AERODYNAMIC PRINCIPLES OF THE DIRECT LIFTING PROPELLER*

By Martin Schrenk

SUMMARY

The purpose of this report is to make the complicated processes on the direct-lift propeller amenable to analysis and observation. This is accomplished by placing the physical phenomena, starting with the most elementary process, in the foreground, while limiting the mathematical treatment to the most essential in view of the fundamental defects of the theorems. Comparison with model experiments supplements and corroborates the theoretical results.

INTRODUCTION

Among the various rotating airfoil systems,** the autogiro, in spite of being the most recent arrival in the series, has been the first to receive general recognition.

---

*"Die aerodynamischen Grundlagen der Tragschraube." Z.F.M., August 14, 1933, pp. 413-419; August 28, 1933, pp. 449-454; and September 14, 1933, pp. 473-481.

**As to the types of rotary airfoil systems, the following definitions are used. Any aircraft with rotating airfoils for producing lift—in contradistinction to aircraft with "fixed" wing systems—falls into this class. At present they may be divided into three different categories:

1) Autogiro: An aircraft having one or more systems of airfoils rotating substantially about a vertical axis; that is, the air flows upward through the propeller disk.

2) Helicopter: An aircraft having one or more sets of airfoils essentially rotating about a vertical axis but driven from the aircraft; that is, the air passes downward through the propeller disk.

3) Cyclogiro (name coined by Dr. Rohrbach): An aircraft having substantially a system of airfoils rotating about a horizontal axis, which can be made to rotate freely in the relative wind or be driven from the aircraft.
thanks to the successful research of Juan de la Cierva. But the development of simple and practical readily applicable scientific principles, has not kept step with it (at least in publicly accessible form).

Admittedly, Glaue (reference 1) and Lock (reference 2) evolved a very detailed mathematical theory in 1926-27; and Lock and Townend (reference 3) published in 1928 the results of elaborate experiments on a model autogiro. But these reports, invaluable as they are, fail to establish a connection between theory and model test. In its particular form, the theory is much too unwieldy for practical application; the meaning of the assumptions and reductions is difficult to survey. The model experiments are limited to one execution and the theory does not permit the application of its data to any other form.

The purpose of the present report is to remove these objectionable features. The road thence leads through a very much reduced mathematical treatment which reveals the physical aspect much better than attained heretofore. Owing to the complexity of the air flow composed of tip and forward speed, together with the flapping motion of the blades of itself, the processes on the autogiro are such that no clear conception can be obtained unless the most elementary basic notions are put forward first and then the effect of the additional processes is superimposed afterward.

There are two methods of analyzing the autogiro (analogous to driving propellers): one, referring to the processes at the individual blade; the other, comprising the total flow. The latter may be based on the Prandtl airfoil theory and yields the induction losses. But the former gives — after more accurate consideration — aside from the thrust, the flapping motion and its effects and — after suitable simplification — an inferior limit value for the axial flow loss.

Upon comparison with model experiments, it is then found that no rational agreement is possible unless the assumption held heretofore and employed without proof by the British research workers, relative to the form and location of the induced field of flow, is discarded in favor of another admitted by only empirically definable assumption for the present. Then it becomes possible to compute an autogiro from the correct profile drag coefficients of
the blades, in contrast to the conjectured increment employed horotofore, which is diametrically opposed to the mathematical accuracy of the theory.

Lastly, a simple relation is deduced in semi-empirical manner, for the residual loss produced by the unsymmetrical air flow on either side of the principal plane. The representation of these three loss quotas in form of lift/drag ratio proportions, yields a profound insight into the effect of the individual design quantities and gives the designer a yardstick for evaluating the effect of his methods and the attainable limits.

A complementary section briefly discusses divers refinements, strength problems, and the phenomena at high angles of attack.

**Notation**

Other than the symbols proposed by the subcommittee of the FALU and published in Z.F.M. (Zeitschrift für Flugtechnik und Motorluftschiffahrt) no. 22, 1932, the following are employed.

**Dimensions of blades:**
- $F$, disk area of autogiro.
- $R$, radius of autogiro.
- $r$, radius of blade element.
- $t$, chord of blade.
- $m$, weight of blade per unit length.
- $J$, inertia moment of blade about hinge.
- $z$, number of blades.
- $\sigma$, surface density, or solidity ratio \( \left( \frac{ztR}{F} \right) \), with $t = \text{chord at } r = R$. 

Forces:

L, air force (general).
S, thrust (resultant force) of autogiro.
T, tangential force (in plane of propeller).
M, moment of T.
M_s, moment of S.
\( k_s \), thrust coefficient \( \frac{S}{\frac{\rho}{2} u^2 F} \)

\( c_s \), resultant force coefficient,\(^*\) \( \frac{S}{\frac{\rho}{2} v^2 F} \) (identical to \( c_T \) on airplane wing).

Motion:

\( u \), tip speed (at \( r = R \)).
\( v_d \), axial velocity (due to permeability of autogiro).
\( w \), induced deflection velocity at the locus of the propeller.
\( c \), resultant air-flow velocity at blade element (\( c_x \) and \( c_y \) components).
\( \omega \), rotational speed.
\( \lambda \), tip-speed ratio \( \frac{v \cos \alpha}{u} \)
\( \lambda_d \), coefficient of axial flow \( \frac{v_d}{u} \).

Angles:

\( \alpha \), angle of attack of normal plane.

\(^*\)In propeller theory \( c_s \) is the load factor, but since it assumes here the role of the resultant force coefficient at the airfoil, it is called such, to differentiate it from the thrust coefficient \( k_s \).
Angles (contd.):

\( \theta \), blade angle (incidence of blade element to normal plane).

\( \phi \), angle of flow at blade relative to normal plane.

\( \psi \), turning angle of blade (zero position aft).

\( \beta \), flapping angle (relative to normal plane).

Constant values:

\( \zeta \), coefficient of flow.

\( \kappa \), coefficient of nonuniformity loss.

\( \gamma \), comparative factor for dynamic similitude

\[ \left( \frac{\rho c'_{ap} t}{2} \right)^{\frac{m}{p}} \]

\( m \), geometrical constants.

Subscripts:

\( p \), blade profile (\( c_{ap}, \alpha_p, \epsilon_p \)).

\( d \), axial flow (\( v_d, \lambda_d, \alpha_d, \epsilon_d \)).

\( i \), induced (\( \alpha_i, \epsilon_i \)).

\( n \), nonuniformity (\( c_u \)).

THE AUTOROTATING WINDMILL

Everybody remembers the toy windmill of his childhood, the original autorotating windmill. It is well to consider for a moment the process involved. Figure 1 illustrates a blade element \( t \, dr \) of an autogiro, which is only to revolve at distance \( r \) about the axis of rotation. There being no input nor output in this elementary windmill, the resultant force \( d \, S \) as well as the velocity of axial flow \( v_d \) through the normal plane is at right angles to it. The
manner, in which \(\nu_d\) depends on external circumstances, is for the time being, disregarded.

Then, figure 1 reveals:

\[
\tan \varphi = \frac{\nu_d}{r \omega} = \lambda_d = \frac{d \varphi_p}{d \Delta}
\]

or

\[
\lambda_d = \epsilon_p \quad \text{(II,1)}
\]

The axial flow coefficient \(\lambda_d = \frac{\nu_d}{u}\) is by nature identical with tip speed ratio \(\lambda = \frac{\nu}{u}\) and becomes so much smaller as the lift/drag ratio of the profile is better.

Now, how must the blade be set to insures the highest possible thrust under any given axial velocity \(\nu_d\)? It is

\[
dS = \frac{\rho}{2} \frac{c_p a^2}{\lambda_d^2} u t \, dr = \frac{\rho}{2} \frac{c_p a^2}{\lambda_d^2} \frac{\nu_d^2}{\epsilon_p} t \, dr
\]

or

\[
\frac{dS}{\frac{\rho}{2} \nu_d^2 \, t \, dr} = \frac{c_p a^2}{\lambda_d^2} = \frac{c_p a^2}{\epsilon_p} = \frac{c_p a^2}{c_w p} \quad \text{(II,2)}
\]

In other words, with constant \(\nu_d\), the thrust depends on the well-known profile characteristic (criterion of climb) \(c_a^3/c_w^2\).

The angle of attack of the profile \(\alpha_p\) (which defines the lift of the profile) \(\xi\) is composed, according to figure 1, of the angle of flow \(\varphi = \lambda_d\) and the fixed blade incidence \(\varphi\). Thus (II,1) gives

\[
\epsilon_p = \alpha_p - \varphi \quad \text{(II,3)}
\]

with normal blade incidence, angle \(\alpha_p\) is solely dependent upon \(\epsilon_p\). This means that the choice of blade angle \(\varphi\) with given profile at the same time establishes the lift coefficient \(c_p\) which the rotating blade maintains during steady attitude independent of the loading.

Equation (II,3) lends itself very readily to graphic
representation (fig. 2). By plotting $\alpha_p$ in degrees of angle against $\alpha_p$ and $\delta$ on the $\alpha_p$-axis, the straight line drawn from the end of $\delta$ with 45-degree slope gives all steady and accelerated attitudes possible with this blade angle. The elementary windmill is accelerated at all angles between points 1 and 2; at point 1 it has its steady, stable turning attitude, beyond point 2 it is quickly decelerated.

This decrease of revolution upon exceeding a stated operating angle of the blade is typical of the autorotation. The process is analogous to the concept of spinning insofar as the rotation in both cases must be initiated by an outside impulse; but for the rest, it is unlike the other, since there is no angle of attack beyond the maximum lift on the autorotating elementary windmill.

The autorotor of constant axial velocity.- In passing from the element to the whole propeller, we must first determine the form and thereby the flow conditions. But instead of choosing the habitual rectangular blade form and coordinating arbitrarily a certain distribution of the axial velocity, we attempt to find a form with possibly simple distribution of lift coefficient and axial velocity. Since, according to the foregoing, the quality of the resultant thrust is contingent upon the expression $c_{ap}^3$, that is, on $c_{ap}$, it is advisable to choose $c_{ap} = \frac{c_{wp}}{c_{wp}}$ constant, attainable when $v_d$ is known by twisting the individual blade elements with respect to each other. It is also desirable to have $v_d = \text{constant}$ for reasons of mathematical simplicity. This grading with given total quantity of axial flow per second corresponds, moreover, to a minimum of kinetic power loss.

Disregarding the boundary effects, the autorotating propeller may then be considered as a stream section through which the air passes with the positive pressure $S/F$. Obviously the flow resistance in this section resolves itself according to the proportion of the thrust produced at the pertinent point; the resistance and through it, the speed are constant across the whole section, even with uniform thrust grading. The result is therefore the same simple thrust grading as with the axial theory of the propeller.
Outwardly, however, a uniform thrust grading across the section means a linearly increasing thrust-loading of the individual blades, so that chord values of the form

\[ \frac{dS}{dr} \sim r^2 \sim r. \]

This grading is obtained with \( c_a = \text{constant} \), when choosing chord \( t \) conformably to

\[ t \sim \frac{1}{r}. \]

Then we have

\[ \frac{dS}{dr} \sim r^2 t \sim r. \]

Admittedly, this equation leads to forms for which the blade chord increases to \( \infty \) on the axis; besides, the blade angles deviate so much from the propeller plane in the vicinity of the axis, that \( c_a \) is no longer decisive for the locally produced thrust (\( \cos \varphi \) is no longer \( \approx 1 \)). On the other hand, the proportion of the blade near the hub to the thrust produced is so small (not exceeding 2 to 3 percent for a propeller of figure 3), as to be safely neglected, especially as the axial flow in the propeller center is, apart from that, disturbed by the more or less large hub.

The decrement of the thrust at the boundary can also be summarily disregarded for, as seen directly, the flow coefficient of the air passing through is unusually low; the individual propeller surfaces thus follow each other very closely.

**Thrust and axial flow coefficient.** - In contrast to the elementary autogiro, the resultant air force \( T \) (fig. 4) on the different parts of the blade of the steadily autorotating propeller is now no longer perpendicular to the plane of rotation, but slopes forward in the direction of rotation at the inside elements and backward at the outside elements. Thus, those on the inside act in a propeller manner, those on the outside, are propelled; somewhere between lies a blade portion which still corresponds to the simple elementary conception.

In the most important part of the blade the angle \( (\varphi - \varepsilon_p) \) (fig. 4) is apparently of the order of \( \varepsilon_p \).
that is, very small, so that $\varphi$ remains small also. In consequence, the small thrust component of the profile drag ($d W_p \sin \varphi$) can be disregarded and the thrust element be expressed with

$$d S = d A \cos \varphi = \frac{\rho}{2} c_{ap} \frac{v_{res}^2}{r} t \, dr \cos \varphi = \frac{\rho}{2} c_{ap} r^2 \omega^2 t \, dr \frac{1}{\cos \varphi}$$

With $\cos \varphi = 1$, we then have

$$d S = \frac{\rho}{2} c_{ap} r^2 \omega^2 t \, dr$$

According to the preceding chapter, the wing chord at point $r$ is

$$t = t_R \frac{R}{r}$$

and the thrust of $z$ blades

$$S = z \int_0^R d S = z \frac{\rho}{4} c_{ap} \omega^2 R^3 t_R$$

Lastly, we put

$$z \frac{R}{r} t_R = \sigma F$$

wherein $\sigma =$ solidity, that is, the ratio of the $z$ rectangles of minimum chord times radius to propeller disk area $F$. Then the thrust is:

$$S = \frac{\rho}{4} \sigma c_{ap} u^2 F = \frac{\rho}{2} k_s u^2 F$$

where the thrust coefficient referred to tip speed is

$$k_s = \frac{\sigma c_{ap}}{2}$$

Since, according to (II,3), $c_{ap} (\alpha_p)$ with given blade form is a constant value independent of the load, $k_s$ is also simply a function of the blade form.

The axial flow coefficient $\lambda_d$ follows from the con-
dition that no free moment occurs with the autorotating propeller. With the notations of figure 4, the component of the tangential force is

\[ \frac{dT}{2} = \rho r^2 \omega^2 \frac{t_r \, dr}{\cos^2 \varphi} (c_a \sin \varphi - c_w p \cos \varphi). \]

The division of the brackets by \( \cos^2 \varphi \) and by \( \cos \varphi = 1 \) together with equation (II,4), yields

\[ \frac{dT}{2} = \rho r^2 \omega^2 \frac{t_r \, dr}{\omega R^2 (c_a - c_w p)} \]  \quad (II,8)

while (II,5) gives the moment at

\[ (\text{II,7}) \quad M = z \int_0^R r \, dT = \rho \omega \sigma \, c_a \, R \, u^2 \, F \left( \frac{x_a}{2} - \frac{c_p}{3} \right) \]  \quad (II,9)

and by putting \( \lambda_a = 0 \),

\[ \lambda_d = \frac{2}{3} c_p. \]  \quad (II,10)

This formula states that the outside \( 1/3 \) of the propeller is driven by the inside \( 2/3 \). When plotting this formula (10) conformably to figure 2, the angle of attack \( \alpha \) referred to a stated incidence \( \beta \) can be obtained for the selected profile. But the values do not apply to extreme radius \( R \), but to point \( r = \frac{3}{5} R \). Figure 5 shows the values for the Gottingen airfoil 429.

Axial velocity \( v_d \): Now, formulas (II,6) and (II,10) would yield the axial velocity \( v_d \) as function of surface loading \( S/F \), the surface density \( \alpha \) and the aerodynamic characteristic. But we prefer to follow a different route which brings the physical aspect of the axial velocity into better relief.

From a glance at figure 4, it becomes apparent that the components of the lifting forces against the profile drag maintain the autorotation. Without this drag the rotation would increase arbitrarily. Now the power necessary to overcome the profile drag must be produced somehow; it is supplied by the quantity of air \( v_d F \) passing through the section per second at positive pressure \( S/F \).
Formula (II,9) gives the moment of the profile drag at

\[ M_p = \frac{\rho}{6} \sigma c_{wp} R u^2 F \]

and the power of the profile drag at

\[ N_p = M_p \omega = \frac{M_p u}{R} = \frac{\rho}{6} \sigma c_{wp} u^3 F. \]

Inserting \( v_d \) from (II,10) and equating the whole to the power \( S v_d \) of the passing air, gives:

\[ N_p = \frac{9}{16} \rho \sigma \frac{c_{ap}^3}{c_{wp}^2} F v_d^3 = S v_d. \]

Whence the axial velocity:

\[ v_d = \frac{4}{3} \sqrt{\frac{S/F}{\rho \sigma \frac{c_{ap}^3}{c_{wp}^2}}} \quad (II,11) \]

But this is simply a kind of axial flow formula:

\[ v_d = \zeta \sqrt{\frac{S/F}{\rho/2}} \quad (II,12) \]

with axial-flow coefficient:

\[ \zeta = \frac{4/3}{\sqrt{2 \sigma \frac{c_{ap}^3}{c_{wp}^2}}} \quad (II,12) \]

The autorotating propeller can be considered as a circular stream section, a kind of diaphragm, through which the air passes at pressure \( S/F \). But owing to the resistance existing in the section only the \( \zeta \)-fold mass passes through rather than the mass \( \rho v_d F \) per second, corre-

In practice, the order of magnitude of \( \zeta \) ranges between \( \zeta = 0.12 \) and 0.25.
spending to \( S/F \). The smaller the absorption of profile power by the propeller while revolving, the smaller \( \varsigma \) is, and the more "dense" the propeller. Formula (II,12) shows that the profile characteristic sets up limits for \( \text{cap}^3/\text{cwp}^2 \); practical reasons prevent arbitrary enlargement of \( \sigma \).

Lastly, the tip speed is obtained from (II,11) and (II,10) at

\[
v_d = u = 2 \sqrt{\frac{S/F}{\sqrt{\frac{\rho}{\sigma \text{cap}}}}} \text{(II,13)}
\]

The greater \( \sigma \cdot \text{cap} \) is; the smaller \( \varsigma \) (II,12) is, the more "dense" the propeller, but so much lower the tip speed.

**AUTOGIRO OF LOW TIP-SPEED RATIO**

(II,\#)

Now we shall see to what extent the just evolved formulas for the autorotating propeller may be utilized on the autogiro in level flight.

Mechanism of lift. \- Lift, that is, a transverse force to the air flow, is always the result of stream deflection. At the locus of the lift generatrix in the usual cases wherein it can be represented by one single lifting vortex, this deflection has precisely reached one half of its final amount. The latter is readily computed for uniform distribution from the lift, or, more rigorously, from the resultant air load \( L \). Prandtl's airfoil theory gives the angle of deflection \( \alpha_i \) of the flow at the locus of the wing at

\[
\sin \alpha_i \ (\approx \alpha_i) = \frac{W}{v} = \frac{L}{\frac{\rho}{2} \frac{v^2}{b^2}} = \frac{c_L}{\pi} \frac{F}{b} \text{(III,1)}
\]

Thus far the analysis has been equally applicable to a fixed-wing system, a direct lifting propeller as well as to any other lift-producing mechanism. But the setting
with angle $\alpha_1$ does not generally suffice to produce air load $L$. 

On the fixed wing, for instance, the profile must further be rotated through the profile setting angle $\alpha_p$, to insure the necessary circulation for $L$. Its amount is computed from the lift curve with slope $dc_a/d\alpha_p$, whose theoretical value is $2\pi$, owing to boundary layer losses $dc_{ap}/d\alpha_p$ drops to from 5.5 to 5.9, according to the Reynolds Number.

These facts are of themselves well known. They are merely repeated here, as a reminder incidental to the transition to the lifting propeller.

One can no longer speak of a profile setting angle for the lifting propeller as a whole as with the fixed-wing system, because the process of lift production occurs at the individual blade elements. But its place is taken by another additional angle, the angle of flow $\alpha_2$ (fig. 6).

Autogiro tip-speed ratio approaching zero.—When on the autogiro exposed at small angle to the air stream (fig. 6), the air forces are applied at the individual blade, the asymmetry in magnitude and direction of the resultant flow at the advancing and retreating blade leads to quite complicated formulas so long as the air-stream velocity is of the same order of magnitude as the tangential velocity. One is then tempted to strike out inconvenient terms during the calculation, without fully realizing the effect of such procedure— a danger which Glauert (reference 1) likewise did not avoid.

On the other hand, the matter becomes immediately more simplified and amenable to survey when limited to the attitude of very low tip-speed ratio:

$$\lambda = \frac{v \cos \alpha}{u} \quad (III, 2)$$

or, in other words, by assuming the forward speed $v \cos \alpha$ as very small compared to tip-speed $u$. Then the effect of $v \cos \alpha$ on the blade forces is mitigated and the tangential velocity $r \omega$ is the sole criterion in first approximation.* In this manner the symmetry of the flow on

*Mathematically this is equivalent in broad outlines to an omission of $(v \cos \alpha)^2$ in the squared sum $(r \omega + v \cos \alpha)^2$, which then becomes $r^2 \omega^2$. 
the lifting propeller is reestablished and the approximation then yields the same formula as for the autorotating propeller in axial flow (see section "The Autorotating Windmill," page 5), which can be employed forthwith.

We thus apply the picture of the slightly permeable circular disk on which the air, because of the S/F pressure, flows at \( v_d \) through the propeller disk in order to maintain autorotation, to the case of oblique air stream also. The aforementioned flow angle \( \alpha_d \) is then found, according to figure 6, from the forward velocity \( v \cos \alpha \) and the axial velocity \( v_d \). as temporarily assumed constant figure for the whole circular surface precisely as the angle of deflection \( \alpha_d \).

Theory of thrust of the "ideal" autogiro. — In connection with the foregoing, an "ideal" lifting propeller is a propeller with its tip-speed ratio approaching zero; that is, of high rotative speed which, in addition, as the result of suitable design, shape manifests constant axial velocity across the entire section (lancet shape). This can be readily expressed by a simple theory of the resultant force coefficient

$$c_a = \frac{S}{\rho \frac{v^2}{2} F} \quad (III,3)$$

in terms of angle of attack, with the simple assumption that the total force \( S \) is to lie at right angle to the plane of rotation, i.e., in direction of the axis of rotation.

According to figure 6,

$$\sin \alpha = \frac{w + v_d}{v} = \frac{w}{v} + \frac{v_d}{v} \quad (III,4)$$

Under the temporarily accepted assumption (as made by Glauert (reference 1) and Lock (reference 2)), that the induced flow at the locus of the wing is plane and has the inclination \( \alpha_i \) (III,1) known from Prandtl's theory of the lifting vortex, equation (III,3) yields:

$$\frac{w}{v} = \frac{c_a}{4} \quad (III,5)$$

with (II,12), we have further,

$$\frac{v_d}{v} = \zeta \sqrt{c_a} \quad (III,6)$$
According to this the induction losses increase with $c_s$, the axial flow losses with $\sqrt{c_s}$. We shall come back to this later.

Lastly, formula (III,7) gives, after resolving the squared equation in $\sqrt{c_s}$, the resultant force coefficient

$$c_s = 4 \left( \sqrt{\zeta^2 + \sin \alpha} - \zeta \right)^2$$

(III,9)

After the remark made incidental to (II,8), $k_s = \frac{S}{\frac{\rho}{2} v^2 F_s}$, here also because of the symmetry of the flow. In practice, this means that, with given form of rotating blade, the tip speed is only dependent on surface loading and air density (as is the case in close approximation on actually built autogiros).

**Comparison with model experiments.**— The only model experiments which by nature and scope are acceptable for comparison with the theory, are those of Lock and Townend (reference 3). The part of the tests referred to here pertains to model blades of 1.80 m (6 ft.) diameter, of wood, constant chord of 136 mm (5.36 in.), without twist, equivalent to a surface density of $\sigma = 0.19$. The model was tested up to approximately $20^\circ$ angle of attack; no higher angles were possible in the Duplex wind tunnel of 2.1 by
4.2 m (7 by 14 ft.) section without introducing serious
errors. At a tip speed of around 65 m/s (145 mi./hr.), the
profile characteristic on the particular radius 2/3 R is
in fair accord with the normal characteristic of the Got-
ttingen profile measurements. The shape was the symmetri-
cal Gottingen section 429 of 0.10 thickness ratio, modi-
fied to give a thicker trailing edge, so that the drag fig-
ures are perhaps a little higher than in the Gottingen
measurements. But in spite of these minor limitations, the
measurements are well suited for comparison with the theo-
ry.

Of course, it is not summarily possible to effect such
comparison with the lancet-shaped plan form used heretofore
in the analysis. At what value shall we put $\xi$?

So we first assume the formula expressed in (III,7)
and (III,9) to be true, i.e., that this equation interprets
the form of the $c_g(a)$ curve correctly. This assumption
is legitimate because the nonuniformity of the air flow
disregarded in the derivation, while being able to affect
the direction, cannot, however, influence the amount of the
resultant thrust $S$ very substantially.

Therefore we determine by trial or insertion of an ex-
perimental value, the coefficient of axial air flow $\xi$ at
which the theoretical curve is in closest agreement with
the test points. Figure 7 shows the result for blade an-
gle $\delta$ = 1.8\textdegree. The model was measured at this angle for
the 4-blader ($a = 0.19$) and the 2-blader ($a = 0.295$)
autogiro. The graph shows that the trend of the curve as
well as the theoretically stipulated relation $1: \sqrt{2}$ is
fulfilled for $(II,12)$. Moreover, this accord holds not
only for low tip-speed ratio (great $c_g$) but also for the
highest $\lambda$ recorded ($\lambda = 0.5$ to 0.6).

From this one is led to infer that certain premises
set up in the preceding section have been confirmed. In
fact, Lockett and Townsend (reference 3) conclude from the ex-
act extrapolation for varying blade numbers that the as-
sumption relative to the inclination and the smoothness
of the induced field of flow is correct. We shall see
hereinafter, to what extent this actually holds true.

But first we examine the conditions of flow and forces
of the rectangular blade.

*The British text gives hereto, $c_g = 2 L_N \sqrt{1 + e^2}$. 
Thrust and coefficient of flow of autogyro with rectangular blade.—The characteristics of the propeller with rectangular blade are:

\[ t = \text{constant and } \dot{\varphi} = \text{constant} \]

But owing to the changeability of tip speed and axial velocity along the radius, the angle of the air stream \(\dot{\varphi}\) (fig. 1), and through it \(\alpha_p\) and \(c_{ap}\) are no longer constant.

As concerns the axial velocity \(v_d\), it may be said, as before, that it will be constant when the thrust is evenly graded. In reality, however, this occurs only when \(\dot{\varphi} = 0\), because then

\[ \alpha_p = \dot{\varphi} - \text{constant } \frac{1}{r} \]

that is, the lift increases as a result in inverse ratio to the radius. As \(\dot{\varphi}\) increases, the outside thrust rises faster than on the inside; that is, the flow at the profile is more strongly deflected on the outside and the axial velocity is thereby reduced against that on the inside. No prediction can be made about the actual trend of \(v_d = f(r)\) without including the mutual interference, and such calculations would exceed the bounds of this report; although this abstract uncertainty was one of the very reasons which led to the propeller of constant axial velocity used at the beginning of the report.

On the other hand, in order to be able to make any prediction whatsoever, about the rectangular blade, some plausible assumption is necessary, and so we assume with Glauert (reference 1) that \(v_d\) is a constant value.

Then the thrust equation is as before

\[ dS = \frac{\rho}{2} c_{ap} r^2 \omega^2 t \, dr \]

Herein

\[ c_{ap} = c'_{ap} \alpha_p \]
\[ \alpha_p = \dot{\varphi} + \varphi = \dot{\varphi} + \frac{v_d}{r \omega} \]

consequently,
N.A.C.A. Technical Memorandum No. 733

\[ c_{ap} = c'_{ap} \left( \frac{2}{3} \frac{v_d}{r \omega} \right) \]  

(III,10)

which, with (II,5) gives the thrust of \( z \) blades at

\[ \frac{R}{\omega} = \sum_{i=1}^{z} \int_{0}^{R} dS = \frac{p}{2} c'_{ap} \sigma u^2 F \left( \frac{2}{3} + \frac{\lambda_d}{2} \right) \]  

(III,11)

The coefficient of flow is again computed from the condition that \( M = 0 \). It is

\[ dT = \frac{p}{2} R^2 \omega^2 \cdot \sqrt{v_d} \cdot c'_{ap} \left( \frac{2}{3} + \frac{v_d}{r \omega} \right) - c_{wp} \]  

(III,12)

and

\[ M = z \int_{0}^{R} r dT = \frac{p}{2} \sigma R u^2 F \]

\[ \left[ \frac{1}{3} \lambda_d c'_{ap} \phi + \frac{1}{2} \lambda_d^2 c'_{ap} - \frac{1}{4} c_{wp} \right] \]  

(III,13)

With \( M = 0 \), one obtains the equation of definition for the coefficient of axial flow

\[ \lambda_d^2 + \frac{2}{3} \lambda_d \phi - \frac{1}{2} \frac{c_{wp}}{c'_{ap}} = 0 \]  

(III,14)

Glauert (reference 1) obtains the same formula by reducing the general equations (\( \lambda \) great) from mathematical reasons, but wherein the physical meaning of this reduction is not forthcoming recognizable. Then he puts \( c'_{ap} = 5.6 \), although it should be \( c'_{ap} = 5.6 \) for the ambit of the model experiments. Then

\[ \lambda_d = \frac{1}{3} \left( \sqrt{9^2 + 0.8 c_{wp}} - 9 \right) \]  

(III,15)

Now \( c_{wp} \) should not be summarily assumed to have a constant value, because \( c_{ap} \) ranges through all possible values across the radius, and \( c_{wp} \) is definitely not independent of \( c_{a} \), especially on symmetrical profiles. Even though the outer half of the blade defines thrust and torque preponderantly, and \( c_{wp} \) still remains sensibly constant, we nevertheless, introduce, for purposes of more exact investigation, a parabolic relationship \( c_{wp} = f(c_{ap}) \), of the form
\[ cw_p = cw_0 + m \, cap^2 \]

and write it in (III,12) for the tangential force. The elementary, albeit somewhat tedious, calculation leads, after inconsequential omissions, to the equation of definition

\[ \frac{\lambda d^2}{d} + \frac{2}{3} \lambda d \, \delta (1 - m \, cap) - \frac{cw_0 + m \, cap^3 \, \delta^2}{2 \, cap \, (1 - m \, cap)} = 0 \]

or, with \( cap = 5.6 \) to

\[ \lambda d = \frac{1}{3} (1 - 5.6 \, m) \left( \sqrt{\delta^2 + 0.8 \frac{cw_0 + 31.4 \, m \, \delta^2}{(1 - 5.6 \, m)^2} - \delta} \right) \] (III,16)

Comparison of rectangular-blade propeller with the model experiments.—From these deduced relations for \( S \) and \( \lambda d \), the connection between \( c_s \) and \( \alpha \) could be established in the same way as previously for the "ideal" propeller, but the ensuing formula would be rather complicated for the theory of the first order. For this reason we shall proceed in a different direction which, at the same time brings out the connection between the two blade forms.

The purpose of the investigation is to ascertain the profile drag coefficient for the rectangular blade propeller of stated dimensions, which corresponds to a definite figure of merit, according to figure 7. The conception of "equivalent lifting propeller" yields the desired connection. "Equivalent" obviously means: equal axial velocity at equal positive pressure, that is, \( v_d \) and \( S/F \) are equal. But it does not signify the same \( \lambda d \), because the rotative speed may be altogether different by equal permeability, according to the blade form.

With (II,6) and (III,11), in conjunction with \( u = \frac{v_d}{\lambda d} \), we write:

\[ S = \frac{c}{4} \, cap \, \sigma \, F \, \frac{v_d^2}{\lambda d^2} = \frac{c}{3} \, cap \, \sigma \, F \, \frac{v_d^2}{\lambda d^2} \left( \frac{\delta}{3} + \frac{\lambda d}{2} \right) \]

The left-hand side is for the lancet blade, the right-hand side for the rectangular blade. In accord with the assumption, \( S, F, \) and \( v_d \) are equal and cancel out, but \( \sigma \) and \( \lambda d \) are not equal. \( \lambda d \) and \( cv \) must be substituted on the left-hand side, according to (II,10). Then
This equation gives $\xi$ as function of $\sigma$, $c_{ap}$, $\delta$ and $\lambda_d$ for the rectangular-blade propeller ($\lambda_d$ from equation (III,15) or else $\gamma_d = f(\xi)$).

The evaluation of parabolic profile drag polars is best effected by defining $\lambda_d$ with assumed values of $c_{wp}$ and $m$ from (III,16), followed by insertion in (III,17).

The numerical interpretation is based on the 4-blade model with $\delta = 1.8^\circ$, which gave $\xi = 0.178$ (fig. 7). With this figure, equation (III,17 and 14) gives the constant profile drag coefficient

$$100 \ c_{wp} = 1.65.$$ 

But the anticipated figure lies at 1.0; according to the polar of the profile, Göttingen 429 (fig. 6), having regard to the thickened trailing edge. The models with smaller $\delta$ manifest a still higher $c_{wp}$.

Now, one could assume that the increment of profile drag with reduced radius be responsible for this discrepancy. Whether this view is correct, can be seen when combining (III,16) and (III,17). By suitable choice of $m$ we obtain for $\xi = 0.178$, for instance, the profile polars $100 \ c_{wp} = 1.3 + 2.4 \ c_{a}$, shown in figure 8. So the discrepancy of $c_{wp}$ cannot be explained in this manner, at least.*

*To enlarge Glaubert's rule of thumb formula $c_{wp}$ (reference 1) by 50 percent, can hardly be considered an expedient.
The situation is therefore, as follows: The visualization of the autogiro of small tip-speed ratio portrays the type of lift curve \( c_s(\alpha) \) in a very elementary formula. But the profile drag figures computed therefrom are considerably higher than anticipated.

So for the present, we analyze the lifting propeller of large tip-speed ratio and the phenomena of "flapping motion."

**THE AUTOGIRO OF LARGE TIP-SPEED RATIO - FLAPPING MOTION**

As soon as the forward speed \( v \cos \alpha \) ceases to be small against the speed \( r \omega \) of the outer blade elements within the circle of rotation, the blade thrust on either side of the median plane of the autogiro differs considerably and induces a rolling moment which increases as the tip-speed ratio. The incipient rotation about this axis further causes, so long as the blades are fixed at the hub, a pitching moment as a result of gyroscopic coupling.

La Cierva had some experience with these disagreeable and dangerous moments in his first flight tests in 1922 (reference 4), and that gave him the idea of hinging the blades.* This has proved so satisfactory that almost all autogiros built since have hinged blades. For this reason, we shall limit the investigation to this design, especially since it can be proved that the case of a variable blade angle is identical with it as soon as the axes are correctly chosen.

The hinged autogiro obtains its rigidity simply through the centrifugal forces of the blades. Because of the equilibrium of thrust and centrifugal force, the blades form when revolving a flat coning envelope. The unsymmetry of the air forces affects the shape and position of this cone, and this in turn modifies the spatial angle of air stream of the blades.

*But there are other methods of equalizing the effects of unequal lift between the advancing and the receding blade as, for instance, shown in the Wilford gyroplane (reference 5), built according to the patents of W. Rieszler. The opposite blades on either side are rigidly connected together, but free to feather about an axis substantially coincident with the longitudinal axis of the blades themselves.
In view of this complicated condition, it is impossible to reach our aim without affecting certain simplifications in the mathematical analysis. Hence the actual deviations from the coning motion do not appreciably affect the calculation so long as the generating coning angle does not differ appreciably from \(90^\circ\). In actual practice the difference is from 8 to 18°. It is obvious that at first its effect on the calculation should be neglected.

This can be achieved by visualizing (reference 2), the blades as being encumbered with very much weight, so that the centrifugal force becomes great compared to the aerodynamic force. These heavy blades are not to be subject to gravity.* Under the effect of an axially symmetrical air stream such a blade will move in the plane perpendicular to the axis of rotation; its coning angle will be negligibly small.

As soon as periodically changing forces begin to act on such a system characterized by weight and directional force, it results in oscillations. Liebers (reference 6), in his investigation on propeller vibrations, proved that the natural frequency of a propeller with hinged blades is exactly equal to the revolution when the hinges lie on the axis of rotation. And since this is so in nearly every case, we shall assume it also in the following.

The blade oscillates at its natural frequency when the exciting force likewise has the frequency of the revolutions as, in fact, is the case with the thrust forces. Judged from their connection with the angle of rotation, they might be of the nature of harmonics.

Then the situation is as follows: The blades lying on the principal plane, i.e., in flight direction, manifest equal mean aerodynamic forces for reasons of symmetry. The advancing blade dodges the increasing thrust up-

*This limitation is necessary because of the changing magnitude and distribution of the aerodynamic forces on the blade.
wardly; this flapping motion is damped by the ensuing angle-of-attack decrease, and becomes thus comparable to the additional force, that is, highest in pitching. The opposite applies to the retreating blade. We therefore may expect the individual blade to move sensibly in a plane inclined relative to the original plane of rotation, and specifically, under the established assumptions about the axis of pitching (fig. 9).

**Equation of flapping motion.**—The mathematical analysis of this generalized motion is largely based on Glauert (reference 1) and Lock (reference 2), but with the following simplifying assumptions: The blade (bending-resistant and straight) is evenly loaded with mass \( m \) per unit length. Then the dynamic equilibrium of the moments about the hinge at each angular blade setting \( \psi \) in flapping motion is

\[
E \int \vec{r} \cdot d \vec{S} = \int m \vec{r} \omega^2 \beta \cdot \vec{r} \, dr + \int m \vec{r} \frac{d^2 \beta}{dt^2} \, dr \quad (IV,1)
\]

Moment of thrust = moment of centrifugal force + mass moment of inertia.

By integrating the right-hand side, the moment of thrust \( (J = \text{inertia moment of a blade about the hinge axis}) \) becomes:

\[
M_{\beta} = J \left( \frac{d^2 \beta}{dt^2} + \beta \omega^2 \right) \quad (IV,2)
\]

Then the flapping motion of the blade is expanded as a Fourier series in \( \psi \):

\[
\beta = \beta_0 - \beta_1 \cos (\psi - \psi_1) - \beta_2 \cos 2(\psi - \psi_2) - \ldots \]

\[- \gamma_1 \sin (\psi - \varphi_1) - \gamma_2 \sin 2(\psi - \varphi_2) - \ldots \quad (IV,3)
\]

This general equation of the flapping motion can be materially simplified by applying the previously cited physical approximation. To begin with, we retain only first harmonics and so reduce the spatial flapping motion to a simple plane motion. Since, in addition, the lateral inclination of the plane of rotation is neglected, i.e., \( \psi \) is computed from the rear point of the symmetry, the formula reduces to

\[
\beta = \beta_0 - \beta_1 \cos \psi \quad (IV,4)
\]
This is written in (IV, 2), whereby \( \frac{d\psi}{dt} = \omega \). Then:

\[
M_s = \beta_0 \omega^2 J
\]  
(IV, 5)

With simple harmonic flapping motion, the moment of thrust at the blade is therefore constant, independent of the angle of rotation. It is equal to the (constant) moment of the centrifugal forces set up as a result of the "coning motion."

With heavy blades, i.e., plane motion, as we shall assume them, \( \beta_0 \to 0 \) (fig. 9). Then \( M_s \) disappears also, compared with the other moments acting on the blade.

Now \( M_s \) must be expressed as function of the thrust.

Velocities and aerodynamic forces at the blade.— As in the section "Auto-giro of Low Tip-Speed Ratio", page 22, the air stream (with respect to the plane at right angle to the axis of rotation) of the auto-giro at angle \( \alpha \) is represented by its components (fig. 9):

- Forward speed, \( v \cos \alpha = \lambda u \),
- Axial velocity, \( v_d = \lambda_\alpha u \).

The forward speed in the normal plane is resolved for each \( \psi \) into its components along and perpendicular to the blade (fig. 10) which, together with the rotary motion, give the \( c_\chi \) and \( c_\psi \) components of the speed \( c \) relative to the blade element at right angle to the blade axis (\( c_\chi \) lies on the plane through the axis of rotation), according to figure 11 and with \( \beta = \beta_1 \cos \psi \) at

\[
\begin{align*}
\phi_x &= c \cos \varphi = r \omega + \lambda u \sin \psi \\
\phi_y &= c \sin \varphi = \lambda_\alpha u + \beta_1 \lambda u \cos^2 \psi - r \frac{d\beta}{dt}
\end{align*}
\]  
(IV, 6)

According to (IV, 4) and Figure 9:

\[
\frac{d\beta}{dt} = \beta_1 \omega \sin \psi
\]  
(IV, 7)
It can be shown that the effect of this flapping motion is identical with a blade-angle change through

\[ \Delta \phi = -\beta_1 \sin \psi, \]

when substituting for the "flapping" a "fixed" propeller whose axis of rotation relative to the first is inclined at \( \beta_1 \) to the rear. This is readily apparent from figure 9. Lock (reference 2) gives elaborate proof, deduces all formulas for both cases, and proves their identity.

Then we put, as before,

\[ c_{ap} = c_{p} c_{iap}, \]

so the thrust element at the blade of constant chord \( t \) becomes

\[ dS = \frac{\rho}{2} c_{iap} t \, dr \, \alpha_p \, c^2. \]

Again

\[ \alpha_p = \phi + \psi \]

at constant blade angle \( \psi \); consequently,

\[ \alpha_p \, c^2 = (\phi + \psi) \, c^2. \]

or with (IV,6), wherein \( \sin \phi = \phi \) (\( c_y = c \phi \)) and \( \cos \phi = 1 \) (\( c_x = c \)):

\[ \alpha_p \, c^2 = c_x \, c_y + \phi \, c^2. \]

Thus the thrust component becomes

\[ dS = \frac{\rho}{2} c_{iap} t \, dr \, (c_x \, c_y + \phi \, c^2) \quad (IV,8) \]

The component of the tangential force is assessed in similar manner:

\[ dT = -\frac{\rho}{2} t \, dr \, (c_{wp} \, c_x^2 - c_{iap} \phi \, c_x \, c_y - c_{iap} \, c_y^2) \quad (IV,9) \]
Flapping angle, thrust, and coefficient of axial flow.—The subsequent stage of the analysis is explained on the very simple calculation of the flapping angle \( \beta_1 \). In the formula (IV,5) for the thrust moment of the flapping motion, we express \( M_3 \) as sine series, stopping as for \( \beta_\infty \) after the first periodic term. Then

\[
\sin \psi = \beta_0 \omega^2 J.
\]

Since there are no periodic terms at the right-hand side, the coefficient of \( \sin \psi \) at the left, must become null. And \( \beta_1 \) is therefore obtained by writing the integral for \( M_3 \) from (IV,1) with the aid of (IV, 6, 7, and 8) and putting the sum of the terms with \( \sin \psi \) equal to zero after integrating. The result is:

\[
\beta_1 = 2 \left( \lambda d + \frac{4}{3} \phi \right) \frac{\lambda}{\lambda^2} \frac{1}{1 - \frac{2}{3}}
\]

Similarly, the total thrust is:

\[
S = \frac{p}{2} c_{ap} c_{ap} u^2 \left[ \frac{\lambda d}{2} + \frac{2}{3} \left( 1 + \frac{3}{2} \lambda^2 \right) \right]
\]

and the coefficient of axial flow \( \lambda_d \) (by putting the moment = 0) from the sensibly symmetrical formula is

\[
\frac{c_{wp}}{2. c_{ap}} \left( 1 + \lambda^2 \right) = \left[ \lambda_d \frac{1 + \frac{3}{2} \lambda^2}{1 - \frac{1}{2} \lambda^2} + \frac{3}{2} \frac{\lambda^2}{1 - \frac{1}{2} \lambda^2} \right]
\]

These are Lock's formulas.

Comparison with model experiments.—This time the comparison is made unlike that in the section "The Auto-rotating Windmill", page 5. The test data for \( k_s \) in

\[
k_s = 2 L_\Omega \sqrt{1 + \epsilon^2}.
\]
reference 3 and the corresponding λ values (fig. 12) are written in the somewhat modified thrust formula (IV,11):

\[ \lambda_d = \frac{2 \frac{k_s}{\sigma} c'_{ap}}{2} \left( 1 + \frac{3}{2} \lambda^2 \right) \]  

(IV,13)

wherefrom \( \lambda_d \) is defined. This permits the calculation of \( c_{wp} \) from (IV,12) (and at the same time renders the comparison independent of the induced flow, as explained elsewhere in this report).

The data shown in figure 13 are not readily interpretable, especially as concerns \( c_{wp} \). To be sure, there already is a rather rational approximation to the anticipated amount at low λ (high \( \alpha \)), but the steep rise at low \( \alpha \) should, if it were real, be followed by a rise of \( \lambda_d \) for reasons of energy requirement (equation IV,15). The opposite is the case.

Aside from the values employed heretofore, we also measured the flapping angles, i.e., the whole flapping motion was recorded with a small mirror attached at the blade root. The first thing noticed was that the actual blade motion differs very little from a simple harmonic oscillation and that the lateral inclination of the plane of rotation disregarded so far (the terms with \( \sin \psi \)), is vanishingly small. Of course, this close agreement is valid only for this particular model, whose massive wooden blades are dynamically unlike to actual design. Lock (reference 2) expresses the relation of aerodynamic force and centrifugal force by a nondimensional factor,

\[ \gamma = \frac{\frac{\rho}{2} c'_{ap} R^4}{J} \]  

(IV,14)

According to his data on actually built autogiros, this ranges between 6 and 10, whereas the model shows \( \gamma = 2 \). Hence his blades are three to five times heavier than at full-scale. They strongly approach the ideal of the "heavy" blade, on which the calculations of this chapter are based.

To be sure, as soon as the computed amounts of flapping angle \( \beta_1 \) are compared with the measured values (fig. 14) the accord ceases. The computed \( \beta_1 \) are only about
two-thirds of the measured \( \theta_1 \), although the trend of the cur-
vves is still fairly the same; and a discrepancy as large as that cannot be explained away by inaccuracy in calculation or experiment.

Criticism of the assumptions.—The very fact of such a discrepancy in flapping angle \( \theta_1 \) goes to show that the timetor moment about the blade hinge producing the flapping motion could not have been correctly conceived. The mistake originates in the fact that the air strikes the re-
treating blade partly from the front and partly from the rear, thus producing angles of attack up to 180° along the blade. Obviously, the assumptions \( c'_{ap} = \text{constant} \) and \( c_{wp} = \text{constant} \) can no longer give even an approximately true picture, in that case,* by virtue of the practically complete breakdown of the flow across the whole blade.

In order to gain some idea of the magnitude of the error, we computed the thrust of a blade and its moment about the hinge axis for \( \psi = 270^\circ \), first according to formula (IV, 8), then with the actual profile-coefficients (Gottingen airfoil 429). (Because of the rapidly chang-
ing air-flow conditions the latter can, of course, also be considered only as approximate.)** The result is plotted in figure 15, in form of a thrust coefficient,

\[
ks = \frac{d S}{\rho t d r u^2}
\]

and a moment coefficient

\[
kms = ks \frac{r}{R}
\]

The difference (shaded portion) represents the margin of error.

*Lock (reference 2) himself states: "Finally, it may be worthwhile to attempt to meet the criticism, that in the analysis ... a structure is erected on the basis of the assumption 2' (namely, \( c_{ap} = c'_{ap} \alpha \), and \( c_{wp} = \text{constant} \), which is too heavy for it to bear."

**Noted at proofreading: Upon closer examination, it is found that the unsteadiness effects are numerically of no great consequence.
the computed over the actual moment, exceeding the latter by more than 50 percent.

Now, since according to the basic law (IV.15) of the flapping motion, the thrust moment shall remain constant during rotation, while on the other hand, the actual moment at $\Psi = 270^\circ$ is much lower than the computed moment, the moment on the opposite side ($\Psi = 90^\circ$), computed correctly because the $C_p$ remain small there, must be reduced by an identical amount. That is, the blade must here intensify its upward motion $\frac{\delta}{dt}$ to insure lower profile angle of attack. For reasons of symmetry the retreating blade follows this motion in inverse direction, but, operating as it does in practically separated attitude throughout, there is scarcely any change in thrust or moment. Consequently, it is the advancing blade which produces all or nearly all of this difference, and thus supplies the explanation for the discrepancy between the actually measured and the computed angles $\beta_1$.

It is hardly possible to express the actual behavior of the profile analytically by any relatively simple formula. Graphical representation with due allowance for the measured profile coefficients yields generally applicable results but only at great expense of time and labor. Thus there remains one alternative, and that is, to bring the mathematical integration data into relation with the "integral values" measured on the whole rotating wing. Then, we obtain with the data of figure 14, the approximation:

$$\beta_{1,\text{eff}} = a \beta_1 = 2 a \left( \lambda_d + \frac{4}{3} \phi \right) \frac{\lambda}{1 - \frac{\lambda^2}{2}} \quad (IV.15)$$

wherein $a \approx 1.5$ for $\phi = 0$, $a \approx 1.4$ for $\phi = 1.8^\circ$. The numerator $a$ obviously varies very little with the different blade angles, but may perhaps be very sensitive to changes in profile or characteristic. The rise in flapping angle must be so much greater as the lift curve is poorer and the maximum lift of the profile is lower.

The thrust of the individual blade at $\Psi = 270^\circ$ is also a little lower than computed, owing to the accelerated flapping motion, it will equally be a little lower at $\Psi = 90^\circ$. But opposed to this is an increment of the thrust quota of the blades lying in flight direction ($\Psi = 0^\circ$ and $180^\circ$), for thoro the spatial air stream angles be-
come somewhat greater as a result of greater $\beta_1$. The ultimate predominating effect, however, can be decided only by elaborate graphical investigations.

On the tangential force* and its moment (fig. 16), the difference in trend and amount is especially conspicuous. The profound impelling moment appearing in the calculation at $\Psi = 270^\circ$ does not exist at all in reality. This explains why, when evaluating the test data according to (IV,12 and 13), $c_{wp}$ shows such a marked increase as $\lambda$ increases without a contemporary rise of $\lambda_d$ (fig. 13). The rotating power of the blade lift, greatly overestimated in the calculation of this part of the path, yields the apparent energy which must be equalized again by correspondingly higher profile drag. In reality, $c_{wp}$ should not increase materially nor should $\lambda_d$ decrease substantially.

The result of these investigations is the knowledge that the mathematical analysis of the processes on the autogiro of high tip-speed ratio is confined within comparatively narrow limits, which are due to the difficulty of reproducing the air force coefficients of the blade profile analytically correct and of accurately appreciating the flow phenomena involved at the blade.

In the following section it is shown that the hitherto accepted considerations themselves are in need of correction as regards their fundamental physical concepts.

THE INDUCED FIELD OF FLOW AND ITS EFFECTS

The airfoil of large chord.—In all considerations thus far the induced flow had been assumed at half the final deflection, in accord with Glauert and Lock (as detailed on page 14, on "Theory of thrust of the ideal autogiro." But, can this hypothesis which, according to Prandtl's airfoil theory, is limited to the simple lifting vortex, actually still be considered here as satisfactory approach?

And experiment is here also more convincing than all deliberations. The validity of the concept of lifting

*Actual $k_t = (c/u)^2 (c_{wp} \sin \varphi - c_{wp})$ with $c_{wp} = 0.012$ to $c_{wp} = 15^\circ$, then $k_t = 0$ (resultant at right angle to chord).
vortex for the airfoil of usual lift/drag ratio is corroborated by the fact that the lift increases linearly with the angle of attack and, upon conversion to different aspect ratio in accordance with Prandtl’s formula, manifests a constant $\frac{dC_L}{d\alpha}$, which is possible only when the field of flow is 2-dimensional. Now, experiments with very thick airfoils, particularly now American sections (reference 7), among which is an airfoil of circular plan form and similar profile (Clark Y) (see fig. 17), disclose for decreasing slenderness ratio, an increasing curvature of the lift curve which, compared to the straight lines obtained according to the simple theory of the lifting vortex, fall off continuously.

Consider, for example, the process on the circular airfoil. Visualize the airfoil divided into separato, transverse strips; that is, transformed, as it were, into a multiplane with wings spaced closely behind one another. The air flowing off from the most forward partial wing is already slightly deflected, because of the lift production. It strikes the second wing broadside at a slightly smaller angle than the free flowing air to the right and left of it. Consequently, the flow within range of the second wing is already somewhat curved. The process continues over the chord and produces through the progressively increasing, yet consistently diminishing, deflection an unsymmetrical curvature in chord direction also. The field of flow must therefore be spatially curved, a kind of "saddle surface."

It can be inferred therefrom that the rear portion of the wing, particularly at low angles of attack, is under a smaller effective angle of attack than with plane flow.

The trend of the moment curve (fig. 17) bears this out. The moment about the focus (referred to a "mean" profile at lateral distance $4R/3\pi$ from the center) is, at low lift, substantially less than for the slender rectangular wing ($A = 6$). The foremost $c_p$ position is $\sim 28$ percent from the leading edge for the circular wing and $\sim 39$ percent for the rectangular wing with the same $c_a$ ($\sim 0.45$). The lift of the circular wing is therefore substantially closer to the leading edge, which may be viewed as an effect of the cited asymmetrical curvature of the flow in chord direction. (We shall not go into the peculiar stable behavior of the moment at higher $c_a$.).
To be sure, the airfoil of large chord has not been mathematically analyzed as yet. Fundamentally, the procedure will probably follow in support of the described process. Each of these partial wings would probably be replaced by a system of trailing vortices and the velocity field induced therefrom computed. But, as the circulation of every one of these partial wings will be affected by all the others, the calculation would become extremely complicated.

The position of the direct lifting propeller is even less hopeful. Whereas, with the fixed-wing, the division into separate rectilinearly bounded strips with constant $dC_{D}/d\alpha$ seems still possible, this strip method would be impossible to apply to the rotating wing; $dC_{D}/d\alpha$ would change from one point to the next. An investigation of this kind would call for expenditures out of all proportion to the gain derived from it. Hence a suitable approximation must suffice.

The "substitute" autogiro. Since we must figure building up the field of flow from the differential, we must begin with the integral, i.e., with the experiment on the whole model and then draw conclusions a posteriori. Admittedly, such summary procedure affords only summary results. But a method which renders the processes at least correct as to type is always preferable to one which is patently wrong. Even if it does not completely answer the demands of physical exactness, it nevertheless gives the engineer some foundation upon which he can base his analysis with some measure of confidence.

The process of reasoning is as follows: The real lifting propeller is replaced by a substitute propeller without flapping motion, whose field of flow is readily computed; it inclines at $\alpha_{d}$ to the normal plane. The difference between the (measured) angle of attack $\alpha$ and the thus defined $\alpha_{d}$ is the induced inclination $\alpha_{i}$ of the flow.

Now what does the substitute propeller look like? Of course, it should have the same shape as the real one, in order to make the transition possible; but relative to its flow conditions, it should correspond to the lifting propeller with tip-speed ratio approaching zero, described in the section "Autogiro of Low Tip-Speed Ratio", page 12; that is, it should be tractable with the simple formulas derived there. The thrust coefficient $k_{g}$ is to remain
unaltered. And the remarkable result - the inner justification of this procedure - is that the corresponding profile drag coefficients with this substitute are actually in quite close agreement with those anticipated from profile measurements, so that conversely, starting with profile measurements, reasonable figures can be obtained for the lifting propeller.*

From (III,11 and 14) we obtain:

\[
ks = \sigma c_{ap} \left( \frac{\phi + \lambda_d}{3} \right)
\]

and

\[
\lambda_d = 2 \left( \frac{ks}{\sigma c_{ap}} - \frac{\phi}{3} \right)
\]

and

\[
w_{wp} = 2 c_{ap} \lambda_d \left( \lambda_d + \frac{2}{3} \phi \right)
\]

The thrust coefficients \(ks\) are taken from figure 12 as mean values in the pertinent range (\(= 5^\circ\) to \(= 15^\circ\)); \(c_{ap}\) is, as before, put = 5.6. Thus, we have:

\[
\begin{align*}
\phi & = 0 \quad 1^\circ \quad 1.8^\circ \quad 1.8^\circ \\
ks & = 0.016 \quad 0.0195 \quad 0.023 \quad 0.0115 \\
\lambda_d & = 0.030 \quad 0.025 \quad 0.022 \quad 0.022 \\
100 c_{wp} & = 1.0 \quad 1.03 \quad 1.08 \quad 1.08
\end{align*}
\]

The amounts of \(c_{wp}\) show the anticipated order of magnitude. For more exact comparison the profile lift figures at which the various propellers operate, should be taken into account. We introduce, according to Glauert (reference 1) a "mean" lift coefficient

\[
\bar{c}_{ap} = \frac{3 ks}{\sigma}
\]

that is, the \(c_{ap}\) at which all profiles of the rectangular blade would have to operate in order to give the same

*The reason for this, at first, astonishing result, lies probably in the fact that even at high tip-speed ratio the flow is still sound over the major portion of the propeller disk and that the portions with separated flow contribute little to the torque.
The figures are:

\[
\begin{align*}
\phi &= 0^\circ \quad 1^\circ \quad 1.8^\circ \quad 1.8^\circ \quad (2 \text{ blades}) \\
\sigma_{\text{cap}} &= 0.25 \quad 0.30 \quad 0.36 \quad 0.36
\end{align*}
\]

At these lift figures our computed \( c_{\text{wp}} \) are accordingly 15 percent higher than the Göttingen measurements for \( t = 0.2 \text{ m} \), \( v = 30 \text{ m/s} \) (fig. 8) which, as already stated, is about equivalent to the profile characteristics at \( 2/3 \delta \). This discrepancy can be unqualifiedly explained by the thickened trailing edge and the probably slightly different surface roughness.

The transition to the whole autogiro is most conveniently accomplished by substituting the "ideal" autogiro (see page 12) for the "substitute" autogiro, which differs from the latter only in its constant axial velocity over the whole propeller disk.

The axial flow coefficient \( \zeta \) can be expressed through (II.7 and 10) in terms of \( \kappa_s \) and \( \lambda_d \):

\[
\zeta = \frac{4}{3 \sqrt{2 \sigma_{\text{cap}}^3}} \frac{c_p}{c_{\text{wp}}} = \frac{2}{3} \frac{c_p}{c_{\text{wp}}}
\]

whence

\[
\zeta = \frac{\lambda_d}{\sqrt{\kappa_s}} \quad (V, 4)**
\]

The results for the four analyzed propellers are:

\[
\begin{align*}
\phi &= 0^\circ \quad 1^\circ \quad 1.8^\circ \quad 1.8^\circ \quad (2 \text{ blades}) \\
\zeta &= 0.240 \quad 0.178 \quad 0.148 \quad 0.208
\end{align*}
\]

*According to (II,7), \( c_{\text{wp}} \) is 1.5 times that of the constant \( c_{\text{cap}} \) for the lancet-shaped blades, which is connected with the definition of \( \phi \).

**Identical with equation (III,17), although (V,4) is generally valid, independent of blade form.
Those axial flow figures are considerably lower than those computed in section, page 12. The rotor blades seem to be more solid, so to speak, because of the lower profile losses.

To establish the induced inclination, $\alpha_1$, of the flow on the "substitute," we revert to equation (III, 6) and figure 6. Then:

$$\alpha_1 = \alpha - \alpha_0 = \alpha - \frac{V_d}{v \cos \alpha} = \alpha - \frac{\sqrt{c_s}}{\cos \alpha}$$

or

$$\alpha_1 = \alpha - \frac{\sqrt{c_s}}{\sec \alpha} \quad (V_{45})$$

The result of the model tests interpreted with this formula, is shown in figure 18. Incidental to this, it should be noted that:

$\alpha_1$ is the inclination of the "substitute" flow, that is, that plane flow yielding the same total propeller force as the actual, 3-dimensional curved flow. The degree of curvature obviously is bound up with the permeability of the autogiro.

This becomes especially clear with the limiting transition ($\text{cwp} \rightarrow 0$) to the "solid" propeller. Here no air passes through at any point. The thrust of each element of the propeller surface is given with the blade form and blade angle and independent of the adjacent elements. The induced flow must follow the plane propeller surface, that is, be plane itself within range of the propeller disk.

However, with the growing permeability continuously larger masses of air pass through the forward part of the propeller disk, are deflected there and lower the effective angle of flow of the rearward lying parts. Through this process the forward part of the propeller is, in consequence, more heavily loaded, the rate of deflection is more rapid, and the curvature in longitudinal direction will, as a result, be greater than in the rearmost part. The major portion of the propeller thus will operate because of this unsymmetrical curvature, in a flow which is already inclined at more than half of the ultimate angle of deflection $c_8/2$. Consequently, the plane substitute flow must incline at more than $c_8/4$. 
It is seen how $\alpha_1$ and $\psi_1$ are so much more closely coupled together as the permeability, expressed by $\xi$, becomes greater.

This is fully substantiated by figure 18. The greater $\phi$, the smaller $\xi$, and consequently, $\alpha_1$ also. The points for each of the three four-blades lie sensibly on a straight line. The figures for the two-blades are, as expected, below those of the four-blades with equal $\phi$, because of greater permeability. Admittedly, they spread more and also are lower than would correspond to the pertinent $\xi$. Perhaps there are boundary or discontinuity interferences in action on account of the small number of blades.

Owing to the small number of experiments available for the evaluation, it is difficult to decide whether the $\alpha_1$ lines actually are straight and to what extent $\psi$ as well as $\lambda$ (owing to the nonuniform lift distribution transverse to the flow) has any effect on $\alpha_1$. Besides, it should be remembered that the matter becomes so much more uncertain as $\alpha$ is smaller. For, since the flapping angle increases (increase of $\lambda$) the agreement of the thrust of the "real" with the "substitute" propeller becomes consistently poorer. The real propeller probably still gives — if it has not already fallen out of step — a small positive thrust, even at $\alpha = 0\circ$, which according to $(\psi, \phi)$ would yield a negative $\alpha_1$. This is, of course, impossible and thus exposes one fundamental defect of our analysis.

It would therefore serve, for the time being, no useful purpose to express the $\alpha_1$ lines conformably to figure 18 in mathematical form. What we lack are further model experiments at sufficiently large scale (and, as much as possible, in an open jet). Until then, the empirical relationship of figure 18 must suffice; intermediate figures are out of the question because of the excessively deviating forms.

Behavior of autogiro in curved field of flow. — The general applicability of our analytical method is contingent upon being cognizant of the fact that the field of flow can be curved considerably without affecting the integral of the thrust and of the moment, as already established by Glaeser (reference 1) for a particular case. To explain the observed lateral components, he temporarily assumed a sonicircular flow curvature which ensues when
is allowed to increase evenly in chord direction from 0 to its ultimate value \( v_c/2 \). He finds that this certainly exaggerated curvature does not affect thrust and moment when compared with the figures for plane flow whose inclination amounts to \( c_s/4 \). That such symmetrical, semicircular flow is impossible by virtue of the interaction of the forward part of the propeller on the rear part, has already been pointed out.

Now let us examine another kind of flow curvature. Against the rectangular-blade propeller, we assumed \( \nu_d \) as constant across the propeller-disk area in first approach (see page 17), although the thrust loading adjacent to the tip is certainly higher than next to the hub; the difference increases with \( \beta \). And we already pointed out that time that the axial velocity next to the hub would be higher than away from it.*

To simplify matters, we chose a rectilinear outwardly decreasing distribution of the axial velocity of the form (fig. 12)**

\[
\nu_d = \nu_d_0 \left(1 - \nu \frac{r}{R}\right)
\]

This \( \nu_d \) must then be brought into relationship with the elsewhere used constant \( \nu_d \); we write these quantities as mean values with a dash, thus:

\[
\overline{\nu_d} = \frac{\nu_d}{u}
\]

The connection between these two terms is established by the physical condition that the total amount of air passing through per second be the same. This is equivalent to a constant mean angle of axial flow,

---

*Visualize the lifting propeller as having a big hole in the center, through which air passes unrestrictedly. In this manner the mutual interference of all parts of the propeller disk is knowingly disregarded.

**Together with forward speed \( v \cos \alpha \), it gives for the field of flow a readily tractable 3-dimensionally curved surface.
The velocity distribution of equal quantities of flow therefore have the point \( r = \frac{2}{3} R \) in common (fig. 19). In this point the axial velocity corresponds to the constant \( v_\alpha \) employed elsewhere. The most important part of the blade lies also in this vicinity. (See (II,10), page 10.)

Then we compute \( S \) and \( \lambda_d \) with (V,9), as before; the result is

\[
S = \frac{c'}{2} c' \sigma u^2 \frac{(2 \frac{\lambda_d}{\lambda_d} - \frac{\lambda_d}{2})}{(\frac{2}{3} + \frac{\lambda_d}{2})} \quad (V,10)
\]

or, exactly the same as formula (III,11). The thrust remains unaltered when putting \( \lambda_d = \lambda_d' \), that is, the resultant amount of flow remains the same. The latter quantity is computed from the equation of definition:

\[
\lambda_d \frac{6 - 8 p + 3 \frac{p^2}{2}}{\left(1 + \frac{2}{3} p\right)^2} + \frac{\lambda_d}{2} \frac{4 - 3 p - 3 \frac{c' a p}{2}}{\left(1 + \frac{2}{3} p\right)^2} = 0 \quad (V,11)
\]

As a check on the accuracy of the method, the 4-blade model with \( \phi = 1.8^\circ \) was chosen, for which at \( v_\alpha = \text{con-} \)
constant, the coefficient of axial flow was $\lambda_d = 0.022$. Instead of computing $\lambda_d$ with given $c_{wp}$ by variation of $p$, it is more convenient to define $c_{wp}$ for $\lambda_d = 0.022$ from $\langle V, l \rangle$. So long as $c_{wp}$ remains constant, $\lambda_d$ also would not change in the other case; but an increasing $c_{wp}$ would have as counterpart a decreasing $\lambda_d$.

Thus, $\langle V, l \rangle$ gives:

$$c_{wp} = 0.001 \frac{6 - 8p + 3p^2}{(1 - \frac{2}{3}p)^2} + 0.131 \frac{4 - 3p}{1 - \frac{2}{3}p}.$$  

The result of varying $p$ is shown in figure 20. $c_{wp}$ remains sensibly constant from $p = 0$ to $p = 3/4$.

The practical range of $p$ must, by virtue of the equalization process, lie between $p = 0$ and the figure assumed for uniform thrust grading, estimated at $p = 4/5$ for the outer third of the blade with $\frac{dS}{dR} = \text{constant}$. Accordingly, the actual value of $p$ for $\gamma = 1.8^\circ$ should lie in the neighborhood of $1/2$ for minimum $c_{wp}$.

According to these examples, the distribution of $v_d$ is not overly important as far as resultant thrust and resultant moment are concerned, provided the correct mean value of $v_d$ has been attained. This fact assures us that the results of the foregoing section will not be much at variance with reality, even when the assumption $v_d = \text{constant}$ has not been wholly complied with.

**THE LIFT/DRAG-RATIO CURVE (CHARACTERISTIC CURVE) OF THE AUTOPIRO**

**Origin and resolution of losses.- For the sake of clarity, the drag of the lifting propeller had been intentionally ignored, so as not to confuse the issue.**

In the deductions for the autogiro of small tip-speed ratio (page 12) it was legitimate, for reasons of symmetry, to take the resultant thrust $S$ at right angles to the plane of rotation, that is, in propeller axis direction. Its setting was at flow angle $\alpha_1$ to the inclined flow with induced angle $\alpha_1$ at the locus of the propell-
W_{\text{sub}} = \text{drag of substitute autogiro}, that is (according to the section "The Induced Field of Flow and Its Effects", page 30), of the autogiro characterized by identical form and thrust but vanishingly small tip-speed ratio.

The form of the polars is not suitable for plotting the drag of the autogiro, because the conditions are sensibly different from those of the fixed wing of the usual dimensions. The drags at high and low $c_a$ are so utterly unlike, that a linear plotting would give only a very incomplete record of the figures at low $c_a$, where the best lift/drag ratios of the lifting propeller really lie. It is therefore better to plot the lift/drag ratio instead of the drag coefficient. Such a curve gives at the same time the drag of a lifting propeller of constant loading at the different operating attitudes.

According to the aforesaid, the lift/drag ratio of the substitute autogiro is with (V,5):

$$\varepsilon_{\text{sub}} = \tan \alpha = \tan (\alpha_1 + \zeta \sqrt{c_s} \sec \alpha)^v$$

(VI,2)

with

$$\alpha_1 = \alpha_1 \sec \alpha \quad \text{and} \quad \varepsilon_d = \zeta \sqrt{c_s} \sec \alpha \quad \text{(VI,3)}$$

for the region within which $\sin$ and $\sec$ may be interchanged; $\alpha_1 (> \frac{c_a}{4})$ results from figure 18, $\zeta = \frac{d}{\sqrt{k_s}}$ from equation (V,4). Both parts being dependent on $c_a$ and $c_s$, it is preferable to plot against $c_s$ rather than $c_a$; $\sec \alpha$ is only a few percent higher than $1$, hence can be estimated in design analyses.

Thus, the plotting of (VI,3) and the corresponding measured values of the pertinent lifting propeller, gives a graphic view of the proportions of the losses at the lifting propeller (fig. 21). Apart from the two quotes, $\varepsilon_1$ and $\varepsilon_d$, there is yet another, that due to nonuniformity, the asymmetry of the air flow at the blade on both sides of the median plane.
Nonuniformity losses. Here we encounter the same difficulties experienced in the treatment of the flapping motion, to wit, a comparatively unwieldy and complex calculation can — owing to fundamental defects of the theorem — produce only moderately exact results. And the chief object of our mathematical analysis is to obtain a formula which then may be compared with the model measurements and adapted to them by a factor, as accomplished for the flapping angle $\beta_1$.

Lock (reference 2) defines the thrust component $H$ perpendicular to the axis of rotation, in the same fashion as indicated in the section "The Autogiro of Large Tip-Speed Ratio - Flapping Motion", page 21, for $\beta_1$; the result can be formulated nondimensionally as affected for $k_s$:

$$k_h = \sigma \left[ \frac{1}{2} \lambda c_{wp} - \frac{1}{2} \lambda c'_{ap} \lambda_d \phi + c'_{ap} \beta_1 \left( \frac{3}{4} \lambda_d + \frac{1}{3} \phi + \frac{1}{4} \lambda \beta_1 \right) \right] \tag{VI,3}$$

Now we rewrite the equation so as to bring the quantity expressing the nonuniformity, that is, the tip-speed ratio $\lambda_u$ before the bracket. To this end, we remove $\beta_1$ by an approximation formula conformably to (IV.10):

$$\beta_1 = 2 \lambda \left( \lambda_d + \frac{4}{3} \phi \right)$$

Then, with (VI.3), the lift/drag ratio of $H$ becomes

$$\epsilon_u = \frac{k_h}{k_s} = \frac{\lambda c'_{ap}}{2 k_s} \left[ 2 \lambda^2 \left( \lambda_d + \frac{4}{3} \phi \right)^2 + \frac{c_{wp}}{c'_{ap}} + 3 \lambda_d^2 + \frac{13}{3} \lambda_d \phi + \frac{16}{9} \phi^2 \right] \tag{VI,4}$$

which, after putting

$$3 \lambda_d^2 + 2 \lambda_d \phi = \frac{3 c_{wp}}{2 c'_{ap}}$$

(according to (III.14), yields:}
And as a last step, we eliminate $\theta$ through (VI,1) and $\delta$ from (VI,5), so that

$$
\epsilon_u = \lambda \frac{c_{\text{ap}}}{c_{\text{ap}}} \left[ \lambda d + \frac{4}{3} \theta \right]^2 + \frac{5}{4} \frac{c_{\text{wp}}}{c_{\text{ap}}} + \frac{7}{6} \lambda d \delta + \frac{8}{9} \theta^2 
$$

The numerical evaluation of this formula with the dimensions of the models manifests a rise in the value of the fraction (as a result of the effect of $\delta$ in the numerator) with $\phi$ (0.21 at $\phi = 1.8^\circ$ against 0.155 at $\phi = 0^\circ$), whereas the first term of the numerator with $\lambda d$ is of no significance. But, according to a previous section (p. 21), the tangential force is much overestimated for the retreating blade; the overestimate increases with $\delta$. Consequently, it may be expected that the value of the fraction in (VI,6) is a little lower and more constant than the calculation discloses.

To check this, we put

$$
\epsilon_u = \kappa \lambda 
$$

and define $\epsilon_u$ by trial insertion of different but constant values of $\kappa$ for each model, so that the test points of the four models compared here are reproduced as closely as possible. As a matter of fact, this is surprisingly well accomplished, according to figures 22-25. The non-uniformity loss for each propeller in close approach is comparable to the tip-speed ratio.

But the numerator $\kappa$ also fluctuates only very little. Admittedly, it does not rise with $\delta$ as it should, according to (VI,6), but rather shows a slight drop. In (round) figures it amounts to:

$$
\begin{align*}
\phi &= 0^\circ & 1^\circ & 1.8^\circ & 1.8^\circ \quad (2 \text{ blades}) \\
\kappa &= 0.135 & 0.13 & 0.125 & 0.125 \quad (\text{at maximum})
\end{align*}
$$
It is fortunate for the check on the reliability of our method that precisely the two practically most important four-bladers with $\phi = 1^\circ$ and $1.8^\circ$ (of which the latter especially, shows numerous test points) are so closely and accurately expressed by the simple law (VI,7). But the two-blader (fig. 25) is difficult to define exactly, because the points scatter irregularly. Since, however, $\sigma$ does not occur in (VI,6), we chose $\kappa$ as for the corresponding four-blader. The curve passes through the middle of the test points.

During the evaluation it should be borne in mind that $\epsilon_u$ amounts to only a fraction, in part even a minor fraction of the total lift/drag ratio, so that errors in measurement in this enlarged by $\epsilon_u$ would be readily shown up. On the other hand, the accuracy of the measurements is limited by the fact that the deduction for the hub drag constitutes a considerable proportion of the total drag (23 percent for the four-blader with best lift/drag ratio and $\phi = 1.8^\circ$, and 39 percent for the two-blader). In spite of the fact that the hub drag had been measured separately with the greatest of care and with all due allowance for mutual interferences, the source for difficultly estimable inaccuracies still remains.

For this reason the data obtained from these experiments should not be considered as definite. Further model experiments at sufficiently large scale are urgently desired. But in the meantime, formula (VI,7) and the figures obtained here may be confidently used. Whatever lack of accuracy the formula may have is more than balanced by its simplicity and practical convenience.

A somewhat deeper insight into the nature of nonuniformity loss $\epsilon_u$ may be gained by following Glauert's (reference 1) and Lock's (reference 2) procedure wherein, however, axial flow and nonuniformity losses ($\epsilon_d + \epsilon_u$) do not occur separately. The power to be exerted by the profile drag of the blades in the propeller disk as used in section "The Autorotating Windmill", page 5, for computing the flow velocity, can equally well be resorted to for defining $\epsilon_u$. Since the flapping motion as a kind of resonance oscillation absorbs no energy, there remains as lost power induced by the nonuniformity only the profile power.

The power due to uneven air flow equals the power of the corresponding drag proportion in path direction.
\[ N_u = \epsilon_u A v. \]

Then with \( A = s \cos \alpha \),

\[ \epsilon_u = \frac{N_u}{v s \cos \alpha}. \]

Confining ourselves conformably to Lock (reference 2), to the velocity component \( c_x \) perpendicular to the blade axis (IV, 6), we have:

\[ N_u = \frac{\rho \lambda^2 c_{wp} z t R^4 \omega^3}{2} \int_0^{2\pi} \int_0^b \left[ (r \omega + \lambda u \sin \psi) \right] dr. \]

which, integrated, gives:

\[ N_u = \frac{3}{8} \rho \lambda^2 c_{wp} z t R^4 \omega^3. \]

Then with (II, 5), (III, 2), and \( k_g \) in place of \( S \), we have

\[ \epsilon_u = 3 \frac{\lambda c_{wp}}{4 k_g \lambda}. \]

This agrees with the second part of the particular formula by Lock. Glaucrt computes the loss by including the component \( \lambda c \cos \psi \) in blade-axis direction, that is, with the actual yawing velocity. The form of \( \epsilon_u \) is retained hereby, the factor 3 becomes 4.5 (for \( \lambda = 0 \)), or 5 (for \( \lambda = 0.5 \)).

But the ultimate reduction has not yet been attained. It is accomplished by inserting \( k_g \) conformably to (V, 1) and \( c_{wp} \) conformably to (V, 4):

\[ \epsilon_u = 3 \lambda d \lambda (c_x \text{ only}) \]

and

\[ \epsilon_u = (4.5 \text{ to } 5) \lambda d \lambda (\text{actual air flow}). \]

This result denotes that the losses on profile power increase with \( \lambda \) and (according to (II, 10)) with \( \epsilon_p \) as a result of uneven air flow.
The following tabulation gives the comparison with the experimental figures:

\[
\begin{array}{ccc}
\phi &=& 0 \\
\lambda_d &=& 0.030 \\
\lambda_d &=& 0.090 \\
\lambda_d &=& 0.150 \\
\kappa &=& 0.135 \\
\end{array}
\]

\[
\begin{array}{ccc}
& l & 1.8^\circ \\
0.025 & 0.022 & (c_x \text{ only}) \\
0.075 & 0.066 & (\text{actual flow}) \\
0.125 & 0.110 & \\
0.130 & 0.125 & \\
\end{array}
\]

The order of magnitude of the factors of \( \lambda \) is, to be sure, correct with a view to the actual air stream, but the change with \( \phi \) is sensibly greater than with the model (\( \kappa \)). The fact of the factor for \( \phi = 0 \) becoming even greater than \( \kappa \), is indicative of this method of calculation to overestimate the profile losses; for there probably is yet another unassessably small proportion to be added, as a result of the turbulence in the detached part of the flow at the retreating blade. So the actual value of the assessable profile losses probably lies between the two mathematical limits.

There is no doubt but that the lower limit (3 \( \lambda_d \)) used by Lock as the starting point of his calculations, gives too favorable lift/drag ratios. Still, it would serve no useful purpose to speculatively form an additional term, say, by starting from \( \phi \), to establish the agreement with the measured \( \kappa \). For that, the test data are not reliable enough yet. However, one fact is certain, and that is that the calculation with \( \kappa \) promises more reliable data by a simple method than any of the analytically adduced relations.

Practical importance of three-way division - Limitation.- Let us return to the diagrammatical representation of figure 21. We have seen that the energy loss at the lifting propeller expressed in lift/drag ratio can be resolved according to physical aspects into three components and assessed by approximation. They were:

a) the induced loss \( (c_1) \); it has a lower limit, for which the induced angle of attack \( \alpha_I = c_8/4 \), but which is not reached in practice by virtue of the curvature of the flow. An approach is given
by subtracting the flow angle $\alpha_d$ from the angle of attack $\alpha$ on model experiments. The then obtained angle $\alpha_1$ (fig. 18) indicates the apparent slope of a plane field of flow, whose resultant effect on the propeller is the same as the actual curved field, which is difficult to assess numerically.

The induction loss on the lifting propeller is essentially given by the plan form, hence difficult to influence.

b) the flow loss ($\epsilon_d$): It covers the power requirement by propeller rotation against the profile drag of the blades. Its relative minimum is obtained by assuming a tip-speed ratio approaching zero, i.e., symmetrical airflow; it is characterized by the axial-flow coefficient $\xi$ with flow angle.

$$\alpha_d = \xi \sqrt{c_s} \sec \alpha \ (= \epsilon_d).$$

$\xi$ is sensibly dependent on the lift-drag ratio of the profile at which the blade operates, and on the surface density $\sigma$; it can, therefore, be markedly influenced by the plan form.

c) nonuniformity loss ($\epsilon_u$): It is a result of the uneven flow at the blades in the different settings with no longer negligibly small tip-speed ratio (as customary by energy conversion in flows of nonuniform velocity). Exact analytical assessment is probably impossible. In accord with model experiments, it can be expressed with

$$\epsilon_u = \kappa \lambda,$$

where $\kappa = 1/8$ approximately for the usual range of blade angles. It can, like $\xi$, be influenced by the plan form.

The detailed process to be followed for reducing $\epsilon_d$ and $\epsilon_u$ is best seen when the formulas for the lancet-shaped propeller, developed in section, page 5, are used as basis.

A slightly modified (II.12) gives
and (II,13) together with (III,2 and 3) give

\[ \zeta = \frac{4}{3} \frac{c_{wp}}{\sigma c_{ap}^3} \]  

(VI,8)

Of the three variables, \( c_{wp}, c_{ap}, \) and \( \sigma \) only the first appears with definite effect. The coefficient of axial flow behaves exactly like the drag coefficient of the blade profile. Contrariwise, \( c_{ap} \) and \( \sigma \) affect \( \zeta \) in the inverse sense of \( \lambda \); the greater \( c_{ap}(\phi) \) and \( \sigma \) is, the smaller \( \zeta \) becomes but \( \lambda \), so much greater.

Formulas (VI,8) and (VI,9) show the designers of autogiros how to proceed in order to reach a particular aim.

On the other hand, it should be borne in mind that \( c_{ap}(\phi) \) can only be increased to a limited extent. Up to now the evaluation of the model experiments had been intentionally limited to \( \phi = 1.8^\circ \), although the measurements included blade angles of \( 2.3^\circ \) and \( 3^\circ \). But the erratic behavior of \( k_{s} \) even at \( \phi = 2.3^\circ \) was indicative of a marked irregularity of the happenings at the blade. Such measurements are unsuitable for checking or confirming a theory.

The data for \( \phi = 2.3^\circ \) are included in figure 26. The improvement with great \( c_{s} \) as against \( \phi = 1.8^\circ \) is slight, while the best values fall considerably behind. This is not simply due to the increasing \( \lambda \) conformably to (VI,10) for, upon closer examination, the numerator \( \kappa \) in (VI,7) is also found to be substantially higher than with \( \phi = 1.8^\circ \) (\( \sim 0.145 \) against \( 0.125 \), increases with \( c_{s} \)). This example shows that a certain amount of care must be exercised in the application of our derivation method.

However, this much is certain: the smaller the tip-speed ratio, the more reliable our relationships. A low tip-speed ratio is attainable by small \( c_{ap} \) or \( \sigma \) with otherwise given conditions, but a certain percent change of \( c_{ap} \) vitiates \( \zeta \) substantially more than an identical
change of $\sigma$. This is the reason why in high-speed aircraft, in which the nonuniformity loss is pronounced ($c_s < 0.05$), a low surface density is of advantage. Its inferior limit today is largely a design problem.

Any attempt at estimating the attainable $c$ encounters first of all, $cwp$, which for physical reasons constitutes an insurmountable obstacle for any appreciable progress. In view of $\lambda$ and $\sigma$ together with the danger of falling out of step, it is imperative that $c_{ap}$ in (VI,8) does not exceed a very limited amount while, on the other hand, $\sigma$ should not become unlimitedly small, or else the flow loss at high $c_s$ would become abnormally great and absorb too much power in climbing and throttle flight. The scope of improving $cwp$ under the conditions existing today is, indeed, very limited. It consists of careful selection and treatment of profile, higher characteristic through high tip speed, and fewer variations of $c_{ap}$ through lower tip-speed ratios. And the total result of these attempts will at the very most, lower $cwp$ not to exceed 20 to 25 percent.

For computing the numerical values, the following formulas are used:

$$c_d = \frac{\lambda_d}{\lambda}$$

$$c_u = \lambda c$$

$\epsilon_1$ is taken from figure 18, whereby

$$c_s = \frac{\cos \alpha}{\lambda^2} k_s \approx \frac{k_s}{\lambda^2}$$  \hspace{1cm} (VI,12)

$\lambda_d$, $k_s$, and $\xi$ from (III,5), (V,1), and (V,4). To illustrate, for $\beta = 2^\circ$, $cwp = 0.008$, and $\sigma = 0.08$, it gives

$$\lambda_d = 0.0173, k_s = 0.0092, \xi = 0.18$$

and the $c$ values for high tip-speed ratio with $\kappa = 0.12$ (estimated from the test data with (VI,6) are:

---

From formula (VI,3) with (V,4) and (VI,12)
The foregoing exposition is essentially limited to the purpose of assessing the aerodynamic quantities of the lifting propeller with a minimum of mathematics yet correct appreciation of the physical fundamental processes involved. Admittedly, they are in need of further improvement in many respects.

In the following, we select only a few of the more outstanding problems from the practical point of view.* To be sure, they will be more in the line of pointers and giving orders of magnitude than of adding definite solutions.

*For general information on autogiros, see references 13 and 14.
Light and curved blades, cross-wind force. — In the developments thus far, the weight of the blades, or their centrifugal force, relative to the thrust had been assumed great enough so that the blade motion was sensibly in a plane. This still holds with sufficient approach for the mass conditions of the model where the recorded deviation from the plane, the angle of the coning motion, did not exceed 1 to 2°, which justified us in disregarding its effect.

But it is quite different with lifting propellers whose blades, as already pointed out in section, page 21, are quite often only from one third to one fifth as heavy as those of the model. Then the angle $\beta_0$ of the coning motion is from 3 to 5 times as large as on the model. Its usual range is between 6 and 9°, and (IV,5) gives it the value

$$\beta_0 = \frac{M_s}{J \omega^2} \quad \text{(VII,1)}$$

As the thrust moment $M_s$ rises with the thrust, while it is proportional to $\omega^2$, $\beta_0$ is independent of the propeller loading and solely defined by the quantities $c$, $\rho$, $\lambda$, $\mu$, and $J$ of (IV,14) and $c_\theta(p)$.

Obviously, the coning form is not without influence on the propeller drag. The drag increment is primarily due to the accelerated air force of the forward blade ($\psi = 180^\circ$) which has the greatest backward slope. Lock (reference 2) gives a general treatment of it in the second part of his report; and his formulas which, admittedly, must be used with certain reservations, give nevertheless a measure of comparison. He finds for an autogiro with $\psi = 10^\circ$ (as against 2° for the model), $\lambda = 2^\circ$, $cwp = 0.012$, and $\sigma = 0.2$; that is, of slow speed and very light blades, that the best lift/drag ratio becomes about 0.0075 poorer.

But the coning motion has yet another effect: It explains the formation of a lateral inclination of the thrust which, without it, would be impossible. The advancing blade sustains, as we have seen, a far greater load

*Apart from the weight of the blades proper, which, however, plays an insignificant part in full-scale designs.
than the receding blade. As the resultant of the air force is consistently at right angles to the blade axis and this describes a cone, the other does likewise but, while revolving, changes its magnitude to such an extent as to set up a component perpendicular to the axis of rotation, which points athwart the direction of the retreating blade. According to Glauert's formula (reference 1), its ratio \( \varepsilon_s \) to the resultant force (a kind of lift-drag ratio) should be proportional to \( \lambda \).

The curvature of the flow induces a second cross-wind force which, according to Glauert (reference 1) should be diametrically opposed to the first and increase with \( 1/\lambda \) (by camber of arc).

Lock's model experiments also include a lateral force measurement for the 4-blader at \( \beta = 1.8^\circ \) (fig. 27). The force direction is indicative of its source from the coning motion, but the rise of its lift/drag ratio \( \varepsilon_s \) is greater than anticipated. This is probably bound up with the equally increased flapping motion (IV, 15) compared to the theory.

Then the coning motion has yet a certain effect on the position of the cone formed by the blades. The forwardly accelerated air force (at \( \psi = 180^\circ \)) causes the blade to deflect, an additional flapping motion, which obtains in a displacement of the highest coning point of from 10 to 30° in the direction of rotation. Naturally this displacement affects, even if subordinately, again the magnitude of the lateral component.

The blade curvature effect ensuing with elastic blades under the combined effect of unevenly distributed thrust and centrifugal force loading is, in a certain sense, related to the just discussed process. Glauert and Lock assumed a mean curvature of the blade axis in circular arc form. Lock (reference 2) obtains for the aforementioned untoward dimensions and a 3-percent pitch of the arc, a drag increment of 0.011 for best lift/drag ratio.

But this result is the most uncertain of all, for the assumption of a constant curvature of blade axis is utterly untenable, as shall be shown hereinafter, because this point is of considerable importance for stress analyses.

Strength problems of the blade. In the solution of
the question concerning the resultant air loads of the
lifting propeller, we had, with success, taken advantage
of the fact that the asymmetry of the air loads is amply
equalized on both sides of the median plane. The correct
resultant forces are obtained by simply assuming a "mean"
symmetrical flow.

Such a method, however, breaks down in blade-stress
analysis, because then it is a matter of maximum rather
than of mean values. So, strictly speaking, we should
equally be unable to have recourse to the simplified approx-
imation of a plane field of flow, but should know the ac-
tual flow at every instant. This, however, remains for
the time being, but a pious wish because of the enormous
mathematical difficulties involved.

And so there remains but one alternative for the
stress analysis, namely, to start with a plane induced
field of flow with the inclination $\alpha_1$ (fig. 18). Happi-
ly, this signifies, with the known equalization processes
of such airfoil flows, an augmentation of the assumptions
for the air loads, that is, added safety factor for the
analysis; for at the points of greater operating angle,
consequently greater locally produced thrust than agree-
able to uniform thrust grading, the flow is more deflected
and actually strikes the blade at a smaller angle than the
calculation stipulates. Thus the highly loaded points are
relieved and the lowly loaded, stressed more.

This consideration, while admittedly not universally
valid, gives however the assurance in the majority of
cases of being on the safe side. An exception might be
the tip load of the forward lying blade at small angles of
attack as a result of the relatively excessive flow curvature.
That would have to be cleared up through measure-
ments.

Now the situation of the load distribution of the
blade in its four settings is basically as follows: On the
straight blade the centrifugal force component's normal
to the blade cancel in every instance the mass forces pro-
duced by virtue of the flapping acceleration. Consequent-
ly, it suffices to analyze the play of the forces at the
pure coning motion, that is, of the (constant and out-
wardly directed) centrifugal force and of the (variable,
and upward acting) air load.

So long as the blade is straight, the normal load in-
creases linearly outward with uniform mass distribution
by virtue of the centrifugal force; but the air load increases rather parabolically outward at \( \Psi = 0 \) and \( 180^\circ \). At this stage the moment of the load discrepancies bends the blade concavely upward. But at \( \Psi = 90^\circ \) the center of gravity of the air load shifts considerably to the inside and it may itself outwardly become negative under stated conditions. The blade is, as a result, severely bent concavely downward. Contrariwise, the air load shifts strongly outward at \( \Psi = 270^\circ \); the upwardly concave curvature should reach its maximum there. Thus the blade executes at each revolution a (not harmonic) forced vibration in bending. There is no imminent danger of resonance, since the frequency of first higher harmonics must be \( > 2 n \) by virtue of the ever-existing blade rigidity. Of course the air loads damp the motion of the individual blade elements again.

The ideal from the standpoint of strength would be a perfectly soft blade, a heavy rope, so to say, which at any instant conforms with the equilibrium of the external mass forces. Such an element would have to transmit longitudinal and transverse forces but no flexural moments. Naturally this is not feasible in view of the rigidity of the blade by nonrevolving rotor, and the designer is forced to some compromise relative to the desired stiffness. For the chosen stiffness and mass distribution, the normal loading is then established by progressive approach, the change of centrifugal force components due to varying blade curvature being of primary importance, followed by the change of air load. The first is directly dependent on the shape of the blade axis, the other on its first derivation with respect to time. A more exact examination of these processes involves an enormous amount of paper work, since no accurate short-cut method has been devised as yet.

Free-flight tests on the autogiro would make matters considerably easier. (There is no adequate wind tunnel in Europe where models at the desired scale could be tested.) The problem is twofold: a) determination of air loads at blade through pressure-distribution measurement at varying distance from the center; b) measurement of deflections along the blade axis.

Both problems present considerable experimental difficulties, because the measurements must be made on a rotating element which, in addition, is very sensitive dynamically as well as hydrodynamically. But they are defi-
nificantly, essential to completely clear up the conditions, especially with a view to the type of the induced field of flow.

**Transition to very high angles of attack.**—"The autogiro cannot be stalled." Undoubtedly this is true when referring to the flight characteristics; for the lift coefficient and the mean air-stream velocity of the individual blade element are in fact, as seen, independent of the angle of attack of the whole autogiro which therefore does not lose its lifting power. But, in spite of that, the flow about the autogiro is not always so smooth as in the previously treated angle-of-attack range.

This is best seen in the picture of the axially impinged autogiro, the attitude of vertical descent, which has also been elaborately treated by Lock (reference 8), and Glauert (reference 9). The flow on the autorotating axially impinged propeller is analogous to the flow of a correspondingly impinged round disk, i.e., in front a symmetrical potential flow, behind it a turbulent zone separated by a more or less expressed inversion layer (area of discontinuity) from the potential flow. The fact that 10 to 20 percent of the flow escapes through the propeller disk on the autorotating propeller does not alter the picture decisively.

This flow, perfectly defined by the vortex field aft of the propeller, now must gradually change in the smooth airfoil flow as the angle of attack declines. The only attempt so far published which covers this whole range (reference 10), is illustrated in figure 28. The 4-blade model of 0.65 m (2.1 ft.) was tested in the 2,10 m (6.9 ft.) closed wind tunnel. The plot shows the lift curve anticipated for smooth flow conformable to (III,7) and (III,9), without particular regard to the induced flow.

The theory agrees very closely with the test data up to \( \alpha = 15^\circ \) (fig. 29a). But at 20\(^\circ\) the test points are already scattered, a sign of disturbance of the smooth flow. Observations are still lacking regarding it, but it may be assumed that, analogously to the fixed-wing system, a dead air zone is formed on the upper side at whose

*In unlimited air stream the angle of incipient vorticity can be slightly higher.*
release the eddying boundary layer of the individual blades will probably come into play. As a result the total flow will be accordingly less deflected (fig. 29) without necessarily inducing an appreciable effect of the sound flow at the individual blade element, for the eddy zone is not formed until above the plane of rotation. As the angle continues to increase, the flow around the leading edge will become more and more difficult, until at last the flow reverses altogether and approaches symmetrical form (see fig. 29c) observed at $\alpha = 90^\circ$ (reference 11).

Another step further leads to the following: According to Prandtl's airfoil theory, the lift of a wing of span $b$ and identical deflection $\alpha_1$ at the locus of the wing can be equated to the momentum per second of an air mass passing at the rate $v$ through a pipe section of diameter $b$ and evenly deflected across the whole section by $2 \alpha_1$, perpendicular to its mean direction. Then, as long as it is possible to make the flow pass along the surface of the lifting propeller without becoming separated, we have $\alpha_1 = \alpha$ if the propeller is "dense" enough; and the fictitious pipe flow is deflected through $2 \alpha$, that is, through $180^\circ$ at $\alpha = 90^\circ$. In this case the propeller force coefficient would be $c_s = 4 \sin \alpha$, according to (III,7). This is the highest, theoretically conceivable amount, according to the momentum theorem. (It corresponds to the perfectly elastic impact.\textsuperscript{*)}

In reality, no such large deflection is realized: first, on account of the necessarily strong flow curvature within the propeller disk, which is not possible according to the mechanics of the propeller; then, it is diametrically opposed to the flow pattern observed at $\alpha = 90^\circ$, for which reason we have the incipient breakdown of the flow. Besides, the cited pipe does not deflect the whole mass flowing through it; part of it escapes beforehand, owing to the permeability of the propeller. The latter process is correctly assessed as to type through formula (III,9). On our propeller (fig. 28), it lowers the theoretical $c_{\text{sm}}$ from 4 to 2.8.

Now the remarkable feature is that the measured $c_{\text{sm}}$ is exactly half of this amount, that is, 1.4. If further experiments should confirm this result the cited Prandtl method could then be extended to include the perpendicularly impinged autorotating propeller, so far as the force could be computed from the same (fictitious)
pipe flow, with the proviso, however, that instead of \( 2 \alpha \) the total deflection angle would be only \( \alpha \), or \( \alpha - \alpha_d \), that is, \( 90^\circ - \alpha_d \). This would give for the perfectly "dense" propeller \((\xi = 0)\) \( c_{\text{max}} = 2 \) as limit, in accord with Glauert's (reference 9) and Lock's (reference 8) curves extrapolated from the experimental values. This would bring us back to Newton, who deduced the same figure for the disk by means of his primitive momentum theory.

Assuming that it actually occurs: Why then does the round disk produce so much less drag \((c_w = 1.15)\)? The difference can only lie in the form of the dead air space, that is, the vortex field in the wake of the disk. Whereas, on the fixed circular disk the air penetrates in the form of irregular, large balls, into the zone aft of the disk; the closely spaced vortex trains leaving the blade tips as helices on the lifting screw, should form a honeycomb-shaped envelope which prevents air from penetrating the dead air space, as well as from setting up any sufficiently large suction before the blade. The boundary layer flung off from the blades is probably very much involved herein. It should be worth while to explore this process thoroughly, especially by searching observation of the flow with smoke filaments.

This much may, however, be averred on the basis of modern knowledge, to wit, that the thrust coefficient will not be in excess of \( c_s = 2 \) in vertical descent — in most cases, even 20 to 30 percent lower. Higher figures observed here and there in free flight tests (reference 12) can be unrestrictedly explained by the almost always accompanying wind, which makes it easily appear as vertical descent when, as a matter of fact, it slopes perhaps 45°. In this case, for instance, the sinking speed would be only \( 1/\sqrt{2} \) times that of vertical descent; that is, the apparent air-force coefficient to be computed therefrom for vertical descent, would be twice as high as the actual.

In spite of that the drag of the autogiro in vertical descent is greater than that of a parachute. The remarkable fact is that this flight attitude with wing control is perfectly controllable, a characteristic in which the autogiro excels any other type of aircraft and which insures safe landing under the most difficult conditions.
SUMMARY AND CONCLUSIONS

It is shown that the flow on the autogiro in level flight can be reduced to the simple symmetrical flow on the axially impinged autorotating propeller. The unusually simple formulas set up yield not only the fundamental laws for flow and tip speed (section, page 5), but also a theory of the thrust of the autogiro which in form is in complete accord with the model experiments (section, page 12).

Discrepancies in the mathematical analysis of the thrust curves, however, point to the possibility of some fundamental error in the assumptions. But the effect of the asymmetry in the air stream, which effects the flapping motion of the individual blades, is described before this basic error is explained (section, page 21). It is shown that the mathematical treatment of these processes finds its comparatively narrow limits in the inadequacy of the formulas for the air forces at the receding blade. This is one reason why the English theory (references 1 and 2) could not produce satisfactory results despite the elaborate mathematical work.

The other reason lies in the assumption regarding the shape of the induced field of flow. The simple Prandtl assumption of a plane flow deflected by half the amount and valid for slender wings, must be altogether discarded. As the actual field of flow is scarcely tractable, a plane substitute flow is introduced whose slope is figured back from the model experiments (reference 3), whereby the real propeller is replaced by a substitute lifting propeller with symmetrical air flow. The latter gives drag coefficients for the blade profiles which agree with the Göttingen model experiments on the same wing section ("The Induced Field of Flow and Its Effects", page 30). It is shown that a moderate curvature of the field has no effect on the result, provided the plane substitute flow has been chosen correctly. Further model experiments with lifting propellers are urgently desired.

Then the total losses expressed in lift/drag ratio is resolved in three parts (see section, page 39):

a) induced loss \( \epsilon_1 \), always greater than \( c_s/4 \) empirically from figure 18 \( \epsilon_1 = \alpha_1 \sec \alpha \);
b) axial flow loss with a minimum of

$$\xi_a = \zeta \sqrt{c_s} \sec \alpha = \frac{\lambda \alpha}{\lambda}$$

whereby the flow coefficient $\zeta$ lies mostly between 0.12 and 0.25, and axial flow coefficient $\lambda$, also a constant (0.015 to 0.03), is sensibly defined from the profile lift/drag ratio.

$\zeta$ nonuniformity loss $\xi_u = \kappa \lambda$, wherein $\kappa$, for good propellers, deviates apparently only a little from 1/8. Since $\xi_a$ and $\xi_u$ depend inversely on the tip-speed ratio $\lambda$, whereas the induction loss is largely contingent upon the circular form, the improvement of total lift/drag ratio is within relatively narrow limits, about 1/10 with the usual form of to-day. The problem is essentially a matter of raising the speed by lowering the surface density and refinement in blade profile, propellers intended for high speed having narrower blades than those intended for good rate of climb.

The coning motion disregarded thus far, vitiates the lift/drag ratio very little, but sets up in conjunction with the curved flow, a lateral force which increases with the tip-speed ratio. (See section, page 49.) Our knowledge concerning it is still very incomplete.

The changing air forces deflect the blade during rotation, inharmoniously upward and downward. The study of this process in flight measurements under simultaneous determination of the actual field of flow in the propeller disk is one of the most pressing problems (section, page 12).

In vertical descent the thrust coefficient $c_s$ is about 50 percent of the value anticipated from the elementary theory. The amount of $c_s = 2$ is not exceeded (page 49). The flow breaks down when changing to high angles of attack, that is, relative to the total area, but remains sound at the individual blades, so that lifting power and controllability are maintained.
