LOW-SPEED LATERAL-CONTROL CHARACTERISTICS OF AN UNSWEPT WING WITH HEXAGONAL AIRFOIL SECTIONS AND ASPECT RATIO 2.5

EQUIPPED WITH SPOILERS AND WITH SHARP- AND THICKENED-TRAILING-EDGE FLAP-TYPE AILERONS

AT A REYNOLDS NUMBER OF 7.6 \times 10^6

By James E. Fitzpatrick and Robert L. Woods

SUMMARY

The lateral-control characteristics of two spans of spoiler and flap-type ailerons on an unswept wing with an aspect ratio of 2.5 and hexagonal airfoil sections are presented. The tests were conducted at a Reynolds number of 7.6 \times 10^6 and a Mach number of 0.15. Measurements of rolling moments, yawing moments, aileron hinge moments, normal forces, and balance-chamber pressures were made for various configurations of the wing with sharp- and thickened-trailing-edge ailerons, and droop-nose and plain flaps in combination with a fuselage.

In the low-lift range, the spoilers (which projected 0.06 chord) produced rolling moments equivalent to 60° of total aileron deflection for the unflapped wing and 120° for the wing with droop-nose flap deflected. The rolling moments due to the spoiler and flap-type ailerons were reduced at angles of attack above 7° and 12°, respectively, for the unflapped configurations. The lift range through which the ailerons and spoilers remained effective was extended by deflecting the droop-nose flap.

The rolling moments due to the flap-type aileron were increased by about 30 percent and those due to the spoilers by approximately 100 percent when the span was increased from 40 to 75 percent of the semispan.

The aileron with trailing-edge-thickness ratio of 0.25 had a slightly higher value of aileron effectiveness through a small deflection range.
than any other degree of trailing-edge thickness tested. At high
deflections, however, the aileron with trailing-edge-thickness ratio
of 1.00 was the most effective. The hinge-moment parameters became
more negative with an increase in trailing-edge thickness. Calculations
showed that the amount of balance chord required for complete balance in
a steady roll in the low-lift range increased from 60 percent of the
aileron chord for the sharp-trailing-edge aileron to 90 percent of the
aileron chord for the aileron with trailing-edge-thickness ratio of 1.00.

Calculations indicate that the hinge-moment parameters in a steady
roll would be smaller than those for the static condition when the droop-
nose flap is not deflected.

Values of pressure-fluctuation amplitude and frequency at 10 percent
of the aileron chord behind the aileron hinge line, which could be asso-
ciated with buffeting, were attained at the angle of attack of initial
stall. The average value of pressure fluctuation was independent of
aileron deflection.

INTRODUCTION

In order to minimize drag at supersonic speeds, thin wings of low
aspect ratio and relatively sharp leading edges have been proposed. A
tapered wing of this type with an aspect ratio of 2.5 and thin hexagonal
airfoil sections was investigated at low speed in the Langley 19-foot
pressure tunnel. The results of the lateral-control investigation of
the wing equipped with 0.75-semispan and 0.40-semispan flap-type and
spoiler ailerons are the subject of the present paper.

The lateral-control characteristics were determined for the ailerons
with several combinations of fuselage, droop-nose flap, and trailing-
edge flaps. Inasmuch as the results of references 1 and 2 have indicated
that improvements can be made in the rolling effectiveness of flap-type
aileron at transonic and supersonic speeds by thickening the trailing
edges, the lateral-control characteristics of the 0.40-semispan aileron
were also investigated on the wing with the trailing edge modified to
three different thicknesses. In addition, the tests included measure-
ments of the instantaneous pressure differential between the upper and
lower surfaces at four spanwise stations.
The data are referred to the wind axes with the origin at 25 percent of the mean aerodynamic chord. Symbols and nondimensional coefficients used are defined as follows:

- **b**  
  wing span, feet

- **bₚ**  
  spoiler span perpendicular to plane of symmetry, feet

- **C_D**  
  drag coefficient (Drag/µS)

- **C_L**  
  lift coefficient (Lift/µS)

- **C_r**  
  rolling-moment coefficient (Rolling moment/µSb)

- **C_m**  
  pitching-moment coefficient (Pitching moment/µSC)

- **C_n**  
  yawing-moment coefficient (Yawing moment/µSb)

- **C_hₐ**  
  aileron hinge-moment coefficient (Hinge moment/2Mₐq)

- **C_h_α**  
  rate of change of **C_hₐ** with **α** at **δₐ** = 0

- **C_h₇₈**  
  rate of change of **C_hₐ** with **δₐ** at **δₐ** = 0

- **C_h₈₉**  
  rate of change of **C_hₐ** with **δₐ** when wing is in a steady roll

- **C_7_p**  
  rolling-moment coefficient due to rolling

- **C_7₆**  
  rate of change of **C_7** with **δₐ** at **δₐ** = 0

- **C_Nₐ**  
  aileron normal-force coefficient (Normal force/µSₐ)

- **c**  
  local wing chord parallel to plane of symmetry, feet

- **c₂**  
  mean aerodynamic chord \(c₂ = \int_{0}^{b/2} c²dy\)
**c_a**
aileron chord aft of hinge line and perpendicular thereto, feet

**c_b**
aileron balance chord forward of hinge line, feet

**c_l_α**
section lift-curve slope

**K**
balance-chamber pressure conversion factor
\[
\frac{\text{Pressure difference across seal}}{\text{Pressure difference across vents}}
\]

**M_a**
moment area of aileron aft of hinge line, taken about hinge axis, cubic feet

**ΔP**
magnitude of resultant pressure fluctuation (difference between pressures on upper and lower surfaces), pounds per square foot

**P_R**
converted balance-chamber pressure coefficient
\[
\frac{\text{Pressure below seal} - \text{Pressure above seal}}{K_q}
\]

**P_R_α**
rate of change of \( P_R \) with \( α \) at \( δ_a = 0 \)

**P_R_δ**
rate of change of \( P_R \) with \( δ_a \) at \( δ_a = 0 \)

**p**
rolling angular velocity, radians per second

**q**
dynamic pressure, pounds per square foot \((\rho V^2/2)\)

**S**
wing area, square feet

**S_a**
aileron area aft of hinge line, square feet

**t**
ratio of trailing-edge thickness to aileron thickness at hinge line

**V**
free-stream velocity, feet per second

**α**
angle of attack of root-chord line, degrees

\((Δα)_p\)
effective change in angle of attack caused by rolling velocity, degrees
The details of the wing and fuselage are shown in figure 1. The model was constructed of solid steel, painted and polished to a smooth finish. The wing had an aspect ratio of 2.5, a taper ratio of 0.625, and neither dihedral nor twist. The symmetrical airfoil section was hexagonal with leading- and trailing-edge angles of 11.42°. Between the 30- and 70-percent-chord lines the surfaces were parallel and the wing had a thickness of 6 percent chord. The fuselage used for some of the tests was of circular cross section and fineness ratio 8 to 1. The wing root-chord line was on the center line of the fuselage.

Details of the lateral-control devices are shown in figure 2. The chord of the flap-type aileron was a constant percentage of the wing chord (0.25c). The aileron extended from 0.20b/2 to 0.95b/2 on the left wing and was divided at the 0.55b/2 station so that the outboard portion could be deflected alone or in combination with the inboard portion. In various parts of the investigation the inboard portion and both portions were deflected 50° in combination with corresponding portions on the right wing to simulate high-lift flaps. The trailing edge of the wing was modified to 0.25, 0.50, and 1.00 of the wing maximum thickness for some of the tests of the 0.40b/2 flap-type aileron. The leading edge of the flap-type aileron was of circular-arc contour with the center at the hinge line and was provided with a flexible seal (fig. 2). The balance chamber was provided with orifices for measuring pressures above and below the seal. The aileron was attached to the wing by means of a balance chamber.
of four strain-gage beams (two on each portion). The strain gages indicated electrically the aileron hinge moments and the component of the aileron force normal to the aileron-chord line. In addition, the magnitude and frequency of pressure fluctuations over the aileron were measured by means of four miniature inductance-type pressure cells installed in the sharp-trailing-edge aileron at a distance of 10 percent of the aileron chord behind the hinge line and at the span-wise positions shown in figure 1. The measurements were transmitted electrically to a recording galvanometer.

The spoilers (0.40b/2 and 0.75b/2) were mounted normal to the wing surface and projected 0.06 chord (see fig. 2). Dimensions of the 0.75b leading-edge droop-nose flap are shown in figure 1.

A two-support system was used to mount the wing alone or the wing-fuselage combination in the tunnel. A photograph of the model mounted in the tunnel is shown as figure 3.

TESTS AND CORRECTIONS

The tests were conducted in the 19-foot pressure tunnel with the air compressed to 33 pounds per square inch. The Reynolds and Mach numbers of the tests were $7.6 \times 10^6$ and 0.15, respectively.

The lateral-control characteristics of the flap-type and spoiler ailerons were determined by measuring the forces and moments through a range of angle-of-attack from $-40^\circ$ through the stall with the flap-type ailerons set at various deflections. Aileron hinge moments, normal forces, and balance-chamber pressures were also measured. The 0.75b/2 sharp-trailing-edge aileron was tested both with and without the fuselage. The 0.40b/2 and 0.75b/2 sharp-trailing-edge ailerons were tested with the wing leading-edge droop-nose flap deflected $30^\circ$ and the fuselage on. The 0.40b/2 aileron was tested in conjunction with the 0.30b flap, with and without the deflected droop-nose flap. Both spans of spoilers were tested with the fuselage on, with and without the deflected droop-nose flap, and with and without the 0.75b flap. The test configurations are listed in table I.

The lift and pitching-moment coefficients have been corrected for support-strut tare and interference as determined by tare tests with an image support system. The angles of attack have been corrected for airstream misalignment as determined during the tare tests. The jet-boundary corrections to the angle of attack and drag were calculated by
the method of reference 3. Jet-boundary corrections to the rolling and yawing moments were found to be negligible. Slight rolling and yawing moments were found to exist at zero deflection due to the small air-stream misalignment across the tunnel. Corrections have been applied for these effects.

A calibration of the balance chambers indicated leakage through the seal; the pressure differences measured across the seal were only 0.80 and 0.56 of the pressure differences across the vents for the sharp and blunt ailerons, respectively. The factor was smaller for the blunt ailerons than for the sharp aileron because smaller vent openings were used with the blunt ailerons (see fig. 2). The same seal was used for all aileron configurations. Using the two conversion factors $K$, the measured pressure differences across the seal were converted to pressure differences across the vents which approximate balance-compartment pressure differences with a perfect seal. This approximation neglects the effects of the leakage on the vent pressures.

RESULTS AND DISCUSSION
Lateral-Control Characteristics

Spoilers.- The characteristics of the plain wing (fig. 4(a)) are indicative of the type of flow associated with unswept wings that have sharp leading edges and low aspect ratio. The rolling-moment coefficients due to the $0.40b/2$ spoiler obtained in the low angle-of-attack range were about 0.01, and an increase in spoiler span to $0.75b/2$ doubled this value. At angles of attack above $4^\circ$, however, the rolling moments decreased, and above $8^\circ$ the longer span showed no appreciable advantage over the shorter. At angles of attack close to $7^\circ$, separation occurred near the wing leading edge (fig. 5) and the loading shifted toward the tips (reference 4). These changes in the flow are probably responsible for the abrupt reduction of spoiler rolling moments and the rearward shift in center of pressure. Because of the separated flow conditions that existed, an increase in spoiler projection would probably have little effect on the rolling moments in the high angle-of-attack range. In the low angle-of-attack range the spoilers produced small, favorable yawing moments.

At a Mach number of 1.9 (reference 5) the spoilers produced rolling-moment coefficients of about half the value presented herein. The $0.75b/2$ spoiler at a Mach number of 1.9 (reference 5) produced yawing-moment coefficients which were favorable and of greater magnitude than those of the present investigation.
By deflecting the 0.75b droop-nose flap 30°, the rolling moments due to each spoiler were increased and the angle-of-attack range for which the spoiler remained effective was extended considerably (fig. 4(b)). The deflected droop-nose flap changed the flow over the wing so as to delay leading-edge separation (fig. 5). The delay of separation by the droop-nose flap enabled the rolling-moment coefficient due to the spoiler to increase with lift coefficient. The yawing-moment coefficients became adverse for this configuration with the 0.75b/2 spoiler (fig. 4(b)).

With the 0.75b flap deflected 50° in combination with the deflected droop-nose flap, the rolling moments due to the spoiler were increased in the angle-of-attack range up to the stall (fig. 4(c)). The rolling moments obtained with this configuration were greater than those of either of the other two configurations. With the 0.75b flap deflected, the yawing moments became adverse at an angle of attack lower than that with the flap neutral. The yawing moments produced by the 0.75b/2 spoiler were more adverse than those of the 0.40b/2 spoiler (fig. 4(c)). With the 0.75b flap deflected, the adverse yawing moment reached about 0.0225 as compared with 0.0075 for the configuration with droop-nose flap alone (figs. 4(c) and 4(b)). At high lift coefficients in a roll, the yawing moments would tend to become even more adverse.

Flap-type ailerons.- The aerodynamic forces and moments produced by the deflected ailerons for the various configurations are presented in figures 6 to 16. The aileron effectiveness $C_{L_{5}}$ was obtained from cross plots of these data and is presented in figure 17. The effectiveness of the 0.40b/2 aileron on the plain wing for each trailing-edge-thickness ratio is presented in figure 17(a). For all degrees of trailing-edge thickness, the control effectiveness was gradually reduced throughout the lift range and a large reduction occurred near maximum lift. The reduction in aileron effectiveness due to an increase in trailing-edge thickness was only about 10 percent at low angles of attack. References 1 and 2 show that an increase in rolling effectiveness with increase in trailing-edge thickness is obtained at transonic and supersonic speeds.

The aileron effectiveness parameter $C_{L_{5}}$ for the 0.40b/2 aileron was calculated according to the method of reference 6. The values of section lift-curve slope and of flap effectiveness $\Delta \alpha/\Delta \delta$ for the sharp-trailing-edge aileron were obtained from the experimental data of reference 7. Values of $\Delta \alpha/\Delta \delta$ and section lift-curve slope for the thickened-trailing-edge aileron configurations were obtained by correcting the values of the sharp-trailing-edge aileron for differences in trailing-edge angle according to figure 19 of reference 8. Values for $C_{L_{5}}$ were obtained by calculating the values of $C_{L_{5}}$ for
t = 0 at given values of \( \theta \). The following are the calculated and experimental values of \( C_{l_{\theta}} \) for the various degrees of bluntness:

<table>
<thead>
<tr>
<th>( t )</th>

Of course, this comparison does not account for the effect of finite trailing-edge thickness but it shows that trailing-edge-angle concepts cannot be used to predict effects of trailing-edge thickness. In the present investigation, the data indicate that after a certain degree of trailing-edge thickness was reached, the aileron effectiveness was reduced. Other effects, such as might be caused by flow around the base, might counteract the effect of a decreased trailing-edge angle.

The 0.40b/2 aileron on the wing with the high-lift devices showed the same general trend of effectiveness through the lift range as it did on the plain wing. Extending the span of the aileron 0.35b/2 inboard increased the effectiveness by about 30 percent in the low-lift range (figs. 17(a) and 17(b)). The calculated and experimental values of \( C_{l_{\theta}} \) for the wing with the 0.75b/2 aileron were 0.00213 and 0.00205, respectively. The slight increase in \( C_{l_{\theta}} \) due to the addition of a fuselage (fig. 17(b)) might mean that the fuselage acted as an end plate to increase the effectiveness of the inboard aileron. The data of references 9 and 10 indicate that at transonic and supersonic speeds the value of \( C_{l_{\theta}} \) for the plain wing and fuselage decreased until at a Mach number of 1.9 it reached about half the value obtained at a Mach number of 0.15. This was true for both aileron spans (fig. 18).

Deflecting the partial-span flap reduced \( C_{l_{\theta}} \) in the low-lift range (fig. 17(c)). Deflecting the droop-nose flap extended the lift range in which the aileron remained effective (fig. 17(d)); this effect was due to the postponement of separation around the sharp leading edge until higher angles of attack were reached. Increasing the aileron span resulted in an increase in effectiveness which was about the same whether or not the droop-nose flap was deflected (fig. 17).
The rolling-moment and yawing-moment coefficients produced by a total aileron deflection of 30° (15° equal and opposite) and, in some cases, 50° are presented in figures 19 and 20. Figure 19(a) shows the effect of various degrees of trailing-edge thickness. These results are quite different from the results shown by the $C_{l}$ curves of figure 17(a). The difference is a result of the nonlinearity of the curves for $C_{l}$ plotted against $\delta$. For the aileron with $t = 0.25$, the slope $C_{l}$ through zero deflection is higher than that for the aileron with $t = 1.0$, but the slope decreases at higher deflections. With the full-blunt-aileron ($t = 1.0$), $C_{l}$ has a lower value through zero deflection but it is more nearly constant at higher deflections.

For the other configurations, the trends shown by the rolling-moment coefficients for a total aileron deflection of 30° are the same as those shown previously by the variations of $C_{l}$.

The yawing moments produced by the deflected aileron tended to become more adverse as the lift increased up to the stall (figs. 6 to 16 and fig. 20). For the configurations without the deflected droop-nose flap, most of the adverse yaw was contributed by the downward-deflected aileron. This effect of the downward-deflected aileron is attributed to the difference in induced drag of the two wings. The downward-deflected aileron increased both the lift and the induced drag of its wing.

Comparison of spoilers and flap-type ailerons. - The rolling moments produced by the spoilers (which projected a distance of 0.06c) are compared with the rolling moments for several total aileron deflections in figure 21. On the unflapped wing (fig. 21(a)), the rolling moment due to the spoiler is seen to be equivalent to that for a total aileron deflection of 60°. Increasing the span of the spoiler to 0.75b/2 increases the rolling moment to that obtained with a total aileron deflection of 10° (fig. 21(b)). At a Mach number of 1.9 (references 5 and 10), the effectiveness of the 0.75b/2 spoiler was found to be equivalent to the same total aileron deflection as that found in the present investigation. Deflecting the droop-nose flap 30° makes the spoiler as effective as a total aileron deflection of 11° or 12° (figs. 21(c) and 21(d)). A similar comparison of spoilers and ailerons may be made in terms of flying qualities. The rolling effectiveness $\frac{pb}{2V}$ for the plain wing was calculated from the equation

$\frac{pb}{2V} = \frac{C_{l}}{C_{lP}}$
A value of -0.22 for \( C_2p \) was interpolated from the theoretical curves given in reference 6. The value of \( \frac{p_b}{2V} \) for the \( 0.40b/2 \) spoiler varied from 0.043 at zero lift to 0.009 at maximum lift (\( \alpha = 12^\circ \)), whereas the value for a total deflection of 30° of the \( 0.40b/2 \) flap-type aileron varied from 0.181 at zero lift to 0.151 at maximum lift. For the \( 0.75b/2 \) aileron, the values were from 0.1 to 0.014 for the spoiler and from 0.30 to 0.24 for a total flap-type-aileron deflection of 30°.

A comparison of the yawing moments produced by oppositely deflected ailerons with those produced by spoilers for the configurations shown in figure 21 are presented in figure 22.

The foregoing comparisons of spoiler and aileron effectiveness must be restricted to the low-speed range because of the following factors:

1. At higher speeds the aileron effectiveness is greatly reduced by wing twist (reference 11). The effectiveness of a spoiler is not reduced as much because the twisting moments due to a spoiler are of lesser magnitude for a given rolling moment.

2. The rigid-wing spoiler effectiveness increases with speed in the subsonic range (reference 12).

3. The higher control-force characteristics of ailerons are partially accounted for by power-booster systems.

4. In the moderate to high-lift range the yawing moment due to the deflected control is more adverse for ailerons than for spoilers (fig. 22), which would reduce the superiority of the aileron over the spoiler.

Aileron Hinge-Moment Characteristics

**Blunt unbalanced ailerons on the plain wing.** - The hinge-moment parameters \( C_{h_b} \) and \( C_{h_\alpha} \) are presented in figures 23 to 25. The effects of seal leakage on these parameters have been neglected. With increasing trailing-edge thickness the hinge-moment parameters increased negatively (fig. 25). As shown in reference 8, a decrease in trailing-edge angle also results in more-negative values of the hinge-moment parameters. The effects of trailing-edge thickness and trailing-edge angle were similar except that the degree of unbalance was not so great with the thickened trailing-edge as would be expected for the same reduction in trailing-edge angle on a sharp aileron (reference 8). The difference is no doubt due to the change in pressure distribution brought
about by the flow around the blunt-end. At angles of attack beyond the stall, the trailing-edge thickness had little effect on the hinge-moment parameters.

Sharp unbalanced ailerons with high-lift devices. The negative value of $C_{h_0}$ was increased by the addition of the fuselage to the wing with the 0.75b/2 aileron, whereas the value of $C_{h_\alpha}$ was essentially unchanged (figs. 23(b) and 24(b)). These effects are associated primarily with the load changes over the inboard portion of the aileron due to wing-fuselage interference. A similar effect was noted when the aileron span was increased with the fuselage on (figs. 23(e) and 24(d)). In the moderate angle-of-attack range, however, both parameters increased negatively with $\alpha$.

Deflecting the 0.35b flap $50^\circ$ added a negative increment or an unbalancing moment to the outboard aileron. Deflecting the droop-nose flap $30^\circ$ had little effect on $C_{h_0}$ but considerably reduced the negative value of $C_{h_\alpha}$ and extended the angle-of-attack range for reasonable values of both parameters (figs. 23(d) and 24(c)).

The effect of several amounts of internal balance on the hinge-moment parameter $C_{h_0}$ was calculated for the steady rolling condition. The effect of a steady roll proportional to total aileron deflection may be approximated by the following equation from reference 8 (in the present paper has the same definition as $\Delta\delta_a$ in reference 8):

$$C_{h_0}' = C_{h_0} + \frac{2(\Delta\alpha)p}{\delta_a} C_{h_\alpha}$$

The values of $2(\Delta\alpha)p/\delta_a$ were estimated from the data given in reference 8 to be $-173C_{\delta_0}$ for the 0.75b/2 aileron and $-242.2C_{\delta_0}$ for the 0.40b/2 aileron.

The effect of a sealed internal balance on the hinge-moment characteristics was taken into account approximately by means of the following relations:

$$\left(C_{h_\alpha}\right)_{bal} = C_{h_\alpha} + \frac{1}{2} P_{R\alpha}\left(\frac{C_{h_\alpha}}{\rho_a}\right)^2.$$
and

\[ (C_{h8})_{bal} = C_{h8} + \frac{1}{2} P_{R_S} \left( \frac{c_b}{c_a} \right)^2 \]

where the subscript \( \text{bal} \) refers to the aileron with an internal nose balance, and \( \frac{c_b}{c_a} \) is the balance-chord ratio. The measured hinge moments are assumed to be for an aileron with a perfect seal; thus the effects of the seal leakage on the hinge moments were neglected.

The values presented beyond the stall should be viewed with caution. The value of \( C_{\alpha p} \) used in determining \( \frac{2(\Delta \alpha)_{p}}{\delta_{st}} \) was assumed constant at -0.22, whereas in reality it would tend toward zero at the stall. The positive values of \( C_{h8} \) beyond the stall are therefore somewhat too high. The trends presented, however, are considered indicative of the effect of balance. The results of these calculations are presented in figure 26. A comparison of figure 23(a) with 26(a) shows that rolling had a slight balancing effect, reducing \( C_{h8} \) by about 0.001 in each case. The amount of balance chord required for balance in the low and moderate lift range increased from about 0.6c_a for the sharp aileron to about 0.9c_a for the ailerons with \( t = 0.50 \) and \( t = 1.0. \)

The addition of a fuselage tended to balance the 0.75b/2 aileron for \( \frac{c_b}{c_a} = 0, \) but did not affect the balance chord required for complete balance (fig. 26(b)). Rolling had little effect on the aileron hinge-moment parameter \( C_{h8} \) when the droop-nose flap was deflected. The aileron balance chord required for balance was about 0.65 at 0.85C_{l_{max}}. With the droop-nose flap deflected, an increase in aileron span increased the degree of unbalance with no balance chord but did not change the 0.65c_a balance chord required for balance at 0.85C_{l_{max}} (fig. 26(c)). The values presented are more nearly applicable in the low-speed high-lift range, since increasing the Mach number has a tendency to increase the degree of unbalance (references 8 and 13). An estimate made from the results of reference 8 indicates that to balance the aileron at a Mach number of 0.8 would probably require a balance-chord ratio about 0.1 higher than the ratios presented in figure 26.
Measurement of Pressure Fluctuation

A sample of the records obtained with the recording galvanometer of the pressure fluctuation over the aileron is shown in figure 27. Certain amplitudes may be considered average (see, for example, that designated $\Delta P/q$ in fig. 27) and they are plotted against angle of attack for several spanwise-locations and two deflections of the 0.40b/2 aileron in figure 28. The curves of figure 28 indicate that the amplitudes of the pressure fluctuations increase with angle of attack and, beyond the stall, attain values approximately equal to the dynamic pressure.

Figure 28 may give an indication of the stall-warning characteristics of an airplane equipped with this type of wing. According to the correlation of pressure pulsations with flight buffeting (reference 14), when the amplitude of the fluctuations reaches 0.15q, buffeting will be encountered. This value is reached at an angle of attack of about 6.5° in all cases (fig. 28). This is also the angle of attack at which the pitching moment breaks in a stable-direction (fig. 4) and the separated flow spreads rearward over the wing (fig. 5).

CONCLUSIONS

The results of the lateral-control investigation of two spans of spoiler and flap-type ailerons on an unswept wing with an aspect ratio of 2.5 and thin hexagonal airfoil sections lead to the following conclusions:

1. In the low-lift range, the spoilers (which projected a distance of 0.06c) produced rolling moments equivalent to 6° of total aileron deflection for the wing without flaps and 12° for the wing with droop-nose flap deflected.

2. The rolling moments due to the spoiler and flap-type ailerons were reduced at angles of attack above 7° and 12°, respectively, for the unflapped configuration. Deflecting the droop-nose flap extended the lift range in which the ailerons and spoilers remained effective.

3. The rolling moments due to the aileron were increased by about 30 percent and that of the spoiler by approximately 100 percent, by extending the spans from 40 to 75 percent of the semispan.

4. An increase in trailing-edge-thickness ratio from 0 to 1.0 resulted in only a 10-percent-change in aileron effectiveness.
5. The amount of balance chord required for balance in a steady roll has been calculated to increase from $0.6c_a$ for the sharp-trailing-edge aileron to $0.9c_a$ for the thickened-trailing-edge aileron.

6. A steady roll did not reduce the magnitude of the aileron hinge-moment parameters with the droop-nose flap deflected as it did when the droop-nose flap was not deflected.

7. The amplitude of average pressure fluctuation at $0.10c_a$ behind the hinge line increased with angle of attack and attained values approximately equal to the dynamic pressure. The amplitude of the fluctuations at which flight buffeting may be obtained ($0.15q$) were attained at the angle of attack of initial stall.
