REPORT 926

SOUND-LEVEL MEASUREMENTS OF A LIGHT AIRPLANE MODIFIED TO REDUCE NOISE REACHING THE GROUND

By A. W. Vogelty

SUMMARY

An army liaison-type airplane, representative of personal airplanes in the 150 to 200 horsepower class, has been modified to reduce propeller and engine noise according to known principles of airplane-noise reduction. Noise-level measurements demonstrate that, with reference to an observer on the ground, a noisy airplane of this class can be made quiet—perhaps more quiet than necessary. In order to avoid extreme and unnecessary modifications, acceptable noise levels must be determined.

INTRODUCTION

An important factor in the problem of increasing the utility of the personal airplane is the provision of more convenient access to airports. For this reason it is desirable that airports be close to centers of population. Strong objections to the noise of airplanes are, however, seriously hindering the proper development and location of airports. A solution to the problem of airplane-noise reduction is therefore necessary to the healthy growth of personal and commercial aviation.

The National Advisory Committee for Aeronautics first began to investigate airplane noise in about 1930. Emphasis was placed almost entirely on the study of propeller noise. Since that time a theory for predicting propeller noise has been developed and a number of papers which aid in the design of quiet propellers for personal airplanes have been issued. These, and other papers relating to the noise problem, are listed as references 1 to 10. Increased emphasis has recently been placed on this work because of the expanding personal-airplane market.

In addition to the theoretical and ground test work, a typical light airplane has been modified for flight tests to determine the applicability of the published data. This modified, or quiet, airplane was first flown and demonstrated at the Sixteenth Annual Inspection at the Langley Laboratory in May 1947. Since that time, this airplane has been tested and the test results compared with those for the unmodified airplane. The results of these tests, showing the sound-pressure levels of both airplanes as measured from the ground, are presented in this report.

DESCRIPTION OF UNMODIFIED AIRPLANE

An army liaison-type airplane was chosen as being representative of personal airplanes in the 150 to 200 horsepower class. This airplane, shown in figure 1, has a wing span of 34 feet, an over-all length of 24 feet, and a normal gross weight of 2,100 pounds.

Specifications of the components relating to the noise problem are as follows:

Engine: Horizontally opposed, six-cylinder, direct-drive, air-cooled; rated 185 horsepower at 2,550 rpm.

Exhaust system: Collector stacks for each bank of cylinders exhausting independently below the engine cowling, as shown in figure 2.

Propeller: Two-blade, 85-inch diameter, fixed-pitch; laminated wood.

FIGURE 1.—Unmodified test airplane.

FIGURE 2.—Exhaust system of unmodified test airplane.
DESIGN CONSIDERATIONS AND DESCRIPTION OF QUIET AIRPLANE

Because acceptable airplane-noise levels have not yet been determined, a level of 65 decibels at 300 feet was assumed to be a satisfactory objective. This value was therefore selected as the design goal for the propeller and muffler. Since little can be done at the present time to reduce the aerodynamic noise of the airframe, it was hoped that this noise level would be less than 65 decibels.

Propeller.—According to reference 8, a number of propellers of various diameters, numbers of blades, and operating speeds would, theoretically, meet the design value of 65 decibels. A five-blade configuration was chosen, however, because a hub suitable for this type happened to be available. The diameter was increased to 96 inches from the original 85 inches in order to take advantage of the available ground clearance and, as a result, the best take-off performance.

Figure 3, which was interpolated from the data of reference 8, shows the theoretical loudness level of the test configuration at various propeller speeds. The total loudness level as shown is the sum of the vortex-noise level (due to the shedding of vortices) and the Gutin or rotational-noise level (due to the steady aerodynamic forces on the blades). This figure indicates that the assumed 65-decibel-loudness-level requirement should easily be met by operation at a propeller rotational speed of approximately 1,000 rpm, which should produce a loudness level of about 67 decibels.

The aerodynamic design of the propeller was based on the charts of reference 7 and conventional theory to give optimum efficiency under the following conditions:

<table>

</tbody>
</table>

The available five-blade hub originally designed for model blades had very small blade sockets, and stress analysis showed that wooden shanks to fit this hub would have an insufficient margin of safety. Consequently, metal blade roots were machined to fit this hub and to flare out into the blade about 6 inches from the base. The wooden blades were glued to these stubs by the Cycleweld process. The usual metal leading edge and tip protective strip were omitted and 1/16-inch sheet rubber was substituted. Figure 4 shows a typical blade with these details.

The use of Cycleweld for blade retention and rubber sheet for protection is rather unusual. These novel methods could be used only because of the low blade stresses and low rotational speeds of the quiet propeller. They are mentioned only to illustrate to a small extent how certain of the characteristics of the quiet propeller may be used to advantage in fabrication.

The five-blade propeller, as tested, was very heavy, but only because the hub was designed for wind-tunnel work and no consideration had been given to weight. Actually the wooden blades each weigh only 6 pounds and it is estimated that, if a complete wooden propeller had been built, the total weight would have been less than 50 pounds as compared with approximately 25 pounds for the conventional two-blade propeller.

Engine.—For a valid comparison of loudness levels an engine developing as much brake horsepower as the standard engine and geared to turn the propeller at 1,000 rpm was required. It was found that an available engine, with a rating of 210 horsepower at 3,000 rpm and geared 1.56 to 1.0 could be modified to provide a gear ratio of 2.79 to 1.0. Operation of this engine at 2,760 rpm in order to obtain the desired propeller speed was originally expected to produce approximately 185 horsepower. Later information indicated, however, that actually about 200 horsepower was developed.

It is interesting to note that no weight penalty need result from the use of gearing since, based on maximum ratings, the geared engine develops 0.515 horsepower per pound as compared with 0.505 horsepower per pound for the direct-drive engine.

The installation of this engine required only slight alterations to the airplane. The original provisions for cooling the standard engine were marginal; and because of the experimental nature of the geared engine, the cooling was improved by installation of a small oil-radiator scoop and small cowl flaps. Figure 5, a photograph of the final modified airplane, shows these details.

Exhaust system.—The available literature on muffler design was studied and found to be rather inadequate. The final design was evolved from application of the principles given in reference 9 and by application of the trial-and-error method to the test setup shown in figure 6. Engine power was absorbed by the electric motor run as a generator and cooling air was provided by the blower.

Before the special high-gear-ratio engine became available, it was the intention to use a standard geared engine at low engine speed. For this reason, the muffler was actually developed to provide attenuation of the first-order firing
frequency of an engine running at about 1,600 rpm. Since, with the acoustical-filter-type muffler, the chamber size is an inverse function of the design frequency, the muffler is larger than necessary for the high-speed engine, and the same amount of noise reduction might have been obtained with a smaller muffler designed for the higher frequency. Details of the exhaust system are shown in figures 7 and 8.

This muffler work was done by the staff of the Langley Full-Scale-Tunnel Section.

**SOUND MEASUREMENTS**

All sound measurements were made with the General Radio Company sound level meter, model 759-A. This instrument has three different scales to be used for measuring sounds at three general intensity levels. The frequency response of each scale approximates the response of the ear when subjected to sounds of the proper sound-pressure level. In this manner, the sound-pressure levels measured by the instrument are made roughly equivalent to the loudness levels as experienced by the ear.

For these tests, however, it was convenient to make all measurements on the “C,” or flat-response, scale. Although the use of this scale may lead to differences of a few decibels between the sound-pressure level and the loudness level under certain conditions, it appears justified for these tests. Most
of the measurements of the standard airplane were made at
a level high enough to require the use of the "C" scale. The
noise from the modified airplane was relatively free of low
frequencies, and because it is the low-frequency response
of the ear that is the primary reason for differences between
sound-pressure and loudness levels, measurements of the
sound from the modified airplane are not materially affected
by changes in the instrument low-frequency response.

As a consequence, the terms noise level, sound-pressure
level, and loudness level (although used properly in each
instance) may all be interpreted as loudness levels.

RESULTS AND DISCUSSION

Sound-pressure-level measurements were taken of both
the unmodified and the modified airplanes while on the
ground and while passing overhead at various altitudes.

Results of ground tests.—The results of the ground tests
are given in figure 9. These measurements were made at a
distance of 50 feet from the center of the propeller. The
engine speeds covered range from essentially idling speed to
full-throttle speed. Except for a variation of about 5
decibels, with a minimum apparently between 60° and 90°,
the sound-level pattern about both airplanes may be con-
sidered uniform.

At the highest engine speeds tested, the sound-pressure
level of the unmodified airplane is about 22 decibels higher
than that of the modified airplane. In terms of distance,
according to reference 5, if an acceptable level of 65 decibels
is assumed, the unmodified airplane must be located at least
2,000 feet from the nearest residence during warm up and
start of take-off. The modified airplane, however, needs
to be less than 200 feet away.

Results of flight tests.—Sound-level measurements of the
airplanes in flight at an altitude of 300 feet are presented in
figure 10. The maximum sound-level meter readings were
taken as the airplanes passed directly overhead. All the
runs of figure 10 were made with power for level flight over
the speed range from near the stall to maximum. This
figure shows clearly the amount of noise reduction that has
been accomplished and that the assumed desirable level of
65 decibels has, for practical purposes, been realized.

The variation of sound-pressure level with altitude for the
two airplanes operating at maximum speed is shown in
figure 11. This figure indicates the large increase in altitude
required before the sound-pressure level of the unmodified
airplane becomes as low as that of the modified airplane
(for example, 1,600 ft compared with 200 ft).

Tests were made of the modified airplane in flight with
throttle closed (power off) to evaluate the amount of noise
generated by the airframe alone. Propeller speeds in this
condition were sufficiently low so that propeller noise did
not affect the sound-pressure-level measurements. The
measured values, corrected to 300 feet altitude, are given in
figure 10. From these data it is estimated that the sound-
pressure level would be approximately 62.5 decibels at the
maximum speed of about 130 miles per hour. According to
figure 3, therefore, the noise of the airplane itself is about
5 decibels higher than the theoretical value of the noise
produced by the propeller. While the values given in ref-
ence 8 are given with a probable accuracy of ±10 decibels
due to uncertainty as to the vortex-noise level, indications
are that the propeller configuration chosen was more effec-
tive than necessary for the test airplane because of the
relatively high aerodynamic-noise level.
The calculated sound-pressure level for the two-blade propeller has also been included in table I. It should be noted that this calculated value is about 8 decibels higher than the level for the complete unmodified airplane. This fact indicates that, although the propeller-noise theory for static conditions seems to be satisfactory, the theory for propellers in flight seems to yield rather conservative values for those cases, at least, in which rotational noise predominates. Also, since the sound-pressure level of the complete modified airplane was 2 decibels lower than the possible maximum level for the five-blade propeller, the uncertainty regarding the vortex-noise level (+10 db) can perhaps be slightly reduced.

Finally, the 20-decibel difference between the sound-pressure levels of the two airplanes as shown in table I represents a reduction in sound energy of 99 percent and can be, according to reference 10, likened to a reduction from a noise slightly louder than "very heavy street traffic" to a noise quieter than an "average automobile."

Performance.—Since the primary concern has been with the noise problem, little attention has been given to the relative performance of the two airplanes. It appears sufficient to show the calculated efficiencies of the two propellers at top speed and take-off speed when driven by engines of the same rated power output. Also given, to show the effect on performance of a change in propeller diameter, are the calculated efficiencies of an 85-inch, five-blade propeller. These values, calculated by use of reference 7, are presented in table II.

Inspection of table II leads to the following conclusions:

(a) As far as top speed is concerned there is practically no difference between the three propellers. The large five-blade propeller should produce speeds about 1 to 2 miles per hour faster, and the small five-blade propeller, about 1 to 2 miles per hour slower than the two-blade propeller.

(b) The small five-blade propeller produces approximately 90 percent of the thrust horsepower of the two-blade propeller at take-off. This smaller power output, which is the normal expectation with fixed-pitch, slow-turning, multi-blade propellers, results in reduced take-off and climb performance.

(c) By increasing the diameter of the five-blade propeller to 85 inches, the thrust horsepower at take-off is increased over that of the two-blade propeller. This fact emphasizes the importance of large diameter.
Pilots report that performance of the modified airplane equals or exceeds the performance of the unmodified airplane. Although some of the superiority may be explained by the higher propeller efficiency, most of it is believed to be due to the higher power output of the geared engine. (See section entitled "Engine.")

CONCLUDING REMARKS

It has been demonstrated that a conventional airplane, representative of personal airplanes in the 150 to 200 horsepower class, may be made quiet by application of known principles of sound reduction.

It is possible that the airplane as demonstrated was more quiet than necessary. The determination of acceptable noise levels is an important phase of future research relating to airplane noise.
