AN INVESTIGATION OF THE LOW-SPEED STATIC STABILITY
CHARACTERISTICS OF COMPLETE MODELS HAVING
SWEPTBACK AND SWEPTFORWARD WINGS

By M. Leroy Spearman and Paul Comisarow

SUMMARY

An investigation has been conducted in the Langley 300 MPH 7- by
10-foot tunnel to determine the static stability characteristics at low
speeds of complete models with various swept wings so that comparisons
might be made with available theoretical and empirical methods of pre-
dicting the stability characteristics. Longitudinal and lateral stability
characteristics, flaps up and down, were obtained for models having 0°,
15°, 30°, and 45° sweptforward and sweptback wings.

The results of the investigation indicate that static stability
characteristics can be estimated with reasonable accuracy in the low-lift
range by means of existing theories.

For lift coefficients near the stall where no theory is applicable, the
longitudinal-stability trends for the complete models were similar to those
that might be expected from an inspection of isolated swept-wing data.

INTRODUCTION

Experimental and theoretical investigations have shown that the use
of wings having large angles of sweep might introduce serious low-speed
stability problems. The results of an investigation reported in
reference 1 on the stability characteristics of small-scale sweptback
and sweptforward wings and in reference 2 for large-scale sweptback and
sweptforward wings indicate that fairly accurate estimates can be made
of the characteristics of isolated swept wings at low and moderate lift
coefficients before separation effects assume any importance.

It was not certain, however, that the characteristics of complete
models with swept wings could be predicted with as high a degree of
accuracy as those of the isolated wing. Heretofore no systematic
investigation of complete models with various sweptback and sweptforward
wings has been made. The purpose of the present paper is to present
The results of such an investigation made to determine the longitudinal and lateral stability characteristics of models with various sweptback and sweptforward wings and to show comparisons with available theoretical and empirical results.

COEFFICIENTS AND SYMBOLS

The results of the tests are presented as standard NACA coefficients of forces and moments. All forces and moments are presented for the stability axes shown in figure 1 with the reference center of gravity at the 25 percent mean aerodynamic chord for each model as indicated in figure 2.

The coefficients and symbols are defined as follows:

- \( C_L \)  
  lift coefficient \((\text{Lift}/qS \text{ where } \text{Lift} = -Z)\)

- \( \Delta C_L \)  
  increment of lift coefficient due to flap deflection

- \( C_X \)  
  longitudinal-force coefficient \((X/qS)\)

- \( C_Y \)  
  lateral-force coefficient \((Y/qS)\)

- \( C_L \)  
  rolling-moment coefficient \((L/qSb)\)

- \( C_m \)  
  pitching-moment coefficient \((M/qSb)\)

- \( C_n \)  
  yawing-moment coefficient \((N/qSb)\)

- \( Z \)  
  force along Z-axis, pounds

- \( X \)  
  force along X-axis, pounds

- \( Y \)  
  force along Y-axis, pounds

- \( L \)  
  rolling moment about X-axis, pound-feet

- \( M \)  
  pitching moment about Y-axis, pound-feet

- \( N \)  
  yawing moment about Z-axis, pound-feet

- \( q \)  
  free-stream dynamic pressure, pounds per square foot \((\rho V^2/2)\)

- \( S \)  
  wing area, square feet

- \( b \)  
  wing span, feet
\( \delta \)  
wing mean aerodynamic chord, feet \( \left( \frac{b/2}{s} \right) \)

\( \rho \)  
mass density of air, slug per cubic foot

\( v \)  
air velocity, feet per second

\( c \)  
airfoil section chord, feet

\( y \)  
distance along wing span, feet

\( \lambda \)  
aspect ratio \( (b^2/s) \)

\( \Lambda \)  
angle of sweep of wing quarter-chord line, degrees (positive for sweepback)

\( \lambda \)  
taper ratio \( \frac{\text{Tip chord}}{\text{Root chord}} \)

\( l_t \)  
tail length measured from center of gravity to the elevator hinge line, feet

\( \alpha \)  
angle of attack of wing chord line, degrees

\( \psi \)  
angle of yaw, degrees

\( \epsilon \)  
angle of downwash, degrees

\( \iota_t \)  
angle of stabilizer with respect to wing chord line, degrees

\( \delta_f \)  
flap deflection measured perpendicular to 80-percent-chord line, degrees

\( n_p \)  
neutral-point location, percent wing mean aerodynamic chord

\( M_o \)  
tunnel free-stream Mach number

Subscripts:

\( f \)  
denotes sweptforward wing tip at \( \Lambda = 0^\circ \)

\( b \)  
denotes sweptback wing tip at \( \Lambda = 0^\circ \)

\( t \)  
horizontal tail

\( v.t. \)  
vertical tail
Symbols used as subscripts denote partial derivatives of coefficients with respect to angle of attack, angle of yaw, and lift coefficient. For example:

\[ C_L \psi_{C_L} = \frac{\partial (\partial C_L)}{\partial (\partial \psi)} \]

**MODEL**

The models tested in the present investigation had the same fuselage and tail surfaces. The wings used could be pivoted from an unswept position to angles of sweep of \( \pm 15^\circ \), \( \pm 30^\circ \), and \( \pm 45^\circ \). Two pairs of wing tips were used, one for the sweptback wings and one for the sweptforward wings, so designed as to be parallel with the fuselage center line at \( \pm 45^\circ \) sweep. No attempt was made to hold the area, span, or aspect ratio constant for the various sweep configurations. Drawings of the models giving pertinent information are presented in figure 2 and the physical characteristics of the models are given in table I. The span for each model was measured to the extreme tips of the wing. Half-span split flaps of 20 percent chord were tested on all models.

Various models mounted in the Langley 300 MPH 7- by 10-foot tunnel are shown in figure 3.

**TESTS AND RESULTS**

**Test Conditions**

Tests were made at a dynamic pressure of 33.6 pounds per square foot \((M_D = 0.15)\). The corresponding Reynolds numbers based on the wing mean aerodynamic chord are as follows:

<table>
<thead>
<tr>
<th>( \Lambda ) (deg)</th>
<th>M.A.C. (ft)</th>
<th>Reynolds number</th>
</tr>
</thead>
<tbody>
<tr>
<td>-45</td>
<td>1.888</td>
<td>2,020,000</td>
</tr>
<tr>
<td>-30</td>
<td>1.460</td>
<td>1,569,000</td>
</tr>
<tr>
<td>-15</td>
<td>1.262</td>
<td>1,357,000</td>
</tr>
<tr>
<td>0</td>
<td>1.181</td>
<td>1,270,000</td>
</tr>
<tr>
<td>15</td>
<td>1.201</td>
<td>1,292,000</td>
</tr>
<tr>
<td>30</td>

<td>1,373,000</td>
</tr>
<tr>
<td>45</td>
<td>1.542</td>
<td>1,657,000</td>
</tr>
</tbody>
</table>
The Reynolds number was computed using a turbulence factor of unity. The degree of turbulence of the tunnel is not known quantitatively but is believed to be small because of the high contraction ratio (14:1).

Corrections

Tare corrections were considered negligible and were not applied. Jet-boundary corrections were computed by the method of reference 3 and an unpublished analysis shows this to be applicable for wings up to 45° sweep. Corrections applied were as follows:

\[
\alpha = \alpha_M + E\alpha_M \\
C_x = C_{x_M} - F\alpha_M^2 \\
C_m = C_{m_M} + G\alpha_M \\
\]

where the subscript M denotes measured values.

The E, F, and G values for each sweep angle are given in the following table:

<table>
<thead>
<tr>
<th>(\Lambda) (deg)</th>

</tbody>
</table>

All forces and moments were corrected for blocking by the method given in reference 4. An increment in longitudinal-force coefficient has been applied to account for the horizontal buoyancy.
Presentation of Results

A table of figures presenting the results is given as follows:

Basic experimental data:  
Aerodynamic characteristics in pitch  .......... 4-7  
Lateral-stability parameters  ................. 8-9

Analysis and comparison figures:  
Static longitudinal stability characteristics  .......... 10  
Variation of neutral point with sweep  .......... 11  
Downwash variation  ............... 12-13  
Variation of effective dihedral with sweep  .......... 14  
Variation of directional stability with sweep  .......... 15  
Flap-lift effectiveness  ............... 16

DISCUSSION

In the analysis of the data each model was considered as an individual configuration. Although the primary physical difference between the models is the angle of sweep, there are irregular variations in the wing area, wing span, mean aerodynamic chord, center-of-gravity location, and tail length accompanying the change in sweep. The results obtained, therefore, do not represent the effect of sweep on the stability characteristics but include all those factors varying as a result of changes in sweep. Consequently, the aerodynamic trends indicated apply only for the models tested and for other configurations may be entirely different. The emphasis then should be placed on the extent to which calculated values of the stability characteristics may be made with reasonable accuracy and not upon the quantitative results shown.

Longitudinal Stability

The static longitudinal stability of a jet airplane in power-off flight at subcritical speeds may be expressed as

\[
\frac{dC_m}{dC_L} = \left(\frac{\partial C_m}{\partial C_L}\right)_{0} - \left| \frac{dC_m}{dI_t} \right| \left( 1 - \frac{\partial C}{\partial \alpha} \right) \frac{1}{C_{L\alpha}}
\]

where \( \left(\frac{\partial C_m}{\partial C_L}\right)_{0} \) represents the longitudinal stability of the wing-fuselage combination and \( \frac{dC_m}{dI_t} \left( 1 - \frac{\partial C}{\partial \alpha} \right) \frac{1}{C_{L\alpha}} \) is the contribution of the tail to
the longitudinal stability. Each of the factors affecting the longitudinal stability was estimated and then by use of the equation the static longitudinal stability for each model was calculated. The results are shown and compared with the experimental results in figure 10.

The variation of the lift-curve slope $C_{L\alpha}$ with sweep was estimated by the method of reference 5. The basic value of $C_{L\alpha}$ for the unswept-wing model was found by adding $C_{L\alpha}$ for the plain wing (0.078 as determined from reference 5) to a value of 0.014 for the fuselage and tail as determined from unpublished results of tests of a similar model.

The stabilizer effectiveness was found from the relation

$$\frac{\partial C_m}{\partial \alpha} = \left( C_{L\alpha} \right) \frac{l_t}{c} \frac{S_t}{S}$$

By the use of reference 6 a value of 0.060 was estimated for $C_{L\alpha}$.

An empirical method presented in reference 7 was used to estimate the variation of the downwash angle with angle of attack $\frac{\partial \theta}{\partial \alpha}$ for the various configurations.

The static longitudinal stability of the wing-fuselage combination $\left( \frac{\partial C_m}{\partial C_{L\alpha}} \right)_0$ was determined by use of the method given in reference 6 which accounts for the interference effects of bodies with swept wings. It is shown in reference 8 that a rearward shift of the wing-fuselage aerodynamic center might occur for bodies with sweptback wings because of a loss in lift on the wing center section caused by the presence of the fuselage. This area of reduced lift, being ahead of the reference center-of-gravity position (0.255), would produce a negative pitching moment in opposition to the positive moment always produced by the fuselage. For sweptforward wings the reverse is true and a positive pitching moment is produced by the loss of wing lift in addition to the positive moment of the fuselage. Hence, in comparison with the aerodynamic-center shift of bodies with straight wings, the shift will be more forward for bodies with sweptforward wings and less forward for bodies with sweptback wings. For these calculations it was assumed that the aerodynamic center of the plain wing remained unchanged with sweep.
Each of the factors affecting the static longitudinal stability was estimated with reasonable accuracy and good agreement was obtained between the calculated and experimental values of the total longitudinal stability \( \frac{dc_m}{dc_L} \) for each model (fig. 10).

The variation of the neutral point with sweep angle in the low-lift range as determined both experimentally and theoretically is shown in figure 11 and indicates that flap deflection has little effect on the longitudinal stability of these models.

Near maximum lift the pitching-moment characteristics of the models were similar to those that might be expected for isolated wings (reference 9) based on the sweep angle and aspect ratio. As pointed out in reference 2, the predictions of reference 9 apply equally as well to sweptforward wings as to sweptback wings. The models with unsweped wings and \( \pm 15^\circ \) swept wings are stable or marginally stable near the stall. The models with \( \pm 30^\circ \) and \( \pm 45^\circ \) swept wings indicate instability with the exception of the \( -45^\circ \) wing model with flaps retracted (fig. 5(d)) in which case it appears that an angle of attack high enough to effect a partial wing stall was not attained. The instability of the \( 30^\circ \) and \( 45^\circ \) sweptback-wing models is caused partly by tip stall as evidenced by the tail-off pitching-moment curve (figs. 11(c) and 11(d)) and partly by the rapid increase in the rate of change of downwash at the higher angles of attack (fig. 12) that results from the inboard shift of the lift. The \( -30^\circ \) and \( -45^\circ \) swept-wing models show no large downwash changes with sweep and instability should result primarily from wing root stall.

When the flaps are deflected the unstable tendencies near the stall are accentuated. For sweptback wings the tip portion of the wing might stall although the flap prevents complete wing stall and the result is a greater nosing-up tendency of the wing. In the case of sweptforward wings the stall over the inboard portion of the wing is more pronounced when the flaps are deflected which also results in a greater nosing-up tendency of the wing.

Lateral and Directional Stability

Effective dihedral.—The effect of sweep on the variation of effective dihedral with lift coefficient \( c_{\psi_{CL}} \) in the low-lift range as determined from figures 8 and 9 is shown in figure 14. Values for the theoretical curve also shown in figure 14 were obtained by adding \( c_{\psi_{CL}} \) for the plain wing to the increment of \( c_{\psi_{CL}} \) contributed
by the tail. For the wing alone
\[ \frac{C_{\psi} \Delta}{C_{\psi} \Delta_{\lambda=0}} + 0.0044 \tan \Lambda \]
where \(0.0044 \tan \Lambda\) is the effect of sweep on effective dihedral (reference 1). The values of \(C_{\psi} \Delta_{\lambda=0}\) are for unswept wings having the same aspect ratio as the swept wing and were determined from a correlation of experimental results for various unswept wings of different aspect ratios presented in reference 10.

In order to determine the vertical-tail contribution to \(C_{\psi} \Delta_{\lambda=0}\), the lateral-force parameter for the tail was first estimated from \((C_{\psi} \Delta)_{v.t.} = (C_{\psi} \Delta)_{v.t.} \frac{S_{\lambda}}{S}\). By the method of reference 6, which takes into account the end-plate effect of the horizontal tail, a value of 0.062 was obtained for the vertical-tail lift-curve slope based on an aspect ratio of 2.4. The contribution of the tail to \(C_{\psi}\) at any angle of attack then is
\[ (C_{\psi})_{v.t.} = (C_{\psi})_{v.t.} \frac{h}{b} \]
where \(h\) is the distance from the X-axis to the center of pressure of the vertical tail. At zero angle of attack \(h\) was estimated from tail-on and tail-off tests of a similar model to be 1.4 feet.

Interference and sideward effects resulting from the fuselage and wing were neglected in the computations.

The results of the calculations (fig. 14) indicate good agreement with the experimental values of \(C_{\psi} \Delta_{\lambda=0}\). It is apparent from figure 14 that flap deflection had a negligible effect on the effective-dihedral variation with lift.

**Directional stability.** An attempt was made to calculate the directional-stability parameter \(C_{\psi} \Delta\) at zero lift for each model and the results are included with the experimental results in figure 15. Using the values previously estimated for \((C_{\psi} \Delta)_{v.t.}\), the yawing moment due to yaw produced by the tail was determined from
\[ (C_{\psi} \Delta)_{v.t.} = (C_{\psi} \Delta)_{v.t.} \frac{h}{b} \]
The tail contributed a negative \(C_{\psi} \Delta\) (stabilizing) that increased negatively both with sweepback and sweep-forward. The fuselage produced a positive \(C_{\psi} \Delta\) (destabilizing) that was calculated by the method of reference 11. The unstable moment
variation with yaw of the fuselage became more positive with sweepback or sweepforward. The summation of the estimated values of $C_n \psi$ for the fuselage and tail (fig. 15) indicate fair qualitative agreement with experimental results in that generally the directional-stability parameter $C_n \psi$ decreases from sweepforward to sweepback. The discrepancy apparent at high angles of sweepback might be caused by interference effects of the wing on the pressure distribution over the aft portion of the fuselage. It is obvious from figure 15 that flaps may have a large effect on the directional stability.

The variation of $C_n \psi$ with lift coefficient is similar to that obtained from investigations of isolated swept wings (references 1 and 2).

Lift and Drag Characteristics

Flap effectiveness. - Theoretically the lift increment produced by deflecting the flap is proportional to $\cos^2 \Lambda$ but an additional correction should be applied to account for the aspect-ratio changes. Inasmuch as the calculations for the theoretical lift-curve slope account for the aspect ratio, the lift increment resulting from flap deflection may be expressed as

$$\Delta C_L = \Delta C_L \Delta \cos \Lambda \left( \frac{C_L \alpha}{\Delta} \right) \left( \frac{C_L \alpha}{\Delta} \right) = 0$$

In figure 16 the theoretical predictions are compared with the experimental results for $\Delta C_L$ and show reasonably good agreement.

CONCLUSIONS

The results of low-speed tests of models having $0^\circ$, $15^\circ$, $30^\circ$, and $45^\circ$ sweptforward and sweepback wings indicated the following conclusions:

1. The static longitudinal stability in the low-lift range can be predicted inasmuch as the factors affecting the stability - the lift-curve slope, downwash, stabilizer effectiveness, and wing-fuselage aerodynamic center - can be estimated accurately by means of existing theories.

2. The variation of effective dihedral with lift coefficient can also be estimated with good accuracy.
3. Predictions of the directional stability can be made with fair accuracy.

4. The increment of lift caused by flap deflection can be estimated with reasonable accuracy.

5. For lift coefficients near the stall where no theories are applicable, the longitudinal stability characteristics for the complete models were similar to those indicated by investigations of isolated swept-wing configurations.
