ABSTRACT

Carbons derived from the phase separation of polyacrylonitrile/solvent mixtures were investigated as lithium intercalation anodes for rechargeable lithium-ion batteries. The carbon electrodes have a bulk density of 0.35-0.5 g/cm³, relatively low surface areas (< 10 m²/g), and micron-size cells. Pyrolysis temperature influences the reversible lithium intercalation and the irreversible capacity (associated with the formation of the passivating layer). Carbon electrodes pyrolyzed at 600°C have first-cycle capacity as high as 550 mAh/g as well as large irreversible capacity, 440 mAh/g. Electrodes prepared at 1050°C have reversible capacities around 270 mAh/g with relatively lower capacity losses (120 mAh/g). Doping the organic precursors with phosphoric acid, prior to pyrolysis at 1050°C, leads to carbon electrodes with reversible capacities as high as 450 mAh/g. The capacity of doped carbon increased with increasing phosphorus concentration in the samples. The doped carbon anodes exhibited good cycleability and excellent coulombic efficiency. The electrochemical performance is related to morphology, chemical composition, and local structural order.

INTRODUCTION

A variety of carbonaceous materials (petroleum cokes, carbon blacks, carbon fibers, graphites, etc.) have been investigated as lithium intercalation anodes for lithium-ion or rocking-chair rechargeable cells [1, 2, 3]. Many of these types of materials have capacity below the theoretical value of 372 mAh/g which corresponds to 1 mole of lithium per 6 moles of carbon (LiC_6). Recently, several types of carbons prepared from polymeric precursors at temperatures below 1000°C were shown to have capacities significantly higher than LiC_6 . Carbon electrodes obtained from carbonized petroleum pitches [4, 5, 6], polyparaphenylene [7], epoxy resin [5], phenolic resin [8] had capacities as large as 1000 mAh/g. Dahn and co-workers [4, 5] relate the high capacity of these materials to the residual hydrogen content in the carbons. The capacities of carbons doped with phosphorus were also demonstrated to exceed LiC_6 . Omaru and co-workers [9, 10] have shown that the presence of phosphorus in their polyfurfuryl alcohol-based carbons enhanced the electrode capacity by as much as 30% (to 450 mAh/g). Work in our laboratory with various types of phosphorus-doped commercial cokes and polyacrylonitrile-derived carbons also showed increased capacities [11, 12, 13]. In this paper, we discuss recent results on both the effect of pyrolysis temperature and the influence of a phosphorus additive on the ability of polyacrylonitrile-derived carbons to intercalate lithium. This work is part of a continuing effort directed at developing an understanding of how electrode morphology, chemical composition and local structural order affect electrochemical performance [11, 12, 13].

EXPERIMENTAL

Porous carbon electrodes were prepared as follows. Polyacrylonitrile (PAN Type A; Dupont) was dissolved in a 97:3 mixture of dimethylsulfoxide/water at elevated temperature in a closed vessel. This slightly yellow solution was then poured over a piece of carbon paper (grade 50; Lydall Corp) lying on a copper plate. A pre-heated glass plate was used to cover the carbon paper and uniformly spread the PAN solution. The copper plate was then placed in contact with an ethanol slush bath at -80 °C to induce phase separation and freeze the solvent mixture. The frozen PAN/carbon paper composite was then placed in methanol and allowed to warm to room temperature. After several solvent exchanges with fresh methanol, the specimens were dried in a circulating oven at 50-85°C. In phosphorus doping experiments, the composite was soaked in a phosphoric acid/methanol solution prior to drying. All specimens were then pyrolyzed in a flowing nitrogen atmosphere for 4 hours at a final temperature of 600-1050 °C using a ramp cycle of ~1°C/min. The presence of the Lydall carbon paper prevented the large amounts of macroscopic shrinkage normally associated with the pyrolysis of PAN foams [14].

The electrochemical experiments were carried out in 15 ml, three-electrode cylindrical cells in which the electrodes and separators were positioned horizontally and stacked vertically. The geometric surface area of the working electrode was 1.12 cm². Lithium foils (Cyprus Foote Mineral) were used as the counter and reference electrodes. Whatman fiberglass filters (934-AH) were used as separators between the working and counter electrodes. The electrolyte was 0.05 M LiAsF₆ (FMC Corp) and 0.45 M lithium trifluoromethanesulfonimide, LiN(CF₃SO₂)₂, (tradename HQ115, 3M Corp) in propylene carbonate (Grant Chemical). The cells were assembled and tested at 16 ± 2°C in a dry argon-atmosphere glove box (< 10 ppm water). Charge/discharge studies were performed using a 64-channel Maccor battery tester. The cell was charged at a constant-current rate corresponding to 1 mole of lithium per 6 moles of carbon in 24 hours (C/24) to a cut-off voltage of 0.005V (Li⁺/Li) and held at this potential for 4 hours. It was then discharged at the same rate to 1.5 V and held there for another 4 hours. This procedure was used to assure complete lithium intercalation/deintercalation. After 4 cycles, the rate was increased to C/8 (i.e., 1 mole of Li per 6 moles of carbon in 8 hours) for further cycle life study.

XPS spectra between 0 and 700 eV were taken using a Kratos X-ray photoelectron spectrometer at a scan speed of 1 eV/sec. Spectra near C, O, and P peaks were obtained using a slower scan speed of 0.167 eV/sec. The step size for all scans was 1 eV/step. The quantitative analysis of the XPS spectrum was done [15] to determine the phosphorus concentration. SEM observations were performed using a Hitachi S570 Scanning Electron Microscope.

RESULTS AND DISCUSSION

The porous carbon electrodes selected for use as lithium intercalation electrodes have bulk density between 0.35 to 0.5 g/cc and low BET surface areas, typically less than 10 m²/g. The low surface areas minimize the first cycle irreversible capacity loss associated with the formation of a passivating film at the carbon/electrolyte interface. SEM observations (Figure 1) show that the carbon/fiber composite consists of interwoven sheets (1-5 μm-thick) of pyrolyzed PAN and carbon fibers. The PAN structure is relatively non-porous while the fibrous matrix provides porous structure (voids) on the order of several microns.

The potential-capacity profiles for the intercalation and de-intercalation of Li in carbonized PAN anodes prepared at various pyrolysis temperatures are presented in Figure 2. Lithium intercalation occurs over a broad range of potentials. Deintercalation from the low-temperature samples (< 900°C) takes place with a steeper slope (compared to the intercalation profile) and has a near linear profile between 0 to 1.5V. The total discharge capacity for these materials decreases with increasing pyrolysis temperature as can be seen from the figure. The PAN-derived carbons prepared at 600°C (designated as PAN600) has capacity exceeding 550

Figure 1. Scanning electron micrograph of a phosphorus-doped PAN carbon

mAh/g while that for carbons pyrolyzed at 1050°C (PAN1050) is 270 mAh/g. The irreversible capacity loss during the first cycle is the difference between the charge capacity and the discharge capacity. This value is 450 mAh/g for PAN600. The capacity loss decreases with increasing pyrolysis temperature. For samples prepared at 1050°C, the capacity loss is 120 mAh/g.

The work of Dahn *et al.* and others [3-8] provides motivation to investigate the combined effect of low temperature pyrolysis and phosphorus doping. The effect of phosphorus doping on the performance of carbonized PAN materials prepared at 1050°C was discussed earlier [13] and is reviewed in Figure 3. The potential for de-intercalation, at a given capacity, is lower for the phosphorus-doped carbon and will provide lithium-ion cells with a higher average cell voltage. A comparison of the profiles of undoped versus doped carbonized PAN prepared at 600°C is included in Figure 3. The discharge/charge curves look similar. They have first-cycle discharge capacity around 550 mAh/g. The irreversible capacities for these materials are significant, 380 mAh/g.

The effect of H_3PO_4 treatment on phosphorus content was investigated by X-ray photoelectron spectroscopy. Figure 4 shows a characteristic XPS spectrum of a phosphorus doped PAN-derived carbon. Comparison of the relative peak areas for phosphorus and carbon in the doped samples shows that the effective phosphorus content increases with H_3PO_4 concentration in the doping solution. Data from the area ratios of $\text{P}_{2s}/\text{C}_{1s}$ and $\text{P}_{2p}/\text{C}_{1s}$ show the same trend.

Figure 4. Representative XPS spectrum of PAN-based carbon doped with 3.26 at.% phosphorus

The variation in the lithium-intercalation capacity with the phosphorus content is shown in Figure 5. The reversible capacity of doped carbon anodes increases with increasing phosphorus concentration. The first-cycle capacity loss associated with passivated film formation decreases with increasing phosphorus content. Electrodes containing > 2 atomic% phosphorus have reversible capacities in the range of 450 mAh/g with relatively low capacity losses (< 110 mAh/g). The undoped and doped PAN-derived carbon anodes prepared at 1050°C have been shown [11, 13] to exhibit excellent cycle-life performance with coulombic efficiency greater than 99%. These electrodes have been cycled for over 100 cycles in our laboratory with less than 10% drop in reversible capacity. Despite the enhanced capacities obtained with low-temperature carbons, these capacities drop by as much as 30% in subsequent cycles. This phenomenon has been discussed earlier [5].

The presence of phosphorous in the samples treated at 600°C did not appear to have any advantageous effect on the carbon electrochemical performance. The presence of hydrogen or

related effects may dominate the electrochemical behavior of these low temperature materials as suggested by Dahn and co-workers [4, 5]. Additional experiments are being carried out to investigate this effect. Since most hydrogen is eliminated at temperatures above 1000°C, the enhanced effect of phosphorous doping for samples prepared at 1050°C is clear. The physical and chemical nature of phosphorus, however, is not well understood. Further work is needed to delineate the role of phosphorus in lithium intercalation.

ACKNOWLEDGMENT

The authors would like to thank Professor R. S. Williams (UCLA) for his assistance with the acquisition and interpretation of the XPS data. This work was performed under the auspices of the US Department of Energy by Lawrence Livermore National Laboratory under contract # W-7405-ENG-48, with financial support from the Office of Basic Energy Sciences - Division of Advanced Energy Projects and Division of Chemical Sciences.
