Abstract

An analytic stability criterion is derived for the vertical mode in a large aspect ratio stellarator. The effects of vacuum magnetic field generated by helical coils are shown to be stabilizing due to enhancement of field line bending energy. For wall at infinite distance from the plasma, the amount of external poloidal flux needed for stabilization is given by $f = (\kappa^2 - \kappa)/(\kappa^2 + 1)$ where $\kappa$ is the axisymmetric elongation and $f$ is the ratio of vacuum rotational transform to the total transform.

52.35.Py, 52.55.Hc
It is known that tokamak plasmas suffer from vertical instability when plasma shaping is sufficiently elongated. On the other hand, the tokamak beta limit tends to increase with elongation as implied by the well-known Troyon limit [1]. Thus, advanced tokamak operations require feedback stabilization of the vertical mode in order to achieve high beta.

Recent numerical calculations have shown that the vertical mode is robustly stable in a current-carrying quasi-axisymmetric stellarator [2,3] whereas an equivalent tokamak is unstable. In this work, we show analytically that the vertical mode is much more stable in a current-carrying stellarator than in an equivalent tokamak. The stabilization comes from vacuum magnetic field generated externally by helical coils. The external poloidal magnetic field enhances the field line bending energy of the vertical motion relative to the current-driven term. In the following, we will derive an analytic stability criterion of the vertical mode in a current-carrying stellarator plasma.

We start from the energy principle [4]. The perturbed plasma energy is a sum of plasma potential energy $\delta W_p$ and vacuum magnetic energy $\delta W_v$, 

$$
\delta W_p = \frac{1}{2} \int_p dv [B_1^2 + J \cdot (\xi \times B_1)] 
$$

$$
\delta W_v = \frac{1}{2} \int_v dv B_1^2
$$

where $B_1$ is the perturbed magnetic field, $J$ is the equilibrium plasma current, $\xi$ is the plasma displacement. We have also assumed that the perturbation is incompressible.

For simplicity, we consider a large aspect ratio, low beta stellarator plasma. The plasma shape can then be approximated by a cylinder with cross-section shape varies along the axial direction due to helical coils. Using the stellarator expansion [5] via averaging along the axial direction, the equilibrium and stability problem is reduced to a two dimensional one. Then, the equilibrium and perturbed magnetic field are reduced to

$$
B = z \times \nabla \Psi + B_z z
$$

$$
B_1 = z \times \nabla \Psi_1
$$

where we have used a cartesian coordinates $(x, y, z)$ with $z$ the coordinate along the axial
direction, and $z$ is the unit vector. Here, $\Psi$ and $\Psi_1$ is the equilibrium and perturbed poloidal magnetic flux respectively. The equilibrium flux $\Psi = \Psi_c + \Psi_v$ is a sum of internally generated flux $\Psi_c$ due to current and externally generated one $\Psi_v$ due to helical coils. To make further analytic progress, we assume uniform current density and uniform vacuum rotational transform, then the total equilibrium flux can be written as

$$\Psi = (\Psi_{v0} + \Psi_{c0})\left(\frac{x^2}{a^2} + \frac{y^2}{b^2}\right)$$

(5)

for an elliptical shape with $\kappa = b/a$ being the ellipticity. Here $\Psi_{v0}$ and $\Psi_{c0}$ are the flux values at the plasma edge due to helical coils and plasma current respectively. The corresponding equilibrium current is $J = J_0 z$ with

$$J_0 = 2\Psi_{c0}\left(\frac{1}{a^2} + \frac{1}{b^2}\right)$$

(6)

We consider the vertical perturbation as a rigid shift along the y direction (i.e., the direction along the elongation). Then $\xi = \xi_y y$, and $\Psi_1 = -2\xi_y \Psi_{v0} y/b^2$ where $\Psi_0 = \Psi_{v0} + \Psi_{c0}$. The potential energy is reduced to

$$\delta W_p = \frac{1}{2} \int_{p} dv \left[|\nabla \Psi_1|^2 + J_0 \xi_y \frac{\partial \Psi_1}{\partial y}\right]$$

(7)

$$= 2V \xi_y^2 \left[\frac{1}{b^4} \Psi_0^2 - \frac{1}{b^4} (\kappa^2 + 1) \Psi_{c0} \Psi_0\right]$$

(8)

where $V$ is the plasma volume. The vacuum energy is reduced to

$$\delta W_v = \frac{1}{2} \int_{v} dv |\nabla \Psi_1|^2$$

(9)

where $\Psi_1$ satisfies

$$\nabla^2 \Psi_1 = 0$$

(10)

in the vacuum. Equation (10) can be solved conveniently using confocal coordinates ($\theta, \mu$) as

$$x = \sqrt{b^2 - a^2} \sinh(\mu) \cos(\theta)$$

(11)

$$y = \sqrt{b^2 - a^2} \cosh(\mu) \sin(\theta)$$

(12)
The solution is then given by
\[ \Psi_1 = -2\xi_y \frac{\Psi_0}{b} \sin(\theta)e^{-(\mu - \mu_0)} \]  
(13)
in absence of a conducting wall. Here \( \mu = \mu_0 \) defines the plasma boundary shape with \( \tanh(\mu_0) = a/b \). The integral in Eq. (9) can be evaluated straightforwardly and gives
\[ \delta W_v = 2V\xi^2 \frac{\Psi_0^2}{ab^3} \]  
(14)

Then the total perturbed plasma energy is given by
\[ \delta W = \frac{2V\xi^2}{b^4}[(1 + \kappa)\Psi_0^2 - (\kappa^2 + 1)\Psi_{c0}\Psi_0] \]  
(15)

Physically, the first term in the bracket is the sume of the field line bending energy and vacuum magnetic energy, and the second term is the destabilizing term driven by current. The externally generated poloidal flux is stabilizing because it enhances the field line bending energy and the vacuum energy by a factor of \( (\Psi_0/\Psi_{c0})^2 \) whereas the current driven term is only enhanced by a factor of \( \Psi_0/\Psi_{c0} \). This is true when the external poloidal flux adds to the internal flux. In case of external flux subtracts the internal flux, the external poloidal flux can be destabilizing when \( 0 < \Psi_0/\Psi_{c0} < 1 \). When \( \Psi_0/\Psi_{c0} < 0 \), the plasma is always stable regardless of value of \( \Psi_0/\Psi_{c0} \).

Equation (15) gives the following stability criterion for the fraction of external rotational transform \( f = \tau_{ext}/\tau \) needed for stabilization,
\[ f = \frac{\kappa^2 - \kappa}{\kappa^2 + 1} \]  
(16)

Note that \( f = 1 - \Psi_{c0}/\Psi_0 \). This result has been confirmed by the numerical calculations using the 3D global stability code Terpsichore [6]. For \( f = 0 \), this stability criterion (i.e., \( \kappa = 1 \)) reduces to that of a tokamak without conducting wall stabilization [7,8].

Finally, we note that effects of stellarator field on positional stability of a current-carrying plasma had been investigated experimentally by Sakurai and Tanahashi [9]. It was found that the stellarator field produced a large negative vertical field index which made the plasma
much more stable in the horizontal direction. It was also found the plasma was vertically stable although the vertical field index was negative. Thus, it was concluded [9] that the field index can not be used as a stability criterion for the vertical mode in a stellarator. This work here explains how a stellarator plasma can be more stable vertically than in an equivalent tokamak plasma.

In conclusions, we have derived an analytic stability criterion for the vertical mode in a current-carrying stellarator plasma. The vertical mode can be stabilized by the externally generated poloidal flux due to enhancement of field line bending energy.

The author is indebted to Dr. Neil Pomphrey for sharing his derivation of an analytic stability criterion of the vertical mode in a straight tokamak and for valuable discussions. The author also acknowledges valuable discussions with Drs. Allen Boozer, Steve Jardin, Steve knowlton, John Johnson and Allan Reiman.
