between these two tests, the lower wall temperature somewhat invalidates the use of loop 7425-10 as a standard loop for comparison with other test loops.

The maximum attack in the loop with the larger cold-zone area, 7425-8, was to a depth of 4 mils, which compares quite closely with the attack to a depth of 4.5 mils in the standard loop, 7425-10. There were no cold-leg deposits in either loop, and fuel analyses made after the tests showed

DECLASSIFIED

ANP PROJECT PROGRESS REPORT

equivalent chromium contents, approximately 400 ppm. Thus the increase in the cold-zone surface area produced no apparent effect on corrosion under the conditions of these tests.

Some increase in the amount of mass transfer, as evidenced by increased hot-leg attack, was expected with increased cold-leg surface area on the basis of thermodynamic studies of the reactions of fluoride salts with pure chromium and with the chromium in Inconel (see Chap. 2.2, "Chemical Reactions in Molten Salts"). These studies predict that mass transfer of Inconel in ZrF_4 -bearing fluoride mixtures should be rate-controlled, in part, by the amount of chromium which can diffuse from the circulated fluid into the cold leg. Such a process would be related directly to the cold-zone surface area.

Examination was completed of loop 7425-43, which was operated as a part of a series of tests to study the effect of the bulk fluoride temperature on the corrosion of Inconel. The loop circulated the fuel mixture (No. 30) $NaF-ZrF_4-UF_4$ (50-46-4 mole %), and it operated with a maximum wall temperature of $1700^\circ F$, a maximum fluid temperature of $1500^\circ F$, and a fluid temperature drop of $200^\circ F$. The results of operation of this loop are to be compared with those for loop 7425-41, which, as reported previously,² was operated with a similar maximum wall temperature and temperature drop, but with a maximum fluid temperature of $1650^\circ F$. Other conditions of operation for these two loops are compared in Table 3.1.1.

The maximum attack was found in the region of maximum wall temperature in both loops. As shown in Figs. 3.1.1 and 3.1.2 the types of attack were quite similar, as were the depths of attack, being 9 mils in loop 7425-43 in which the maximum fluid temperature was $1500^\circ F$ and 10 mils in loop 7425-41 in which the maximum fluid temperature was $1650^\circ F$. The amounts of chromium in solution in the fluoride mixtures in both loops, as shown in Table 3.1.2, were also comparable, with the amount in the fluid circulated at $1500^\circ F$ actually being greater. If variations in Reynolds number are neglected, as argued previously,² the insignificance of the effect of the differences in bulk fluoride mixture temperature in these two tests is apparently the result of the similarity in maximum wall temperatures ($1700^\circ F$ in both loops).

²J. H. DeVos, ANP Quon. Prog. Rep. Dec. 10, 1955, ORNL-2012, p 105.

The importance of the wall temperature to corrosion in Inconel-fluoride fuel systems was discussed previously.²

SODIUM AND NaK IN INCONEL
FORCED-CIRCULATION LOOPS

J. H. DeVan R. S. Crouse

An Inconel forced-circulation loop completed 1000 hr of operation with sodium which had been specially treated to removed oxide contamination prior to testing. During this test the maximum fluid temperature was 1500°F, and the temperature drop was 300°F. Prior to the actual test, sodium was circulated through the loop at 1500°F under isothermal conditions to remove oxide films from both the hot and cold legs of the loop. This sodium was then dumped at 1500°F and replaced with a charge that had been cold trapped and filtered in a service loop operated at 300°F. A circulatory cold trap maintained at 300°F was also used during the test. An evaluation of mass transfer in this loop showed that the weight of deposit was equivalent to that found in loops operated with normal sodium either with or without circulatory cold traps.

An experiment to evaluate the effect of a lower cold trap operating temperature, in which NaK rather than sodium was used, likewise failed to show a reduction in mass transfer. Loop 7439-3, also constructed of Inconel, was operated 1000 hr with the cold trap temperature held to the minimum for which flow through the trap could be maintained, approximately 100°F. The operating conditions, except for cold trap temperature, were identical to those for the above-mentioned loops. A visual examination of the loop failed to show a reduction in deposits in comparison with the deposits found in loop 7439-1, described previously,³ which also circulated NaK and operated with a 300°F cold trap temperature.

SODIUM-BERYLLIUM-INCONEL
COMPATIBILITY IN DYNAMIC SYSTEMS

J. H. DeVan R. S. Crouse

Previous compatibility studies of Inconel-beryllium-sodium systems, conducted by inserting small beryllium tubes in the hot legs of toroid, thermal-convection, or forced-circulation loops, showed little effect on temperature-gradient mass transfer at temperatures up to 1300°F that could be attributed to the presence of the beryllium. To determine whether increasing the beryllium surface area relative to the surface area of the Inconel would affect the compatibility, two forced-circulation loops, in which equivalent surface areas of beryllium and Inconel were in contact with the flowing sodium, were operated at 1250°F. Only one of the loops had an oxide cold trap.

The beryllium, in the form of rectangular blocks with drilled holes, was canned in Inconel and inserted in the hottest section of the loop; the remaining sections of the loop were constructed of Inconel. A temperature drop of 300°F was maintained between the hot and cold fluid temperatures in each test. After 1000 hr of operation, no increase in the amount of mass transfer was seen in either of these loops as compared with the mass transfer found in similar loops with smaller beryllium inserts. The mass-transferred deposits found were not sufficient in quantity to permit chemical analysis. They were similar in amount and appearance to deposits seen in Inconel loops without beryllium inserts. The addition of the cold trap had little effect on the test results.

ANP PROJECT PROGRESS REPORT

THERMAL-CONVECTION LOOP TESTS OF INCONEL CASTINGS

J. H. DeVan E. A. Kovacevich

In order to evaluate the use of Inconel castings for large, intricate sections required in the ART, three standard Inconel thermal-convection loops with cast Inconel inserts in the hot legs were operated for 500 hr. The castings, whose compositions are given in Table 3.1.3, contained approximately 1.2% manganese, 2% niobium, and 1 to 2% silicon. Inserts 321 and 322, which had the lowest and the highest silicon contents, respectively, were tested in loops which circulated the fuel mixture (No. 30) $\text{NaF-ZrF}_4\text{-UF}_6$ (50-46-4 mole %) at 1500°F, while the remaining insert, 323, with an intermediate silicon content, was

tested in a loop which circulated sodium at 1500°F.

As shown in Table 3.1.4, very severe corrosion of the cast specimens was found in the loops which circulated the fuel mixture. The attack occurred not only in the form of the subsurface voids that are typical of the attack of wrought Inconel, but, in addition, very deep intergranular penetrations appeared, which reached in the worst case to a depth of 70 mils, as shown in Fig. 3.1.3.

These intergranular penetrations, although a result of rapid attack of grain-boundary constituents, were aided considerably by the porosity and the shrinkage cracks present in all the castings in the as-received condition, as shown in Fig. 3.1.4. The casting containing 1% silicon was found to be

Region of Maximum Attack Near Casting-Weld Interface in Inconel Casting No. 321 Exposed for 500 hr to the Fuel Mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %) at 1500°F as an Insert in the Hot Leg of a Wrought Inconel Thermal-Convection Loop. Etched with modified aqua regia. 100X. Reduced 32.5%. (Secret with caption)

Fig. 3.1.4. Porosity in As-Received Inconel Casting No. 321. 100X. Reduced 32.5%.

no better from the corrosion standpoint than the one containing 2% silicon.

Metal deposits were seen metallographically and visually in the hot legs of both loops. Spectrographically, the deposits were found to be predominantly nickel, with aluminum, chromium, and iron reported as major elements. The silicon and manganese contents in these deposits were low.

Loop 879, which contained insert 323 and circulated sodium, revealed very little corrosion

(<1 mil) in the insert section. Metallic deposits, which were found by analysis to be predominantly nickel, were visible in the trap area. The amount of deposited material was approximately the same as that normally found in wrought Inconel loops.

It is apparent that Inconel castings of the compositions tested are not suitable for use in contact with the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %). While the castings showed resistance to sodium, further tests of longer duration will be required to completely evaluate mass-transfer effects.

FLUORIDE FUEL MIXTURES IN HASTELLOY THERMAL-CONVECTION LOOPS

J. H. DeVan E. A. Kovacevich

Three Hastelloy X (ref. 4) thermal-convection loops, which were constructed from 1/2-in.-dia tubing, were operated 1000 hr, two with sodium at 1500°F and one with the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %) at 1500°F. Loops 855 and 856, which operated with sodium, had no hot-leg attack and no evidences of metallic deposits in the cold leg. Loop 857, however, which circulated the fuel mixture, showed considerable hot-leg attack to a depth of 27 mils. The cold leg of this loop was attacked to a depth of 1 mil, and there were evidences of metallic crystals and a metallic layer, as shown in Fig. 3.1.5. The metallic crystals in the trap area were analyzed and found to be predominantly chromium.

Two loops, 872 and 873, constructed of 3/4-in.-dia Hastelloy W (ref. 5) tubing were also operated for 1000 hr with sodium and with the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %), respectively, at 1500°F. Neither loop showed hot-leg attack; however, loop 872, which operated with sodium, had scattered metallic crystals in the cold leg. The hot-leg samples of both loops were similar metallographically to the as-received samples of each loop.

The significant difference in attack on the two alloys, Hastelloys X and W, by the fuel mixture can undoubtedly be explained by the difference in the chromium content of the two alloys, 22

⁴The nominal composition of Hastelloy X is 22% Cr-23% Fe-9% Mo-1.5% Co-balance Ni.

⁵The nominal composition of Hastelloy W is 5% Cr-5% Fe-24% Mo-1% Co-balance Ni.

ANP PROJECT PROGRESS REPORT

and 5%, respectively. As may be seen in Table 3.1.5, the chromium content of the fuel mixture circulated in the Hastelloy X loop was much higher than that of the fuel mixture circulated in the Hastelloy W loop. This reflects the greater tendency toward chromium removal and the resultant void formation in alloys with high chromium contents, such as Hastelloy X.

FLUORIDE FUEL MIXTURES IN MONEL THERMAL-CONVECTION LOOPS

J. H. DeVan

Three monel thermal-convection loops, 806, 808, and 809, completed 500, 545, and 1027 hr of operation, respectively, with the fuel mixture

(No. 107) NaF-LiF-KF-UF₄ (11.2-41-45.3-2.5 mole %) circulating at a hot-leg temperature of 1500°F. Loops 808 and 809, which were scheduled to operate 1000 and 1500 hr, respectively, were terminated before completion of the scheduled operating period because of excessive oxidation of the outside surface of the monel tubing. The oxidation did not completely penetrate the tube wall in either loop. Metallographic examination revealed hot-leg attack to a depth of 1 mil, as shown in Fig. 3.1.6, in all these loops. Three other monel loops, 880, 881, and 882, that had been chromium-plated to provide oxidation protection were operated under the same conditions, but, apparently, the platings were imperfect, and two of these three loops, 881 and 882, were

TABLE 3.1.5. CHEMICAL ANALYSES OF THE FUEL MIXTURE (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %) BEFORE AND AFTER CIRCULATION FOR 1000 hr AT 1500°F IN HASTELLOY X AND W THERMAL-CONVECTION LOOPS

Loop No.	Loop Material	Sample Taken	Uranium Content (wt %)	Impurities Found (ppm)		
				Ni	Cr	Fe
857	Hastelloy X	Before filling	8.39	260	135	115
		After draining	8.68	40	1060	125
873	Hastelloy W	Before filling	8.78	80	60	75
		After draining	8.82	85	275	110

terminated after 1217 and 1339 hr of the 1500 hr scheduled because of excessive oxidation and resultant leaks in the heated areas of the loops. The remaining loop, 880, completed its scheduled 1000 hr of operation. Metallographic analyses of these loops have not been completed.

SPECIAL FLUORIDE FUEL MIXTURES IN INCONEL THERMAL-CONVECTION LOOPS

J. H. DeVan

Additional Inconel thermal-convection loops have been operated to evaluate corrosion properties

of several special fluoride fuel mixtures. Tests of 500 hr duration were completed for mixtures in the MF-ZrF₄-UF₄ system, where M is KF, LiF, NaF, or RbF. Mixtures with each of these fluorides and 40 or 46 mole % ZrF₄ have been tested; each mixture contained 4 mole % UF₄. The results obtained for the fuels containing 46 mole % ZrF₄ were reported previously,³ but they are repeated in Table 3.1.6 for comparison. Lowering the ZrF₄ content, as shown in Table 3.1.6, had no effect on attack by the NaF-containing mixture, but the attack by the KF- and RbF-containing mixtures increased from 1 to 2 mils. The LiF-containing

ANP PROJECT PROGRESS REPORT

mixture showed quite anomalous behavior in that the attack decreased markedly with the decrease in ZrF_4 . These results are being rechecked.

The loops containing mixtures with 56 mole % of the alkali-metal fluoride, with the exception of the loop operated with the KF-containing mixture, showed traces of metallic crystals in the cold legs. These crystals were most pronounced in the RbF-containing mixtures. Specimens of the crystals found in loop 933, which circulated the fuel mixture RbF-ZrF₄-UF₄ (56-40-4 mole %), are shown in Fig. 3.1.7.

Two additional Inconel loops, 883 and 884, were operated under similar conditions to obtain further corrosion data for the KF-ZrF₄-UF₄ (50-46-4 mole %) system. An increase in the operating time from 500 to 1500 hr caused an increase in maximum attack of 2 mils. Thin metallic layers were noted in the cold legs after both operating periods. As yet these layers are unidentified.

Fig. 3.1.7. Metallic Crystals and Layer Deposited in Cold Leg of Inconel Thermal-Convection Loop 933 Which Circulated the Fuel Mixture (No. WR5) RbF-ZrF₄-UF₄ (56-40-4 mole %) for 500 hr at a Hot-Leg Temperature of 1500°F. Etched with modified aqua regia. 250X. Reduced 32.5%. (Secret with caption)

3.2. GENERAL CORROSION STUDIES

E. E. Hoffman

BRAZING ALLOYS IN LIQUID METALS AND
IN FLUORIDE FUEL MIXTURES

D. H. Jansen

Two Inconel thermal-convection loops with inserts brazed with 70% Ni-13% Ge-11% Cr-6% Si brazing alloy in the hot-leg section were operated for 500 hr. In one loop NaK (56-44 wt %) was circulated, and in the other the fuel mixture (No. 44) NaF-ZrF₄-UF₄ (53.5-40-6.5 mole %) was circulated. The hot-leg sections of these loops consisted of seven Inconel segments brazed with the alloy being tested. This type of thermal-convection loop test assembly was illustrated previously.¹ The hot legs of both loops were

maintained at a temperature of 1500°F for the duration of the tests. The cold-leg temperature of the loop that circulated NaK was maintained at 1165°F, and the cold-leg temperature of the loop that circulated the fuel mixture was held at 1150°F.

The inner walls of the Inconel segments and two samples from each brazed joint were examined after the tests for evidence of attack. The results of the examinations are summarized in Table 3.2.1.

The attack of the fuel mixture on the brazed joints averaged about 5 mils. Typical samples are shown in Fig. 3.2.1. The attack of the fuel mixture on the Inconel tubing adjacent to the joint ranged from 4.5 mils in the coolest (1450°F) portion of the hot leg to 9 mils in the hottest (1500°F) portion of the hot leg, as shown in Fig. 3.2.1. A slight trace of metallic crystals

¹D. H. Jansen, ANP Quar. Prog. Rep. Dec. 10, 1955, ORNL-2012, p 113, Fig. 5.9.

TABLE 3.2.1. RESULTS OF THERMAL-CONVECTION LOOP TESTS OF INCONEL SEGMENTS BRAZED WITH 70% Ni-13% Ge-11% Cr-6% Si BRAZING ALLOY

Operating time: 500 hr

Brazed Joint No.	Metallographic Notes	
	Effect of Fuel Mixture	Effect of NaK
1*	Brazing alloy attacked to a depth of 4.5 mils; adjacent Inconel tube attacked to a maximum depth of 9 mils	No attack apparent; large crack through brazing alloy to center of tube wall
2	Brazing alloy attacked to a depth of 4.5 mils; spotty, nonuniform attack on tube wall to a maximum depth of 7 mils	Attack to a depth of 0.5 mil
3	Brazing alloy attacked to a depth of 6 mils; spotty attack on tube wall to a depth of 7.5 mils	No attack; large crack, as in joint 1 above
4	Brazing alloy attacked to a depth of 3 mils; tube wall attacked to a depth of 4.5 mils	Attack to a depth of 0.5 mil; large crack in brazing alloy
5	Brazing alloy attacked to a depth of 5 mils; tube wall attacked to a depth of 4.5 mils	Large crack in brazing alloy
6**	Brazing alloy attacked to a depth of 5 mils; tube wall attacked to a depth of 4.5 mils	Attack to a depth of 1.5 mils; some porosity in brazing alloy; no large cracks

*Brazed joint No. 1 was located at the hottest (1500°F) portion of the hot leg.

**Joint No. 6 was located at the coolest (1450°F) portion of the hot leg.

DECLASSIFIED

Fig. 3.2.1. Specimens of Inconel Joints Brazed with the 70% Ni-13% Ge-11% Cr-6% Si Brazing Alloy and Exposed for 500 hr to the Fuel Mixture (No. 44) $\text{NaF-ZrF}_4\text{-UF}_4$ (53.5-40-6.5 mole %) in the Hot Leg of an Inconel Thermal-Convection Loop. (a) Joint located in coolest (1450°F) portion of hot leg. (b) Joint located in hottest (1500°F) portion of hot leg. Etched with 10% oxalic acid. 150X. Reduced 19%. (Secret with caption)

was found in the cold leg of the loop that circulated the fuel mixture. Spectrographic analyses of these crystals showed strong lines for chromium and nickel and weak lines for iron. There was no evidence of mass transfer in the loop that circulated NaK.

The brazing alloy showed good corrosion resistance to NaK, as shown in Fig. 3.2.2, but large cracks which extended to a depth of one-half the tube wall thickness were found in some of the brazed joints, Fig. 3.2.3. It is not known whether these cracks were caused by thermal stresses or shrinkage. Analysis of the NaK after the test showed 1160 ppm of oxygen. This is admittedly high, but no efforts were made to purify the NaK which was received in container lots.

A third Inconel thermal-convection loop was operated for 500 hr in which the hot leg contained Inconel inserts brazed with the 82% Au-18% Ni brazing alloy. The fluid circulated was the fuel mixture (No. 30) $\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %). The hot and cold legs were maintained at temperatures of 1500 and 1175°F, respectively. Micro-

scopic examination of samples from each brazed joint showed the attack on the alloy to average about 8 mils, with a maximum depth of 10 mils.

Tests were also conducted on a series of buttons of Coast Metals brazing alloy No. 52 (89% Ni-5% Si-4% B-2% Fe), which were exposed in seesaw apparatus to NaK (56-44 wt %) and to the fuel mixture (No. 44) $\text{NaF-ZrF}_4\text{-UF}_4$ (53.5-40-6.5 mole %). Since previous tests of this alloy showed depletion of the second phase at the exposed edge,² these tests were conducted to determine whether the high-cross-section boron component was removed and, if so, whether the removal was time dependent. The buttons were contained in nickel tubes with hot-zone temperatures of 1500°F for both tests and with cold-zone temperatures of 1100°F in the tests with NaK and 1200°F in the tests with the fuel mixture. In all the tests, the specimens were retained in the hot zone of the test capsule. The duration of the exposures to

²D. H. Jansen, ANP *Quar. Prog. Rep.* Dec. 10, 1955, ORNL-2012, p 119, Fig. 5.17.

NaK were 100 and 350 hr, and the exposures to the fuel mixture were of 100 and 500 hr duration.

The results of the tests are presented in Table 3.2.2. Boron was found only in very small quantities in the areas depleted of the second phase by exposure to NaK and to the fuel mixture. A microspark traverse on the sample exposed to the

fuel mixture for 500 hr showed that the concentration of boron was less than 1% from the surface to a depth of 8 mils. The boron content then rose sharply to its normal value (4%) and stayed there for the remainder of the traverse. Samples of the depleted area, obtained by microdrilling, were analyzed and were found to contain 0.6% boron.

Fig. 3.2.2. Specimens of Inconel Joints Brazed with the 70% Ni-13% Ge-11% Cr-6% Si Brazing Alloy and Exposed for 500 hr to NaK at 1500°F in the Hot Leg of an Inconel Thermal-Convection Loop. These two specimens, No. 2 and No. 6, illustrations (a) and (b), respectively, were the only samples examined that did not have large cracks in the brazing alloy. Etched with 10% oxalic acid. 150X. Reduced 8%.

TABLE 3.2.2. RESULTS OF SEESAW CORROSION TESTS OF COAST METALS
BRAZING ALLOY No. 52 (89% Ni-5% Si-4% B-2% Fe)

Bath	Duration of Test (hr)	Weight Loss of Specimen (%)	Depth of Edge Depleted of Second Phase (mils)
NaK (56-44 wt %)	100	0.07	0.5
	350	0.23	4
NaF-ZrF ₄ -UF ₄ (53.5-40-6.5 mole %)	100	0.06	3
	500	0.34	6

ANP PROJECT PROGRESS REPORT

It was also found that the silicon content had dropped to about one-third its normal value (5%) in the depleted area. Evidence of the time dependence of the amount of depletion is presented in Fig. 3.2.4. None of the buttons tested showed attack to a depth of more than 0.5 mil.

Hardness measurements on the interior of the

Fig. 3.2.3. Typical Crack Found in an Inconel Joint Brazed with the 70% Ni-13% Ge-11% Cr-6% Si Brazing Alloy After Exposure for 500 hr to NaK at 1500°F in an Inconel Thermal-Convection Loop. Etched with 10% oxalic acid. 100X. Reduced 29%.

button exposed to NaK for 350 hr gave a value of 716 DPH, while measurements at the edge gave a value of 145 DPH, as shown in Fig. 3.2.5. The buttons tested in the fuel mixture gave similar hardness traverse results. Chemical analysis of the fuel mixture from the 500-hr test and of the NaK used in the 100-hr test showed significant concentrations of boron.

NIObIUM IN STATIC SODIUM

D. H. Jansen

Specimens of niobium were tested in static sodium at 1500°F for a period of 1000 hr to determine the suitability of liquid sodium as a protective environment for niobium during high-temperature mechanical property tests. The tests were designed to show whether the niobium would be corroded by the sodium and whether the hardness of the niobium would be appreciably altered through the pickup of oxygen from the sodium.

The specimens were contained in type 304 stainless steel and Inconel capsules, and the variables such as the volume of the bath, the container size, and the area of the specimen were adjusted to obtain a surface-area-to-volume ratio that would be as close as possible to that found in creep-test equipment. Cold traps were utilized on the bottom of each capsule to reduce the amount of oxygen in the sodium bath. The niobium specimen tested in the type 304 stainless steel capsule showed more evidence of surface roughening than did the specimen tested in the Inconel capsule, Fig. 3.2.6, and the thickness loss was also more than that of the specimen tested in the Inconel capsule, Table 3.2.3. A thin, brittle layer, approximately

TABLE 3.2.3. RESULTS OF TESTS OF NIOBIUM IN STATIC SODIUM

Exposure time: 1000 hr
Temperature of sodium: 1500°F

Sample	Hardness (VHN)	Thickness Loss (mils)	Impurity Analysis of Sample (ppm)			
			H ₂	O ₂	N ₂	C
As-received material	130.5		2.4	40	125	300
Specimen tested in type 304 stainless steel tube	135.0	3.0	3.8	84	250	370
Specimen tested in Inconel tube	116.4	1.8	3.4	90	92	1180

Fig. 3.2.4. Specimens of Coast Metals Brazing Alloy No. 52 (89% Ni-5% Si-4% B-2% Fe) After Exposure in Seesaw Apparatus to the Fuel Mixture (No. 44) $\text{NaF-ZrF}_4\text{-UF}_4$ (53.5-40-6.5 mole %) for (a) 100 hr and (b) 500 hr. 150X. Reduced 12.5%. (Secret with caption)

Fig. 3.2.5. Specimen of Coast Metals Brazing Alloy No. 52 (89% Ni-5% Si-4% B-2% Fe) After Exposure in Seesaw Apparatus to NaK for 350 hr. Note differences in hardness. Etched with 10% oxalic acid. 150X.

Fig. 3.2.6. Specimens of Niobium After Exposure to Static Sodium at 1500°F in (a) an Inconel Capsule and (b) a Type 304 Stainless Steel Capsule. Etched with 25% HF-25% H₂SO₄-50% H₂O. 250X. Reduced 17%.

0.3 mil thick, formed on the surface of both specimens during the test. This layer, which is very hard (~1180 VHN), is probably a niobium-nickel alloy resulting from dissimilar-metal transfer, but it has not yet been positively identified.

Vickers hardness traverses were made on the as-received and as-tested specimens. The hardness of the specimen tested in the type 304 stainless steel capsule increased (130 to 135 VHN) during the test, whereas the hardness of the specimen tested in the Inconel capsule decreased (130 to 116 VHN). A correlation of the hardness values with the impurity analyses indicates that nitrogen is the major hardening agent. A niobium specimen previously tested in argon at 1500°F for 2000 hr showed a hardness increase from 127 to 168 VHN. The impurities (H₂O, H₂, N₂, and O₂) of the argon used in the test totaled 130 ppm.

THERMENOL IN STATIC SODIUM

D. H. Jansen

Samples of Thermenol (82% Fe-15% Al-3% Mo) cut from a piece of hot-rolled strip were corrosion tested in static sodium for 100 hr at 1500°F. The specimens were contained in AISI 1035 steel and type 430 stainless steel capsules. The specimen tested in the AISI 1035 steel capsule showed a

weight loss of 0.22%, and the specimen tested in the stainless steel capsule showed a weight loss of 0.07%. A slight roughening of the surface occurred on both samples, Fig. 3.2.7. Neither the type 430 stainless steel nor the AISI 1035 steel capsule was attacked during the tests.

STATIC TESTS OF ALFENOL

E. E. Hoffman

Specimens of Alfenol (84% Fe-16% Al), submitted by The Glenn L. Martin Co., were tested under static conditions at 1500°F in the fuel mixture (No. 44) NaF-ZrF₄-UF₄ (53.5-40-6.5 mole %), lead, lithium, and sodium for 100 hr. Since no Alfenol container tubes were available, Inconel was used as the container material for all the tests. The Alfenol specimens used in these tests were 1/4-in. cubes. The specimens were placed in 1/2-in.-OD, 0.035-in.-wall Inconel tubes, together with sufficient test medium to give 3 in. of liquid bath at the test temperature.

The specimen tested in the fuel mixture was covered with black crystals and showed a 30% weight increase. The crystals were analyzed and found to be UF₃. The specimen was attacked throughout its thickness along the grain boundaries, Fig. 3.2.8.

Fig. 3.2.7. Specimens of Thermanol (82% Fe-15% Al-3% Mo) After Exposure to Static Sodium at 1500°F in (a) a Type 430 Stainless Steel Capsule and (b) on AISI 1035 Steel Capsule. Etched with aqua regia. 250X. Reduced 16%.

Fig. 3.2.8. Specimens of Alfenol (84% Fe-16% Al) in (a) As-Received Condition and (b) After Exposure for 100 hr to the Static Fuel Mixture (No. 44) $\text{N}_2\text{F}_4\text{-ZrF}_4\text{-UF}_6$ (53.5-40-6.5 mole %) at 1500°F. The grain-boundary attack shown in (b) is typical of the attack found throughout the specimen. (a) Etched with aqua regia. (b) Unetched. 250X. Reduced 13.5%. (Secret with caption)

ANP PROJECT PROGRESS REPORT

No weight change data were taken on the specimen tested in lead because particles of lead adhered to the specimen. Metallographic examination revealed attack only in a few scattered areas to a depth of 0.5 mil.

The specimen tested in lithium was attacked throughout its thickness along the grain boundaries, which were apparently aluminum-rich regions. Gentle tapping caused the specimen to break up into individual grains, Fig. 3.2.9. The lithium bath was found to contain 0.2 wt % aluminum after the test.

The specimen tested in sodium lost only 16 mg (0.009 wt %) during the test and metallographic examination revealed no attack. The sodium bath was found to contain 0.001 wt % aluminum after the test.

SODIUM-BERYLLIUM-INCONEL COMPATIBILITY IN STATIC SYSTEMS

E. E. Hoffman

A test was conducted in order to determine the thickness of Inconel that would be consumed by

an alloying reaction between Inconel and beryllium in direct contact under pressure while immersed in sodium at 1300°F. The apparatus used for the tests is shown in Figs. 3.2.10 and 3.2.11. The surfaces of two of the Inconel specimens used in this test, as shown in Fig. 3.2.12, were chromium plated to study the effect of chromium in reducing the extent of the alloy formation between nickel (from the Inconel) and beryllium. The test specimens were $\frac{1}{4} \times \frac{1}{2} \times 1$ in. with the $\frac{1}{2} \times 1$ -in. surfaces in contact. Sufficient load was applied through a compression rod and bellows to yield a 500-psi stress on the specimens. The test assembly was loaded with sodium and held at 1300°F for 1000 hr. The load was applied to the specimens when the test temperature was reached.

It was found after the test that the chromium-plated Inconel specimens could be separated from the adjacent beryllium specimens; however, it was impossible to separate the unplated Inconel specimens from the beryllium specimens. The results of metallographic examination of the four specimen interfaces, presented in Table 3.2.4, indicate that

Fig. 3.2.9. Alfenol (84% Fe-16% Al) Cube That Disintegrated After 100 hr of Exposure to Static Lithium at 1500°F. 12X.

Fig. 3.2.10. Apparatus for Studying the Extent of Alloying Between Beryllium and Various Metals Under Stress While Immersed in Molten Sodium.

a thin chromium plate on Inconel does not eliminate alloying reactions with beryllium when the two materials are in contact while immersed in high-temperature sodium, but the plate does substantially reduce the extent of alloy formation. Approximately 4 mils of Inconel was consumed in the formation of the 24-mil nickel-beryllium alloy layer which was found where the Inconel and the beryllium were in direct contact (Fig. 3.2.13a). The major portion of reaction layer was found to be $Be_{21}Ni_5$, with a small percentage of $BeNi$ adjacent to the Inconel. The reduction in alloy formation brought about by the 2-mil chromium plate is illustrated in Fig. 3.2.13b. A second test is now under way in which the effectiveness of 4- and 6-mil chromium platings will be evaluated.

Fig. 3.2.11. Enlarged View of Test Specimens Shown in Figs. 3.2.10 and 3.2.12.

Fig. 3.2.12. Sodium-Beryllium-Inconel Compatibility Test Specimens After Exposure to Sodium at 1300°F for 1000 hr.

ANP PROJECT PROGRESS REPORT

TABLE 3.2.4. RESULTS OF METALLOGRAPHIC EXAMINATION OF THE INTERFACES OF THE SPECIMENS SHOWN IN FIG. 3.2.13

Test environment: sodium
 Test duration: 1000 hr
 Test temperature: 1300°F
 Stress on specimens: 500 psi

Interface	Metallographic Notes
A-B: Inconel vs beryllium - direct contact	10 to 24 mils of alloy formation ($Be_{21}Ni_5$ plus BeNi) along interface; 4 mils of Inconel consumed in the production of reaction layer
B-C: Beryllium vs Inconel - direct contact	22 to 24 mils of uniform alloy formation along interface
C-D: Inconel with 1-mil chromium plate vs beryllium	3.5 to 7 mils of alloy formation; 7-mil layer found where plating was thinnest
D-E: Beryllium vs 2-mil chromium plate on Inconel	2 mils of interaction between specimens along 90% of interface; 6-mil layer detected at one area where plating appeared to have been defective

*See Fig. 3.2.12 for location of interface.

STATIC TESTS OF INCONEL CASTINGS

R. Carlander

In thermal-convection loop tests of Inconel castings in the fuel mixture (No. 30) $\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %), much heavier attack of the cast material occurred than is normally observed for wrought Inconel (see Chap. 3.1, "Dynamic Corrosion Studies"). Metallographic examination of the as-received material showed the presence of cracks, stringer porosity, and large grains, with the grain boundaries perpendicular to the surface. In order to obtain further information on the effect of the composition of the cast material on its corrosion resistance, static tests of three Inconel castings that differed primarily in silicon content were performed in the fuel mixture (No. 30) $\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %) in wrought Inconel capsules for 1000 hr at 1500°F. Examination of the tested specimens revealed that the casting with the highest silicon content (1.93%) was the least attacked, while the casting with the lowest silicon content was the most severely attacked. In all cases, the attack was a combination of subsurface voids and intergranular penetration. The depth of subsurface voids on the Inconel castings was 3 to 4 mils, as compared with 2 to 4 mils on the wrought Inconel capsules. The intergranular penetration, however, varied from 3 mils on the high-silicon-content casting to 12 mils on the low-silicon-content casting. This

difference is attributed to the porosity and to the grain boundaries running perpendicular to the surface of the casting. The results of metallographic examinations of the three cast specimens are presented in Table 3.2.5, and the wrought Inconel capsule and cast Inconel specimen No. 321 are shown in Fig. 3.2.14. In every case the wrought Inconel container was more corrosion resistant than was the cast Inconel specimen.

INCONEL AND STAINLESS STEEL IN NaK CONTAINING LITHIUM

R. Carlander

Type 316 stainless steel and Inconel were exposed to NaK containing lithium in static and in dynamic systems in order to determine the effect of the lithium on corrosion resistance. In the static tests the specimens were exposed to NaK (56-44 wt %) with lithium additions of 1, 5, 10, 20, and 30 wt % for 100 hr at 1500°F. No attack occurred in any of the tests.

For the dynamic tests, 12-in.-long capsules were filled to 40% of their volume with NaK plus lithium (5 or 10 wt %) and placed in a tilting-type furnace (1 cpm) at a hot-zone temperature of 1500°F (cold zone, 1100°F) for 100 hr. No mass transfer occurred in any of these systems. The Inconel exposed to NaK with 10 wt % lithium added was attacked to a depth of 1 mil in the hot zone, while the other capsules were unattacked.

TABLE 3.2.5. RESULTS OF METALLOGRAPHIC EXAMINATION OF CAST INCONEL SPECIMENS AFTER EXPOSURE TO STATIC $\text{NaF-ZrF}_4\text{-UF}_4$ (50-46-4 mole %) FOR 1000 hr AT 1500°F

Cast Inconel Specimen No.	Silicon Content (wt %)	Depth of Attack (mils)		Metallographic Notes on Cast Inconel Specimen
		Wrought Inconel Capsule	Cast Inconel Specimen	
321	1.04	4	12	Subsurface voids to depth of 4 mils; intergranular penetration to depth of 12 mils; no cracks apparent
322	1.93	2	3	Subsurface voids and intergranular penetration to depth of 3 mils; no cracks apparent
323	1.34	2	8	Subsurface voids to depth of 3 mils; intergranular penetration to depth of 8 mils; no cracks apparent

Fig. 3.2.14. Specimens of Wrought Inconel Capsule (a) and Cast Inconel Specimen No. 321 (b) After Exposure to the Fuel Mixture (No. 30) $\text{NaF-ZrF}_4\text{-UF}_6$ (50-46-4 mole %) for 1000 hr at 1500°F Etched with aqua regia. 250X. Reduced 3%. (Secret with caption)

Thermal-convection loop tests were also conducted. In these tests the hot-leg temperature was 1500°F (cold leg, $\sim 1250^\circ\text{F}$), and NaK with 5 wt % lithium added was circulated for 1000 hr. A slight amount of mass transfer, in the form of small adherent crystals containing 71.5% Ni, 4.6% Cr, and 0.7% Fe, occurred in the Inconel loop, while no mass transfer was found in the stainless steel loop. Portions of the hot and the cold legs of the Inconel and the stainless steel loops are shown in Figs. 3.2.15 and 3.2.16, respectively. The Inconel was attacked to a depth of 1.5 mils in the hot and in the cold legs. The stainless steel was unattacked in the hot leg but was attacked to a depth of 6 mils in the cold leg. Photomicrographs of the cold legs of the Inconel and of the stainless steel loops are shown in Fig. 3.2.17. The addition of 5 wt % lithium to the NaK did not decrease the normal corrosion resistance of Inconel to NaK, but it did decrease

that of type 316 stainless steel. The difference in attack between the hot and cold legs of the stainless steel loop may be attributed to the larger amount of carbides present as a network in the cold leg than in the hot leg, where more carbides are in solution because of increased solubility at the higher temperature.

TRANSFER OF CARBON BETWEEN DISSIMILAR METALS IN CONTACT WITH MOLTEN SODIUM

R. Carlender

The decarburization of AISI 1043 steel by molten sodium in Armco iron and type 304 ELC stainless steel containers was demonstrated in tests at 1830°F of 100 hr duration, as described previously.³ An additional test has been performed to determine

ANP PROJECT PROGRESS REPORT

the effect of time on the extent of decarburization of the steel specimens.

Two AISI 1043 steel specimens and sodium were loaded into evacuated Armco iron and type 304 ELC stainless steel containers and tested at 1830°F for 400 hr. The conditions and results of the tests are given in Table 3.2.6. As expected on the basis of the previous investigation, extensive decarburization of the steel specimens oc-

curred in both the iron and the stainless steel containers. The extent of decarburization of the AISI 1043 steel specimens was greater in these 400-hr tests than in the previous 100-hr test, and, in addition, the vapor zone of the stainless steel container was carburized in the 400-hr test and not in the 100-hr test. This discrepancy may be due to the vapor zone sample having been taken closer to the bath zone after the 400-hr test than

after the 100-hr test. The extent of the decarburization of the AISI 1043 steel was greater in the Armco iron container than in the stainless steel container. Furthermore, sufficient nickel mass-transferred to the surface of the steel specimen in the stainless steel container to cause a phase transformation to a depth of 2 to 4 mils, but the amount of nickel that mass-transferred did not seem to increase appreciably in comparison with the amount transferred during the 100-hr test. Photomicrographs of the as-received and as-tested AISI 1043 steel specimens are shown in Figs. 3.2.18 and 3.2.19.

RARE-EARTH OXIDES EXPOSED TO STATIC SODIUM IN INCONEL CONTAINERS

W. H. Cook

In considering rare-earth oxides as possible control rod materials for the ART, sodium was suggested as a heat transfer medium for cooling the control rod material, and it was proposed that Inconel be used as the container material for the sodium and the rare-earth oxides. Tests were therefore conducted to investigate the corrosion

resistance of the rare-earth oxides to sodium and the effects, if any, on the Inconel containers.

One specimen of Sm_2O_3 (density, 5.88 g/cm^3 ; apparent porosity, 25.4%) was tested for 1000 hr in static sodium at 1500°F in an Inconel capsule. Two specimens from a body of a mixture of rare-earth oxides (density, 6.58 g/cm^3 ; apparent porosity, not determined) were tested similarly, one for 500 hr and the other for 1000 hr. The body, fabricated from a commercially available powder known as Lindsay Mix, obtained from the Lindsay Chemical Co., had the composition 63.8 wt % Sm_2O_3 -26.3 wt % Gd_2O_3 -balance primarily other rare-earth oxides.

The results of the tests indicated negligible corrosion attack by the sodium on the three specimens and their Inconel capsules in 1000 hr, but there may have been some reduction in their strengths. The weight and dimensional changes of the three specimens were all positive, as would be expected with porous materials, and were less than 0.5%. The original buff colors of the specimens changed to gray black, but this was the only macroscopically visible change. It was found

Fig. 3.2.18. Specimens of AISI 1043 Steel (a) in the As-Received Condition and (b) After Exposure to Sodium in an Armco Iron Container for 400 hr at 1830°F . Etched with 4% picral. 200X. Reduced 10.5%.

ANP PROJECT PROGRESS REPORT

that the gray-black color extended throughout the specimens. This is evidence that the sodium completely penetrated the specimens, probably along the pore spaces.

Powder x-ray diffraction patterns of the untested and tested pieces of Sm_2O_3 and the two Lindsay Mix specimens did not reveal any reaction products. Chemical analyses of the sodium baths indicated

negligible quantities of rare earths, chromium, iron, and nickel, which also supports the conclusion that there was negligible attack on either the rare-earth oxides or the Inconel capsules. The major losses of rare-earth oxides were calculated on the basis of the chemical analyses, and the results are summarized in Table 3.2.7. In comparing the results from the 500- and 1000-hr

Fig. 3.2.19. Specimens of AISI 1043 Steel After Exposure to Sodium in a Type 304 ELC Stainless Steel Container at 1830°F for 400 hr. (a) 200X. Reduced 13%. (b) 500X. Reduced 13%. Etched with 2% nital.

*These values were calculated on the basis of the rare earths found by chemical analyses in the sodium from each test.

**Composition: 63.8 wt % Sm₂O₃, 26.3 wt % Gd₂O₃, balance primarily other rare-earth oxides.

tests of the Lindsay Mix specimens, no significant differences were found.

Metallographic polishing and examination of the rare-earth oxide specimens before and after exposure to the sodium indicated that the specimens may have been slightly weakened by the tests, but there was no microscopically visible corrosion, as shown in Fig. 3.2.20. Metallographic examination of the Inconel capsules revealed slight surface roughening to a depth of less than 0.5 mil in spots on the inner surfaces that contacted the liquid sodium and the Lindsay Mix specimens. There was no surface roughening and no attack of the Inconel capsule that contained the Sm_2O_3 specimen and sodium. Spectrographic examinations of the inner surfaces of the three capsules did not reveal any rare earths.

The corrosion resistance to molten sodium shown by the Lindsay Mix with a density of 6.58 g/cm^3 prompted further tests that were designed to approximate more closely the expected operating conditions and for which a Lindsay Mix body with the proposed density and configuration was used.

The purposes of these tests were to determine the relationship of the apparent porosity of the Lindsay Mix body for water to that for molten sodium and to study the corrosion resistance of the body and Inconel when separated by only a small thickness (approximately 0.05 in.) of sodium.

A hollow cylinder of porous Lindsay Mix body was used that was nominally 0.9 in. OD, 0.5 in. ID, and 1 in. long, with a density of 3.53 g/cm^3 and an apparent porosity to water of 53.5%. This body had an apparent porosity of 52% to sodium after exposure to static sodium for 100 hr at 1300°F in an evacuated Inconel capsule. To determine the apparent porosity of the body to sodium, the sodium was allowed to cool and solidify around the body at the end of the 100-hr test period. The test capsule was then opened in a helium atmosphere, the excess sodium was removed from the surfaces of the body with plastic scrapers, and the body and its absorbed sodium were weighed. The absorbed sodium was then removed by vacuum distillation, and the body was again weighed. The apparent porosity of the body

Fig. 3.2.20. Rare-Earth Oxide Specimens (63.8 wt % Sm_2O_3 -26.3 wt % Gd_2O_3 -Balance Primarily Other Rare-Earth Oxides) (a) in As-received Condition and (b) After Exposure to Static Sodium in an Inconel Container for 500 hr at 1500°F . Unetched. 500X. Reduced 5.5%.

ANP PROJECT PROGRESS REPORT

to sodium was calculated by using the latter weight, the density of 3.53 g/cm^3 , the weight of the absorbed sodium, and a sodium density at 97.8°C (the melting point of sodium) of 0.951 g/cm^3 .

As shown in Table 3.2.7, the losses of rare-earth oxides by this low density (3.53 g/cm^3) body were greater than the losses by the higher density (6.58 g/cm^3) Lindsay Mix body, which is in keeping with the general trend for the lower density ceramics to have lower corrosion resistance. There is no explanation for the relatively large loss of Y_2O_3 . The exposure to sodium also slightly weakened the body; its hardness, on the Mohs' scale, changed from 3 to 2 during the test. Long-term corrosion tests of finished ART control rod Lindsay Mix shapes and sodium in Inconel containers have been initiated to determine the extent of the corrosion of these materials under the most adverse operating conditions expected and for periods equal to and greater than the proposed operating time.

SOLID-PHASE-BONDING SCREENING TESTS

W. H. Cook

Molybdenum has been tested for 100-hr periods for solid-phase bonding with itself, tungsten,

K150A (80% TiC-10% NbTaTiC₃-10% Ni), and K152B (64% TiC-6% NbTaTiC₃-30% Ni) with calculated contact pressures of 20,000 psi in the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %) at 1500°F . Bonding was absent only for molybdenum vs tungsten and molybdenum vs K150A. The surface roughnesses of the contacting surfaces of all specimens were 1.5 to 2 μin , rms, as determined with a profilometer.

The contact pressure was reduced from the standard 50,000 psi to 20,000 psi in an effort to get below the yield strength of molybdenum at 1500°F . The 20,000-psi loading was not low enough, inasmuch as the molybdenum deformed slightly in all the tests. All examinations were made with a low-power microscope.

In the test of molybdenum vs molybdenum, the solid-phase bonding was accompanied by some deformation and considerable upsetting. In the bonding between molybdenum and K152B, a thin film appeared to have been transferred from the molybdenum surface to the K152B surface in the contact area. This was probably a nickel-molybdenum diffusion layer, but it has not yet been identified.

3.3. FABRICATION RESEARCH

J. H. Coobs

DEVELOPMENT OF NICKEL-MOLYBDENUM
BASE ALLOYS

H. Inouye T. K. Roche

The available supply of Hastelloy B and W tubing was prepared by redrawing tubing formed from welded strip, and it is not of high quality. Since these alloys are characterized by high-temperature strength and resistance to fused-salt corrosion, a source of seamless tubing is desired, and therefore considerable effort has been devoted to the study of extrusion techniques for the production of seamless tubing of these Hastelloys and other related alloys.

Extrusion of Hastelloy W

Early attempts to extrude tube blanks of Hastelloy W failed. In these experiments forged billets canned in Inconel were extruded at 2050 and 2100°F at an extrusion ratio of 7:1. Severe fracturing of the tubing occurred during the extrusion process as a result of melting. An excessive temperature rise as a result of the rapid deformation of the material is believed to have caused the difficulty. Recently this alloy was successfully extruded under conditions identical to those used earlier, as listed below, except for the extrusion temperature and rate:

Billet	Forged Hastelloy W canned in Inconel
Billet size	3 in. OD, $1\frac{1}{8}$ in. ID, 3 in. long
Die size	$1\frac{1}{2}$ in., 30-deg core
Mandrel size	1 in.
Extrusion ratio	7:1

The rate of extrusion was controlled by regulating the flow of high-pressure water to the ram of the extrusion press by means of a throttle valve which opened completely in four turns. The rate settings, in terms of the number of turns that the valve was opened, were $3\frac{1}{2}$ and $3\frac{3}{4}$ for the unsuccessful extrusions and $2\frac{1}{2}$ for the successful extrusion. Actual extrusion rates, in feet per minute, were not determined during these experiments.

The extrusion temperature of 2200°F used for the successful extrusion was an increase over

the 2050 and 2100°F used for the unsuccessful extrusions. It was concluded from this work that Hastelloy W could be extruded on a laboratory scale by raising the extrusion temperature and lowering the extrusion rate to allow time for the heat generated in the work to dissipate to the surroundings. The successful and unsuccessful tube-blank extrusions are illustrated in Fig. 3.3.1.

Extrusion of Hastelloys B, W, and X
on a Commercial Scale

An experiment was performed at the Huntington Works of the International Nickel Company on March 27, 1956, to determine the feasibility of producing tube blank extrusions of Hastelloys B, W, and X on a commercial scale. The experiment was carried out as a cooperative effort between the Oak Ridge National Laboratory, the International Nickel Company, and the Haynes Stellite Company.

Forged and machined billets of the Hastelloys were prepared by the Haynes Stellite Company. Based upon extrusion experience on a laboratory scale at ORNL, as described above, a schedule was prepared for the extrusion of the Hastelloy B billets. Since small tube blanks had been prepared successfully by using a slow extrusion rate at 2200°F, it was proposed that these larger billets be extruded at as slow a rate as practical. The extrusion temperature could be lower, of course, because of the larger size of the billet. The results of the Hastelloy B extrusions, which are summarized in Table 3.3.1, were reported to ORNL by the International Nickel Company upon completion of the experiment. The actual extruded tube blanks of Hastelloy B are shown in Figs. 3.3.2 and 3.3.3.

Although the Hastelloy W and X billets were not extruded under the direction of ORNL, the fabrication of these alloys is of interest to the over-all alloy development program. The available results of these extrusions are presented in Table 3.3.2.

The following general conclusions have been drawn regarding the extrusion of 6.9-in.-OD, 10-in.-long billets of Hastelloys B, W, and X:

1. Forged billets of Hastelloys B, W, and X can be successfully extruded to tube blanks.

CONFIDENTIAL

2. Canning of the billets with $\frac{1}{8}$ -in.-thick type 316 stainless steel appears to be advantageous from the standpoint of reducing the extrusion pressure. Because of the number of variables involved, however, this point needs to be confirmed.

3. The larger mass of the commercially produced billets made possible the use of lower soaking temperatures at the smaller extrusion ratios (i.e., 5.5:1) than were found to be optimum for the extrusion of small laboratory billets.

4. For successful extrusion of these alloys it is necessary that the billets be upset with sufficient pressure to start the material through the die and then extruded at a relatively slow rate to prevent hot-short cracking.

These were the first successful attempts to extrude these materials on a large scale, and it now appears to be feasible to produce seamless tubing of these alloys. Three Hastelloy B tube blanks and one Hastelloy W tube blank are scheduled to be reduced to 1-in. pipe and small-diameter tubing for use at ORNL.

Extrusion of Special Alloys

The study of single-phase alloys in the nickel-molybdenum alloy system that contain 15 to 20% molybdenum was continued. It is hoped in this study to find a solution to the problem of embrittlement of the Hastelloy-type alloys as a result of aging. At present the only readily apparent solution is to change the composition of the alloys.

It was reported previously that the corrosion resistance to fused salts of the binary alloys of nickel and molybdenum which contain more than 15% molybdenum was exceptionally good but that their high-temperature strength was not adequate. Thus in order to obtain alloys with greater strength the special alloys described below are being studied. In addition to the binary alloys, ternary alloys are being made that will be tested to determine the effect of a third element on corrosion resistance of these alloys in fused salts.

International Nickel Company Compositions. As reported previously,¹ 40-lb heats of five special alloys were received from INCO for corrosion testing and strength evaluation. The nominal compositions of these alloys are given in Table 3.3.3.

TABLE 3.3.3. COMPOSITIONS OF SPECIAL ALLOYS PREPARED BY INTERNATIONAL NICKEL COMPANY

Alloy No.	Composition (wt %)							
	Mo	Cr	W	Nb	Al	Ti	C	Ni
T-23011	15	5	3	3	0.5			73.5
T-23012	17				0.5			82.5
T-23013	15		3	3	0.5			76.5
T-23014	15				1	1.5		82.5
T-23015	15		3	3	0.5		0.25	78.25

Four extrusion billets, 3 in. in diameter and 3 in. long, were machined from each ingot, three for tube blanks and one for rod fabrication. The rod extrusions were for rolling to 0.065-in. strip for the preparation of test specimens for strength evaluation. The initial tube blank extrusion experiments involving one billet of each composition met with little success. When a fast extrusion rate was used, the alloys demonstrated the hot-short tendencies of Hastelloy B, with the exception of alloy T-23013, 15% Mo-3% Nb-3% W-0.5% Al-78.5% Ni. The results of this initial experiment are presented in Table 3.3.4.

Before the remaining billets of these alloys were extruded, the results obtained in the fabrication of Hastelloy W at a slow extrusion rate were sufficiently favorable to prompt an alteration in

T-23015	2080	Tube blank cracked on the inside

DECLASSIFIED

the extrusion conditions for the special compositions. Two billets, T-23012 and T-23014, were extruded slowly at 2200°F with a $\frac{3}{4}$ -in.-dia mandrel at an extrusion ratio of 5.4:1. Both alloys responded satisfactorily, but the mandrel broke within the tube blank in each case. With a decreased rate of extrusion the billet remained in contact with the mandrel for an excessive length of time, and the resultant overheating of the tool caused a subsequent decrease in its ultimate strength. The utilization of a 1-in.-dia mandrel alleviated this problem. The final results of slow extrusion of these alloys at 2200°F are presented in Table 3.3.5. Extrusions 1 through 5, shown in Fig. 3.3.4, are representative of the good tube blanks obtained from these special compositions. The tube blanks have been sent to the Superior Tube Company for redrawing to 0.500-in.-OD, 0.035-in.-wall tubing.

TABLE 3.3.5. RESULTS OF THE FINAL EXTRUSIONS OF SPECIAL ALLOYS PREPARED BY THE INTERNATIONAL NICKEL COMPANY

Mandrel sizes: 1 in. dia			
Alloy No.	Extrusion Ratio	Extruded Shape	Number of Successful Extrusions
T-23011	7:1	Tube blank	2
T-23012	7:1	Tube blank	1
T-23013	7:1	Tube blank	2
T-23014	7:1	Tube blank	1
T-23015	7:1	Tube blank	2
T-23011	6.25:1	Rod	1
T-23012	6.25:1	Rod	1
T-23013	6.25:1	Rod	1
T-23014	6.25:1	Rod	1
T-23015	6.25:1	Rod	1

Hot rolling of the extruded rods was only moderately successful. The rolling temperature was varied between 1925 and 2100°F, and the scheduled reduction was approximately 10% per pass. In general, the lower temperature proved to be more satisfactory for minimizing edge cracking. Each alloy was hot rolled to 0.250-in. strip, pickled, annealed at 2050°F for 1 hr, and

cold finished to 0.065-in. strip with an intermediate anneal at 2050°F for $\frac{1}{2}$ hr. Final annealing of each alloy was scheduled to yield a grain size of ASTM 6-7. Alloy T-23015 edge-cracked severely during hot rolling. The other alloys for which edge cracking did not interfere with the machining of sound test specimens will be evaluated for strength.

Battelle Memorial Institute Compositions. — In cooperation with Battelle Memorial Institute in the development of nickel-molybdenum-base alloys for high-temperature use, extrusion experiments were conducted on three promising compositions with the intention of producing seamless tubing for corrosion testing. A total of 10 forged billets representing portions of 220-lb air-melted heats was fabricated. The results of the experiments are presented in Table 3.3.6.

Although fast extrusion at a ratio of 5.4:1 resulted in cracking on the inside, all these tube blanks are being salvaged at the Superior Tube Company by drilling the as-extruded tube blank and thus increasing the inside diameter from $\frac{3}{4}$ to 1 in. before tubing reducing. Tube No. 6, shown in Fig. 3.3.4, is representative of a good extrusion obtained from these alloys. As is typical of most of these high-strength nickel-molybdenum-base alloy extrusions, a certain amount of surface roughening was found on the inside, but it was not so severe as it appears to be in Fig. 3.3.4. Slight conditioning of the blanks before redrawing will eliminate these defects. The cause of this roughening is not completely understood at this time, but it may be related to the surface condition of the billet before extrusion or to lubrication practice during extrusion. All the blanks are being fabricated to 0.500-in.-OD, 0.035-in.-wall tubing.

ORNL Compositions. — The basic nickel-molybdenum alloy containing 15 to 20% molybdenum possesses corrosion resistance on a par with that of Hastelloy B, better ductility and fabricability, but poorer strength properties. Consequently, alloy additions to the basic composition are required for improving the strength properties. The elements being investigated as strengtheners are Ti, Al, W, Nb, Cr, Fe, V, and C. In order to determine the effect of these elements individually on corrosion resistance and to establish the maximum quantity of each element that can be

Vacuum-induction heats of each composition are being prepared in 36-lb billets. A small amount of carbon is added to each charge to bring the resultant carbon level to 0.06%. It is possible to machine three tube-blank extrusion billets from each ingot for the fabrication of sufficient tubing to make three standard thermal-convection loops for corrosion testing. Thus far the chromium-bearing alloys have been prepared, as well as the alloys with 2 wt % tungsten, 2 wt % titanium, and 2 wt % aluminum. Good tube blanks were obtained

by extrusion of the chromium-bearing alloys at 2100 and 2150°F. In all cases, a slow extrusion rate of approximately 1 in. of billet length per second at a ratio of 7:1 was used. Tubes 7 and 8 of Fig. 3.3.4 are representative product samples. It is known that chromium additions above a certain minimum amount are detrimental from the standpoint of corrosion by fluoride fuels, but chromium is a desirable addition for imparting oxidation resistance to the alloy. Results of previous tests of chromium-bearing nickel-molybdenum alloys in the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %) indicated that chromium additions in excess of 5% caused decreased corrosion resistance; at least 7% chromium is required, however, to make the alloy resistant from an oxidation standpoint. The chromium level that can be tolerated when the alloy is in contact with the fuel mixture (No. 107) NaF-KF-LiF-UF₄ (11.2-41-45.3-2.5 mole %) is to be determined.

In all extrusion experiments carried out this quarter, difficulty was encountered occasionally with billets failing to extrude to completion. This trouble was attributed to excessive chilling of the billets by the cold ram at the slow extrusion rates being used. Therefore a new billet was designed that has mild-steel nose and tail plates tack welded to it. The plates were expected to

allow the billet to start through the die more easily, as well as to transfer the chilling action by the ram to a more easily extruded material. The mild steel is cropped from the tube blank after extrusion. Steel washed back on the outside surface of the tube is machined off before the tube blank is reduced to tubing.

Improved lubrication of the billet was obtained by coating the container of the press, as well as the mandrel, with Necrolene grease prior to each extrusion. Low-melting-point Fiberglas mats are also placed around the hot billets before they are introduced into the extrusion press. This lubrication practice has resulted in lowering the pressure required for extrusion of these materials.

Consumable-Electrode Experiments

As indicated previously,¹ arrangements were made with Battelle Memorial Institute for the preparation of arc-melted ingots of nickel, Hastelloy B, Hastelloy W, a 76% Ni-17% Mo-7% Cr alloy, and an 83% Ni-17% Mo alloy. The melts were to be made by the consumable-electrode process to take advantage of the high arc temperatures for vaporizing "tramp" elements in an effort to improve the strength and fabricability of these alloys. Electrodes of the first three alloys were to be supplied in the form of rolled rods. The special nickel-molybdenum alloys were to be prepared by vacuum melting, and the electrodes were to be fabricated by threading together extruded rods of the material. All the electrodes are now ready for shipment.

OXIDATION OF HASTELLOY B

H. Inouye

J. E. Spruiell²

It was reported previously³ that the oxidation rate of Hastelloy B in air at 1500°F was not excessive. When the alloy was thermally cycled from 1500°F to below about 660°F, however, the rate was increased by an order of magnitude as a result of spalling of the protective NiMoO₄ scale from the metal surface. This spalling is caused by a phase transformation in the NiMoO₄ layer at about 660°F.

The oxidation of Hastelloy B in static air has now been investigated at 1200, 1400, 1600, and 1800°F. Data were obtained for mechanically polished specimens exposed to air at the various temperatures for periods of 168 hr. The increases in the specimen weights were determined at frequent intervals to obtain oxidation-rate curves. The total weight increases of the specimens during the tests at the various temperatures are shown in Table 3.3.7. The curves of the weight gain vs time were parabolic at all test temperatures, and thus the oxide scale appears to be protective.

The oxidation rate of the alloy at 1200°F is very low, and the superficial scale which forms does not spall upon cooling. Preliminary x-ray data show that this scale is principally NiO.

Thus far in these studies of the oxidation characteristics of nickel-molybdenum alloys, evidence has been found that the formation of NiMoO₄ depends upon the molybdenum content. However, its formation may also be a function of temperature, as indicated in the tests described above.

COMPOSITE TUBING

H. Inouye M. R. D'Amore⁴

The fabrication of composite tubing by coextrusion was described previously.^{5,6} Initially these studies were made in order to develop billets which, when extruded, would result in composite tubing with predetermined thicknesses of the various metal layers. To date, billet configurations for the fabrication of two- and three-ply tube blanks have been developed.

An extrusion billet design used for the fabrication of two-ply tube blanks of equal layer thicknesses is shown in Fig. 3.3.5. The effect of various alloy combinations on the layer thicknesses after extrusion was of particular interest, since it is known that the thickness of metals with higher resistance to plastic deformation will be greater after hot rolling than was calculated. Billets of the configuration shown in Fig. 3.3.5 were extruded at 2100°F to 1½-in.-OD, ¼-in.-wall tube blanks. Tube blanks of several combinations of alloys were sectioned longitudinally and the layer thicknesses determined. The results, as presented in Table 3.3.8, show that variations in the layer thicknesses are independent of the

combination of alloys, although the resistances of the alloys to plastic deformation may vary greatly. Accurate thickness measurements were difficult to obtain because of the roughness of the extruded blank.

Tube blanks of the combinations listed were redrawn to 0.187-in.-OD, 0.020-in.-wall tubing with fair success. As a result of inexperience in processing duplex tubing, however, a few longitudinal cracks were present in the Inconel layer of the Inconel-type 316 stainless steel combination. Also, the Hastelloy B-type 316 stainless steel combination was rejected during processing because of longitudinal splitting. Preliminary examinations of the small-diameter tubing obtained showed that thermal bonds were maintained at the metal interfaces throughout the processing and that the layer thicknesses were about equal.

ANP PROJECT PROGRESS REPORT

The as-received Lindsay Mix is composed of very fine particles about 1μ in size. Dry mixing of the Lindsay Mix and carbonyl nickel powders in an oblique blender resulted in segregation and lumping of the rare-earth oxide particles. A satisfactory dispersion of the oxide and carbonyl nickel powders could be obtained only by wet milling.

One section of a control rod core has been fabricated by hot-pressing a cylinder of 36.9 vol % Lindsay Mix-63.1 vol % carbonyl nickel to a density of 88.7% of theoretical. Additional extrusions of Lindsay Mix-nickel cores clad with either Hastelloy X or Inconel are planned.

TUBULAR CONTROL RODS

M. R. D'Amore J. H. Coobs
R. E. McDonald¹²

The feasibility study on the extrusion of tubular control rods, described previously,¹³ was continued. An Inconel billet can was fabricated, and the core was prepared by tamping a loose powder mixture of 36.9 vol % Lindsay Mix rare-earth-oxide particles dispersed in nickel into the billet can. Fracturing of the outer layer of this three-ply billet during extrusion at 2100°F resulted in a nonuniform core. The core was quite dense after extrusion and appeared to be bonded to the inner and outer Inconel cladding.

3.4. WELDING AND BRAZING INVESTIGATIONS

P. Patriarca

PUMP FABRICATION EXPERIMENTS

P. Patriarca G. M. Slaughter

Welding Studies

The dimensional changes associated with the welding of Inconel pump volutes representative of those designed for the main NaK pumps (PK-2) of the ART were determined in a preliminary investigation.¹ These changes were considered to be in excess of those allowable. Accordingly the welding procedure was modified and the test was repeated in the interest of improving the ability to more nearly conform to acceptable tolerances.

Two test pieces essentially similar to those used previously were machined from 2-in. Inconel plate. A shrinkage of 0.100 in. was provided for in the fabrication of these pieces. Four spacers were also machined from Inconel plate to act as rigid supports during welding of the volutes after

¹P. Patriarca, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 142.

the initial shrinkage occurred. These are shown in Fig. 3.4.1, along with the component parts of the test. The spacers were subjected to an aluminizing treatment prior to assembly of the components in order to prevent self-welding during the subsequent operations. The two volutes were welded in accordance with the welding procedure described in Fig. 3.4.2.

Micrometer measurements were made at four radial sections, as described in Fig. 3.4.3, prior to and after each operation. The results of these micrometer measurements are summarized in Table 3.4.1. It may be noted that the shrinkage decreased with increased distance from the weld, an effect noted previously.¹ It appears that an improvement of the shrinkage prediction at position 3 by reducing the shrinkage allowance can be accomplished only at a sacrifice in the absolute shrinkage at positions 1 and 2, the over-all error being of the order of 0.012 in.

A compromise would be to provide for a 0.090-in. shrinkage allowance and thereby reduce the absolute error to 0.006-in. The ability to reproduce

* Shrinkage allowance: 0.100-in.

** Revised shrinkage allowance: 0.090-in.

the shrinkage data described herein should be determined by conducting another test prior to attempting fabrication of a pump with a complex volute.

Since the shrinkage at position 3 was less than expected, it was not possible to use the spacers, as machined, to prevent further shrinkage during annealing. The pump casing was annealed at 1850°F for $\frac{1}{2}$ hr in order to determine the necessity for this operation. The additional shrinkage of 0.002 to 0.004 in. observed indicates that the role of residual stresses is significant. Properly machined spacers should be used to prevent further shrinkage during annealing, as was accomplished in the previous investigation.¹

Brazing Studies

Tests have also been performed to study the feasibility of a brazed NaK (PK-2) pump volute. The component parts for the test are shown in Fig. 3.4.4. The bottom volute is shown with eight 0.187-in.-dia, 1-in.-long Inconel shear pins inserted into 0.197-in.-dia holes drilled to a depth of $\frac{1}{2}$ in. These pins were intended to provide approximately 5 in.² of shear area to supplement the 18 in.² of area that constitutes the faying surfaces of the upper and lower volutes in the brazed assembly. The top volute is shown with 0.200-in.-ID tubes welded over the shear pin holes to act as reservoirs for the Coast Metals No. 52 brazing alloy. The alloy was applied in the form of 3.16-in.-dia slugs, which ranged from 3.8 to $\frac{1}{2}$ in. in length and were fabricated by casting in graphite molds. Several of these slugs are shown in the center of Fig. 3.4.4. A total of 30.8 g of Coast Metals No. 52 alloy was used. This amount was calculated to supply approximately 0.19 in.³ of alloy, of which 0.048 in.³ would fill the space between the shear pins and the shear pin holes and approximately 0.054 in.³ would comprise a 0.0003-in.-thick brazing alloy layer between the faying surfaces of the volutes. It was expected that a surplus of brazing alloy would be desirable to ensure complete brazing. The excess alloy was to remain in the reservoirs. A 0.003-in. separation between the parts of the volutes was achieved by using 0.003-in.-dia nickel wire as a spacer.

Micrometer measurements were made before and after brazing at the positions described in Fig. 3.4.5. The assembly was brazed at 1050°C in dry hydrogen. The heating and cooling rate of the brazing cycle was approximately 350°C/hr,

and a hold time of $\frac{1}{2}$ hr at 1050°C was used. A photograph of the completed assembly is shown in Fig. 3.4.6. As may be seen, excess brazing alloy flowed out of the capillary and down the side of the casing. A similar condition was evident on the inside of the volute; there was a fillet of brazing alloy thinly distributed around the bottom volute.

The failure of the reservoirs to retain the excess brazing alloy is attributed to the relatively large clearance between the Inconel shear pins and the shear pin holes. It is expected that a clearance of 0.001 to 0.002 in., coupled with a supplementary capillary on the periphery of the casing, which could be removed later, would remedy this difficulty.

The braze joint was subjected to dye-penetrant and radiographic inspections and was considered to be sound. The degree of correlation between the radiographic interpretation and the joint soundness should be determined by metallographic examination.

The results of the micrometer measurements are summarized in Table 3.4.2. As may be noted, most of the dimensional changes found are within the limit of error of the measurements. As was expected, the data indicate that the brazed construction affords a high degree of dimensional control and should be given consideration as a fabrication method.

REVISED

FABRICATION OF JOINTS BETWEEN PUMP
BARRELS AND THE PRESSURE SHELL
OF THE ART

P. Patriarca

The ability to weld an accurately machined and properly stress-relieved pump barrel to a thick-walled pressure shell without the need for finish machining or subsequent stress relieving would simplify considerably the assembly of the "north head" of the ART. A design was suggested to permit such a procedure, and a test was conducted to evaluate the feasibility of the design.

The component parts of the joint used for the test are shown in Fig. 3.4.7. The liner flange is shown attached to the pump barrel sleeve, which in turn was welded to the pump barrel. The liner flange is also shown attached to a carbon-steel pipe, which was in turn welded to a 2½-in.-thick carbon-steel base plate. This auxiliary weldment was intended to provide a degree of restraint comparable to that to be expected from the north-head expansion tank.

It may be noted that the shell flange is quite large, the intent being to minimize distortion of the flange and thereby require a realistic proportion of the distortion during welding to occur in the barrel sleeve and hence in the barrel itself. The restraint provided by the auxiliary weldment shown in Fig. 3.4.8 was intended to supplement the afore-mentioned condition and, hence, to more nearly simulate the north-head pressure shell.

The shell flange was welded into the pump-barrel sleeve by using the welding procedure described in Fig. 3.4.9. The completed test weldment is shown in Fig. 3.4.10. Diametrical changes in the pump barrel were determined by micrometer measurements at the positions described in Fig. 3.4.11. The restraints were then removed by cutting the carbon steel with an oxyacetylene torch, and the barrel assembly was subjected to a 6-hr soak at 1500°F prior to further micrometer measurements on the barrel diameter. The results of these diametrical measurements are summarized in Table 3.4.3. It may be noted that the maximum changes are remarkably small considering the extent of welding involved.

It is interesting to note that at least partial relief of residual stresses was accomplished by cutting the barrel assembly from the restraints and soaking at 1500°F. This procedure resulted in additional diametrical changes, which indicate that some distortion will occur in the north head in service that may be unacceptable.

Axial changes were also determined by micrometer measurements at the positions described in Fig. 3.4.12. The results of the measurements are summarized in Table 3.4.4. It may be noted that an axial shift occurred that was significant in magnitude but remarkably small for the amount of welding involved. These results indicate that some distortion is inevitable and must be either accepted or removed by subsequent machining and that a stress relief anneal will be necessary to remove effects of residual stresses during operation.

INVESTIGATION OF SHRINKAGE OF INCONEL CORE SHELL WELDS

P. Patriarca A. E. Goldman

A series of tests are being carried out to determine the weld shrinkage to be expected during fabrication of the Inconel core shell welds. Comparisons of the weld shrinkage formulas given in the literature with preliminary results obtained at ORNL revealed wide discrepancies. It was decided that actual experiments that would yield empirical data would be required. A program of welding Inconel plates under controlled conditions and close observation was therefore carried out. Based upon the results of these tests, the welding of large Inconel hoops was begun. These tests were performed in a manner that as nearly as

possible duplicated the fabrication problems and restrictions of the actual core shells.

Each test of the initial program consisted in the inert-arc welding of two $\frac{1}{4}$ -in. Inconel plates, each 6×20 in., in accordance with the established procedure specifications (PS-1). A 50-deg bevel with a $\frac{1}{16}$ -in. land was machined on one long edge of each plate. A total of nine tests was performed.

Each pair of plates was assembled as shown in Fig. 3.4.13. The root gap was fixed at $\frac{1}{8}$ in. by using four $\frac{1}{8}$ -in. tool-steel spacers. The plates were held against a flat horizontal plate by means of C-clamps. Two large clamps were used to draw the plates tightly against the tool-steel spacers. The edges of the plates were securely taped to prevent air leakage into the gap, since only the

torch gas was used to supply backup gas and weld coverage.

A $\frac{1}{2}$ -in.-long tack weld was placed at each end of the root gap, and two more $\frac{1}{2}$ -in.-long tack welds were equally placed along the root gap. The clamps were removed after the tack welds were made, and the spacers were driven out. Shrinkage measurements were taken, and the plates were again fastened to the flat base. The root pass was applied after the tack welds had been wire brushed and the edges had been feathered. Measurements of the root pass shrinkage were then taken.

The plates were then assembled in the vertical welding jig as shown in Fig. 3.4.14. The remaining five weld passes per plate were deposited in accordance with the sequence shown. The completed weldment is shown in the vertical jig in Fig. 3.4.15. Dial-gage readings were taken at 1-min intervals during the deposition of the

ANP PROJECT PROGRESS REPORT

final passes, and micrometer measurements were taken after the final pass had been made. The shrinkage measurements and welding data are presented in Table 3.4.5; the results of tests 106, 107, 108, and 109 were in close agreement, although two different welding operators made the welds.

The welding procedure used for these tests of plates was then used for test welds of hoops. For these tests $\frac{1}{8}$ -in. Inconel plates, 6 x 138 in., were bent into hoops approximately 44 in. in diameter. One edge of each hoop had a 50-deg bevel and a $\frac{1}{16}$ in. land. The hoops were placed on the weld-positioner bed in a horizontal plane in the manner shown in Fig. 3.4.16. Tool-steel spacers, 4 in. long and $\frac{1}{8}$ in. thick, shown in Fig. 3.4.17, were placed between the beveled edges at 6-in. intervals to maintain the root gap. Large C-clamps were used to draw the two hoops tightly against the spacers. Smaller C-clamps were halved and tacked to the bottom hoops to aid in the alignment of the upper hoop. Asbestos string was used to seal the gaps between the

spacers prior to tacking. The area behind the root gap was sealed with a cover formed from 0.010-in. annealed brass sheet and masking tape, and the enclosed space was purged for 30 min prior to tacking. Alignment was checked constantly as the tack welds were placed between the spacers. After removal of the tool-steel spacers, the root pass was deposited. No dressing of the land or feathering of the tack welds was permitted prior to the root-pass deposition.

After completion of the root pass, the weld was wire brushed and the five final weld passes were deposited by using the sequence described in Fig. 3.4.14. For these welds, two welders worked 180-deg apart around the hoop while the positioner was slowly rotated. As shown in Fig. 3.4.18, four dial gages were used to record the shrinkages of the final passes. The welders worked on a 15-min-work, 5-min-rest cycle. A typical plot of dial-gage readings is shown in Fig. 3.4.19. The micrometer and dial-gage measurements obtained are summarized in Table 3.4.6.

Fig. 3.4.16. Inconel Hoops on Weld Positioner Bed.

Within the limits of this investigation, the following conclusions can be drawn.

1. The results of the last four tests on plates indicated that, under controlled conditions, the effect of the welding variables could be minimized so that a welding operator could, essentially, duplicate his performance from test to test when welding manually. Also, for a given set of conditions, a welder could nearly duplicate another welder's performance.

2. The use of various lengths of tool-steel spacers in the tack welding of the plates caused wide variations in the resulting tack-weld shrinkage. The amount of tack-weld shrinkage was found to be inversely proportional to the length of the spacers.

3. The results of the tests on the hoops indicated that the inevitable variations in conditions and techniques while the operators were progressing around the circumference caused greater

UNCLASSIFIED
PHOTO 11267

Fig. 3.4.18. Hoop Welding Assembly Showing Dial Gages Used for Measuring Shrinkage.

variations in shrinkage within a hoop than the variations observed from hoop to hoop.

4. The over-all results indicate that for $\frac{1}{2}$ -in. Inconel plate, inert-arc welded by two welding operators under the conditions utilized for these tests, the transverse shrinkage to be expected will be from 0.111 to 0.138 in., with an average

Fig. 3.4.19. Typical Plot of Dial-Gage Measurements of Shrinkage During Final Five Passes of the Welding of Inconel Hoops.

TABLE 3.4.6. WELDING CONDITIONS AND RESULTS OF SHRINKAGE MEASUREMENTS ON WELDS OF INCONEL HOOPS

value being 0.120 in. The longitudinal shrinkage to be expected will be 0.250 to 0.375 in. for a circumferential length of 138 in.

As previously mentioned, the values for the transverse and longitudinal shrinkage for the 44-in. hoops do not correspond to the values obtained by calculation from the formulas given in the literature. Only through the accumulation of empirical data from actual experience can predictions be made for future weld shrinkages. Since each variation in the thickness of the Inconel plate to be welded will create new problems solvable only by more actual test results, ad-

ditional tests will be conducted on each of the plate thicknesses of interest.

EXAMINATION OF NaK-TO-AIR RADIATOR
PWA NO. 2 AFTER SERVICE

R. J. Gray P. Patriarca

A 500-kw high-conductivity-fin radiator, designated PWA HCF radiator No. 2, failed on December 23, 1955, as the result of a leak. This radiator had been operating in a test rig for a period of 1199 hr in the temperature range 1000 to 1600°F. For 546 hr of the operating period a temperature differential was imposed on the NaK flowing

through the radiator by passing cold air across the fin surfaces. The radiator is shown in Fig. 3.4.20 as it appeared when received from the test site.

The entire radiator was leak checked by pressurizing it under water and observing it to locate the origin of air bubbles. This procedure revealed the point of failure, which is indicated by the arrow in Fig. 3.4.20. The radiator was then sectioned for further examination, as shown in

Fig. 3.4.20. NaK-to-Air Radiator PWA No. 2 That Failed in Service. Arrow indicates point of failure.

Fig. 3.4.21. NaK-to-Air Radiator PWA No. 2 After Sectioning for Metallographic Examination.

Fig. 3.4.21. The side portions of the support members were removed by using a rubber-banded masonry wheel in a portable, electric handsaw adjusted for a shallow cut. Each bank of fins was separated by slicing the support members and the bottom flanged plate, as shown, with a fine-toothed, high-speed, steel hacksaw blade in a portable electric drill equipped with a portable power-saw attachment. The failed area was then carefully removed for metallographic preparation on a standard wet-cutoff machine equipped with an abrasive wheel.

The area of the failure was again pressurized under water to locate the exact position of the leak before additional preparation for metallographic examination was undertaken. The failure was found to exist in the corner tube on the periphery which faced the side support member. The support member was subsequently removed for unobstructed observation of the emergence of the water bubbles. The point of failure may be seen in Fig. 3.4.22.

Fig. 3.4.22. Failed Tube After Removal from NaK-to-Air Radiator PWA No. 2 as Viewed from the Support Member Side of the Radiator.

ANP PROJECT PROGRESS REPORT

The tube that failed and two adjacent tubes were mounted intact and carefully ground to permit examinations of their longitudinal cross sections as seen against the direction of air flow. The tube that failed is shown in Fig. 3.4.23. The neckdown of the tube wall indicates a tensile fracture similar to that observed² in York radiator No. 1.

Longitudinal cross sections of the two adjacent tubes that were examined are shown in Figs. 3.4.24 and 3.4.25. Incipient fractures may be seen in both these tubes. Three tubes were also taken from corresponding positions on the air exit face and prepared for examination in a similar manner. Only one tube exhibited evidence of incipient fracture, as shown in Fig. 3.4.26.

It is concluded that the radiator failed as a result of the initiation of a fracture in a braze alloy fillet by shear forces and the propagation

of this fracture through the tube wall by tensile forces or combinations of tensile and shear forces during periods of cyclic operation. Since the incidence of incipient fractures was associated exclusively with the presence of support members or plates, it is recommended that these transverse restraints be removed entirely. This can be accomplished, as suggested previously, by using a high-conductivity fin to provide transverse support at 2- or 4-in. intervals³ and modifying the brazing procedure accordingly.

The tensile loading contribution to the York radiator failure was attributed at the time of examination to the restraining influence of the support member, which extended up the side of the radiator.³ In view of this conclusion, the support members of subsequent radiators, including PWA No. 2, were slit, as shown in Fig. 3.4.20,

Fig. 3.4.26. Corner Tube from Air Exit Face of NaK-to-Air Radiator PWA No. 2 as Viewed in the Direction of the Air Flow. 75X. Reduced 36%.

prior to installation. It may be noted, however, that the radiator as redesigned retained the bottom flanged plate, a top plate, and the four support members. During the brazing cycle the NaK tubes were brazed to these members, and a relatively rigid condition resulted at each of the five transverse sections across the radiator matrix. Local differences in rates of heating and cooling, particularly between the air inlet face and the remainder of the radiator during blower startup, could therefore bring about the development of tensile loading. This condition could be partially relieved by slicing the support members and plates in a manner similar to that utilized during dissection for metallographic examination, as shown in Fig. 3.4.21.

The development of tensile forces alone, however, cannot be assigned the full responsibility for failure. The incidence of numerous incipient fractures in this radiator has been related to the presence of a support member or heavy plate. Over 13,000 tube-to-fin joints have been examined

metallographically without the observation of a single incipient fracture. The differences in mass and thermal conductivity of the support members and plates as compared with the high-conductivity fins could result in significant differences in heating and cooling rates during cyclic operation. These differences could create lateral forces that could be responsible for the initiation and propagation of fractures in brazed joints between tubes and support members in any portion of the radiator.

EXAMINATION OF FUEL-TO-NAK HEAT EXCHANGER AFTER SERVICE

G. M. Slaughter

Tests of the fuel-to-NaK heat exchanger, designated as IHE-3, were terminated as a result of the detection of a leak in a tube bundle after a total of 1794 hr of operation in the temperature range 1100 to 1500°F. There was a temperature differential imposed on the heat exchanger for 1015 hr of this total time, and 21 thermal cycles were applied over this period.

The NaK inlet and NaK outlet headers of the tube bundle that leaked were separated from the heat exchanger to facilitate examination and inspection. Top and bottom views of the inlet header are shown in Figs. 3.4.27 and 3.4.28. The general location of the failure is evident in Fig. 3.4.28, in that a dark reaction product can be distinguished from the lighter solidified fuel mixture. Forty tubes in the area of the failure were individually inspected with a dye penetrant and a Boreoscope, and at least five tubes were found to contain obvious cracks. The NaK inlet header after dissection with an abrasive cutoff wheel

Fig. 3.4.27. Top of NaK Inlet Header of Fuel-to-NaK Heat Exchanger IHE-3 Showing Tube Welds.

to permit the examination of individual tubes is shown in Fig. 3.4.29. Each tube was numbered for the subsequent investigation as shown in Fig. 3.4.30.

The frequency and severity of the cracks detected in the initial inspection were most pronounced in the forward rows of tubes, that is, those with short bends. The distance from the tube bend to the headers was significantly shorter

for the first row of tubes, being $3\frac{1}{4}$ in. as compared with 6 in. for the last row of tubes. For a given expansion of the 6-ft over-all straight length of the tubes as a result of heating, a substantial degree of strain occurs in these locations. As would be expected, cracking was more pronounced on the tension sides of the tubes. A crack in the tension side of tube 2 could be seen upon visual examination (Fig. 3.4.31). Further evidence of tube distortion at the headers can be seen in Fig. 3.4.32, which shows the NaK outlet header.

Several of the tubes of interest were mounted intact in Costolite and polished to the approximate

center line for metallographic examination. The tensile side of tube 3, shown in Fig. 3.4.33, illustrates typical severe cracking and corrosion by the fuel mixture which circulated on the outside of the tubes. A similar condition is evident in Fig. 3.4.34, which is a panorama of the tension side of tube 17. The opposite face of tube 17, a panorama of which is shown in Fig. 3.4.35, does not exhibit so serious a condition. It appears that the corrosion and the stresses combined to form an abnormally unfavorable condition.

Fig. 3.4.32. Bottom Side of NaK Outlet Header Showing Distortion of Tubes.

The extent of the corrosion was investigated by examining tube 93 to ensure that the large degree of attack observed in the previous samples did not result from the reaction of the two fluids at the locations of the failures. The results of the examination (Fig. 3.4.36) indicate that, in general, severe corrosion was prevalent throughout the tubes in the inlet header. The inner tube wall of a typical tube is shown in Fig. 3.4.37; cracks and corrosion emanating from the outer wall may also be seen. A white deposit was found in the cracks in some areas, as shown in Figs. 3.4.38 and 3.4.39. The nature of this deposit, as well as a detailed investigation of the mass transfer and corrosion, will be reported later.

3.5. MECHANICAL PROPERTIES STUDIES

D. A. Douglas

EFFECT OF ENVIRONMENT ON CREEP-
RUPTURE PROPERTIES
OF HASTELLOY BC. R. Kennedy¹

Revised design data obtained from creep tests of solution-annealed Hastelloy B sheet stock in various environments at 1300, 1500, and 1650°F are summarized in Figs. 3.5.1, 3.5.2, and 3.5.3. The times to 0.5, 1, 2, 5, and 10% total strain at each temperature in the various environments are the same, and for stresses for which the rupture life is more than 300 hr the effect of environment is shown to be negligible. The creep curves obtained at 1500°F in air and in argon, shown in Fig. 3.5.4, appear to indicate that the better performance in air than in the other environments at stresses for which the rupture life is less than

300 hr is caused by the ability of air to strengthen Hastelloy B during third-stage creep. For rupture lives longer than 300 hr there is considerably less third-stage creep because of the aging characteristics of the alloy, and, as seen in Figs. 3.5.1, 3.5.2, and 3.5.3, the effect of environment diminishes. Design curves produced from limited data for solution-annealed Hastelloy B sheet tested at 1800°F in argon and in the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %) are shown in Fig. 3.5.5. At 1800°F Hastelloy B does not age perceptibly and the amount of third-stage creep is great in tests at all stress levels. Thus the fuel mixture strengthens the alloy at all stress levels. Of the environments tested, only those which are "surface active" (produce a thin, tightly adherent film on the surface of the metal) affect the creep properties of the metal. It can be seen from Figs. 3.5.1, 3.5.2, 3.5.3, and 3.5.5 that, of the environments tested, only

air and the fuel mixture seem to be surface active. Air, of course, produces an oxide film which is ever present, and the fuel mixture, in effect, creates a very thin surface film by leaching one of the alloy constituents and producing another phase on the surface, as shown in Figs. 3.5.6 and 3.5.7.

SHORT-TIME HIGH-TEMPERATURE TENSILE PROPERTIES OF HASTELLOY B

C. R. Kennedy

The short-time high-temperature tensile properties of solution-annealed Hastelloy B are illustrated in Fig. 3.5.8, which gives the yield and ultimate strengths and the final elongations in the temperature range 1000 to 1800°F. As may be seen there is a distinct decrease in the final elongation and in the ultimate strength at temperatures around 1200°F. This change in properties occurs in the temperature range in which the type of fracture transforms from predominantly transgranular to intergranular. It is interesting to note that the change in the yield strength with temperature is relatively small.

CREEP-RUPTURE PROPERTIES OF HASTELLOY W

C. R. Kennedy

Creep testing of Hastelloy W is now in progress, and design data are presented in Figs. 3.5.9, 3.5.10, and 3.5.11 for solution-annealed sheet tested in argon at 1300, 1500, and 1650°F. Hastelloy W, which has almost the same composition as Hastelloy B, except for the addition of 5% chromium and the deletion of 3% molybdenum, has creep properties very similar to those of Hastelloy B. Although Hastelloy W exhibits less of a tendency to age than Hastelloy B, as shown in Figs. 3.5.12 and 3.5.13, a decrease in ductility occurs at 1300°F. This is also shown in Fig. 3.5.9, in which the absence of a 10% curve indicates that the total strain at rupture was less than 10%.

Rupture points obtained from tests with the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %) are also shown in Figs. 3.5.9 and 3.5.10. The times to 0.5, 1, 2, 5, and 10% total strain are identical for the same stress and temperature, and, as shown, only the rupture life is affected by

the environment. The effect of the fuel mixture on the creep properties of Hastelloy W sheet appears to be the same as that shown for Hastelloy B.

SHORT-TIME HIGH-TEMPERATURE TENSILE PROPERTIES OF INCONEL

J. R. Weir, Jr.

The tensile properties of Inconel sheet have been determined at temperatures from 78 to 2200°F. The yield point, by 0.2% offset, and the ultimate strength are shown in Fig. 3.5.14 for both fine-grained and coarse-grained material. As may be seen, the fine-grained material has the better strength properties at temperatures up to 1700°F.

Transient loads induced by thermal fluctuations may, in some cases, be of greater concern than the static loads that result from pressure differential. Therefore, even though the fine-grained Inconel has less creep resistance in the fused salts than the coarse-grained Inconel (Fig. 3.5.15), the fine-grained material may be the more desirable structural material because of its better tensile properties in the temperature range of interest.

CREEP TESTS OF INCONEL IN FUSED SALTS

J. R. Weir, Jr.

Inconel was creep tested at 1500°F and a stress of 3500 psi in NaF-ZrF₄ (50-50 mole %) in order to compare the severity of attack with that found after similar creep tests in the fuel mixture (No. 30) NaF-ZrF₄-UF₄ (50-46-4 mole %). The results are shown in Figs. 3.5.16 and 3.5.17. Very little surface void formation is seen in the case of the specimen tested in the nonuranium-bearing mixture, in comparison with the attack by the fuel mixture. These results are further evidence that much of the attack by the fuel mixture on Inconel at 1500°F may be attributed to the reaction

CREEP TESTS OF WELDED INCONEL

J. R. Weir, Jr.

Several 0.060-in.-thick sheet-type creep specimens were machined from welded $\frac{1}{8}$ -in. Inconel sheet stock and a few creep tests were run in the

RARE-EARTH-OXIDE COMPACTS FOR ART CONTROL RODS

J. A. Griffin L. M. Doney

The design of the ART control rods calls for a porous compact of rare-earth oxides. The pores of the compact are to be filled with metallic sodium, and the compacts are to be canned in Inconel. The following process was developed for the fabrication of the compacts. The as-received rare-earth-oxide material (Code 920 from Lindsay Chemical Co.) was pressed at 4000 psi into compacts, which were calcined at 1325°C for 1 hr. The calcination step was carried out to reduce the shrinkage of the oxide during the final sintering. These compacts

were crushed to pass an 80-mesh screen. The final mixture was compounded from 75% of the 80-mesh calcined material and 25% of the as-received Lindsay Code 920 oxide. This combination was thoroughly mixed and pressed, with no binder, at a pressure of 4000 psi. These compacts were then sintered at 1425°C for 55 min in air. Samples of the sintered compacts are shown in Fig. 3.6.1.

The compacts were oversize in all dimensions so that they could be ground accurately to size and so that no difficulty would be encountered during canning. The grinding was carried out by a commercial ceramic firm. The inside and outside

Fig. 3.6.1. Sintered Rare-Earth Compacts Before Being Ground to Desired Dimensions.

of each compact was ground to the required dimension, and the ends, as well as being ground to the required length, were made flat and parallel. The ground pieces are shown in Fig. 3.6.2.

The Lindsay Chemical Co. supplied the following analysis of the Code 920 rare-earth oxides used in the fabrication of the compacts:

Samarium oxide	45.0-49.5%
Gadolinium oxide	22.5-27%
Neodymium oxide	0.9-4.5%
Praseodymium oxide	0.9-3.6%
Cerium oxide	0-0.9%

Europium oxide	0.9-1.2%
Other rare-earth oxides	8.1-14.8%
Total rare-earth oxides	90% (minimum)

PETROGRAPHIC EXAMINATIONS OF FLUORIDE FUELS

G. D. White T. N. McVay, Consultant

Examinations of fluoride fuel samples with the petrographic microscope were performed at a rate of about 200 samples per month. The materials examined included quenched samples for equilibrium-diagram determinations, control samples from experimental runs, and samples from production batches. The results of these examinations are reported in Part 2, "Chemistry."

Fig. 3.6.2. Rare-Earth Compacts Shown in Fig. 3.6.1 After Being Ground to Required Size.

3.7. NONDESTRUCTIVE TESTING STUDIES

R. B. Oliver

EDDY-CURRENT TESTING OF
SMALL-DIAMETER TUBING

J. W. Allen

Continued study of the application of the cyclograph¹ to the problem of the inspection of small-diameter tubing has revealed that, in addition to its use as a flaw detector, the cyclograph may also be used to gage adherence to dimensional tolerances. Although changes in diameter and in wall thickness are inseparable in the readout of the instrument, the tolerance limits for both dimensions may be established by utilizing two standards: (1) the minimum acceptable diameter and wall thickness and (2) the maximum allowable diameter and wall thickness. Dimensional checks made by using this method, augmented with mechanical measurements, have been used successfully to determine the dimensional acceptability of approximately 6000 ft of $\frac{3}{16}$ -in.-OD, 0.025-in.-

wall and 0.229-in.-OD, 0.025-in.-wall CX-900 Inconel tubing.

The 200-kc cyclograph trace of a 0.229-in.-OD, 0.025-in.-wall Inconel tube that has small wall-thickness variations along its length and no perceptible diameter variations is shown in Fig. 3.7.1. The wall thickness was plotted from Vidigage (ultrasonic-resonance-type thickness gage) and mechanical measurements. It may be seen that, although there is not perfect agreement, there is a fairly close correspondence between the two types of checks. The disagreement is probably due to minute amounts of eccentricity and intergranular attack on the inside surface of the tube having been detected by the cyclograph.

The confidence level of the interpretations of indications from this instrument is increasing with continued use. Because the sensing coil observes at any one instant a section of tubing approximately $\frac{3}{8}$ in. long, it is not possible to detect pin holes, except when they occur in clusters. In general, defects can be resolved if they have a length of $\frac{1}{16}$ in. or longer and have

¹R. B. Oliver, J. W. Allen, and K. Reber, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 164.

Fig. 3.7.1. Cyclograph Record at 200 kc from a 0.229-in.-OD, 0.025-in.-Wall CX-900 Inconel Tube Compared with Dimensional-Variation Measurements Made Mechanically and with the Vidigage.

depths greater than the background dimensional variations in the tube.

ULTRASONIC INSPECTION OF TUBING

R. W. McClung

Approximately 6000 ft of CX-900 Inconel tubing has been inspected by the immersed ultrasound method. Two sizes of tubing $\frac{3}{16}$ in. OD, 0.025 in. wall and 0.229 in. OD, 0.025 in. wall, were inspected and the average rejection by this test was about 2%. Each tube received a double inspection, with the ultrasound being beamed around the tube in two different directions to improve the chance of detection of unfavorably oriented crack-like defects. This double inspection of the precut tubing reduced the inspection rate to below the original estimate. The current inspection rate is approximately 500 ft in an 8-hr day for lengths up to 10 ft.

Defects 0.0015 in. deep and $\frac{1}{16}$ in. long on polished, scratch-free tubing can be detected with

an estimated confidence of 80 to 90%. If scratches are present they will produce signals comparable to those from the very small defects and effectively increase the minimum detectable defect size. If the defect is appreciably deeper than the scratches and if its length exceeds the maximum dimension of the transducer, it is not difficult to differentiate between defects and scratches. Since the ultrasonic method is insensitive to dimensions, the inherent dimensional variations that give trouble in an eddy-current inspection have no effect on ultrasonic inspection. Both the eddy-current and the ultrasonic methods are capable of detecting very small defects, with the eddy-current inspection being confused by dimensional variations and the ultrasound method being confused by scratches. A comparison of the results of the two tests aids in the identification of spurious signals.

A typical small defect found on the inside of the $\frac{3}{16}$ -in.-OD, 0.025-in.-wall CS-900 tubing is shown in Fig. 3.7.2. This crack is 0.0015 in. deep (6%) and about $\frac{1}{16}$ in. long.

Fig. 3.7.2. Small Defect Found by Ultrasonic Inspection on the Inner Surface of a $\frac{3}{16}$ -in.-OD, 0.025-in.-Wall Inconel Tube. The defect is 0.0015 in. deep and approximately $\frac{1}{16}$ in. long.

ULTRASONIC INSPECTION OF PIPE

J. K. White²

No development work on the ultrasonic method for the inspection of pipe had been planned, because the currently employed contact method was reported to be adequate. Preliminary attempts to employ this method, however, revealed several problems that detracted from the reliability of contact inspection. It was found to be very difficult to fabricate Lucite shoes that would fit the contour of the pipe and would, at the same time, limit the sound beam to the proper spectrum of incident angles. A sizable part of the sound was propagated as a surface wave and produced inordinately large signals from surface scratches. For this reason, defects and scratches could not be separated. Also, the contact method requires that a thin film of oil be maintained between the transducer and the pipe surface, and, thus, any surface roughness, vibration, ovality, or an inadequate supply of oil resulted in a loss of signal and frequent failure to detect defects on the inner surface. Immersed ultrasound permitted a solution to these difficulties, and the use of the "B" scan for data presentation permitted a high inspection speed with rapid interpretation of the signals produced in the tube wall.

A scanning tank of maximum simplicity was designed and fabricated for the ultrasonic inspection of pipe. The tank is 26 ft long, 14 in. wide, and 20 in. deep and is equipped with a variable-speed headstock and chuck and an assembly of

two 3-in.-dia casters, in lieu of a tail stock. This assembly contains and rotates the pipe around its own axis. The transducer mounting is aligned with reference to the pipe axis by a pair of Micarta guides, and it is manually translated along the pipe. Very straight pipe can be rotated at speeds of 200 rpm, but much of the pipe is too crooked for this speed. Even in the worst case, however, rotational speeds of 60 to 100 rpm are attainable. This equipment is being used for the inspection of large quantities of pipe in sizes from $\frac{3}{8}$ to 6 in. IPS for the ETU and the ART.

Satisfactory inspection of tubular shapes is dependent upon obtaining reference notches of the proper depth (3 to 5% of the wall thickness) on both the inner and outer surfaces. A known, reproducible notch is easily produced on the outer surface of both pipe and tubing; however, it is difficult to produce such notches on the inner surface of even large pipe. No really satisfactory notch has yet been produced on the inner surface of small-diameter tubing, and the inside reference notch is necessary to prove that the alignment will reveal defects on the inner surface. Therefore this method is not being used for the inspection of small-diameter tubing.

Four of the eight nozzle welds on the cell being fabricated to house the ART in Building 7503 were inspected by the ultrasound method. The observed indications of cracking in the weld and in the heat affected zone resulted in the removal of all the welds. The cracks revealed were confirmed by arc gauging and by Magnaflux tests with sufficient frequency to justify the rejection of the welds on the basis of the ultrasound indications.

ART FUEL-TO-NAK HEAT EXCHANGER

S. I. Cohen J. L. Wantland

The ART fuel-to-NaK heat exchanger test system¹ was modified for further studies of heat transfer and friction characteristics. Six 60-deg staggered spacers and six 60-deg inclined spacers were placed alternately on the tube bundle, and transverse pressure taps were installed across one spacer of each type. The average transverse pressure drop across each instrumented spacer was plotted in terms of the ratio of the transverse pressure drop to the velocity head times the fluid density over the Reynolds modulus range of 3000 to 8000. For the inclined spacer this term varied from 1.4 to 1.1, and for the staggered spacer the data fell randomly between 0.01 and 0.03, with no definite trend established. The analytical investigation, referred to previously,² on a method of correlating fluid-friction data for flow parallel to a square array of cylindrical tubes in rectangular cross-section flow channels was completed.³

An experimental study is being made of the fuel-side fluid-friction characteristics of a mockup of the present design of the ART fuel-to-NaK heat exchanger. The dimensions of this apparatus and the spacer configuration will simulate the ART heat exchanger as nearly as possible, except that there will be no headers and the tube bundle will not have the curvature specified for the ART; that is, the friction characteristics for a straight length of tube bundle will be determined.

An experimental heat exchanger has been designed and is now being fabricated that will be similar to the one on which tests were conducted previously,⁴ with the exception that the tubes will be spaced on a triangular array rather than a square array. This investigation will provide

Sodium Flow in Reflector Cooling System

A 5/22-scale model of the reflector-core shell cooling annulus and inlet system was designed and fabricated (Fig. 4.1.1) in order to determine quantitatively the flow distribution in the annulus and the various pressure drops in the sodium system. The fluid used in the model was water at temperatures between 20 and 50°C. Although the model does not incorporate the reflector cooling holes, 12 nozzles were spaced radially around the inlet header to take off fluid at various sectors of the inlet header to mock up flow through the cooling holes.

The flow distribution was studied by three methods: (1) the static pressure measured axially across the annulus in conjunction with the total annulus flow rate measured by a rotameter gave the average velocities through the annulus for the two positions nearest the inlets and the two positions furthest away, (2) pitot-static combination measurements were obtained at positions 1-3 and 3-3 (Fig. 4.1.1), and (3) high-speed motion pictures were made of periodic ink injections.

A quantitative measurement of the flow distribution was defined as

$$\frac{Q_f}{Q_n} = \frac{\bar{V}_2 + \bar{V}_4}{\bar{V}_1 + \bar{V}_3}$$

where

Q_f = volumetric flow rate in annulus furthest from inlet,

Q_n = volumetric flow rate in annulus nearest to inlet,

\bar{V} = average linear velocity at station indicated by subscript number.

⁵On assignment from Pratt & Whitney Aircraft.

Fig. 4.1.1. Vertical Section Through Reflector-Core Shell Annulus Model.

037220.030

This relationship gives the ratio of the averages of the velocities at the two stations farthest from the inlets to the averages of the velocities at the two stations nearest the inlets. The relationship for the flow distribution when only one pump was operating was defined as

$$\frac{Q_f}{Q_m} = \frac{\frac{\bar{V}_3}{\bar{V}_1} \left[\begin{array}{l} \text{pump A} \\ \text{operating} \end{array} \right] + \frac{\bar{V}_1}{\bar{V}_3} \left[\begin{array}{l} \text{pump B} \\ \text{operating} \end{array} \right]}{2}$$

Some of the experimental results are presented in Fig. 4.1.2 in terms of these relationships. The predicted flow distribution in the ART system

was obtained by extrapolating the data to the Reynolds numbers for the actual system at the mid-plane of the annulus. A summary of the results is given in Table 4.1.1.

The minimum flow rate was found in the portions of the annulus nearest the inlets, while the maximum flow rate was observed in the portions farthest away. These conditions are the reverse of those anticipated, and a possible explanation is that the fluid entering the annulus from the inlet header must abruptly change direction and it probably undergoes high velocity losses, particularly near the inlet to the annulus where the momentum is the greatest. After the model inlet header used in these experiments had been fabricated, the design of the actual ART sodium system was modified so that uniform distribution of sodium flow would exist in the annulus if there were no eccentricities. The flow in such a concentric annulus will be axial; that is, there will be no spiraling. Studies of the motion pictures of the flow in the model indicated that, for a constant pump pressure, the average velocity fluctuation at any point in the annulus would probably be less than $\pm 5\%$.

The flow distributions in the annulus for two possible conditions of eccentricity of the core shell were also studied. Buckling of the core shell between the spacers was simulated to produce a local eccentricity. Since the reduction in flow as a function of the reduction in flow area was the prime concern, the buckling of the core shell was simulated by adding pieces of tape, as shown in Fig. 4.1.3. For a local reduction in annulus thickness of 50% ($r_p/r_o = 0.5$), the flow from inlet to outlet through that sector of the annulus was 73% of the average flow.

Radial eccentricity was also simulated to study the effect of a slight canting of the core shell on

Fig. 4.1.2. Flow Distribution in Concentric Reflector-Core Shell Annulus.

TABLE 4.1.1. SUMMARY OF CONCENTRIC ANNULUS FLOW DISTRIBUTION STUDIES

Annulus width, in.	0.135		0.1875	
Reynolds modulus at mid-plane	0.72×10^5		1.01×10^5	
Ratio of annulus flow to cooling hole flow for two conditions	0.386	1.00	0.609	1.00
Q_f/Q_m				
For two pumps operating	1.045	1.025	1.025	1.02
For one pump operating (70% normal flow assumed)	1.08	1.06	1.075	1.07

Fig. 4.1.3. Effect of Local Eccentricity on Flow Distribution.

the flow distribution in the annulus. Radial displacement of the shell was found to cause a slight spiraling of the flow through the annulus. The configuration studied and the experimental data obtained are shown in Fig. 4.1.4. The data are in good agreement with a simple, derived expression based on parallel and equal system flow resistances. For a mean radial eccentricity (r_1/r_2) of 0.8 the maximum deviation of the ratio Q_1/Q_3 is about 0.8. The static pressures as a function of position in the annulus and in the inlet header were also obtained for the concentric and eccentric cases and are being analyzed.

Fuel Flow in Core

Further studies of the flow through the 21-in. ART core model with the Pratt & Whitney vortex generators installed in the entrance region were delayed pending the construction of a second test stand for the core-model experiments. Studies of other core configurations that may give stable flow were, however, initiated. In the preliminary study the following three configurations are being considered: a core with an area expansion rate obtained from Nikuradse's gamma function, a

Fig. 4.1.4. Effect of Radial Eccentricity on Flow Distribution.

cylindrical annular core with a large area expansion at the entrance and screens of perforated plates placed in the region of expansion to obtain good flow characteristics, and the present 21-in. core with screens or perforated plates in the expansion region.

ART CORE HEAT TRANSFER EXPERIMENT

- | | |
|--------------|------------------|
| N. D. Greene | F. E. Lynch |
| G. W. Creene | G. L. Muller |
| L. D. Palmer | H. F. Poppendiek |

The instrumentation and operating characteristics of the ART volume-heat-source experiment, described previously,⁶ were checked, and the galvanometer used with the transient thermocouples was calibrated. Fifteen complete power runs were made for the swirl entrance system.

⁶N. D. Greene et al., ANP Quar. Prog. Rep. Dec. 10, 1955, ORNL-2012, p 174.

The parameters of the experiment were the following:

Helical Reynolds modulus	66,000 to 256,000
Prandtl number	4 to 5
Axial temperature rise	5 to 10°F
Total power generated	0.08 to 0.12 Mw

The heat balances obtained for the system were within $\pm 5\%$ of being perfect. Two power runs were also made with the swirl entrance system for the simulated case of "one pump off."

A photograph of the one-half-scale model used for these experiments is presented in Fig. 4.1.5; it is made almost entirely of Micarta and platinum. The mixing chamber, pump-scroll head, core, power leads, and thermocouple leads for the outer core shell can be identified in the photograph. The panel board containing recording and power control equipment for the experiments is shown in Fig. 4.1.6, and a view of the fuel annulus after the pump-scroll head was removed at the end of the experiments is shown in Fig. 4.1.7. The platinum-platinum rhodium thermocouples, as well as the platinum electrodes, which are visible in Fig. 4.1.7, were in good condition at the end of the experimental study.

A two-dimensional plot of the electric potential field for the 24-electrode power circuit is presented in Fig. 4.1.8. Except for the very ends of the system where some flux distortion exists, the axial voltage gradient was within about 5.5% of being uniform; consequently, the power density was within about 11% of being uniform. In the actual ART system in which the heat sources will be generated by fission, the volume heat sources will not be uniform; in fact, near the wall they will be from 2 to 3 times as great as they will be near the center of the channel. The mean, uncooled wall and fluid temperature profiles obtained in these experiments with a uniform volume heat source are presented in Fig. 4.1.9 in normalized form. The asymmetries in the outer core shell and island core shell wall temperatures can be explained on the basis of hydrodynamic flow asymmetries. For example, the high island core shell wall temperature in the northern hemisphere exists because a separation region completely encompasses the island shell in that region. The solution for an idealized ART (parallel-plates system)⁷ is also plotted on Fig. 4.1.9; this predicted uncooled wall temperature profile lies

Fig. 4.1.5. One-Half-Scale Model of ART Core for Volume-Heat-Source Experiments.

between the island and outer core shell wall temperature measurements.

ANP PROJECT PROGRESS REPORT

Experimental transient wall and fluid temperature data are shown in Fig. 4.1.10 in terms of the total temperature fluctuation divided by the axial temperature rise of the fluid going through the core. The frequencies of the temperature fluctuations for this one-half-scale volume-heat-source system vary from about $\frac{1}{2}$ to 4 cps. The frequency range of temperature fluctuations in the full-scale ART system operating with fluoride fuel should be similar to that in the one-half-scale volume-heat-

source system in which an acid was circulated. The frequencies of the temperature fluctuations were found to be in agreement with the frequencies of the velocity fluctuations observed in the full-scale core model used for flow studies.

The results of a study of the temperature structure in an idealized ART core were presented in the previous report.⁸ The increase in the

Fig. 4.1.10. Transient Surface and Fluid Temperatures Obtained for ART Core Model with a Uniform Volume Heat Source.

uncooled wall temperature that would arise if a hyperbolic cosine power density distribution existed rather than a uniform one was determined. The uncooled wall temperature increment, above the fluid temperatures, for this nonuniform power density case was found to be more than twice as great as the corresponding increment for a uniform power density case. The experimental measurements obtained for the uniform power density case have been modified by this factor and are plotted in Fig. 4.1.11, along with the mathematical prediction for an idealized ART core with a hyperbolic cosine power distribution. As may be seen, temperatures as high as 1800°F might occur if the walls are not cooled properly for this very high Reynolds number case.

Elastic thermal stress calculations were also made for the core shell and heat exchanger tubes on the basis of the experimental temperature fluctuations that were observed in this experiment

for the uniform-power-density case. For the uniform-power-density system the results indicated that cyclic stresses exist that are similar in magnitude to the endurance limit or fatigue stress of Inconel. It is believed that the stresses in the actual ART system may be higher than those calculated for the uniform-power-density case.

A third set of volume-heat-source experiments is under way. For these experiments entrance vanes that will reduce the rotational velocity component are located in the core throat.

THERMAL-CYCLING EXPERIMENT

H. W. Hoffman D. P. Gregory³

The volume-heat-source experiments with the one-half-scale model of the ART core have verified that the hydrodynamic instabilities that exist in some regions of the ART core, as presently designed, would result in rapid, high-temperature-differential cycling of the Inconel core-shell surfaces. These studies have also indicated that the tube bends at the fuel inlet end of the fuel-to-NaK heat exchanger will be subjected to this temperature cycling. The volume-heat-source experiments indicate that the temperature fluctuation at the Inconel surface may be of the order of ±60°F. The thermal diffusivity of Inconel is poor, and therefore these large temperature fluctuations will occur, chiefly, in a region close to the metal-fuel interface. For example, the amplitude of a temperature fluctuation with a 1/2-sec period will be reduced to 40% of its original value at a position 35 mils below the metal surface. A possible result of this cyclic thermal expansion within the metal will be cracking of the surface because of metal fatigue. The possibilities of accelerated creep and corrosion under these circumstances also arise.

The effect of thermal cycling on material strength must be determined experimentally, and a system for accomplishing this study at reactor temperatures with a fuel environment is currently being constructed and tested. The apparatus is shown schematically in Fig. 4.1.12. The fuel mixture NaF-ZrF₄-UF₄ (50-46-4 mole %) will flow through the heater under gas pressure and will be subjected to cyclic heating. The surface of the unheated test section will experience the resulting periodic

Fig. 4.1.11. Temperature Profiles of the Mean, Uncooled Outer Core Shell, Island Core Shell Wall, and Fluid of the One-Half-Scale ART Core Model Adjusted for the Nonuniform Volume Heat Source.

³On assignment from Pratt & Whitney Aircraft.

Fig. 4.1.12. System for Thermal Cycling of Inconel Tubing in a Fuel Environment.

temperature fluctuations as the fluid moves downstream. Effects of the thermal cycling will be determined by metallographic examination of the Inconel surface subsequent to the test.

The heater and the test section are fabricated from a single 10-in. length of Inconel tubing ($\frac{1}{4}$ -in. OD, 0.035-in. wall). The heater comprises the first 4 in. of this tube and will be supplied with a pulsed current through a device designed to provide a range of pulse frequencies. In order that the stresses imposed on the test section will result only from the thermal cycling of the tube surface, the heater electrodes are floated in pools of molten tin to eliminate tube bending, and

a bellows is provided at the outlet end of the test section to take up the over-all thermal expansion.

Preliminary tests with NaNO_2 - NaNO_3 - KNO_3 (40-7-53 wt %) as the heated fluid were terminated when oxidation at the electrodes resulted in loss of power. This situation is now being corrected. The results of these first experiments for a $1\frac{1}{4}$ -sec power-on - $1\frac{1}{4}$ -sec power-off cycle are given in Fig. 4.1.13. The amplitude of the temperature fluctuation at two points in the test section is shown as a function of the heater power. The "tailing-off" of the data at high heater powers is caused by the slow response of the measuring equipment. The cycle period will be varied in future experiments.

SHIELD MOCKUP REACTOR STUDY

L. C. Palmer

A general study of the heat transfer and fluid flow characteristics of the proposed Shield Mockup Reactor (see Chap. 5.5, "Shield Mockup Reactor Design and Construction") has been initiated. An analysis of the temperature structure within the fuel elements and the coolant and a study of the pressure distribution within the core were com-

pleted. The studies are being extended to other regions of the reactor.

TEMPERATURE STRUCTURE IN THE REGION BEYOND THE ART REFLECTOR

H. W. Hoffman

The previous calculations¹⁰ on the temperature structure in the region beyond the reflector in the ART were extended to include a recent system modification. The new system, illustrated in Fig. 4.1.14 and designated System C, differs from those previously studied (Systems A and B)¹⁰ in that a portion of the boron carbide has been replaced by a stainless-steel-clad copper-boron carbide matrix. This layer, located between the reflector and the remaining B₄C, will absorb the leakage neutrons from the core and thus prevent radiation damage of the more brittle boron carbide. A detailed description of the idealized system used in this study has been presented in a separate report.¹¹ Based on these idealizations the system can be analyzed by an iterative procedure to obtain both the temperature rise of the sodium and the temperature profile for the region between the sodium and fuel return streams. The heat deposition rates used in this analysis were tentative upper limits.¹²

UNCLASSIFIED

ANP PROJECT PROGRESS REPORT

The recent system modification resulted in a temperature rise of 33°F for the sodium coolant stream and a maximum boron carbide temperature of 1526°F for a sodium inlet temperature of 1200°F. These values may be compared with the previous results for a system without the copper-boron carbide matrix in which the sodium temperature rise was 24°F and the boron carbide attained a maximum temperature of 1586°F. The sodium temperature rise was found to vary 10% (decreasing from 36 to 33°F) when the sodium inlet temperature was changed from 1150 to 1200°F. Typical temperature profiles at the inlet and outlet ends of the system for a sodium inlet temperature of 1175°F are presented in Fig. 4.1.15, and the temperature profiles for the system without the Cu-B₄C (System B) are also shown for comparison.

¹³C. J. Barton, *Fused Salt Compositions*, ORNL CF-55-9-78 (Sept. 16, 1955).

The system modification increased the temperature drop across the inner Inconel shell by 30 to 35°F. The temperature gradient in the outer Inconel shell was essentially unchanged.

HEAT CAPACITY

W. D. Powers

The enthalpies and heat capacities of two mixtures were determined in the liquid and solid states. For one mixture, NaF-LiF-ZrF₄ (22-55-23 mole %), two distinct discontinuities in the temperature-enthalpy relationship were found; one was at 370 to 380°C and the other was at 565 to 585°C. The reported¹³ liquidus temperature is 570°C. The lower discontinuity is assumed to be a phase transition from the alpha form to the beta form, the beta form being stable below 375°C. The discontinuity at the higher temperature is the fusion of the alpha form to the liquid at 570°C. Enthalpy and heat capacity measurements of a second salt mixture, LiF-NaF (60-40 mole %), showed no unusual characteristics. The enthalpy and heat capacity equations for these two salts follow:

NaF-LiF-ZrF₄ (22-55-23 mole %)

Beta form (106 to 368°C)

$$H_T - H_{360^\circ\text{C}} = -8.7 + 0.2392T + (7.20 \times 10^{-5})T^2$$

$$c_p = 0.2392 + (14.39 \times 10^{-5})T$$

Alpha form (407 to 556°C)

$$H_T - H_{360^\circ\text{C}} = 64.2 - 0.009165T + (41.82 \times 10^{-5})T^2$$

$$c_p = -0.009165 + (83.64 \times 10^{-5})T$$

Liquid (603 to 897°C)

$$H_T - H_{360^\circ\text{C}} = -20.2 + 0.4526T - (5.95 \times 10^{-5})T^2$$

$$c_p = 0.4526 - (11.89 \times 10^{-5})T$$

At 375°C

$$H_\alpha - H_\beta = 28$$

At 570°C

$$H_{114} - H_\alpha = 24$$

LiF-NaF (60-40 mole %)

Solid (112 to 572°C)

$$H_T - H_{360^\circ\text{C}} = -9.8 + 0.3191T + (9.94 \times 10^{-5})T^2$$

$$c_p = 0.3191 - (19.87 \times 10^{-5})T$$

Liquid (688 to 898°C)

$$H_T - H_{30^\circ\text{C}} = -88.2 + 0.9249T - (24.62 \times 10^{-5})T^2$$

$$c_p = 0.9249 - (49.23 \times 10^{-5})T$$

At 652°C

$$H_{\text{liq}} - H_{\text{sat}} = 170$$

In these expressions

H = enthalpy in cal/g,
 c = heat capacity in cal/g·°C,
 T = temperature in °C.

VISCOSITY AND DENSITY

S. I. Cohen

A study was made of the effect of fission products on the viscosity of a fused fluoride reactor fuel. The increase in viscosity as a result of the presence of dissolved fission-product additives was found to be less than 5%. The formula for the fission-product additives was, however, based on a much higher burnup rate than would actually be encountered in the ART. The formula called for an amount of LaF_3 (the component used to represent all the rare-earth fluorides formed by fission) that exceeded the solubility limit in the fuel at temperatures below 800°C. It is felt that the only serious possible problem that might arise would be the precipitation of solids. This problem is being investigated in solubility studies on fission products in the reactor fuel (see Chap. 2.3, "Chemical Reactions in Molten Salts").

Interest in the fuel mixture NaF-KF-LiF-UF₄ (11.2-41-45.3-2.5 mole %) prompted a redetermination of its viscosity, since the previous measurements¹⁴ were made on a relatively impure sample and over a narrow temperature range. The viscosity of a highly pure sample prepared for these measurements varied from 8.1 centipoises at about 525°C to 2.7 centipoises at about 725°C and may be represented by the equation

$$\mu = 0.0292 e^{4507/T},$$

where T is in °K. These values are in satisfactory agreement with the previous data; the new measurements are about 10% lower than the previous ones.

¹⁴S. I. Cohen, *ANP Quar. Prog. Rep.* Sept. 10, 1955, ORNL-1947, p 156.

Measurements were also made¹⁵ on NaF-LiF-KF-UF₄ (10.9-44.5-43.5-1.1 mole %). The viscosity varied from 8.8 centipoises at about 500°C to 1.8 centipoises at about 800°C and may be represented throughout this range by the equation

$$\mu = 0.0348 e^{4265/T},$$

where T is in °K.

A modest program has been initiated to measure the physical properties of some fused chloride mixtures. Two instruments have been designed to study the viscosities of these materials. One is a special Brookfield viscometer, which has a spindle assembly that contains two large shear surfaces. This increased shear is necessary because of the low viscosity range in which this class of materials falls. The other instrument is an adaptation of the capillary viscometer currently being used for fluorides. The principal modification is the use of commercial hypodermic needles for the capillary tubes. This affords a number of advantages, such as ease of replacement and interchangeability of needle sizes to cope with different viscosity ranges.

A density measurement was made on one chloride mixture, LiCl-KCl-NaCl (56-41-3 mole %), by using the buoyancy principle with a balance and a plummet. The density varied from 1.675 g/cm³ at 425°C to 1.50 g/cm³ at 770°C and may be expressed as

$$\rho = 1.885 - 0.00050T,$$

where T is in °C. These values are in excellent agreement with values obtained on very similar mixtures by Van Artsdalen and Yaffe.¹⁶

THERMAL CONDUCTIVITY

W. D. Powers

Two new devices have been built that are being used to determine the conductivities of liquids. In both systems a measured amount of heat flows down through a horizontal sample of known thickness and area. The thickness of the sample may be varied so that contact resistances at the surfaces of the sample can be eliminated.

One device has been fabricated in which the sample is contained within glass. This makes it possible to observe whether any gas bubbles or films are present in the cell at the time measurements are being made. Good agreement with the known thermal-conductivity data for water was obtained. Initial experiments with heat-transfer salts have shown the formation of gas bubbles on the surfaces. The effect of this gas on the thermal conductivity is currently being studied.

One of the difficulties associated with the measurement of thermal conductivity is in knowing

exactly where the heat is flowing. The second device has two heat meters, one directly above and the other directly below the sample. It was assumed that if the heat flow were the same in both meters, the heat flow through the sample would be well established. The original design did not meet this specification and therefore a modification of the system is now being made.

ELECTRICAL CONDUCTIVITY

N. D. Greene

An electrical conductivity cell has been standardized at high temperatures with molten potassium chloride, and the cell constant so obtained agreed within experimental error with those determined by means of standard, aqueous solutions. Further cell standardization with molten NaCl and ZnCl₂, as well as refinements of existing measuring techniques, will precede measurements of the conductivities of fluoride melts.

4.2. RADIATION DAMAGE

EXAMINATION OF THE DISASSEMBLED MTR
IN-PILE LOOP NO. 3

A. E. Richt

C. Ellis W. B. Parsley
E. J. Manthos R. N. Ramsey

E. D. Sims

Metallographic examination of MTR in-pile loop No. 3 has been completed except for the straight sections of the fuel line. Disassembly of the fuel-circulating pump was found to be more difficult than had been anticipated. The first operation was the removal of the water jacket from the pump bulkhead. The pump was then sectioned by sawing through the bulkhead. During this cutting operation the oil finger below the forward bellows was exposed, and no evidence of oil was seen in the finger. The pump shaft rotated freely and showed no signs of binding after it was freed from the impeller. The pump shaft, forward bellows, bearings, and seals were removed from the bearing housing. The forward bellows was partially filled with oil. The bellows, bearings, and seals were cleaned ultrasonically in perchloroethylene to remove any traces of oil. The face and inside of the forward bellows contained a brittle, amber-colored, amorphous deposit, as shown in Figs.

4.2.1 and 4.2.2. The rear bearings, Fig. 4.2.3, appeared to be in excellent condition.

The neck of the pump, between the pump sump and the heat exchanger, was partially filled with oil; however, no evidences of fuel or ZrF_4 -vapor deposits were found in this region. The slinger assembly was removed and examined, and the slingers were found to be coated with a black, shiny deposit, Fig. 4.2.4. No evidences of fuel or ZrF_4 -vapor deposits were found on the slingers.

Fig. 4.2.1. Front Face of Forward Bellows of Fuel Pump from MTR In-Pile Loop No. 3. 1/2X. (Secret with caption)

Fig. 4.2.2. Enlargement of Deposit Shown in Fig. 4.2.1. 2X. Reduced 25.5%.

Fig. 4.2.3. Rear Bearing from MTR In-Pile Loop No. 3 Fuel Pump. 2X. Reduced 14%. (Secret with caption)

Fig. 4.2.4. Slingers from MTR In-Pile Loop No. 3 Fuel Pump. Note shiny, black deposit. 2X. Reduced 24.5%. (Secret with caption)

The fuel in the pump appeared to be inhomogeneous in that it was made up of two phases. One phase was green and had the normal appearance of the fuel mixture used, and the other phase was black. Samples of both phases were obtained for chemical analyses. The two halves of the pump sump, with the fuel still present, are shown in Fig. 4.2.5. The impeller showed no evidence of erosion, Figs. 4.2.6 and 4.2.7.

Charcoal samples were obtained from two of the fission-gas adsorption traps in the purge system. A black deposit that was found around the inlet

hole to one of the traps is shown in Figs. 4.2.8 and 4.2.9. The walls of the trap on the inlet side also showed a black deposit around the sides for a depth of approximately 1 in., as shown in Fig. 4.2.10.

MTR in-pile loop No. 4 has been sectioned at NRTS, and the active portion is being shipped to Oak Ridge. Disassembly of the loop will begin as soon as the hot cell equipment has been repaired and checked out. Priorities have been established for the examination of sections that were removed from the ARE, and these exami-

nations will proceed as rapidly as cell time allows.

INVESTIGATIONS OF MATERIALS REMOVED FROM MTR IN PILE LOOPS NOS. 3 AND 4

W. E. Browning

C. C. Bolta¹

R. P. Shields

Operation of MTR in-pile loop No. 3, described previously,² was terminated because a plug formed somewhere in the purge system. Therefore a postoperational inspection of the fission-gas adsorption traps was undertaken. A gas sample was obtained by purging the traps for 2 hr with helium and collecting the effluent fission gas in two refrigerated charcoal traps. A radioassay of the gas is to be made. The purged traps were sectioned, and samples of the charcoal adsorber and tubing were collected for radioassay. An extensive black deposit was observed around the inlet to one trap, and a thin brownish film was present around the inlet to the second trap. These deposits were photographed (Figs. 4.2.8, 4.2.9, and 4.2.10) and then collected for analysis. The results of the analyses of the samples are not yet available, but it is suspected that oil or decomposition products of oil entered the traps from the fuel-pump bearing housing and sump and caused

a plug when they came in contact with the refrigerated trap inlet.

A study of an apparent chemical change brought about in the fuel during operation of MTR in-pile loop No. 3 is also being conducted. Determinations are being made of the nickel, chromium, and iron content of the fuel, and radiochemical analyses of the fuel are nearly complete. The analysis of the foreign materials taken from the pump is partially completed.

The fission-gas adsorption traps from MTR in-pile loop No. 4 have been received, and analyses of copper tubing sections and of acetone washes of the carbon adsorber are under way.

A. S. Olson
J. C. Zukas

A heat transfer test of the stress-corrosion apparatus designed³ for operation in HB-3 of the LITR was made in the LITR to check the heating to be expected from the fuel. It was not possible to reach the desired temperature of 1500°F with the 2.5 g of the fuel mixture (No. 41) NaF-ZrF₄-UF₆ (63-25-12 mole %) used in this test. A bench mockup which reached the same temperature as that attained in the reactor indicated that only about 70 w of heat was generated by fission. About 200 w of heating was expected from this fuel at the depressed flux measured in HB-3 of the LITR. For the next test a fused salt with more uranium will be used, or the number of conductive fins will be reduced.

Three more tube-burst stress-corrosion specimens were exposed to radiation in the LITR, and two more bench tests were completed. The irradiated specimens failed after 164, 260, and 285 hr at 1500°F with a maximum stress of 2000 psi, whereas one specimen bench-tested under similar test conditions had not failed in about 935 hr. The other bench test was made at 1450°F, 50 deg lower, and the specimen ruptured after only 500 hr under stress.

Tubing stock of the type to be used in ART NaK-to-air radiators is expected to be available soon for use in tube-burst and stress-corrosion

experiments. Components for the MTR tube-burst test apparatus are being fabricated.

One of the specimens tested previously in the MTR tensile-creep-test apparatus⁴ ruptured outside the gage length, and therefore the postirradiation elongation measurement was made on this specimen. The elongation was 1.7% after 760 hr at 1500°F in helium; this value is higher than was expected. The corresponding bench tests have still not been completed, because experimental difficulties (mainly leaks in the bellows) required that the apparatus be rebuilt.

A pneumatic stressing device for bench and in-pile tensile-creep tests was built and is being leak tested. Two pneumatic extensometers for use with this device have been tested. The pneumatic device will provide a powerful, compact means for stressing creep specimens with loads as great as 10,000 lb.

Parts for a stress-relaxation machine are being built. A pneumatic valve operator has been adapted for stressing the specimen, and a pneumatic strain-controlling system is being developed.

MTR STRESS-CORROSION APPARATUS

J. C. Wilson

C. D. Baumann W. E. Brundage

The stress-corrosion equipment formerly designated as the alternate stress-corrosion apparatus was modified to change the platinum heater to a simpler, helically wound heater made from molybdenum wire. The design, described previously,⁵ is completed, and fabrication and assembly have been partially completed on a model with which heat transfer tests will be made in the LITR.

DUCTILITY OF NICKEL-BASE ALLOYS

J. C. Wilson

T. C. Price⁶

An investigation is being made of the factors that govern the ductility of nickel-base alloys. As a part of this study, tensile tests were run on Inconel and Nichrome V at strain rates of 0.002 and 0.2 in./min at temperatures ranging from 500 to 1400°F. At no temperature was any abrupt

AMP PROJECT PROGRESS REPORT

decrease in ductility observed in either alloy. The ductility of Inconel remained constant between 800 and 1100°F at the slower strain rate and between 800 and 1200°F at the faster strain rate. At higher temperatures the ductility steadily increased. The ductility of Nichrome V decreased steadily as the temperature was increased from 800 to 1400°F.

Both alloys showed stress fluctuations at both strain rates, the fluctuations being more noticeable at the slower strain rate, but this may have been the result of the inadequacy of the recording system at high speeds. In the tests on Inconel the stress fluctuations were present at temperatures from 500 to 1200°F and were largest in number and amplitude between 600 and 950°F. The lower temperature limit of these fluctuations has not yet been determined for Nichrome V, but the upper limit seems to coincide with that of Inconel.

Specimens of Monel, Inconel, and Nichrome V have been prepared for testing in the LITR (and later in the MTR) to determine the effect of irradiation on ductility. Out-of-pile tests will be made on the Hastelloys.

EFFECT OF RADIATION ON STATIC CORROSION OF STRUCTURAL MATERIALS BY FUSED-SALT FUELS

W. E. Browning H. L. Hemphill

The study of the effect of radiation on the corrosion of Inconel capsules containing static fused-salt fuels was continued.⁷ Two additional Inconel capsules containing the fuel mixture (No. 30) $\text{NaF-ZrF}_4\text{-UF}_6$ (50-46-4 mole %) were irradiated in the MTR for six weeks each at 1500°F at a power density of approximately 3.5 kw/cm³. Two other Inconel capsules containing the fuel mixture (No. 44) $\text{NaF-ZrF}_4\text{-UF}_6$ (53.5-40-6.5 mole %) are being irradiated at 1500°F at a power density of approximately 6 kw/cm³.

Further mockup tests were run on Hastelloy B capsules under simulated MTR conditions. A method was developed for mounting thermocouples on the capsules without damaging the chromium-nickel plating required to protect the capsule from the atmosphere. Hastelloy B capsules are being prepared for bench tests and for MTR irradiation.

They will be filled with an NaF-KF-LiF-UF_6 fuel mixture containing approximately 25 wt % enriched uranium and LiF enriched in Li⁷.

LITR VERTICAL IN-PILE LOOP

W. E. Browning

D. E. Guss⁸ H. E. Robertson
M. F. Osborne R. P. Shields

A vertical in-pile loop, which was essentially the same as the one operated previously,⁹ was installed in the LITR and put into operation; however, the pump stalled when the reactor was started. By reducing the pump temperature it was possible to operate the loop with the reactor at 500 kw; but at higher power levels the temperature drop in the loop was great enough to freeze the fuel in the cold leg. The pump stalled permanently during an effort to increase the pump temperature gradually so that the reactor could be brought to full power. The specifications for the power characteristics of the loop were: total power, 11.5 kw; maximum specific power, 577 w/cm³; dilution factor, 7.64.

While the cause of the pump failure cannot be precisely determined until the loop has been examined, it is known, from the sounds emanating from the pump and heard through a microphone, and from variations in electric power demands of the motor, that contact of moving solid parts overloaded the motor.

The parts that had already been fabricated for three additional loops will be changed to eliminate most of the possible causes of pump failure. The changes will include a shorter, more rigid impeller shaft and improved bearings. Also, pump models are being tested to determine the effect of increasing the clearance around the pump impeller. When these tests are completed, existing parts will be modified and assembled for bench and in-pile tests.

Although failure of the pump prevented operation of the loop, the experiment provided a test for the reliability of other components. Thermocouples, heaters, safety circuits, the temperature control system, the tachometer, the lead wires, and the entire instrumentation system performed satisfactorily. Platinum-platinum-rhodium thermo-

⁸On assignment from United States Air Force.

couples were used on this loop to eliminate the severe oxidation that occurred in previous loop assemblies where the Chromel-Alumel thermocouple leads passed through heaters. The change in thermocouple materials necessitated a redetermination of thermocouple corrections.

Three conditions contributing to errors in temperature measurement were investigated for the platinum-platinum-rhodium thermocouples used. First, the thermoelectric output of the couples might be changed because of incompatibility with Inconel; second, the junction of the thermocouple is cooler than the Inconel surface to which it is attached because of air cooling; third, the outside surface of the Inconel is cooler than the surface in contact with fuel because of the heat flux through the wall.

A compatibility test was run in which the platinum-platinum-rhodium thermocouples were welded to Inconel and heated for 1000 hr at 900°C. The thermocouples were found to be mechanically sound after this treatment, and their absolute calibration has changed not more than 1.2°C.

Tests were also run to determine the temperature correction necessary because of air cooling of the thermocouple bead. A segment of the loop was mocked up in full scale, with electrical heating

instead of fission heating, and the thermocouples were mounted on the fuel tube in the same way that they are mounted on the loop. Surface temperatures were observed, with an optical pyrometer, through a quartz window and compared with the thermocouple readings. These tests were similar to those reported previously,¹⁰ which yielded different results for different thermocouple materials. The differences are no doubt due to bead geometry differences that result from melting-point differences during thermocouple fabrication. The results of these tests are shown for six thermocouple assemblies in Fig. 4.2.11. For the operating conditions of the LITR vertical in-pile loop the correction amounts to $15 \pm 10^\circ\text{C}$.

The correction for the differential temperature through the wall of the loop was calculated by using theoretical heat transfer relationships in the loop and experimental flux data obtained from previous loop operation in the LITR.¹¹ The heat

ANP PROJECT PROGRESS REPORT

transfer calculations of Robinson and Weekes¹² were modified to apply to the presently planned position for the loop in the LITR by using certain simplifying assumptions. The tip of the loop is to be 1.5 in. below the center line of the reactor. This is more than 4.5 in. below the position of maximum flux. The flux measured near the fuel tube in the previously operated loop¹¹ was taken as the depressed flux for that loop. It was assumed that the flux depression was the same for corresponding parts of the present loop. The difference in shape of the flux profile for the two loop positions was ignored in calculating the fuel tube wall temperature differential. Fission-product poison contributions to the macroscopic cross section of the fuel were assumed to be negligible.

¹²M. T. Robinson and D. W. Weekes, *Design Calculations for a Miniature High-Temperature In-Pile Circulating Fuel Loop*, ORNL-1808 (Sept. 19, 1955).

The transmission coefficient for neutrons in the fuel was determined from work reported by Holmes,¹³ and it was used in conjunction with the flux distribution along the loop, as shown in Fig. 4.2.12, to determine the total loop power.

Finally, to find the temperature differential through the Inconel fuel tube wall, the curves of heat transfer variations along the loop designated Mark VIII in the work of Robinson and Weekes¹² were modified for the higher total power of the loop being investigated. A plot of the calculated temperature differential through the tube wall vs the position on the loop for proposed operating conditions is presented in Fig. 4.2.13. The maximum combined temperature corrections for all three errors totaled 35°C.

FURTHER DESIGN CALCULATIONS FOR LITR VERTICAL IN-PILE LOOP

M. T. Robinson

F. P. Green J. F. Krause¹⁴

The method described previously¹² has been used to estimate cooling-air requirements and fuel-temperature profiles for a new configuration of the miniature vertical in-pile loop. The loop is physically identical to the Mark VIII loop described previously,¹² but it is to be inserted to the bottom of the core of position C-46 of the LITR instead of reaching only to the position of maximum thermal-neutron flux. The thermal-neutron flux used was that measured¹⁵ in position C-46 and extrapolated to the bottom of the lattice by re-

¹⁴On assignment from Pratt & Whitney Aircraft.

¹⁵M. T. Robinson, *Solid State Semian. Prog. Rep.* Feb. 28, 1954, ORNL-1677, p 27.

flexion of the measured flux in the plane of its maximum value. The computations were carried out on the Reactor Controls Computer according to the technique previously described,¹⁶ except that the flux function was generated electronically instead of mechanically.

Calculations were made for the fuel mixture (No. 44) NaF-ZrF₄-UF₄ (53.5-40-6.5 mole %) contained in Inconel in the new position and for the fuel mixture (No. 107) NaF-KF-LiF-UF₄ (11.2-41-45.3-2.5 mole %) contained in Hastelloy B in both positions. The physical property data used for air, for Inconel, and for the zirconium-bearing fuel mixture were the same as those used previously. The data for the alkali-metal fuel and Hastelloy B are given below:

Density of fuel, ¹⁷ g/cm ³	2.09
Specific heat of fuel, ¹⁸ w·sec/g·°C	2.28
Viscosity of fuel, ¹⁹ g/cm·sec	0.022
Thermal conductivity of fuel, ²⁰ w/cm·°C	0.035
Thermal conductivity of Hastelloy B, ²¹ w/cm·°C	0.113

As before, the depression of the thermal-neutron flux because of the presence of the loop was neglected.

The results of the calculations are summarized in Table 4.2.1. It is shown that, in spite of the greater length of the irradiated loop in the "deep" position, the fuel temperature differential is less than that in the position of maximum flux. The principal result of the change in position of the loop is a substantial decrease in the dilution

factor from about 11 in the "shallow" position to about 6 in the "deep" position.

FAST-NEUTRON DETECTORS

D. Binder

A great variety of radiation-damage studies require a knowledge of the fast-neutron flux of the reactor being used for the irradiations. For instance, changes in the mechanical and electrical properties of metals and insulators are dependent on the shape of the neutron-energy spectrum. As the neutron energy increases, the number of atoms displaced increases until a critical energy is reached at which the effect saturates.²² Therefore, it is essential to know the number of neutrons per unit energy up to about five times the critical energy and the integrated flux above this energy.

The energy spectra in two types of reactors from thermal to 100 ev or 1 kev and from 0.7 to 8 Mev

have been investigated by Trice.^{23,24} For the remaining investigation, that is, the 1-kev to 0.7-Mev region, a detector must be developed with which to study the variation of displacements with neutron energy. The development of useful detectors is dependent on a knowledge of this variation, and vice versa. The first step therefore is to calculate a known case based on simple assumptions.

Germanium was selected as the material to be studied because it is sensitive to neutrons and the relationship between the solid-state effect and the number of displacements is known. From the work of Cleland *et al.*²⁵ at low temperatures, it is known that five electron traps are introduced per

²³J. B. Trice, *Fast Neutron Flux Measurements in E-25 of the Brookhaven Graphite Reactor*, ORNL CF-55-7-130 (July 27, 1955).

²⁴J. B. Trice, *A Series of Thermal, Epithermal and Fast Neutron Measurements in the MTR*, ORNL CF-55-10-140 (Oct. 28, 1955).

²⁵J. W. Cleland, J. H. Crawford, Jr., and J. C. Pigg, *Phys. Rev.* 98, 1742 (1955).

²²G. H. Kinchin and R. S. Pease, *Reps. Progr. in Phys.* 18, 152 (1955).

"fast" neutron in a graphite reactor and that there are two traps per displacement. The question is whether it is possible to calculate the number of displacements on the basis of a reasonable graphite reactor spectrum and to achieve approximate agreement with the experimental result of 2.5 displacements per fast neutron. (A fast neutron is defined²⁵ by Cleland *et al.* to be a neutron with energy greater than that required to displace an atom.)

For the calculation the method of Kinchin and Pease²² was modified to include a spectrum which is the sum of $1/E$ distributions extending to each element of a fission spectrum.²⁶ The agreement between the calculation and the experimental result was within a factor of 4. The spectrum and the variation of displacements with energy are then roughly correct, or at least there are compensating errors.

In order to test the variation with neutron energy alone, it is planned to use neutron sources of known energy. The flux from these sources is reduced by factors of 10^3 to 10^5 from graphite reactor fluxes, but the sensitivity of pure germanium allows for experiments even at these low levels. Two sources will be used: a uranium converter plate in a thermal column and an antimony-beryllium source. The converter plate gives a pure fission spectrum, and, when used in the slanting animal tunnel of the ORNL Graphite Reactor, emits 2×10^8 fission neutrons/cm²·sec near the center of the plate. A first irradiation of 5.8×10^{13} neutrons/cm² introduced 1.9×10^{15} acceptors/cm³ in a germanium crystal. This experimental value agrees to within a factor of 2 with the calculated value of 3.4×10^{15} .

The result of the first experiment indicates that the present assumptions on the variation of displacements with neutron energy are roughly correct. This will be checked by further irradiations with fission neutrons and with 30-kev neutrons from the antimony-beryllium photon-neutron source. More adequate neutron monitoring is to be used for future germanium irradiations. This may lead to a complete understanding of displacements in at least one solid-state reaction.

VISCOMETER FOR REMOTE MEASUREMENTS OF THE VISCOSITY OF IRRADIATED FUSED-SALT FUELS

C. C. Webster

A viscometer was designed for use in a hot cell which will be capable of measuring the viscosities of irradiated fused-salt fuels at temperatures up to about 750°C in an inert (helium) atmosphere within a shielded cell. The apparatus consists of two vessels, 6 in. long, 1.25 in. OD, mounted in a vertical position, with 2 in. between centers. An Inconel tube 3 ft long and bent into a U-shape connects the bottoms of the vessels. A small ferromagnetic ball travels with the liquid through the tube, and the position of the ball is detected at two points on each leg of the U-tube by electronic equipment.

Swagelok connections are provided at the top for inserting liquid-level probes and for allowing helium pressure to be applied on the surface of the liquid in either vessel. The whole apparatus is inserted into a 4-in.-dia vertical furnace with an 18-in. controlled-temperature heated zone. End heaters are provided to control the heat loss out the ends of the furnace.

EFFECTS OF RADIATION ON ELECTRICAL COMPONENTS

J. C. Pigg C. C. Robinson²⁷

Insulation

In previous experiments^{28,29} on the effect of radiation on electrical insulation the insulated wire to be irradiated was placed in the reactor as if it were a sample lead. Care was taken to ensure that possible leakage paths from the central conductor to the shield were as long as possible. Whenever practicable, the end of the insulation that was in the reactor was sealed over at the end of the central conductor. However, the possibility of conduction by end surface contamination and ionization of the air still existed when there was no seal or when the seal was defective.

In order to determine whether such leakage was important in the experiments previously conducted,

²⁷On assignment from Wright Air Development Center.

²⁸J. C. Pigg and C. C. Robinson, *Solid State Semiannu. Prog. Rep.* Aug. 30, 1955, ORNL-1945, p 6.

²⁹J. C. Pigg *et al.*, *Communication and Electronics* 22, 717 (January 1956).

two samples were taken from the same spool of Teflon-insulated wire. One sample was the usual length, 25 ft long, and the second was 50 ft long. The two samples were installed at the same time in hole 50-N of the ORNL Graphite Reactor. The 25-ft Teflon-insulated sample was installed in the same manner as in the previous experiments, with no seal at the end. The 50-ft sample was doubled back on itself so that both ends of the wire were outside the reactor. The leakage between the shield and the central conductor was measured to be twice as large for the 50-ft sample as for the 25-ft sample. The photo-emf measurements on the two wires were identical. It can therefore be concluded that the radiation effects described previously²⁸ were due to bulk properties rather than to end surface conduction or to air ionization.

Barriers

A 1N38A germanium point-contact rectifier was exposed in a 2×10^6 r/hr Co^{60} gamma-ray source, and the forward and reverse currents were measured at 1-v bias. The behavior of the current is shown in Fig. 4.2.14. These data are in qualitative agreement with those obtained by Young.³⁰ The increase in reverse current, followed by a return toward its initial value, is an effect not found in reactor irradiation experiments because it occurs at low total damage. As may be seen from the change in forward current, the effect illustrated in Fig. 4.2.14 would have occurred before the sample

³⁰R. C. Young, *Gamma Radiation of Crystal Diodes*, Wright Air Development Center, WCRT-TN-54-255 (Dec. 28, 1954).

Fig. 4.2.14. Effect of Gamma Radiation on Conduction Through a Barrier. Germanium point-contact rectifier 1N38A-B exposed to 2×10^6 r/hr from Co^{60} source; 1N38A-A exposed to 2.5×10^5 r/hr from Co^{60} source.

reached thermal equilibrium in an in-pile experiment. Whether or not the effect does result from neutron irradiation has not yet been determined.

A series of exposures were also made in a 5×10^4 -r/hr Co^{60} source, and the voltage-current characteristics of the rectifier were measured after the samples were removed from the source. The change in the characteristic curve can be seen in Fig. 4.2.15. There is little change in the forward curve, which is in agreement with the data in Fig. 4.2.14. The current at 1-v reverse bias was normalized to make the preirradiation value coincide with that of the sample exposed in the 2×10^5 -r/hr Co^{60} source. The normalized data are shown in Fig. 4.2.14.

Fig. 4.2.15. Effect of Gamma Radiation on Voltage-Current Characteristic of Germanium Point-Contact Rectifier 1N38A-A at 20°C. The M values are the slopes of the lines.

The forward characteristic corresponds to the voltage-current behavior of the emitter of a transistor. The reverse curve corresponds to the collector characteristic of a transistor. It may be seen in Fig. 4.2.15 that, although the emitter characteristic is little changed, the collector characteristic changes drastically both in magnitude and slope. The magnitude of the current at 1-v bias changed by a factor of about 6, and the slope

changed by a factor of about 5.3. The changes in the characteristics are similar to those caused by neutron irradiation.³¹

A series of transistors were irradiated in the circuit shown in Fig. 4.2.16 to measure the amplification of the unit during, as well as before and after, irradiation. The series resistances in the emitter and in the collector circuit were changed to match the unit being considered in each experiment. Provisions were made to switch from grounded-emitter to grounded-base circuitry so that both types of circuitry could be studied simultaneously with the same unit. Exposures were made both in Co^{60} gamma-ray sources and in the ORNL Graphite Reactor.

The changes in the collector current at a 2-v bias and in the amplification of a Minneapolis-Honeywell H-2 power transistor as a function of gamma irradiation may be seen in Fig. 4.2.17. The collector, base, and emitter voltages were adjusted to the original values before each reading. Hence, the changes in amplification were due to changes in characteristics and not to changes in operating voltages. It may be seen that the collector current and the amplification were essentially the inverse of each other. Whether the change in amplification was due to a change in the slope of the collector characteristic, a change in separation of the collector curves, or a change in impedance matching has not yet been determined.

The changes in amplification of two Minneapolis-Honeywell power transistors as a function of irradiation in hole 51-N of the ORNL Graphite Reactor are shown in Fig. 4.2.18. These curves illustrate the same type of behavior as that observed for RCA transistor No. 1241.³² The temporary increase in amplification observed previously in RCA transistor No. 1266 was not noted. Again, the flux level was such that this region of the curve would have been traversed before thermal equilibrium was obtained in the in-pile experiment.

Influence of an Electrical Field on Diffusion of Interstitial Atoms

When germanium is bombarded by high-energy neutrons, the recoils from the neutron-atom collision and secondary collisions of the original

³¹ J. C. Pigg, *Solid State Semicon. Prog. Rep. Aug. 31, 1953, ORNL-1606, p 81.*

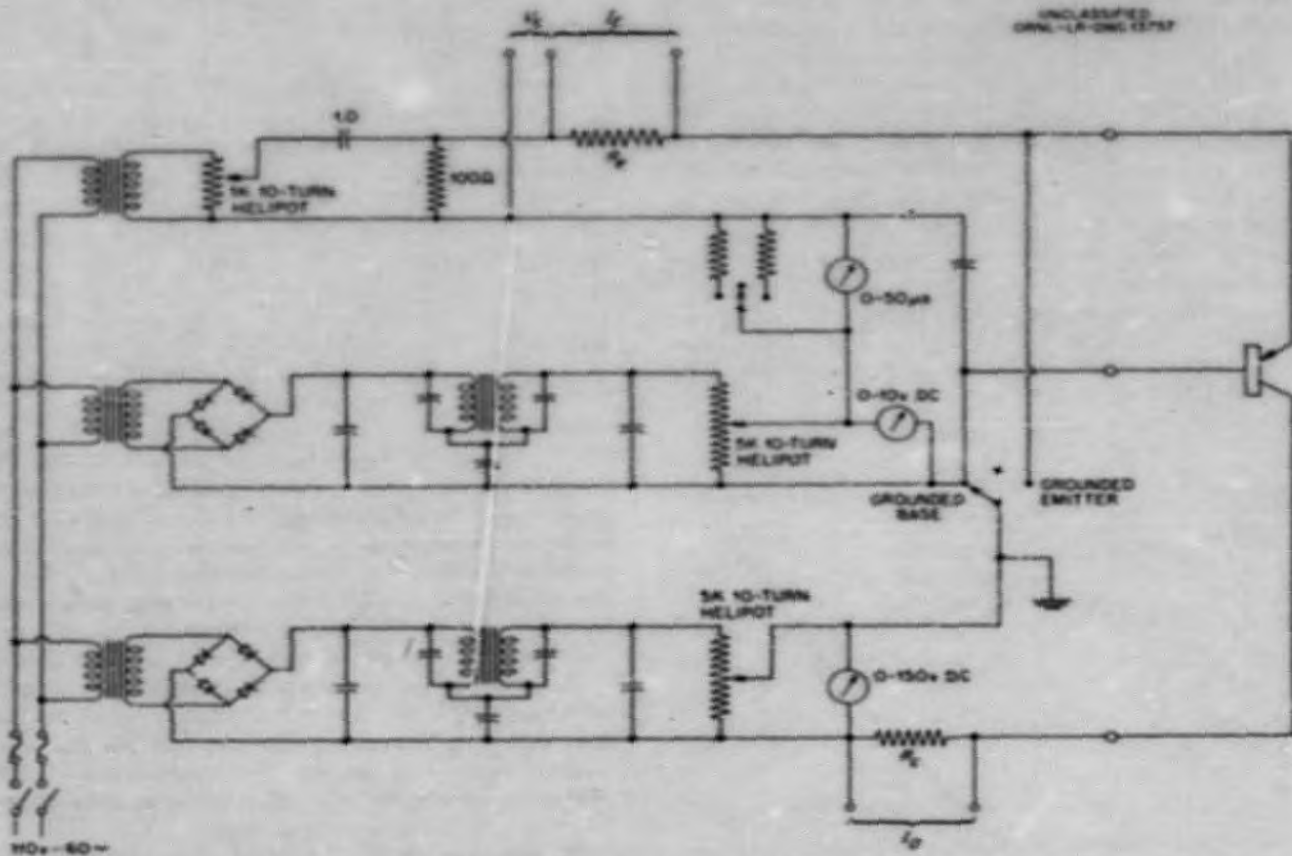

Fig. 4.2.16. Transistor Test Circuit.

atom as it travels through the lattice result in the formation of lattice vacancies and interstitial atoms. Since the germanium lattice is fairly open, the interstitial atoms can diffuse readily through the crystal. Because of the high dielectric constant of germanium, the interstitial atom is ionized at room temperature, and hence its diffusion should be influenced by the presence of an electric field. Fields of the order of tenths of a volt per micron are available in the barrier region of a diode, and the conductivity of the diode is extremely sensitive to changes in carrier concentration in the region of the barrier.

A 1N38A point-contact germanium rectifier was exposed for 5 min in hole 51-N of the ORNL Graphite Reactor. After removal from the reactor the rectifier was biased in the forward direction

at 0.7 v in order to remove the potential gradient in the barrier region. The measured current was low because of radiation damage. This unit was then placed in an oil bath to maintain a constant temperature of about 25°C for six days. At the end of the six-day period there had been no observable change in the current passing through the sample at 0.7-v bias. The bias was removed for 2 hr, then restored. When the bias had been restored, it was noted that the current had increased by about an order of magnitude. After eight days in the biased condition, the current had not changed.

When the bias was removed, an electric field was established at the barrier to cause the relative interstitial atoms to diffuse from the barrier region. This removal of interstitial atoms from the p-type

side of the barrier results in annealing out the type of damage which tends to make the p-type side less p-type and transporting it to the n-type side. Hence both sides of the barrier are annealed toward their initial condition and the forward current increases toward its initial value.

Fig. 4.2.17. Effect of Radiation on Collector Current and Amplification of a Minneapolis-Honeywell H-2 Power Transistor irradiated in Gamma-Ray Source of 2.57×10^5 r/hr.

THE EFFECT OF RADIATION ON POLYMERS

O. Sisman

W. W. Parkinson

W. C. Sears

There has been a continuing program in the Solid State Division to study the effects of high-energy radiation on plastics and elastomers. This work has heretofore been reported only in the Solid State Division progress reports, but because of increasing interest in this work in connection with allied ANP projects and because there is an increasing need for radiation-damage data on organic materials, some of the current polymer work will now also be presented in the ANP progress reports.

The plastics and elastomers have been studied quite extensively, and some of the chemical reactions have been identified which cause the changes that have been observed in the physical properties of irradiated polymers. A study is currently under way of the reaction products of irradiated polymers. A summary of this work, for

24E-219

DECLASSIFIED

ANP PROJECT PROGRESS REPORT

which the infrared spectrometer is used, is presented here.

The infrared spectra of polystyrene, polyethylene, polybutadiene, GR-S, natural rubber, deproteinized rubber, polyvinyl chloride, and Teflon have been measured before and after irradiation. The conditions of irradiation of these materials and some others which were not studied so thoroughly after irradiation are given in Table 4.2.4.

The polymer films were cemented on a 2.9 x 1.1 cm rectangular aluminum wire frame, evacuated for 2 to 5 hr, and then measured to provide a preirradiation spectrum. The films to be irradiated in vacuum were evacuated for three to five days at 0.2 μ and sealed in vacuum in pyrex or quartz tubes prior to irradiation. These sample tubes

were packed with aluminum foil in aluminum cans for irradiation. The polymers were irradiated in one or more of the following facilities: (1) a Co^{60} gamma-ray source, (2) water-cooled hole No. 19 in the ORNL Graphite Reactor, and (3) lattice position C-46 in the LITR. The maximum permissible dosage was limited by the formation of open slits in some polymer films (caused by shrinkage and loss in film strength). It was found that the dosage on polystyrene, polyvinyl chloride, mylar, and polymethyl methacrylate could be increased by irradiating unmounted films.

The discovery that postirradiation oxidation had occurred in irradiated polymers during exposure to air necessitated opening the evacuated sample tubes in a helium atmosphere. A glove box that

could be evacuated was used for this operation and for transferring the specimens to a gas-tight infrared absorption cell for spectral measurement. The absorption cell was then opened in air, and measurements of the spectrum were repeated after various periods of exposure to the atmosphere.

As an example of the spectral changes observed in polymers, the spectrum of a polystyrene sample is shown in Fig. 4.2.19. While polystyrene is more

Fig. 4.2.19. Infrared Spectra of Polystyrene.

resistant to change by radiation than most polymers are, the changes that may be seen in Fig. 4.2.19 are typical of the alterations of the infrared spectra by irradiation. Dosages of the order of 10^8 to 10^{10} rads were required to produce significant changes in the infrared spectra of most polymers.

A large postirradiation effect was observed in the spectra of polystyrene, GR-S, and natural rubber. Upon exposure to air following irradiation in vacuum, oxidation products continued to form for periods of up to 95 days. These reactions were indicated by the growth of strong hydroxyl and carbonyl bands. The oxidation products formed in postirradiation oxidation were different from those produced by irradiation in oxygen.

Irradiation of polystyrene in vacuum to high doses produced a wholesale disruption in which both the aromatic and aliphatic components were equally affected. On the other hand, the aliphatic component of GR-S (a styrene-butadiene copolymer) showed a greater percentage change than did polybutadiene at equal dosages.

All polymers showed significant changes in the double-bond regions as a result of irradiation. In polyethylene, $RR_1\bar{C}=\text{CH}_2$ groups disappeared as *trans* $\text{RCH}=\text{CHR}_1$ groups formed. In GR-S and polybutadiene the number of terminal vinyl groups decreased and the unsaturation in the hydrocarbon chains of GR-S and of natural rubber was decreased. Irradiation increased the number of *trans* $\text{RCH}=\text{CHR}_1$ groups in natural rubber, as it did in polyethylene. Conjugated and unconjugated unsaturation was produced in polyvinyl chloride.

4.3. FUEL RECOVERY AND REPROCESSING

H. K. Jackson

D. E. Ferguson W. K. Eister H. E. Goeller

VOLATILITY PILOT PLANT DESIGN
AND CONSTRUCTION

R. P. Millford F. N. Browder

The design of the volatility pilot plant for recovering fused-salt fuels is complete except for the molten-salt sampling device for the fluorinator and the trap-door closing device for the waste-salt carrier. All major equipment items were received, as well as the electrical power and control center and the instrument panelboards. The equipment, with the exception of the ARE fuel hold tank, which is not required until later, is in place; and piping, electrical work, and instrument installation are proceeding rapidly. It is expected that the plant will be completed by June 30.

NICKEL FLUORIDE SLUDGE
FORMATION STUDIES

G. I. Cathers M. R. Bennett

The behavior of NiF_2 in molten NaF-ZrF_4 and $\text{NaF-ZrF}_4\text{-UF}_6$ systems was studied to determine whether the presence of this corrosion product would cause the formation of sludges which would interfere with salt transfer in the fluoride-volatility process. In order to determine the solubility of NiF_2 in the salt mixtures, NiF_2 was added to molten NaF-ZrF_4 (50-50 mole %), and the mixture was heated until a clear solution was obtained. It was then cooled until turbidity reappeared. Solubility values estimated by the disappearance of turbidity were in fairly good agreement with solubility values determined electrochemically¹ for the solvent NaF-ZrF_4 (53-47 mole %). Based on the visual determinations, the estimates of the solubility of NiF_2 in NaF-ZrF_4 (50-50 mole %) were the following:

Temperature (°C)	Solubility of NiF_2 (wt % NiF_2)
640	0.7
670	1.0
685	1.3

¹L. E. Topol, ANP Quar. Prog. Rep. March 10, 1956, ORNL-2061, p 89.

These values show the very definite increase in solubility with temperature when compared with the reported solubility of 0.2 wt % Ni at 600°C.

The addition of as much as 6 wt % NiF_2 to molten NaF-ZrF_4 (50-50 mole %) at 600°C resulted in the formation of a viscous dispersion which was fairly stable, and thus other tests were made to determine the effect of concentration on sedimentation. These tests were made by dry mixing the required amount of salt (~30 g total) and melting it in a $\frac{1}{2}$ -in.-ID nickel tube. Nitrogen was used initially for agitation and then as a blanket while the material was kept at 600°C for various times. The tube was quickly quenched with cold water at the end of the test to fix the NiF_2 concentration at various heights in the tube. The tube was then cut into $\frac{1}{2}$ -in.-long sections, and the salt was analyzed for nickel. Although some settling of NiF_2 was evident after only 0.5 hr when 2 wt % Ni was added (as NiF_2), complete settling had not occurred even after 72 hr (Table 4.3.1). When only 1 wt % Ni was added, settling was more nearly complete at 72 hr; since the NiF_2 concentration was lower, the increase in viscosity at the bottom was not so great and thus was not so much of a deterrent to settling.

In further experiments the sedimentation of NiF_2 in molten $\text{NaF-ZrF}_4\text{-UF}_6$ (48-48-4 mole %) at 600°C (Table 4.3.2) was similar to that found in the uranium-free system. However, with 2 wt % Ni and with uranium present, the settling was less after 2 hr than in the test with no uranium. Since the solubility of NiF_2 in NaF-ZrF_4 is near the lower of the nickel concentrations found in these settling tests, it appears that the solubility of NiF_2 is approximately the same in uranium-bearing and uranium-free mixtures. These experiments have demonstrated that NiF_2 concentrations of up to 2 wt %, more by a factor of 10 than is expected in aircraft reactor fuel reprocessing, would not interfere with salt transfers unless the molten salt were permitted to stand unagitated for long periods of time.

DECOMPOSITION OF $\text{UF}_6\text{-3NaF}$ COMPLEX

G. I. Cathers R. L. Jolley

Some exploratory work was carried out on the decomposition of the $\text{UF}_6\text{-3NaF}$ complex at high

temperatures in an effort to develop a UF_6 desorption procedure which avoids UF_6 decomposition. The decomposition reaction would lead to uranium being held up on the NaF bed and would thus necessitate a subsequent recovery step. Tests were conducted by saturating the NaF bed with UF_6 at 100°C and then heating the bed, as a closed system, at the desired temperature for 1 to 4 hr. In some of the tests the bed was subjected to as much as 55 psia UF_6 pressure during the high-tempera-

ture cycle. However, no significant correlations were apparent as to the effect of UF_6 pressure or length of time of treatment. The residual uranium content in several tests at 400°C varied in the range 18 to 26%. At 300°C the decomposition effect was much less, a residual uranium content of 2% being produced. Use of excess F_2 (10 psia) in tests at 400°C also resulted in less decomposition, with residual uranium contents of 8 to 14%.

The residual uranium present in the product of all

DECLASSIFIED

ANP PROJECT PROGRESS REPORT

runs was pentavalent. As a result of disproportionation of the pentavalent uranium in the analytical procedure, however, the tetravalent uranium content in each case was approximately equal to the hexavalent content. The decomposition reaction is therefore believed to be

These results indicate that, if a significant partial pressure of UF_6 is retained in the NaF bed because of a plugged line or cold trap during UF_6 desorption, excessive UF_6 decomposition will occur when the temperature reaches the 300 to 400°C range. Therefore precautions must be taken to ensure that full sweep-gas flow through the NaF bed is maintained during UF_6 desorption.

4.4. CRITICAL EXPERIMENTS

A. D. Callihan

CRITICAL EXPERIMENTS FOR THE
COMPACT-CORE REFLECTOR-MODERATED
REACTOR

E. Demski ¹	J. J. Lynn
W. J. Fader ¹	D. E. McCarty
D. A. Harvey ¹	E. V. Sandin ¹
D. Scott	

The study of the NDA²-proposed, sodium-cooled, reflector-moderated reactor with solid fuel elements³ has been completed. In the critical assembly the fuel region contained 0.004-in.-thick uranium sheets interleaved between aluminum and stainless steel sheets. This fuel region was separated from the beryllium of the island and of the reflector by stainless steel shells. As described previously,⁴ additional uranium, in the form of 0.01-in.-thick disks, was added in one section of the fuel region to provide excess reactivity for other measurements. An evaluation of the effect of this local nonuniform fuel distribution on the reactivity was made by replacing 2636 g of U²³⁵ in 0.004-in.-thick sheets with 2678 g of U²³⁵ in 0.01-in.-thick disks in another section of the core. With the other materials unchanged, there was a reactivity loss of only 19 cents.

Evaluation of Stainless Steel Shell

The loss in reactivity caused by the stainless steel shells was determined by substituting aluminum shells of the same dimensions. The exchange of 4.4 kg of aluminum for 11.9 kg of stainless steel resulted in a gain in reactivity of \$4.20, estimated to be equivalent to a 14% decrease in the critical mass. The excess reactivity was partly compensated for by the removal of some of the outer layer of the 11½-in.-thick reflector. Removal of a 2⅞-in.-thick section that extended

over the 28¾-in. length of the outer reflector and comprised 70% of the outer cylindrical layer resulted in a loss in reactivity of \$2.39.

Measurements of Gamma-Ray Heating in Beryllium

Capacitive ionization chambers were used to measure the distribution of gamma-ray heating in the beryllium of the island and the reflector of the critical assembly by a method developed at the Knolls Atomic Power Laboratory.⁵ The chambers are constructed of beryllium and have a 10-mil-thick annular cavity $\frac{5}{16}$ in. OD and $\frac{5}{8}$ in. deep. The results are expressed as power dissipated as heat in a unit volume per unit reactor power. The reactor power was determined from a calibration based on the intensity of a fission-product gamma ray from an irradiated uranium foil.⁶

A plot of the data obtained from radial traverses $\frac{3}{4}$ and $10\frac{9}{16}$ in. from the mid-plane of the reactor is given in Fig. 4.4.1. Three longitudinal traverses, one along the axis of the reactor and the others $4\frac{5}{16}$ and $7\frac{3}{16}$ in. from the axis, are plotted in Fig. 4.4.2. These data have not been corrected for the ionization resulting from the (n, p) reaction in the air-filled chambers and may overestimate the heating adjacent to the fuel by as much as 25%, an estimate based on the work at KAPL. An attempt was made to measure this error by filling the chambers with CO₂, but it was apparent that they were not gas-tight during these experiments. It may be possible to make a correction to these data by using the results of similar measurements in another assembly.

A layer of beryllium, 2⅞ in. thick, was removed from the top of the reactor, and one traverse was repeated with this thinner reflector. The heating was observed to be unaffected in the region between the fuel and a point 3 in. from the surface of the modified reflector. In this outer 3-in. layer the heating decreased to a value, at the surface, about 35% less than it was at the same distance from the fuel in the thicker reflector.

Fast-Neutron Leakage

Relative measurements of the fast-neutron leakage at points on the outer surface of the reflector were made with a Hornyak button, 2 in. in diameter and $\frac{1}{4}$ in. thick, mounted on a Du Mont 6292 photomultiplier tube. The button had the same composition, 0.15 g of powdered ZnS in 1.0 g of Lucite, as a similar button described by Hornyak.⁷ By proper choice of a discriminator bias it was possible to detect neutrons with energies above

⁷W. F. Hornyak, *Rev. Sci. Instr.* 23, 264 (1952).

0.5 Mev against the gamma-ray background of the reactor.

A polar plot of the fast-neutron leakage distribution observed in a longitudinal traverse over the top of one end of the reactor is presented in Fig. 4.4.3. The observed counting rates, normalized to the counting rate at point 19, near the axis of the assembly, have been plotted on the polar radii drawn through points on the reflector surface where measurements were made. For this traverse, the reflector thickness was approximately $11\frac{1}{2}$ in., and the top layer of beryllium was $28\frac{3}{4}$

in. long, $18\frac{1}{16}$ in. wide, and $2\frac{7}{8}$ in. thick. The beryllium layer immediately below it was $34\frac{3}{4}$ in. long and $24\frac{5}{16}$ in. wide.

The top layer and the corners of the second beryllium layer were subsequently removed, and the resulting reflector was $8\frac{5}{8}$ in. thick. The new top layer was $18\frac{1}{16}$ in. wide and $34\frac{3}{4}$ in. long. A second longitudinal traverse was then made. The results are shown in Fig. 4.4.4, in which the top lobe is plotted to a scale one-half that used to plot the end lobe.

Two series of lateral traverses were also made at the side of the reactor at several distances from the mid-plane. For reflector thicknesses of $11\frac{1}{2}$ and $8\frac{5}{8}$ in. the outer slab dimensions for each side reflector thickness were the same as those given above. The latitudinal variations of the fast-neutron leakage for the two reflector thicknesses are shown in Figs. 4.4.5 and 4.4.6. The curves show a slight asymmetry about the center of the reactor, which is attributed to the reflection of neutrons by the aluminum and steel structure on which the critical assembly rests. The area under each curve of Figs. 4.4.5 and 4.4.6 is proportional to the counting rate observed at the corresponding distance from the mid-plane in the longitudinal traverses made at the top of the reactor. By integrating the results of the two longitudinal traverses over the distance from the mid-plane, it was possible to determine that the removal of the $2\frac{7}{8}$ in. layer of beryllium from the top of the reactor increased the fast-neutron leakage there by a factor of 3.7.
