SUMMARY

The safety of people throughout the world is seriously threatened by nuclear weapons stockpiles and by weapons-grade plutonium (WGPu) from nuclear weapons dismantled in arms-reduction programs. An intense worldwide effort is now under way to find means of reducing this danger. One of the most attractive solutions would be to use WGPu as fuel in existing light water reactors (LWRs) in the form of mixed oxide (MOX) fuel - i.e., plutonia (PuO_2) mixed with urania (UO_2). Before U.S. reactors could be used for this purpose, their operating licenses would have to be amended.

Numerous technical issues must be resolved before LWR operating licenses can be amended to allow the use of MOX fuel. These issues include the following:

- MOX fuel fabrication process verification
- Whether and how to use burnable poisons to depress MOX fuel initial reactivity, which is higher than that of urania
- The effects of WGPu isotopic composition
- The feasibility of loading MOX fuel with plutonia content up to 7% by weight
- The effects of americium and gallium in WGPu
- Fission gas release from MOX fuel pellets made from WGPu
- Fuel/cladding gap closure
- The effects of power cycling and off-normal events on fuel integrity
- Development of radial distributions of burnup and fission products
- Power spiking near the interfaces of MOX and urania fuel assemblies
- Fuel performance code validation.

The Advanced Test Reactor (ATR) at the Idaho National Engineering Laboratory (INEL) possesses many advantages for performing tests to resolve most

of the issues identified above. It has ample core test volume, high neutron flux, test loops with cooling systems independent of the core coolant, and extensive support facilities. However, to be useful for MOX fuel testing, the ATR must be able to deliver a neutron flux of appropriate intensity and energy distribution to the MOX test specimens while simultaneously accommodating test requirements for other programs.

We have performed calculations to show that the use of hafnium shrouds can produce spectrum adjustments that will bring the flux spectrum in ATR test loops into a good approximation to the spectrum anticipated in a commercial LWR containing MOX fuel while allowing operation of the test fuel assemblies near their optimum values of linear heat generation rate. The ATR would be a nearly ideal test bed for developing data needed to support applications to license LWRs for operation with MOX fuel made from weapons-grade plutonium.

The requirements for planning and implementing a test program in the ATR have been identified.

The facilities at Argonne National Laboratory-West can meet all potential needs for pre- and post-irradiation examination that might arise in a MOX fuel qualification program.

1.0 INTRODUCTION

Nuclear arms reductions by the United States and the states of the former Soviet Union have led to an accumulation of weapons-grade plutonium that could conceivably be obtained by terrorists or renegade nations and reconstituted into nuclear bombs. Because it clearly recognizes this threat, the United States government has established a program to render this material permanently impractical to recover. As discussed at length in Section 2, several alternative disposition methods are currently under consideration in this program.

One of the leading alternatives is to use the weapons-grade plutonium in a mixed oxide (MOX) fuel for existing commercial light water reactors (LWRs). After the MOX fuel completes a standard residence time in an LWR, it will be protected (at least for several decades) by intense radiation from fission products in the spent fuel.

This prospect for the disposition of weapons-grade plutonium as spent MOX fuel offers a major business opportunity for the Advanced Test Reactor (ATR) at the Idaho National Engineering Laboratory (INEL). Before a commercial reactor in the United States could be licensed for operation with MOX fuel, a substantial test program would have to be completed. For much of this testing, the ATR would be very well suited.

The work summarized in this report begins to lay the groundwork for a MOX fuel testing program in the ATR. Section 2 introduces the subject of plutonium disposition in the context of political policy and disposition options. Section 3 summarizes the technical issues that must be resolved by a testing program. Section 4 qualitatively addresses the suitability of the ATR for performing these tests. Section 5 contains analysis results that answer specific questions about the

suitability of the ATR. Section 6 presents a synopsis of the process that must be followed to install and conduct a test in a loop facility of the ATR. Section 7 describes the facilities of Argonne National Laboratory-West (ANL-W) that can support the suggested ATR test program. Section 8 discusses transportation of irradiated specimens from ATR to ANL-W. Section 9 explores future research and development.

Because much of the testing that would be required to qualify MOX fuel for use in LWRs could be done in such LWRs directly, and because the ATR is not the only test reactor that might be used for MOX fuel testing, a good case must be made that the ATR is the best test bed for most, if not all, necessary MOX fuel qualification tests. In large part, the material in Sections 2-4 and 6-7 brings together previously known information to make that case; Section 5 is the principal location of new analytical results specifically obtained in the subject LDRD project.

2.0 BACKGROUND

World stability is seriously threatened by nuclear weapons stockpiles and by weapons-grade plutonium that is now accumulating from nuclear warheads being dismantled in the arms reduction programs agreed upon by the United States and the former Soviet Union. The familiar dangers posed by nuclear weapons in operational military forces will be with us for the foreseeable future; however, the arms reductions programs have introduced a new but reducible hazard. As long as weapons-grade plutonium remains in retired weapons or in a form usable in weapons, it can be obtained by terrorist groups or renegade governments and used for extortion or outright mass murder. Therefore, an intense worldwide effort is now under way to find means of making weapons-grade plutonium unavailable for use in fission weapons. As part of this effort, the National Academy of Sciences has studied a broad range of possible ways to dispose of excess weapons-grade plutonium.

The Academy's report¹ provides valuable insight on the problems associated with weapons-grade plutonium disposition and presents a well-reasoned assessment of the various disposition options. Some of the report's principal insights and conclusions serve as an appropriate foundation for this discussion of the INEL's potential role in weapons-grade plutonium disposition.

Plutonium is bred in nuclear reactors by a sequence of reactions that begins with the absorption of a neutron by a uranium-238 (U-238) nucleus. The form of plutonium that results initially from this absorption is plutonium-239 (Pu-239). Absorption of neutrons in Pu-239 produces Pu-240, and an additional absorption produces Pu-241. Plutonium derived from the transmutation of U-238 in power reactors is called "reactor-grade" plutonium. Weapons-grade plutonium is produced in specially designed reactors in which the U-238 is irradiated for

relatively brief time intervals before it is removed for extraction of plutonium. Because of the much longer residence of uranium fuel in power reactors, considerably more Pu-240 and Pu-241 accumulate from the subsequent neutron absorptions in power reactors than in weapons-production reactors. The lower Pu-240 and Pu-241 content in weapons-grade plutonium is highly desirable for the manufacture of nuclear weapons. However, the Academy is careful to stress the fact that a very dangerous fission weapon can be constructed from reactor-grade plutonium (contrary to widespread belief). Spent fuel taken from commercial power reactors therefore contains plutonium that could be extracted for nuclear weapons production by a straightforward chemical separation process.

The worldwide stock of reactor-grade plutonium in spent fuel is much larger than the stock of excess weapons-grade plutonium from the arms-reduction programs, and it is growing. Therefore, the Academy observes that it would add little to overall world security to provide protection for weapons-grade plutonium more stringent than the protection provided (by the aggregate of institutional and physical barriers) for plutonium in commercial spent fuel. The Academy proposes a "spent-fuel standard" by which to evaluate disposition options: the chosen method for long-term disposition of weapons-grade plutonium should render this material roughly as inaccessible as the plutonium in commercial spent fuel; the additional cost of making weapons-grade plutonium less accessible than this would not provide significant benefits. (However, the Academy asserts that the protection currently provided for plutonium in spent fuel is not adequate in the long run, and that long-term disposition of all plutonium should meet higher standards of protection than presently provided.)

The Academy finds that two of the possible disposition options seem more promising than any of the others, and that a third option, which is still in an early stage of study, may upon further investigation prove competitive with the two leaders. The first leading candidate is the use of plutonium as fuel in existing or

modified reactors, followed eventually by burial in a mined geologic repository in the form of unprocessed spent fuel. The second leading candidate is vitrification in a mixture with high-level radioactive waste from spent fuel, also followed by burial in a repository. The third option is burial in deep boreholes (at depths much greater than that of a mined geologic repository - e.g., 4 km).

It is the first leading option that is of interest here: using plutonium in nuclear reactor fuel, so that the plutonium remaining at the end of the fuel cycle is an integral part of spent reactor fuel. Although this approach would not transform all the plutonium into fission products, the plutonium remaining in the spent fuel would be difficult to extract for the manufacture of fission weapons because of the intense radiation emitted by fission products contained in the spent fuel. (However, the decrease of this radiation over several decades is the principal reason that the Academy urges better protection for spent fuel in the long run.)

In the United States, all the reactors suitable for the first leading option are light water reactors (LWRs) that burn uranium fuel in the form of uranium oxide (UO_2) ceramic pellets. For plutonium disposition, the UO_2 would be mixed with plutonium oxide (PuO_2) to form "mixed-oxide" (MOX) fuel. Most LWRs in the U. S. are believed to be able to operate without modification with a 1/3-core loading of MOX (in which the PuO_2 content is as high as 7% by weight). Three operating reactors and one unfinished reactor in the U. S. (the Combustion Engineering System-80 models) were designed to operate with a full-core MOX fuel loading. However, none of the U. S. reactors, including the System-80s, are currently licensed to burn any MOX fuel.

The Academy presents a list of major unresolved issues that must be addressed before a program to dispose of weapons-grade plutonium in LWRs can begin in the U. S. Some of the key technical issues on this list will require a reactor testing program for resolution. Resolution of these issues can essentially

be characterized as demonstrating, with sufficient assurance to gain public support and to obtain licensing from the Nuclear Regulatory Commission (NRC), that LWRs can be operated safely with MOX fuel. It is important to realize that an operating reactor must undergo a new licensing review fully as stringent as its initial licensing review before it can receive NRC approval to operate with MOX fuel. The application to license operation with MOX fuel must be amply supported by experimental data. Numerous tests must be performed to obtain these data. In the next section, the issues that can be resolved by test irradiation of MOX fuel are identified and discussed.

3.0 ISSUES TO BE RESOLVED BY MOX FUEL IRRADIATION TESTING

All of the specific requirements for MOX fuel testing can be subsumed into one broad requirement: In each type of reactor selected for plutonium disposition, MOX fuel must be shown to function without compromising the safety of operation. As discussed in Section 2.0, the operating license of a selected reactor must be amended by the NRC before the reactor can be operated with MOX fuel. To receive licensing approval for use in a commercial reactor, MOX fuel rods must be shown capable of withstanding a specified level of burnup (expected to be approximately 35 GWd per metric ton of heavy metal (MTHM)) without losing structural integrity or releasing fission product gases through the cladding. This capability must be demonstrated by a test irradiation program. After irradiation, fuel samples will be subjected to various kinds of physical examination, including visual inspection, ceramography, electron microscopy, and chemical analysis.

Also, before a commercial reactor can be licensed to operate with a partial core loading of MOX fuel, the compatibility of MOX fuel assemblies and urania (uranium oxide ceramic) fuel assemblies must be demonstrated. Incompatibility can potentially arise from the different neutronic properties of MOX and urania, as explained below. Although MOX fuels have been used extensively for partial core loading in Europe, where plutonium bred from uranium in LWRs is recycled into new fuel assemblies, the European MOX fuel contains reactor-grade plutonium, and therefore it has an isotopic composition different from that of MOX fuel made from weapons-grade material. Furthermore, the plutonia (plutonium oxide ceramic) content of the European MOX fuel is lower - only about 4% by weight. Therefore, MOX fuel assemblies made from weapons-grade plutonium, and containing as much as 7% plutonia, cannot be shown to perform acceptably or to be compatible with urania fuel assemblies solely on the basis of the European experience.

It is recognized by reactor vendors^{2,3} that experimental irradiations of special MOX fuel assemblies, called "Lead Test Assemblies" (LTAs), must take place in commercial reactors of a given type before such reactors can be licensed to use MOX fuel in a significant portion of their cores. Because only a very small portion of the core would be occupied by the LTAs, these experiments could be completed without significantly perturbing the core neutronic or thermohydraulic behavior; hence, these experiments could be performed under a special waiver of normal licensing requirements. Even for an LTA irradiation program, the safeguards concern of using weapons-grade plutonium in commercial reactors must be addressed.

However, even before the irradiation of LTAs in commercial reactors, a great deal of useful testing could be done in a test reactor such as the ATR. In subsequent paragraphs, specific issues are discussed that must be resolved before a commercial reactor can be licensed to operate with MOX fuel. Many of these issues can be resolved more economically in a test reactor than by using LTAs in a commercial reactor. Other issues could not be resolved at all in a commercial reactor. Table 1 lists the issues and indicates whether they could be tested in the ATR and in a commercial reactor. The assessment of the suitability of the ATR and commercial reactors for testing the issues is discussed specifically in Section 4.

Table 1. Issues and appropriate test facility for MOX fuel qualification.

Issue	Commercial Reactor	Test Reactor
MOX fuel fabrication process verification	Yes	Yes
Burnable poisons	Partially	Yes
Effect of low Pu-240 content	Yes	Yes
Effect of high plutonium content	Yes	Yes
Americium and gallium content	Yes	Yes
Fission gas release	Yes	Yes
Fuel/cladding gap closure	Yes	Yes
Effects of power cycles on fuel integrity	No	Yes
Off-normal events	No	Yes
Radial distribution of burnup and fission products	Partially	Yes
Thermohydraulic behavior	No	Yes
Power spiking	Yes	No
Code validation	Yes	Yes

The full test program for MOX fuel, including the test-reactor and LTA phases, should address the following issues. Some of the issues are interrelated.

3.1 MOX Fuel Fabrication Process Verification

Fuel performance may be expected to depend significantly on the details of the fuel fabrication process. The plutonia may be produced by the oxidation of plutonium metal and calcination of the oxide. The particle size distribution and the effective surface area of the resulting PuO_2 powder will not be controlled during this oxidation process; these properties will have to be altered by milling to optimize the sinterability of the urania-plutonia powder mixture and the plutonium homogeneity in the sintered pellets. Pre- and post-irradiation examination of MOX fuel pellets can help correlate the performance parameters with features that

depend on the fabrication process. Pre-irradiation examination is necessary to ensure that the pellets are fabricated as intended. Post-irradiation examination is required to determine how performance changes as the as-fabricated features vary. Physical characteristics that depend on the fabrication process and affect fuel performance include fuel homogeneity, porosity, density, stability, stoichiometry, plutonia content, sintering schedules and temperatures, grain size, and others. It is expected that an iterative process will be needed as measured performance parameters guide the selection of process specifications to achieve optimum performance. ATR testing can be used to help select and qualify the fuel rod manufacturing process.

Specific kinds of post-irradiation examinations that will be required are discussed in Section 7.

3.2 Burnable Poisons

The thermal neutron fission cross sections of Pu-239 and Pu-241 are higher than that of U-235. Also, the average number of neutrons released in a fission reaction is higher for plutonium fission than for uranium fission. Therefore, until some of the plutonium initially in the MOX fuel pellets is consumed, the thermal neutron flux in the MOX fuel must be somehow depressed to prevent excessive power density in these pellets. The natural way to achieve this goal is to include burnable poisons in the MOX pellets, either as a mixture in the pellets or as a coating on them (e.g., the Westinghouse IFBA (Integrated Fuel Burnable Absorber) boron coating). U. S. reactor vendors have proposed to use gadolinium³ and erbium⁴ for this purpose. European reactor vendors do not use erbium or gadolinium with MOX fuel, so little if any experience exists for judging their use in this application. The selected burnable poison technique must be demonstrated to

work as intended, and the material compatibility of the burnable absorber with the MOX fuel pellet and cladding must be determined.

3.3 Effect of Low Pu-240 Content

Reactor-grade plutonium, which accumulates in a light-water reactor by the transmutation of U-238 in a thermal neutron spectrum, contains a higher isotopic percentage of Pu-240 than does weapons-grade plutonium. The thermal fission cross section of Pu-240 is minuscule and its thermal capture cross section is high; thus, the presence of this isotope makes reactor-grade plutonium significantly less reactive than weapons-grade plutonium. All of the European experience with MOX fuel in commercial reactors has been based on reactor-grade plutonium. Therefore, the differences in reactor behavior and in post-irradiation fuel morphology caused by the differing Pu-240 content in reactor-grade and weapons-grade MOX must be understood before the European experience can be transferred to the weapons-grade plutonium disposal program.

3.4 Effect of High Plutonium Content

In the MOX-fueled European commercial reactors, the maximum plutonia content of the MOX fuel pellets (PuO_2 as a fraction of the total mixed oxide) has been around 4% by weight. It is expected that MOX fuel pellets developed for plutonium disposal will have up to 7% plutonia. The effects of the increased plutonium content must be understood. It is unlikely that LTAs with plutonia contents representative of the full MOX core can be designed and approved for operation in existing commercial plants. To demonstrate the in-reactor behavior of MOX fuel with the full expected plutonia content, and to achieve bounding power histories, short rods should be irradiated in the ATR.

3.5 Americium and Gallium Content

The weapons-grade plutonium removed from warheads contains significant quantities of americium, which is a strong gamma-ray emitter. Americium tends to be released during the sintering process by which the MOX pellets will be made. This release creates a contamination hazard for workers. In the development of the pellet fabrication process, an assessment will be made of the need to remove americium and of the difficulty of doing so. Weapons-grade plutonium also contains about 1% gallium by weight to enhance the stability of the weapon pit. The gallium may be retained in the MOX fuel or removed, depending on the pit-metal-to-oxide conversion process. If gallium is not removed during oxide conversion, gallium oxide could affect the homogeneity or the hot-pressing characteristics of the plutonium oxide powder.⁵

If americium and gallium are removed, then a significant waste-disposal problem will be created.

3.6 Fission Gas Release

As fission burnup proceeds, gaseous fission products tend to migrate to grain boundaries in the pellet, then to the pellet surface, and finally on into the gap between the pellet and cladding. Buildup of fission gas in the gap causes an increase in the pressure inside the cladding tube. In order to be sure of the integrity of the cladding, this pressure must be known quantitatively. Some of the European experience suggests that the fission gas pressure may be greater for MOX fuel than for uranium fuel.⁶ The ATR can be used to confirm thermal-mechanical parameters such as fission gas release, swelling, and pore distribution.

3.7 Fuel/Cladding Gap Closure

As materials undergo irradiation, they change dimensionally by such processes as creep and swelling. Therefore, the gap between the fuel pellet surface and the cladding inner surface will change over time. Clearly, the course of this change will depend on the cladding material as well as on the pellet material. A Westinghouse study raises a concern that excessive departure from nucleate boiling can occur if the gap closes because the pellet and cladding swell at different rates.² Evidently, this concern is based on the possibility that sudden gap closure would allow the stored-up heat in the pellet to flow out through the cladding rapidly and dry out the cladding outer surface. This dryout could lead to cladding failure.

3.8 Effects of Power Cycles on Fuel Integrity

In commercial reactors, fuel changeout is done in stages. Only about a third of the fuel in a commercial reactor core is removed during each refueling outage; the rest is relocated in the core to allow its remaining fissile material to be used to its potential. Thus, MOX fuel assemblies would normally remain in the reactor through two shutdowns. Also, the operating power level is subject to some fluctuation, even though nuclear power plants are ordinarily operated as base-load facilities. Because of these changing power levels, the fuel pellets heat and cool repeatedly. Since the thermal conductivities of ceramic materials such as plutonia are low, these materials can develop very high thermal stresses during heating and cooling. The consequences of fluctuating pellet temperatures for pellet structural integrity should be investigated.

3.9 Off-Normal Events

Operating nuclear power plants are licensed only after extensive analysis of their response to a variety of hypothetical "off-normal events" - i.e., events that are thought to have potential to cause accidents. Examples of such events that could be simulated in the ATR are power ramps, overpower excursions, and coolant flow coastdowns. It must be shown that the change in fuel form from urania to MOX does not threaten the favorable outcome of such off-normal event scenarios. Many off-normal events can be simulated in a test reactor by changing the thermohydraulic conditions and the operating power in the test location. The ATR can be used to generate data for off-normal conditions as required by the NRC.

3.10 Radial Distribution of Burnup and Fission Products

In order to validate fuel performance codes, which predict in detail the radial distribution of burnup and fission product accumulation, the fuel development team must determine the actual radial dependency of post-irradiation composition by destructive examination of irradiated pellets.

3.11 Thermohydraulic Behavior

Heat transfer characteristics of MOX fuel rods will be different from those of urania fuel rods operating in the same neutronic and thermohydraulic environment. This will be especially true if stainless steel is chosen as the cladding material for MOX fuel. MOX fuel must be shown to release fission heat into the coolant without exceeding temperature limits or departing from safe, stable heat transfer regimes.

3.12 Power Spiking

Because MOX fuel has higher average fission cross sections and fission neutron yields than does urania fuel, the outermost fuel rods in a MOX fuel assembly would tend to produce a higher power density than the adjacent urania fuel assemblies if the fissile content were the same in the MOX and urania regions. Then the higher neutron absorption in these outer fuel rods would tend to shield the inner rods in the MOX assembly, leading to lower power density in the inner region. To prevent this "power spiking" in the outer MOX rods, the fissile content in these outer rods should be reduced. The very outermost layer of fuel rods in the assembly would have a plutonia content as low as about 2%, and the plutonia content of rods located deeper in the assembly would be graduated to a maximum of about 7%. Testing is needed to verify the level of power peaking and its impact on the performance of the fuel.

3.13 Code Validation

Sophisticated computer codes are used in every stage of nuclear power plant fuel cycle planning and operation. These codes must be benchmarked for the actual conditions encountered in each reactor. In preparing to load a commercial reactor with MOX fuel made from weapons-grade plutonium, a great deal of preliminary benchmarking must be done. Fuel performance codes, in particular, can be benchmarked by data obtained from testing in the ATR.

4.0 THE POTENTIAL ROLE OF THE ATR IN MOX FUEL TESTING

To be suitable for effective testing of nuclear fuel, a test reactor should possess several desirable qualities. It should have large test space capacity in and around the core, high neutron flux, a wide latitude of experiment parameter control, extensive instrumentation facilities, and a regular operating schedule. It should be supported by a wide range of facilities for handling and examining irradiated test specimens, and it should be staffed and supported by personnel with a broad range of technical expertise for experiment planning and analysis. Because the ATR was designed specifically for fuel testing, and because it has performed this mission for nearly thirty years, it possesses all of these qualities to a greater extent than any other test reactor in the world. In the following three subsections, the capabilities of the ATR for fuel testing are described in detail. The fourth subsection discusses the ability of the ATR to address the issues identified in Section 3.

4.1 In-Pile Tubes and Flux Traps

As shown in Figure 1, the ATR has an unusual core shaped like a four-leaf clover. In the center of each leaf, between each adjacent pair of leaves, and in the center of the core are located test facilities called flux traps.

The name "flux traps" arises from the effects of variations in the neutron energy spectrum in and around these facilities. Because the test spaces are close to fuel "lobes" that nearly surround them, the neutron current coming into the test regions includes a large contingent of high-energy fission neutrons. However, the region in and immediately around the test space contains cooling water that moderates the neutrons. In fact, there is normally so much water in this region that the neutrons become "overmoderated"; i.e., the spectrum is highly

Figure 1. Cross-sectional diagram of the ATR.

thermalized and reductions in the water density cause positive net feedback reactivity because the loss of moderation decreases the reactivity less than the loss of absorption increases it. The amount of water around the test space is enough to absorb a large fraction of the thermal neutrons departing the test region; that is, the thermal neutrons are "trapped" in the test space and cannot escape.

As it is presently configured, the ATR includes four flux traps that are cooled by water from the primary core cooling system (PCS). The remaining five flux traps are cooled by their own independent cooling systems, which may be operated at pressures and inlet temperatures different from those of the PCS. These independent cooling systems are called pressurized water "loops" or In-Pile Tubes (IPTs). They can be operated in a pressure range from 2.069 MPa to 23.44 MPa (300 psig to 3400 psig), a temperature range from 366.5 K to 633.2 K (200°F to 680°F), and a flow rate range from 1.26 L/s to 5.05 L/s (20 gpm to 80 gpm). They can accept heat generation rates up to 2000 kW from test fuel assemblies. In addition, each loop can be operated with a specific desired water chemistry different from that of the reactor coolant water.

Four of these loop facilities are currently available (the other is committed for a testing program of the U. S. Navy); all of them are relatively large spaces, but one (the Large In-Pile Tube) is especially large, allowing a maximum sample diameter of 13.65 cm. Since these loops are closely surrounded by fuel assemblies, they offer high neutron flux levels (about 10^{15} neutrons/cm²-s of total flux).

4.2 Drop-in Capsules

Located within the ATR core-reflector tank are 62 irradiation test "holes" in addition to the flux traps. These cylindrical cavities, extending the full length of the core, are cooled by water from the PCS. Test specimens irradiated in the test holes are usually contained in sealed capsules, although bare specimens are sometimes inserted into the holes. Figure 1 illustrates the locations of the various types of test holes, and Table 2 shows the diameters and the fast and thermal unperturbed neutron fluxes (i.e., the neutron flux levels that would exist in the absence of the test specimen and related hardware) attainable in each of the holes. (The data in Table 2 are taken from Reference 7.) Figure 2 shows a typical drop-in capsule in the ATR.

Table 2. Approximate peak flux values for various ATR capsule positions at maximum allowable power (250 MW).

Position	Diameter cm (in.)	Thermal Flux ($\text{cm}^{-2}\text{s}^{-1}$) (2200 m/s)	Fast Flux ($\text{cm}^{-2}\text{s}^{-1}$) (1 MeV)
B-Holes			
(B-1 thru B-8)	2.223 (0.875)	5.75×10^{14}	1.85×10^{14}
(B-9 thru B-12)	3.810 (1.500)	2.48×10^{14}	0.37×10^{14}
H-Holes			
(H-1 thru H-16)	1.588 (0.625)	4.28×10^{14}	3.83×10^{14}
A-Holes			
(A-1 thru A-8)	1.588 (0.625)	4.28×10^{14}	3.83×10^{14}
(A-9 thru A-12)	1.588 (0.625)	4.64×10^{14}	5.25×10^{14}
I-Holes			
Large (I-1, I-6, I-11, I-16)	12.70 (5.000)	3.89×10^{13}	3.05×10^{12}
Medium (I-2, -3, -4, -5, -7, -8, -9, -10, -12, -13, -14, -15, -17, -18, -19, -20)	8.255 (3.250)	7.71×10^{13}	3.01×10^{12}
Small (I-21, -22, -23, -24)	3.810 (1.500)	1.89×10^{14}	7.00×10^{12}

In addition to the test spaces enclosed in the core-reflector tank, there are numerous test holes located in two capsule irradiation tanks that hang on the outside of the core-reflector tank. These test holes are contained within the pressure vessel, but they receive neutron fluxes and gamma-ray heating rates one to two orders of magnitude lower than those inside the core-reflector tank. There are many more test locations available in the fuel storage grid, but these are only suitable for testing the effects of gamma rays.

Typical Drop-In Capsule

Figure 2. Typical drop-in capsule in the ATR.

4.3 Instrumented Lead Experiments

The ATR IPTs are provided with instruments to monitor coolant flow rates, coolant temperatures, coolant pressures, and sample temperatures. Instruments from which a continuous signal is needed are connected with data processing equipment by electric wiring called "leads." It would probably be feasible to install additional instrumented leads, but it would be necessary to perform analyses to demonstrate that the added hardware would not invalidate the safety margins determined in the Upgraded Final Safety Analysis Report.⁸

The ATR flux traps without IPTs are not currently instrumented. Again, safety analyses would have to be performed to justify the installation of instrumented leads in these flux traps.

Instrumented leads are commonly installed in the capsule test holes. These leads are contained within lead tubes, which are conduits that route the leads from data processing equipment outside the reactor to the experiment capsules. Typical instrumentation would consist of a set of thermocouples to monitor the temperature of test specimens.

4.4 Ability of the ATR to Resolve Specific MOX Fuel Qualification Issues

Since it is a fuel-testing reactor by design, the ATR has the capability to address most of the issues identified in Section 3. The ATR can perform the irradiations needed to confirm the process and product qualifications for fuel fabrication and to generate data for off-normal conditions as required by the Nuclear Regulatory Commission. The ATR test loops are large enough to

accommodate a 5x5 subassembly of partial-length (1.22-m (4-ft.)) pressurized-water-reactor fuel rods. (Rods for boiling-water reactors are larger, so fewer of them could be accommodated in the ATR - for the Advanced BWR, a 4x4 array.) For some of the issues, the ATR is almost ideally suited, while commercial reactors are not suitable at all. Only for one issue - power spiking - is the ATR unsuitable, but no other test reactor would be any better; for that issue, LTA irradiations will be necessary. For the other issues, use of the ATR should avoid a safeguards concern that would arise with the irradiation of MOX LTAs in a commercial reactor.

As discussed in the next section, the ATR can deliver a neutron spectrum in the test loop location that would be very representative of the spectrum a MOX fuel assembly would encounter in a commercial reactor. Commercial reactors with LTAs may not have neutron spectra representative of those in a full MOX or 1/3-MOX core. Beyond this basic requirement, the ATR has outstanding flexibility for performing a MOX fuel test program. Some of the ATR's capabilities could allow testing on an accelerated schedule. The neutron flux level can be kept considerably higher than that in a commercial reactor,⁹ so that the required burnup level can be reached more quickly. Loop flow velocity can be modulated arbitrarily, so that off-normal conditions can be simulated at will. The short duration of the typical ATR cycle (about 40 days) will produce frequent power cycles. The ATR's Powered Axial Locator Mechanism (PALM) test facility can impose even more rapid power fluctuations on the test fuel. Such tests could not be performed in a commercial reactor.

Obviously, it would be highly detrimental to the mission of a commercial reactor to shut it down between scheduled refueling outages to remove LTAs for assessment; therefore, access to the LTAs would be unavailable except during these scheduled shutdown events. Therefore, examination of MOX fuel at shorter intervals would be impractical in a commercial-reactor testing program. Typically, refueling outages occur annually in a commercial reactor. However, the erbium

and gadolinium materials contemplated for use as burnable poisons would be consumed in less than a year in a commercial reactor radiation environment. In the ATR, MOX fuel elements could be removed at much shorter intervals. Some ATR cycles are planned to last only a week or two. Thus, testing in the ATR would allow determination of the time-dependency of the burnable poison content.

Similarly, frequent access to MOX fuel rods in an ATR test program would allow frequent examination of MOX fuel for studying the time-dependency of fission gas release, pellet/cladding gap distance, neutron fluence, and the radial distribution of burnup and fission products.

Issues that could be treated as well in the ATR as in the LTA program include the effect of the Pu-240 level and the behavior of pellets with full expected plutonia content. The issue of whether or not to extract americium before pellet fabrication is independent of where the test irradiations take place. Experience with handling MOX containing americium could be gained in an ATR test program.

Resolving the issue of power spiking is likely to require tests with a full-size MOX fuel assembly located among uranium assemblies. Although a commercial reactor would be required to study this phenomenon, the INEL could support studies of power spiking by performing computer calculations using Monte Carlo techniques.

Even if all the issues could be addressed by the ATR, a test reactor program would not be intended to replace the LTA program, which is an indispensable part of the MOX fuel licensing process. Instead, the test reactor program can provide otherwise unobtainable test data, identify potential fuel performance problems early in the fuel development program, and build an experience base for a successful and less costly LTA program. It can shorten and complement the LTA

program, provide better data for the resolution of many issues, and address some issues for which the LTA program is not suited at all.

The ATR is supported by a wide variety of facilities and experienced personnel for all types of post-irradiation handling and examination. The INEL has a variety of hot cell facilities. Also, the facilities at Argonne National Laboratory-West (ANL-W) are located on the grounds of the INEL; ANL-W has vast experience in handling plutonium (in forms appropriate for the fabrication, use, and recycling of metallic fuel). These facilities at ANL-W are discussed in detail in Section 7.

5.0 FEASIBILITY STUDIES FOR MOX FUEL TESTING IN THE ATR

Some preliminary analyses were performed to resolve fundamental questions about the suitability of the ATR for a MOX fuel testing program. The test results from a MOX fuel testing program must give valid data from which to draw conclusions about MOX fuel performance in a commercial reactor. Also, the presence of MOX fuel test specimens in the ATR must not impair the ability of the reactor to perform simultaneous irradiations in other test locations. Most important, the tests must not jeopardize the operating safety of the ATR. The analyses that have been performed to address these concerns are summarized in this section.

5.1 Neutronics Analyses

Neutronics analyses were performed with the code MCNP,¹⁰ using a full-core input model¹¹ that has been applied for many ATR studies during the past few years.

Figure 3 illustrates the geometric configuration of the model in horizontal section at the midplane.

Figure 4 shows a 21-pin MOX fuel assembly that was put into the model's northeast loop test space. As the model was initially specified, the MOX fuel pellets contained 6.67% plutonia by weight; however, as explained below, the composition was changed for some of the pins in subsequent revisions of the model. The figure shows one of these revised configurations.

The four quadrants of the ATR's clover-shaped core are somewhat independent, and they are usually operated at different power levels. However, there are limits to this independence; typically, the northeast and northwest

Figure 3. MCNP model of the ATR.

BOL Pin Average LHGR (kW/ft) for the 21-pin MOX Array in the North-East Loop (25.6 MW_{th}/lobe)

Figure 4. MOX fuel array in northeast loop in MCNP model of the ATR.

quadrants are each operated at approximately 25 MW (thermal), and the southeast and southwest quadrants are each operated at approximately 35 MW. At the unperturbed neutron flux levels associated with these quadrant powers, the fission rate in MOX fuel specimens would be so great that they would overheat. For MOX targets of the dimensions appropriate to represent fuel assemblies for commercial pressurized water reactors (PWRs), the linear heat generation rate (LHGR) for any pin, averaged over the length of the pin, should not exceed 32.81 kW/m (10 kW/ft) (see Section 5.2 below). For an unshrouded 21-pin array of MOX fuel containing 7% plutonia, this limit on LHGR would require that the quadrant power not exceed 7 MW. Such a low quadrant power would not be possible without severely limiting the total reactor power, so that test programs in the remainder of the reactor could not be conducted in an appropriate neutron flux regime.

However, placing hafnium shrouds around the MOX fuel assembly would shield the MOX fuel so that higher quadrant power could be sustained for a given test-pin LHGR. Table 3 shows the results of MCNP calculations in the ATR northeast loop when the 21-pin MOX fuel assembly is unshrouded and in two cases when it is enclosed by a hafnium shroud 2.032 mm (80 mils) thick. In the second shrouded case, the plutonia content is reduced in the pins at the periphery of the assembly, as shown in the table. Use of the hafnium shroud allows the reactor to be operated in a normal regime of quadrant power. Similar results for a slightly different configuration are displayed in Figure 4. In addition, the hafnium shroud also shields the target from thermal neutrons, producing a neutron energy spectrum in the target that is similar to that in a commercial MOX-fueled LWR.

Table 3. BOL pin average linear heat generation rates for a 21-pin array of weapons-grade MOX fuel rods irradiated in the ATR northeast loop at the given core quadrant power level.

^a ATR core quadrant power containing the northeast loop flux trap.

Results have also been obtained for LHGR in other potential MOX fuel testing locations than a loop facility. Table 4 shows LHGR values for unshrouded tests with weapons-grade MOX fuel in the north quadrant small B-holes, large B-holes, and small I-holes. The regions identified in Tables 4, 5, 6, and 7 are twelve equally spaced axial segments going from the top of the core to the bottom. For example, region B912 is in the B9 position near the bottom of the core. To keep the LHGR values below 32.81 kW/m (10 kW/ft), a hafnium shroud slightly thicker than 1.524 mm (60 mils) is required in the large B-hole, as shown in Table 5. Calculations for shrouded tests have not been performed for the small B-hole or the small I-hole. Tables 6 and 7 show analogous results for reactor-grade (RG) MOX fuel. Figure 1 shows the locations of these facilities.

6.0 / 197	35	8.42 + 20	838	20	2.7

*Constant LHGR over all irradiation cycles

Based on 41-day irradiation cycle + 7-day refuel shutdown

ATR CF = 85%

ATR NE lobe power $\leq 30 \text{ MW}_{\text{th}}$

In order for tests in a test reactor to represent best the ultimate commercial reactor environment, the neutron energy spectrum in the test space should be close to the spectrum the MOX fuel assemblies would encounter in the commercial reactor. Preliminary MCNP calculations¹² indicate that an appropriate amount of hafnium shielding around the test space could produce a spectrum in the ATR that matches the MOX-fuel commercial reactor spectrum very closely. Figure 5 displays the spectra for a hypothetical MOX lattice expected to be typical in a commercial reactor, for a MOX test assembly surrounded by a hafnium shroud 80 mils thick in an ATR loop, and for a UO₂ lattice in a commercial reactor. It is most desirable that the ATR spectrum agree well with the commercial MOX spectrum in the thermal neutron energy range; agreement in the fast neutron energy range is not as important.

Figure 6 shows the spectra for a MOX test assembly in the ATR B-9 location, both unshrouded and with a 60-mil shroud, and for the hypothetical MOX lattice in a commercial reactor. The shroud brings the spectrum in the ATR B-9 location towards the hypothetical commercial MOX spectrum, but some additional

Figure 6. Comparison of normalized flux spectra of WG-MOX fuel pellet and typical lattice.

refinements would evidently be required to produce close agreement in the thermal neutron energy range. Figure 7 shows the spectra for unshrouded tests in several ATR locations, together with the spectrum in the MOX lattice of the hypothetical commercial reactor. Figure 8 shows that the spectral differences between weapons-grade MOX fuel and reactor-grade MOX fuel are negligible.

5.2 Thermohydraulics Analyses

Some simple thermohydraulics calculations have been performed to estimate fuel, cladding, and coolant temperatures in a MOX fuel testing installation in the ATR. These calculations used an analytical model of a pin with cladding in axial turbulent flow, with the heat transfer coefficient on the cladding surface given by the Dittus-Boelter heat transfer correlation. The heat transfer coefficient across the fuel-cladding gap is specified as an input parameter. A computer program was used to perform the repetitive arithmetic calculations required to conduct parametric studies with this analytical model. Because of the flow conditions assumed for these calculations (flow velocities from 5 m/s to 7 m/s), these results are most representative of the hot pin in the 21-pin array in an IPT.

Table 9 shows the maximum temperatures on the pin centerline, on the cladding surface, and at the coolant outlet for two different pin-length-average values of LHGR: 19.69 kW/m and 32.81 kW/m (6 kW/ft and 10 kW/ft). At a pressure of 2.068 MPa (300 psia), a typical operating pressure in the ATR, the saturation temperature of water is 487 K, so the coolant is far from saturation; thus, the simple one-phase heat transfer correlation used in the model is appropriate. The heat transfer coefficient across the fuel-cladding gap was estimated to be 2400 W/m²-K by applying the analytical model to data¹³ for a Combustion Engineering (CE) System 80 PWR and assuming for conservatism that the axial power distribution is a full cosine and that the maximum fuel centerline

Figure 7. Comparison of normalized flux spectra in ATR test positions and typical WG-MOX lattice.

Figure 8. Comparison of normalized flux spectra of RG-MOX and WG-MOX fuel lattices.

temperature is 2800 K (the melting point of UO_2 is approximately 2900 K). The corresponding results for the CE PWR are also presented. It is shown in Table 9 that the maximum fuel centerline temperature in the ATR test specimens is less than that in the CE PWR; even though the peak LHGR is slightly higher in the ATR (for an average LHGR of 32.81 kW/m (10 kW/ft)), the much greater length of the PWR fuel pins and the much higher PWR coolant inlet temperature (574 K, as opposed to 325 K in the ATR) cause higher temperatures in the PWR. Therefore, it can be concluded that the MOX fuel tests can be conducted safely in the ATR at the desired LHGR values.

Table 9. Peak fuel, cladding, and coolant temperatures in MOX fuel pins (T_{f} = fuel centerline temperature, T_{s} = cladding surface temperature, and T_{c} = coolant outlet temperature, K)

Coolant Velocity (m/s)	LHGR (kW/m) 32.81 (ATR, Avg.)			LHGR (kW/m) 19.69 (ATR, Avg.)			LHGR (kW/m) 41 (CE PWR, Peak)		
	T_{f}	T_{s}	T_{c}	T_{f}	T_{s}	T_{c}	T_{f}	T_{s}	T_{c}
4.46							2801	650	630

6.0	2671	387	340	1733	362	334			
7.0	2664	380	338	1729	358	333			

6.0 CONDUCTING A TEST PROGRAM IN ATR LOOP AND CAPSULE FACILITIES

Before a test can be installed in the ATR, it must be shown to be compatible with the design and operational constraints on the reactor. The test hardware must fit geometrically into a test space that can provide the required neutron flux. The materials used in the test must be compatible with the reactor materials. The thermohydraulic environment in the test locations must be suitable for successful completion of the test. The scheduling requirements for the test must fit with the scheduling commitments that have been made for the reactor to conduct other test programs. Most important of all, the test hardware and the test program must not compromise the operational safety of the reactor. These considerations are discussed in more detail below.

6.1 Description of Test Hardware

A complete description of the test-specific hardware must be provided to ATR operations personnel. This description must include drawings of all components, showing dimensions and specifying materials.

6.2 Specification of Requirements for Operating Conditions

ATR operations personnel must be informed of all the constraints on operating conditions that are required to obtain meaningful data from the test program.

Examples of such constraints are given below:

- Reactor power
- Coolant temperature, pressure, and flow rate
- Coolant chemistry requirements

- Neutron flux and fluence
- Requirement for use of Powered Axial Locator Mechanism (PALM)
- Requirement for installation in Standard or Large In-Pile Tube (SIPT or LIPT)
- Specification of all parameters that must be measured or controlled.

The requirements for performing the test will be reviewed against the requirements of the ATR Technical Specifications to ensure that the limits imposed by the Technical Specifications are not violated. This review will be performed by the ATR operations technical staff.

6.3 Scheduling Requirements

A time window should be provided to ATR operations personnel so that the test can be conducted during a time interval when the required test location is available. The detailed test specifications must be provided at least six weeks before the start of the test, in order to allow the test characteristics to be represented in a Core Safety Assurance Package (CSAP).

6.4 Safety Considerations

The CSAP calculations ensure adequate reactivity margins in normal operating conditions. Assurance must also be given that off-normal events do not create conditions that exceed the operating limitations of the reactor. One way to provide this assurance is to show that the consequences of all plausible events are bounded by the consequences of acceptable events that have already been analyzed. The other way to provide the required assurance is to perform the appropriate analyses. Events that must be considered include the following:

- Loss of hafnium shroud from around the MOX fuel rods
- Melting of MOX fuel rods and release of fissile material into the loop coolant
- Reactor coolant and test loop coolant flow coastdown events
- Loss of coolant events
- Events involving loss of temperature control or loss of heat sink.

Also, it will be necessary to determine the margins to critical heat flux (CHF) and flow instability in normal operating conditions. Adequate lead time will have to be provided for analysis of these off-normal events. In general, such analyses can be expected to take several FTE-months. Before these analyses can be performed, the temperature and void coefficients of reactivity will have to be determined.

The Upgraded Final Safety Analysis Report would have to be modified if any events were shown to have consequences not bounded by previous analyses.

7.0 POST-IRRADIATION EXAMINATION CAPABILITIES AT ANL-W

The Hot Fuel Examination Facility (HFEF), at Argonne National Laboratory-West on the INEL, is a large alpha-gamma hot cell facility which was designed to characterize highly irradiated fuel and structural materials by remote handling. The wide range of fuel handling and measurement capabilities at HFEF, coupled with ANL-W's experience in testing and analyzing fuel behavior, make HFEF an ideal facility in which to carry out MOX fuel characterization activities.

The kinds of nondestructive and destructive examinations that will need to be performed on irradiated specimens in a MOX fuel qualification program are discussed below. Then the specific examination capabilities available in HFEF are described.

7.1 Non-Destructive Examinations

Visual Examination

Although gross deviations of the performance of MOX fuel from that of uranium fuel are not expected, MOX fuel rods tested in the MOX qualification program should be visually examined. Photographs should be taken to document the occurrence or absence of any unusual features or obvious cladding degradation observed during the visual examination.

Weight Measurement

Measurements of the weight of a fuel rod can often help in the identification of breached fuel rods that have failed by very small cracks that may not be seen during the visual examination. For this reason, the intact irradiated fuel rods should be weighed.

Cladding Dimensional Measurements

Differences in linear heat generation rates between MOX and uranium fuel rods will influence cladding mechanical behavior. Cladding profilometry measurements should be made to quantify rod length change, rod bowing, cladding ovality, and cladding diameter as functions of axial position, in order to identify and evaluate cladding creepdown, pellet interface ridging, and pellet-cladding mechanical interaction.

Neutron Radiography

Fuel column length change, or axial growth, affects core reactivity and can place axial stresses on the cladding following pellet-cladding contact; conversely, pellet-cladding mechanical interaction can restrain fuel growth. Fuel axial growth should be identified by neutron radiography of the intact irradiated fuel rods. Neutron radiography of the fuel column will also reveal longitudinal fuel cracking patterns.

Gamma Spectroscopy

Axial gamma scanning and spectral analysis are needed to confirm that there is no unexpected migration of fission products or burnable poisons within the fuel rod. Information on interactions between pellets will also be revealed by axial gamma scans. These scans will confirm power and burnup profiles in the fuel rods. Finally, gamma scanning can be used as another means of checking for cladding breach.

7.2 Destructive Examinations

Plenum Gas Pressure and Volume Analysis

It is important to understand fission gas release by MOX fuels in order to quantify the internal pressurization rate in the fuel rods. By puncturing the fuel

rods and collecting the plenum gas into a known volume at a reference temperature, one can determine the quantity of gas released to the plenum. Then a sample of this gas can be analyzed isotopically to determine its chemical makeup. Repressurization of the fuel rod using a known amount of gas will yield the free volume within the rod, allowing the internal pressure of the intact irradiated fuel rod to be inferred.

Microstructural Evaluation

It will be necessary to quantify the chemical and microstructural evolution of the fuel and cladding in order to evaluate the radial migration of fuel constituents, burnable poisons, and fission products, and to determine the microstructure and porosity distributions and the extent and type of pellet-cladding chemical interactions. These goals can be accomplished by sectioning the fuel rods transversely, and possibly longitudinally, and examining the cladding, the fuel, and the fuel-cladding interface by optical and/or electron microscopy. Electron microprobe analysis will yield radial distributions of fuel constituents, burnable poisons, and fission products. During the sectioning process, fuel samples can be taken for analytical chemistry analyses to determine burnup, irradiated fuel density, and retention of fission gas.

7.3 Examination Capabilities in HFEF

HFEF is composed of a shielded main cell, where the characterization work is performed, and a connected shielded air cell that houses aqueous decontamination facilities. The main cell has an inert argon atmosphere (maintained at less than 100 ppm oxygen and water vapor) that protects exposed fuel constituents from air/moisture reactions and suppresses fires. The main cell has 15 work stations, each equipped with its own pair of master-slave manipulators. This cell is 9.1 m (30 ft.) wide, 21.3 m (70 ft.) long, and 7.6 m (25 ft.) high inside. Components up

to 9.1 m tall can be transferred into the cell by a roof bay. Casks up to 45 Mg (50 tons) can be handled. HFEF possesses the following characterization capabilities.

Physical Condition of Irradiated Fuel

HFEF personnel routinely measure and document the general physical condition of irradiated fuel and other materials. At the Vertical Assembling/Dismantling Machine (VAD), engineers record and macro-photograph all unusual features, including corrosion deposits, mechanical damage, warpage, bulges, breach sites, etc. Higher-magnification stereo photographs at precisely-known locations on individual fuel rods are routinely made at the Visual Examination Machine (VEM). Corrosion deposits can be sampled and quickly transferred to the Analytical Laboratory for assay, and suspicious areas can be smeared for the presence of fuel particulate matter or fission products.

Metrology

For the case of cylindrical fuel rods, diameter data are collected at the Element Contact Profilometer (ECP). This computer-automated apparatus determines the diameter of fuel rods up to 21 mm in diameter with an accuracy of ± 0.008 mm. The amount of fuel rod bowing and the fuel rod length are measured optically at this same station.

An in-cell balance is provided, which can weigh fuel elements up to 4 kg in mass. Weight measurements are often useful in identifying breached fuel elements that have very small cracks or pits which are difficult to observe visually.

Gas Sampling and Analysis

For fuel rods that contain a fission gas plenum, the Gas Assay Sample and Recharge (GASR) apparatus is invaluable. The plenum free volume, gas pressure, and molar quantity can be determined by laser-puncturing and calibrated gas collection hardware. Samples of the gas are taken and transferred to the

Analytical Laboratory for the determination of their chemical and isotopic composition.

Neutron Radiography

The Neutron Radiography (NRAD) facility within HFEF uses a 250 kW TRIGA reactor as a neutron source. Round components up to 152 mm in diameter or square components up to 241 mm across, and weighing up to 273 kg, can be radiographed. Neutron radiography is a powerful tool for detecting such fuel heterogeneities as pellet separations, cracks, fission product relocation, etc. Indium neutron detector foils are used for high-enrichment fuels (and thick structures), while dysprosium neutron detector foils are used for low-enrichment fuels (and thin structures). Neutron tomography can be performed if detailed three-dimensional imaging is required.

Fission/Activation Product Data

Fission and activation product spatial distributions in irradiated fuel can be determined using HFEF's automated Precision Gamma Scanner. Such data have been found useful in locating cladding breach sites and as a complement to quantitative assays made at the Analytical Laboratory.

Microstructural Evaluation

A detailed microstructural evaluation is often necessary for understanding and modeling of fuel degradation mechanisms. HFEF has a shielded auxiliary cell for optical and scanning electron microscopy. A microhardness tester is also available to ascertain mechanical property degradation. Should the need arise, samples can be shipped to the Alpha-Gamma Hot Cell Facility (AGHCF) in Illinois, where electron microprobe and scanning Auger microscopy capabilities exist.

8.0 TRANSPORTATION OF IRRADIATED SPECIMENS

Transportation of irradiated specimens from the Test Reactor Area (TRA) hot cells to HFEF requires additional work. ANL-W has a variety of shipping casks, some of which interface with and can be easily handled by the TRA hot cells. The problem with all of the ANL-W casks that the TRA hot cells can handle is that they are not licensed. That does not mean that they cannot be used; it means a transportation plan has to be written and approved by the U.S. Department of Energy (DOE), and a government driver must be used. This is too expensive for "small" projects such as irradiating a few MOX pellets in the ATR.

ANL-W has a shipping cask called the T-2 cask. The T-2 cask is fully U.S. Nuclear Regulatory Commission (NRC) and U.S. Department of Transportation (DOT) licensed for a wide variety of fissile materials including metals, alloys, oxides, carbides, and nitrides. It simply has heat and curie limits. ANL-W can use their own vehicles and drivers for transporting this cask and does not have to submit any transportation plans. This cask has been used extensively for shipments between ANL-W and Chicago, but with the shutdown of EBR-II, the cask is currently underutilized. This is the cask to use for shipping materials between the TRA hot cells and HFEF. However, the TRA hot cells cannot handle this cask well (they have done it, but with some contamination problems).

HFEF engineers have designed, or helped design, fixes that have enabled many other hot cell facilities to interface with and handle the T-2 cask, including hot cells at ANL-East, Hanford, and Oak Ridge. They are also familiar with what it would take to enable the TRA hot cells to handle the T-2 cask. These needs include: 1) design and fabrication of a tray to accept the shield plug, the 2R container, and the basket from within the cask; 2) a grappling tool to pull the shield plug and container out of the cask; and 3) possibly a cradle for the cask

dolly. The material costs for these tools are estimated to be \$10K. If the INEL would agree to fabricate these tools for the TRA hot cells, Argonne is willing to perform all the engineering services needed for such a project. Having this interface available between our two hot cell facilities would be a great benefit, not simply for this project, but for the INEL and ANL in general.

9.0 FUTURE RESEARCH AND DEVELOPMENT NEEDS

A proposed continuation of this Laboratory Directed Research and Development (LDRD) project is to irradiate a few pellets of plutonium-based material contained in a drop-in capsule in the ATR. The results of this test would provide useful information on how weapons-plutonium-based materials perform under irradiation. If this can be accomplished successfully over the next two years, a high probability exists for receiving a multimillion dollar plutonium test program at the ATR. The major objective of a large externally-funded test program is to show that plutonium-based fuel performs as expected under prototypical light water reactor conditions.

Taken together, the fabrication, irradiation, and examination of MOX fuel are the single most expensive task recently identified by Oak Ridge National Laboratory (ORNL) and Lawrence Livermore National Laboratory (LLNL) in the long range R&D plan for reactor-based plutonium disposition technologies¹⁴. The prototypical fuels testing program was conservatively estimated to cost \$50M and to last nine years. The plan also states that this R&D area is likely to be a critical path item.

The objective of the ongoing LDRD project funded in FY 1995 is to determine the feasibility of MOX fuels testing in the ATR. As shown in this report, it is feasible to test MOX in the ATR. This report also identifies a few issues such as the problems associated with shipping the irradiated MOX material. Actual testing of a few plutonium specimens in the ATR will demonstrate that testing can be accomplished successfully and will provide some useful information about the material properties after irradiation.

This LDRD has answered some of the following questions:

- What are the requirements?
- What target compositions will be used?
- What target dimensions will be used?
- Where in the ATR should the targets be irradiated?
- How long should each target remain in the ATR?
- What are the target burnup levels?
- What are the target heating rates?
- What are the target temperatures?
- Are the temperatures acceptable (safe)?
- What are the safety issues?
- Are target dose levels acceptable for transportation and related handling?
- How long should the targets remain in the ATR canal?
- What are the issues associated with shipping the targets to ANL-W?
- How will the targets be disposed of ultimately?

Los Alamos National Laboratory (LANL) is currently fabricating a variety of plutonium-based fuel pellets (both MOX and nonfertile fuels). John Buksa of LANL stated that LANL will provide a few pellets to the INEL, at LANL's expense, sometime in the middle of FY 1996. Detailed answers cannot be determined for some of the questions until LANL provides information on the compositions, dimensions, and other material properties (heat capacity, thermal conductivity) of the fuel pellets they actually plan to ship to the INEL. All of these questions must be answered before an actual test program begins.

Before a test can be installed in the ATR, it must be shown to be compatible with the design and operational constraints on the reactor. Other requirements for conducting a test program at ATR are described in Section 6.0.

To prepare for an ATR MOX fuel testing program, more preliminary analyses can be performed. One kind of analysis is the type discussed in Section 6.4, which would demonstrate that the tests could be conducted in the ATR without degrading the performance or safety of ATR operation. Another kind of analysis would provide a context for the evaluation of test results. Both of these kinds of analysis can be used to support a formal test program proposal.

The analyses described in Section 6.4 can be performed with existing RELAP5/MOD3 computer models of the ATR system and the test loops. Recently, comprehensive models have been developed in which a detailed test loop model is combined with the reactor system model (a separate model was developed for each of the IPTs). Reactivity insertion values for these analyses would be obtained from MCNP or PDQ¹⁵ calculations. Since these tests are described above, they are not discussed further in this section.

In summary, a MOX testing program would require the cooperation of at least three national laboratories. This report documents the issues associated with MOX testing in the ATR. MOX testing in the ATR is feasible. Furthermore, several advantages exist for using the ATR, as stated in this report. MOX testing and the subsequent Post-Irradiation Examination will provide useful information on how weapons plutonium-based materials perform under irradiation. This information is required for plutonium disposition in Light Water Reactors.
