ABSTRACT

As part of the U.S. Department of Energy's Superconductivity Technology Program, Argonne National Laboratory and Babcock & Wilcox are developing high-temperature superconductor (HTS) current leads for application to electric utility superconducting magnetic energy storage systems. A 16,000-A HTS lead has been designed and is being constructed. An evaluation program for component performance was conducted to confirm performance predictions and/or to qualify the design features for construction. Performance of the current lead assemblies will be evaluated in a test program that includes assembly procedures, tooling, and quality assurance; thermal and electrical performance; and flow and mechanical characteristics. Results of the evaluations to date are presented.

INTRODUCTION

A superconducting magnetic energy storage (SMES) system stores electrical energy to provide power during voltage sags and momentary power losses. SMES devices store electric energy as a circulating current in a magnetic coil.

High-temperature superconductor (HTS) current leads are particularly advantageous for SMES devices because they have the potential to reduce coolant refrigeration requirements to values significantly below the best values achievable with conventional leads.

As part of the U.S. Department of Energy's Superconductivity Technology Program, Argonne National Laboratory is developing, with industry, HTS current leads suitable for application to SMES systems.

MID-SIZED SMES APPLICATION

Babcock & Wilcox is engaged in a project to design, build, and demonstrate a mid-sized SMES system, which has been sized in response to the requirements of Anchorage (Alaska) Municipal Light and Power. The 0.5-MWh energy-capacity system, with a discharge power of 30 MW, is a basic unit that could be grouped with other modules at a utility site to meet much larger energy storage needs.

Performance Specifications

Major elements of the system's performance are given in Table 1.¹

General Arrangement

The general arrangement of the current lead is shown in Fig. 1.

Upper-Stage Current Lead

Gas-cooled leads (GCLs) are designed to efficiently transmit current from 300 K to the upper-stage-to-middle-stage transition that operates at ≈ 60 K. Helium gas at 42 K, supplied by a refrigerator, removes the resistive and conductive heat from the GCL itself. The GCL is an adaptation of a vendor-manufactured vapor-cooled lead with a cross section and wetted perimeter based on a standard vapor-cooled design optimized for minimum lower-end heat flow.

Upper-Stage-to-Middle-Stage Transition

Electrical and structural connection to the upper stage is by a large, fine-pitch screw thread. The mating threaded sections are copper and are plated with nickel and gold to improve electrical and thermal conductance across the joint. The male thread is tinned with indium.

Table 1. Performance requirements of HTS current leads.

Parameter	Design value
I_{op} , V_{max} , B_{max}	16 kA, 5 kV, SMES + self
Dimensions	0.1 m diam. x 1 m length
HTS temperature	$T_{warm} < 60$ K, $T_{cold} = 5$ K
Heat leakage @ 5 K	< 15 W/lead
300-60 K cooling	Helium gas
60-5 K cooling	Conduction

Fig. 1. General arrangement of current lead

Current flow through the transition can follow two paths. During superconducting operation, all current flows through the female portion of the threaded connection to a circular array of current buses. To accommodate nonuniform contact resistance to the HTS elements, the buses are made of copper and their geometry, area, and length are selected to control the current-sharing among the HTS elements. Bus resistance is designed to be five or more times that of the sum of the other resistances in the current path of the conductor element. During an upset condition corresponding to the HTS elements being in the normal state, a fraction of the current flows through the female portion of the threaded connection to the middle-stage safety lead, while the remaining fraction flows through the conductor element's Ag-Au sheath. The amount of current flowing through the safety lead will depend on the magnitude of the disturbance, which controls the amount of HTS that has become a normal conductor.

Helium gas at 42 K with a mass flow rate of 2.5 g/s is injected at the lower end of the transition. The gas absorbs the ohmic heating of the normal metal components and electrical connections and then enters the upper stage to be cooled.

Middle-Stage Current Lead

The axial cross section of the middle stage is as shown in Fig. 2. The middle stage incorporates 18 parallel HTS elements configured in a cylindrical array. The conductor elements are supported by an internal safety lead and are connected at their ends to current collectors. Most of the middle stage is cooled by conduction from its 5-K end.

The major features of the selected conductor element are PIT tape with a Bi-2223 multifilamentary core in an Ag + 3 at.% Au sheath, composite conductor of stacked PIT tapes sintered together, critical current of >1100 A @ 60 K in an applied magnetic field, 4 K-heat load of ≤ 0.4 W/element, irreversible strain limit of $\geq 0.1\%$, thermal cycling results in $<4\%$ predicted degradation in critical current, size = $0.48 \times 1.07 \times 54$ cm, and end caps of unalloyed silver.

The safety lead is the core of the middle-stage assembly, which provides an alternate current path and, more importantly, additional thermal mass in the event of HTS element quench. The current path is through a 304 stainless steel tube that is slotted in order to guide and mechanically support the conductor elements. The external surface is nickel- and gold-plated. The conductor elements are fixed axially at their warm ends, strain-relieved at their cold ends, and soldered into the slots of the stainless steel cylinder.

The safety lead is designed to limit the temperature of the HTS to <400 K during a quench and has a conductive heat leak <2 W to 5 K. In the event of catastrophic failure of

Fig. 2. Axial cross section of middle-stage current lead

the HTS leads, the burnout time of the safety lead is >100 s so that current in the SMES magnet can be brought down to safe levels without causing damage to the magnet and its subsystems.

Middle-Stage-to-Lower-Stage Transition

The electrical connection to the lower-stage current junction consists of seven twisted parallel low-temperature superconductor (LTS) strands for each conductor element. The strands are shaped to provide axial strain relief. The 5-K heat load due to connection ohmic heating is 1 W.

Lower Stage

Electrical and structural connection to the middle/lower-stage transition is by a clamp connection. The cross-sectional area and length of the lower-stage copper bus are selected to provide adequate thermal conduction so as to limit the temperature rise of the middle/lower-stage transition to <1 K. Associated overall ohmic heating is 1.23 W.

Thermal Performance

Numerical analysis of the HTS lead with a 60-K intercept shows a reduction in a 5-K equivalent heat load by nearly 50% that of a conventional vapor-cooled lead. This reduction translates to <100 W equivalent heat load at 5 K.

EVALUATIONS OF COMPONENT PERFORMANCE

Upper-Stage-to-Middle Stage Transition

A threaded connection identical to that of the upper-stage-to-middle-stage transition was constructed and employed to measure the electrical resistance of the joint. The joint resistance vs. ambient assembly torque was measured in LN_2 . The measured joint resistance was $0.0023 \mu\Omega$, as compared to the predicted value of $0.0015 \mu\Omega$. The resistance is flat with respect to assembly torque for torques greater than $400 \text{ N}\cdot\text{m}$ ($\approx 300 \text{ ft}\cdot\text{lb}$).

HTS Conductor Elements

The conductor elements were constructed from sintered stacks of multifilamentary composite conductor; geometry is as shown in Fig. 3. The conductor is made by the PIT method, and is in the form of an aspected tape⁵ composed of fine BSCCO-2223 filaments in a silver/gold alloy matrix.

A test matrix was developed to evaluate the performance of the preproduction conductor elements relative to their performance specifications. The test matrix is given in Table 2.

The current used to evaluate the critical current (I_c) of the preproduction conductor elements was pulsed at a low duty cycle to avoid errors caused by effects of current-contact heating. The I_c measurements were made in a facility consisting of a variable-temperature helium cryostat, a superconducting magnet, and a current pulser. The variable-temperature cryostat was configured to contain two samples and was rotatable in the magnet to provide B//b and B//c applied field orientations.

Results of the 60 K I_c tests of Sample L94-345 in transversely applied magnetic fields are shown in Figs. 4 and 5. As expected, the superconductive performance of both bars was most sensitive to magnetic fields applied in the B//c direction.

A thermal cycling test was performed on Sample L94-345 after the testing in magnetic fields had been completed. Critical current in a 45-cm-long segment of the bar at 77 K was measured by the pulsed current technique. Fifty thermal cycles were applied. No significant changes attributable to thermal cycling were found.

An electrical cycling test was performed on Sample L94-346 at 77 K after the testing in magnetic fields had been completed. The initial I_c was found to be 990 A. A total of 600 square-wave current pulses, each of 1000-A amplitude and >300 ms length, was then applied at a low duty cycle. Afterward the I_c was found to be 978 A. The values before and after electrical cycling differed by only 0.6% from their averages.

Fig. 3. HTS conductor element geometry

Table 2. Performance evaluation matrix for preproduction conductor element

Sequence of events, performance evaluation ^a		Sample
1	I_c @ 77 K @ 1 μ V/cm • B = 0 T • B = 0.2 T a • B = 0.1 T b • B = 0.02 T c	L94-345 & L94-346
2	I_c @ 60 K @ 1 μ V/cm (in variable-temperature cryostat) • B = 0 T • B = 0.1 T b • B = 0.02 T c	L94-345 & L94-346
3	I_c vs. 300 K $\rightarrow$ 77 K $\rightarrow$ 300 K for 50 thermal cycles	L94-345
4	I_c vs. 0-1000 A for 600 cycles	L94-346
5	End connection joint resistivities @ 77 K	L94-345
6	Irreversible strain limit @ 77 K	L94-345 & L94-346

^a I_c = critical current

Specific resistivities of metallic contacts to the superconductive cores of American Superconductor Corporation (ASC) tape samples comparable to those used in the composite bars were measured by the lap-joint method.^{6,7} Half-joint resistivities at 77 K ranged from 0.031 to 0.037 $\mu\Omega\cdot\text{cm}^2$. The values consisted of contributions from the silver-gold/superconductor interface, one thickness of the silver-gold sheathing, and 1/2 thickness of a minimal quantity of tin-lead solder used to form the lap joints tested.

Lap-joint resistivity tests were done also with the specially formed silver metal connectors sintered to the tapes in Sample L94-345. The average resistivity of the half-joints at 77 K, including the contribution from the silver connector and its sintered interface to the tapes, was $\approx 1 \mu\Omega\cdot\text{cm}^2$.

Fig. 4. Sample L94-345 voltage drop vs. current @ 60 K @ B/b

Fig. 5. Sample L94-345 voltage drop vs. current @ 60 K @ B/c

Fig. 6. Sample L94-346 variation of retained I_c with axial strain

Fig. 7. Sample L94-345 variation of retained I_c with axial strain

Strain tolerance evaluation of the composite conductor elements was carried out by subjecting the conductor elements to room-temperature tensile strains and then testing for I_c . The specimen was loaded at 300 K to predetermined strains, unloaded, and then measured for I_c in liquid nitrogen at 77 K and 0 T. This process was repeated with increasing strains until sample failure. Sample L94-346 fractured completely at a strain of $\approx 5\%$. Figure 6 shows the variation of retained I_c (%) with axial strain. Figure 7 shows a typical variation of retained I_c (%) with axial strain for Sample L94-345. Greater than 90% I_c was retained at 1.2% strain.

PROTOTYPE CURRENT LEAD ASSEMBLY

A prototype middle-stage assembly was designed and is being constructed. The prototype assembly is being employed to evaluate safety lead brazing, middle-stage machining, conductor element soldering, LTS cable fabrication, and quality control methods.

CURRENT LEAD ASSEMBLY PERFORMANCE EVALUATION

The HTS lead assembly, consisting of the conventional gas-cooled upper stage and the HTS middle stage, will be tested in two phases. The first phase will consist of performance evaluations of the conventional upper stage beginning with initial evaluations of the background heat load of the test cryostat vessel without the upper stage present. Once the background heat load of the test cryostat has been established, the upper stage will be installed and heat load measurements will be performed at both zero current and operating current (16,000 A) plus an additional 10%. Initial helium mass flow rates in the gas-cooled lead will be based on design calculations for the modified lead. A preliminary parametric study of the optimal mass flow and inlet temperature will be performed. These values will be used initially during the second phase of testing.

During the second phase of testing, the HTS portion of the current lead will be attached via a screw connection to the conventional upper stage. Initially, mass flow rates and inlet temperatures to the gas-cooled upper stage will be based on results obtained during the first phase of testing, with adjustments based on the additional calculated heat loads of the HTS portion of the current lead. Testing will begin by ramping the current lead assembly to operating current plus 10% (17,600 A) in zero applied field. The next test will consist of applying an external magnetic field of 0.2 T perpendicular to the axis of the lead assembly and ramping the current lead to 17,600 A. The external magnetic field will be supplied by a split solenoid magnet. Requirements for the external field are that it provide 0.2 T field with an active region of 10 cm in the axial direction, homogeneous to within 20%, in a clear bore > 15 cm. The active region of the field will be positioned at the warm end of the middle stage. A final parametric study to determine the optimal helium mass flow rate and inlet temperature will be performed at both zero current and operating current in an 0.2 T applied field. Once the optimal flow rate and inlet temperature have been established, heat load measurements will be performed at zero current and operating current in an 0.2 T field.

The next tests will be for reliability. The current lead assembly will undergo three separate sets of five thermal cycles and 70 electrical cycles, for a total of 15 thermal cycles and 210 electrical cycles. A thermal cycle is defined as room temperature $\rightarrow$ 100 K $\rightarrow$ room temperature. An electrical cycle is defined as zero current $\rightarrow$ operating current $\rightarrow$ zero current at a ramp rate of 50 A/s increasing and 200 A/s decreasing.

The final tests of this phase will be the safety lead test, which will use two different methods. The first will be at operating current, magnetic field, and optimal inlet gas temperature. Mass flow will initially start at the optimal flow rate and slowly be decreased to a predetermined minimum value. The second method will be at operating current, magnetic field, and optimal flow rate. Inlet gas temperature will initially start at the optimal value and slowly increase toward the critical transition temperature (B_c) of the HTS material.

CONCLUSIONS

- An HTS current lead with a 16-kA operating current has been designed for incorporation into a near-term, 0.5-MWh-capacity SMES system. The helium-gas-cooled upper-stage lead operates between 300 and 60 K. Features include multiple gas flow passages and two-stage heat exchange. The 60-K heat load for both leads is 196 W. The conduction-cooled middle-stage lead operates between 60 and 5 K. Current flow is shared by a cylindrical array of 18 parallel composite conductor elements fabricated from Bi-2223 PIT tapes and having a silver-with-gold alloy sheath. Protection is provided by a stainless steel safety lead installed in parallel to the conductor element array. The 5-K heat load for both leads is 11.2 W.

- Two preproduction conductor elements have been evaluated relative to their performance specifications. Critical current @ 60 K @ $B_{//b}$ and $B_{//c}$ @ 1 μ V/cm was measured in a pulsed-current mode. One sample conductor element was subjected to 50 thermal cycles of 300 K $\rightarrow$ 77 K $\rightarrow$ 300 K, with no significant change in I_c . One sample conductor element was subjected to 600 electrical ramp cycles corresponding to those predicted for the SMES current lead application, with no significant change in I_c . Specific resistivities of metallic

contacts to the superconductive cores of tape samples comparable to those used in the composite bars were measured. Half-joint resistivities at 77 K ranged from 0.031 to 0.37 $\mu\Omega\text{-cm}^2$. Lap-joint resistivity tests were done with the specially formed silver metal connectors sintered to the tapes. The average resistivity of the half-joints at 77 K, including the contribution from the silver connector and its sintered interface to the tapes, was about 1 $\mu\Omega\text{-cm}^2$. Both sample conductor elements were evaluated for their irreversible strain limit. Greater than 90% I_c was retained at 1.2% strain. The sample conductor elements displayed a high degree of structural and electrical integrity, especially because they each were handled many times by various individuals but displayed no discernible performance degradation.

- A prototype middle stage assembly is being constructed for the purpose of evaluating manufacturing methods.
- Current lead assembly performance evaluation program will be carried out. Included will be performance of the upper stage, the integrated lead assembly, and safety and reliability studies.
