NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS
WASHINGTON
June 27, 1958
SUMMARY

A wind-tunnel investigation was conducted to determine the drag increment due to the superposition of wedges with various plan-form shapes along the trailing edge of a sweptback wing. Data were obtained at a model angle of attack of 0° and a Mach number range of 0.60 to 1.15. Reynolds number varied from 6,000,000 to 7,000,000.

Trailing-edge wedges similar to two sets reported on herein have been used on the control surfaces of unswept wings to alleviate or eliminate unstable aerodynamic damping at subsonic Mach numbers. All the trailing-edge wedges tested increased the drag over that of the basic wing-body combination. Drag computations indicated the possibility of reducing the transonic drag rise by contouring the body.

INTRODUCTION

The investigation reported in reference 1 revealed that triangular-shaped wedges placed on a control surface eliminated unstable aerodynamic damping and thereby prevented a single-degree-of-freedom flutter from occurring at subsonic speeds. However, an increase in environmental pressure fluctuations was observed, indicating that the wedges increased buffeting. Also, it is evident that drag penalties could be associated with the addition of the wedges. Because of the method of installation of the model for reference 1, drag measurements were not obtained. It is the purpose of this investigation to determine the magnitude of the drag penalty associated with various trailing-edge wedge configurations that may alleviate or eliminate control-surface flutter (see refs. 1 and 2). Data are presented for six trailing-edge modifications.
MODELS AND TESTS

Basic Model

The basic model is illustrated in figure 1. The wings had an aspect ratio of 3, a taper ratio of 0.4, a leading-edge sweep angle of 45.3°, and modified NACA 64AO06 sections perpendicular to a line sweptback 39.45° which was the quarter-chord line of these sections. The body was a Sears-Haack body and had a closed fineness ratio of 12.5. A complete description of the wing-body combination is given in reference 3.

The model was mounted in the wind tunnel by means of a sting, and the drag force was measured as an electrical output from a strain-gage balance located within the model. A photograph of the model support system is shown in figure 2.

Drag force data are presented in this report for an angle of attack of 0°. The drag data were adjusted to the condition of zero base drag by use of the static pressures measured over the base of the body.
Data were obtained at Mach numbers ranging from 0.60 to 1.15. The corresponding Reynolds numbers based on the mean aerodynamic chord of the wing varied from about 6,000,000 to 7,000,000.

Trailing-Edge Modifications

Three basic types of trailing-edge devices were tested, with two types having several variations. The following is a list of these trailing-edge modifications including reference to sketches and photographs of each:

RESULTS AND DISCUSSION

The zero-lift drag coefficients of the six trailing-edge modifications and the basic model are presented in figure 5. The drag increment, due to the various trailing-edge modifications, expressed as a percent, is shown in figure 6.

The Effect of Triangular Wedges

It can be seen in figure 6 that the addition of the short-chord wedges with a 0° ramp angle increased the drag approximately 20 percent over the value for the basic model in the subsonic Mach number range. This increment was slightly lower in the higher speed range. Increasing the ramp angle of the wedges to 3-1/2° resulted in an 80-percent increase in drag in the subsonic Mach number range; again there was a reduction in the drag increment at the higher Mach numbers.
The effect of wedge chord can be seen by comparing the long-chord and short-chord triangular-wedge modifications with a 0° ramp angle. The drag increments are approximately the same for both modifications up to 0.87 Mach number, but the long-chord wedges had a greater drag rise throughout the transonic Mach number range. The transonic drag rise of the wedges might be substantially reduced by a properly contoured body. To explore this possibility the method of reference 4 was used to compute the transonic drag rise for the short- and long-chord wedges (ramp angle = 0°) and for the basic model for a Mach number of 1.05. These computed drag increments were added to the zero-lift subsonic drag. The relatively good agreement with measured total drag for this Mach number is shown in figure 5. Since the transonic drag rise can be computed by the linear theory of reference 4, it follows that similar computational methods could be used to recontour the body shape so as to essentially eliminate the transonic drag rise due to the various wedges.

The Effect of Solid Spanwise Wedges

Examination of figure 6 shows that the blunt trailing-edge modification gave the largest drag rise of all the modifications presented at both subsonic and supersonic Mach numbers (drag rise was approximately 325 and 140 percent, respectively).

Removing the rear 50 percent of the blunt trailing-edge modification, thus forming a splitter plate, reduced the drag increment to approximately 125 percent in the subsonic Mach number range.

The Effect of Parabolic Shaped Wedges

In order to determine the effect of wedge shape on the drag, wedges having a parabolic plan form were constructed. Each parabolic shaped wedge occupied about the same volume and had the same ramp angle (0°) as the short-chord triangular wedge it replaced. Figure 6 shows that changing the shape of the wedge had little effect on the drag increment throughout the range of the test.
