REPORT 1185

THE CALCULATION OF PRESSURE ON SLENDER AIRPLANES IN SUBSONIC AND SUPERSONIC FLOW

By MAX. A. HASLET and HARVARD LOMAX

SUMMARY

Under the assumption that a wing, body, or wing-body combination is slender or flying at near sonic velocity, expressions are given which permit the calculation of pressure in the immediate vicinity of the configuration. The disturbance field, in both subsonic and supersonic flight, is shown to consist of two-dimensional disturbance fields extending laterally and a longitudinal field that depends on the streamwise growth of cross-sectional area. A discussion is also given of couplings, between lifting and thickness effects, that necessarily arise as a result of the quadratic dependence of pressure on the induced velocity components.

INTRODUCTION

This paper is concerned with the prediction of pressure distribution on or in the immediate vicinity of a wing, body, or wing-body combination under conditions in which the geometric configuration is slender in the flight direction or is flying at near sonic velocity. The material to be presented is thus associated with the rather extensive group of results that belong to what is usually referred to as slender-wing theory. The basic assumptions and methods can be found in publications by Munk, R. T. Jones, and Ward (refs. 1, 2, and 3) and a discussion of the applicability of the methods to the prediction of loading on slender wings at sonic flight speeds has been given in reference 5. In reference 2, attention was directed toward the calculation of load distributions over wings in subsonic and supersonic flight and reference 3 was devoted to the consideration of supersonic flight velocities. It is therefore of interest to investigate further the effects attributable to thickness on wings and wing-body combinations at both subsonic and supersonic flight speeds. Such investigations lead to valid approximations of interference effects and also indicate the way in which thickness and lifting effects can produce couplings in the calculations of pressures induced in the flow field.

ANALYSIS

It is proposed to take the basic solutions of the linearized partial differential equations governing three-dimensional compressible flow and to obtain a simplification of the expressions by restricting attention to the induced field in the immediate vicinity of slender airplanes or missiles. These simplified expressions contain solutions used previously to study the forces and moments on lifting wings and bodies. In addition, however, they can be used to evaluate the first-order thickness effects on the pressure in the vicinity of the wing and body.

Consider, first, the construction of a weakly disturbed flow field. Let a uniform stream flow in the direction of the positive z axis of a Cartesian coordinate system, as in figure 1. Immerse in the stream, which has a velocity $U_0$ and a Mach number $M_0$, a slender wing-body shape the surface of which is inclined at a small angle to the freestream direction. This angle of inclination must be small...
enough so that nearly everywhere in the fluid the magnitude of the perturbation velocity vector divided by the speed of the free stream is much less than one; that is,

$$\frac{\sqrt{u^2+v^2+w^2}}{U_0} \ll 1 \tag{1a}$$

Moreover, large supersonic Mach numbers are to be avoided and as a measure of this condition the inequality

$$M_\infty^2 \frac{\sqrt{u^2+v^2+w^2}}{U_0} \ll 1 \tag{1b}$$

is imposed.

Consider, next, the linearized partial differential equation governing weakly disturbed isentropic fluid flow. In terms of the perturbation velocity potential $\varphi(x, y, z)$, the lowest order approximation consistent with inequalities (1a) and (1b) is

$$(1-M_\infty^2) \varphi_{xx} + \varphi_{yy} + \varphi_{zz} = 0 \tag{2}$$

where the subscripts denote partial differentiation with respect to the indicated variable.

Consider, finally, the expression for the pressure coefficient that is again consistent to the lowest order with inequalities (1a) and (1b). By expanding the pressure-velocity relation for steady isentropic flow and neglecting higher-order terms, one finds

$$C_p = \frac{p-p_0}{\frac{1}{2} \rho U_0^2} \approx \frac{2u}{U_0^2} \left(1-M_\infty^2\right) \frac{\sqrt{u^2+v^2+w^2}}{U_0^2} \tag{3}$$

where $p$ and $\rho$ are pressure and density, respectively, and the subscript 0 refers to conditions in the free stream. It follows from inequalities (1a) and (1b) that pressure coefficient can be expressed in the form

$$C_p \approx -\frac{2u}{U_0^2} \frac{v^2+w^2}{U_0^2} \tag{3}$$

Equation (3) is the simplest general expression for pressure coefficient that is still entirely consistent with the assumptions basic to the development of equation (2).

Special solutions applying to problems of the class indicated can be obtained by appropriate simplification of general solutions to equation (2). Such a procedure will be discussed in the next section. The pressure coefficient is then determined by substituting these results into equation (3). The simplifications that can be made in evaluating the pressure on the surface of the airplane will also be discussed.

THE REDUCED SOLUTIONS

Subsonic.—As it applies to subsonic flow, equation (2) can be written in its normalized form as

$$\varphi_{xx} + \varphi_{yy} + \varphi_{zz} = 0 \tag{4}$$

The analysis of equation (4) can be interpreted as applying to the condition $M_\infty = 0$ but one can extend the solutions throughout the subsonic Mach number range by applying the Prandtl-Glauert rule.

A well-known solution to equation (4), resulting from an application of Green's theorem, is given by the expression

$$\varphi(x, y, z) = -\frac{1}{4\pi} \int_0^\infty dx_1 \int_0^\pi \left(\frac{\partial \varphi}{\partial n'} - \varphi \frac{\partial}{\partial n'}\right) \frac{ds_1}{\sqrt{(x-x_1)^2 + r^2}} \tag{5}$$

where $ds_1$ is the element of surface area on the airplane or its vortex wake, $r$ equals $\sqrt{(y-y_1)^2 + (z-z_1)^2}$, and $\partial/\partial n'$ is the derivative normal to the surface $S_1$. When this solution is applied to boundary-value problems for slender configurations it can be simplified considerably.

For example, when the airplane shape is slender it is justifiable to introduce simplifications in the form of the derivative $\partial/\partial n'$ and the differential area $ds_1$. The operator $\partial/\partial n'$ can be expressed as

$$n_1 \frac{\partial}{\partial x} + n_2 \frac{\partial}{\partial y} + n_3 \frac{\partial}{\partial z} \tag{6}$$

where $n_1$, $n_2$, and $n_3$ are the direction cosines between a normal to the surface $S_1$ and the $x$, $y$, and $z$ axes, respectively. The differential area $ds_1$ can be expressed as

$$\frac{ds_1 dx_1}{\sqrt{1-n_1^2}} \tag{7}$$

where $ds_1$ is a differential length along the surface in a $yz$ plane. If the shape is slender, $n_1$ is small and can be neglected relative to either unity or $\sqrt{n_2^2 + n_3^2}$.

By means of these simplifications, equation (5) can be approximated by the expression (from now on, the configuration will be considered to lie along the positive $x_1$ axis with its foremost part in the $x_1 = 0$ plane)

$$\varphi(x, y, z) = -\frac{1}{4\pi} \int_0^\infty dx_1 \int_0^\pi \left(\frac{\partial \varphi}{\partial n'} - \varphi \frac{\partial}{\partial n'}\right) \frac{ds_1}{\sqrt{(x-x_1)^2 + r^2}} \tag{8}$$

where $\partial/\partial n'$ represents $n_2 \partial/\partial y + n_3 \partial/\partial z$, the normal derivative to a section in the $yz$ plane, and $s$ is the curve bounding this section.

If the wing-body configuration is slender, the ratio $[r/(x-x_1)]^2$ is small over almost all of its surface and vortex wake provided the point $x$, $y$, $z$ is on or in the vicinity of these surfaces. This implies the approximation

$$\sqrt{(x-x_1)^2 + r^2} \approx |x-x_1| \tag{9}$$

can be used to simplify further equation (6). However, since, in the limiting case of $r = 0$, equation (6) is a divergent integral, it is necessary to introduce this approximation with some care.

First let us consider in equation (6) only the portion of the integral multiplying $\partial \varphi/\partial n'$. Designating this by $\varphi_1(x, y, z)$ one can readily show

$$\varphi_1(x, y, z) = -\frac{1}{4\pi} \frac{1}{\partial x} \int_0^\infty dx_1 \int_0^\pi \frac{\varphi(x, y, z) (\partial \varphi/\partial n')}{r \sqrt{(x-x_1)^2 + r^2}} ds_1 \tag{8a}$$

which, with the approximation given by equation (7), reduces to

$$\varphi_1(x, y, z) = -\frac{1}{4\pi} \frac{1}{\partial x} \int_0^\infty dx_1 \int_0^\pi \frac{\varphi(x, y, z)}{|x-x_1|} \frac{\partial}{\partial n'} ds_1 \tag{8b}$$
Since this can be written

\[ \varphi(x,y,z) = -\frac{1}{4\pi} \frac{\partial}{\partial x} \left( \int_0^x dz_1 - \int_z^y dz_2 \right) \int_0^x \frac{\partial \varphi}{\partial n} \ln r \, ds_1 \]

it simplifies to

\[ \varphi(x,y,z) = -\frac{1}{2\pi} \int_0^y \frac{\partial \varphi}{\partial n} \ln r \, ds_1 \]  

(9)

The other term in equation (6) requires more attention. Designating the velocity potential induced by this term as \( \varphi_i \), we can write

\[ \varphi_i(x,y,z) = -\frac{1}{4\pi} \frac{\partial}{\partial x} \int_0^y \frac{\partial \varphi}{\partial n} \ln r \, ds_1 \]

ln \left[ \frac{x-x_1}{x-x_2} + \frac{\sqrt{(x-x_1)^2 + r^2}}{r} \right] \, ds_1 \]  

(10)

The logarithm in the integrand separates into two parts and if the term containing \( \ln(1/r) \) is further simplified, in the manner used to derive equation (9) from equation (8), one has

\[ \varphi_i(x,y,z) = -\frac{1}{2\pi} \int_0^y \frac{\partial \varphi}{\partial n} \ln r \, ds_1 \]

\[ \int_0^y \frac{\partial \varphi}{\partial n} \ln \left[ \frac{x-x_1}{x-x_2} + \frac{\sqrt{(x-x_1)^2 + r^2}}{r} \right] \, ds_1 \]

(11)

To the second term in equation (11) we now apply the mean-value theorem. First divide \( s \), the curve bounding the airplane’s normal cross-sectional area, into \( \sum s_j \) so that \( \partial \varphi/\partial n \) has the same sign everywhere along each \( s_j \). This has a clear physical interpretation, for, since \( \varphi \) is the perturbation velocity potential, to the order of our approximations

\[ \frac{1}{U_0} \int_0^y \frac{\partial \varphi}{\partial n} \, ds_1 = \frac{\partial S'(x)}{\partial x} \]

(12)

where \( S'(x) \) is the part of the cross-sectional area with its only exterior boundary along the arc \( s_j \). (Since we are concerned only with the rate of change of \( S'(x) \), the internal boundary is immaterial.) Hence, if \( \partial \varphi/\partial n \) is everywhere positive along \( s_j \), the surface is everywhere expanding there; and, conversely, if \( \partial \varphi/\partial n \) is negative, the surface is contracting.

Using these definitions, we can apply the mean-value theorem to the second term in equation (11) and write

\[ \int_0^y \frac{\partial \varphi}{\partial n} \ln \left[ \frac{x-x_1}{x-x_2} + \frac{\sqrt{(x-x_1)^2 + r^2}}{r} \right] \, ds_1 = U_0 \sum \int_0^y \frac{\partial \varphi}{\partial n} \ln \left[ \frac{x-x_1}{x-x_2} + \frac{\sqrt{(x-x_1)^2 + r^2}}{r} \right] S'(x) \]

(13)

where \( r = \sqrt{(y-y_j)^2 + (z-z_j)^2} \) and \( y_j, z_j \) is a point on the surface of the configuration in the \( z_1 \) plane somewhere along \( s_j \). Combining the above results, and applying the Prandtl-Glauert transformations (\( \beta = \sqrt{2M^2 - 1} \), \( x \to x, y \to \beta y, z \to \beta z \)) one can now approximate equation (5), when it is applied to the flow field in the vicinity of slender wing-body configurations, and further, when it is applied to configurations for which \( S'(x) \) is continuous, and for which \( S'(x) \) exists, by the equation

\[ \varphi(x,y,z) = \frac{1}{2\pi} \int_0^y \frac{\partial \varphi}{\partial n} \ln r \, ds_1 - \frac{U_0}{4\pi} \sum \int_0^y \frac{S'(x)}{x-x_1} \ln \left[ \frac{x-x_1}{x-x_2} + \frac{\sqrt{(x-x_1)^2 + r^2}}{r} \right] \, dx \]

(14)

Notice that the limitation of equation (14) to the vicinity of slender shapes has, as yet, entered only in the approximation of equation (8a) by equation (8b), that is, in approximating the effect of the \( \varphi/\partial n (\ln r) \) (or doublet) term as given in equation (14). If equation (14) is applied to the study of thin, nonlifting, uncambered wings, therefore, it is only limited by the assumption that \( S'(x) \) is continuous. Further, if such wings are slender, the position of the point \( y_j, z_j \) does not deviate far from zero. Hence, we can chose for \( r_1 \) the value \( r_0 \), where \( r_0^2 = y^2 + z^2 \). Then, since \( \sum S'(x) = S''(x) \), integrating equation (14) by parts yields

\[ \varphi(x,y,z) = \frac{1}{2\pi} \int_0^y \frac{\partial \varphi}{\partial n} \ln r \, ds_1 - \frac{U_0}{4\pi} \frac{S'(x)}{x-x_1} \ln \left[ \frac{x-x_1}{x-x_2} + \frac{\sqrt{(x-x_1)^2 + r^2}}{r} \right] \, dx \]

(15)

which is the result presented by Keune in reference 6.

If we continue to study the flow in the vicinity of general slender shapes, however, equation (14) can be further simplified by applying the approximation given in expression (7). In the first place, if \( S''(x) \) is continuous (and, therefore, vanishes at \( x = 0 \) and \( l \), \( l \) being the total airplane length), the equation for the potential can be approximated everywhere in the vicinity of the configuration by the simple expression

\[ \varphi(x,y,z) = \varphi(x+y,z) - \frac{U_0}{4\pi} \int_0^y \frac{S'(x)}{x-x_1} \ln \frac{2|x-x_1|}{\beta} \, dx \]

(16)

where \( S(x) \) is the total cross-sectional area in a plane normal to the free stream and where

\[ \varphi(x,y,z) = \frac{1}{2\pi} \int_0^y \frac{\partial \varphi}{\partial n} \ln r \, ds_1 \]

(17)

On the other hand, if \( S''(x) \) has a discontinuity, the approximation given by equation (16) yields a logarithmic discontinuity in the value of \( \varphi/\partial x \), that is, (see eq. (3)), in the pressure coefficient. This discontinuity is spurious (it does not exist in solutions given by exact linearized theory) and it can be avoided by modifying slightly the simplifying procedure followed above.

Suppose, for example, \( S''(x) \) has a finite discontinuity \( \Delta S''(x) \) along the arc \( s_i \) in the plane \( x = z_1 \), so that

\[ S''(x) = \begin{cases} S''(x); & x < z_1 \\ S''(x) + \Delta S''(x); & z_1 < x \end{cases} \]

(18)

Notice that \( \varphi(x,y,z) \) is a solution to Laplace’s equation in two (the \( y \) and \( z \)) dimensions. The \( x \) dimension does not appear explicitly in this part of the complete solution for \( \varphi(x,y,z) \), but enters as a parameter when \( x \) is adapted to particular boundary conditions.

Any integrable singularity in \( S''(x) \) could be treated but the analysis was restricted for the sake of simplicity.
where \( S''(x) \) is everywhere continuous and \( \Delta S''(l_i) \) is a simple step function. Then equation (14) reduces to

\[
\varphi(x, y, z) = \varphi(x, y, z) - \frac{U_0}{4\pi} \int_0^x S''(x) \frac{z-x_1}{|z-x_1|} \ln \frac{2|z-x_1|}{\beta} \, dx_1 - \frac{U_0}{4\pi} \int_0^x S''(l_i) \frac{x-x_1}{|x-x_1|} \ln \left[ \frac{z-x_1}{|z-x_1|} + \sqrt{\frac{(z-x_1)^2 + \beta r_j^2}{\beta}} \right] dx_1
\]

(19)

Further, when \( z \) lies between 0 and \( l_i \), equation (19) can be written (since \( S''(x) = -\Delta S''(l_i) \) for \( x > l_i \))

\[
\varphi(x, y, z) = \varphi(x, y, z) - \frac{U_0}{4\pi} \int_0^x S''(x) \frac{z-x_1}{|z-x_1|} \ln \frac{2|z-x_1|}{\beta} \, dx_1 - \frac{U_0}{4\pi} \int_0^x S''(l_i) \left\{ \ln \left[ \frac{x-x_1}{|x-x_1|} + \sqrt{\frac{(x-x_1)^2 + \beta r_j^2}{\beta}} \right] - \ln \left[ \frac{z-x_1}{|z-x_1|} + \sqrt{\frac{(z-x_1)^2 + \beta r_j^2}{\beta}} \right] \right\} dx_1
\]

(20)

The physical significance of equations (16) and (20) is clear. If the second derivative of the area distribution is continuous, the three-dimensional velocity field induced by airplanes that are slender is approximated in the vicinity of their surfaces, by

1. A velocity field that is independent of the Mach number and satisfies the two-dimensional Laplace equation and boundary conditions in transverse planes
2. A longitudinal field that depends on the Mach number and streamwise variation of cross-sectional area and is independent of \( y \) and \( z \).

If the second derivative of the area distribution is discontinuous, part (2) of the above interpretation should be modified to apply only to the continuous portion of \( S''(x) \) and additional terms, depending on the number and location of discontinuities in \( S''(x) \), are included.

Supersonic—In the case of supersonic flow, the normalized form of equation (2) becomes

\[
\varphi(x, y, z) - \varphi(x, y, z) - \varphi(x, y, z) = 0
\]

(21)

An analysis based on equation (21) applies specifically to the condition \( M_c = \sqrt{2} \) but these results can be extended throughout the supersonic Mach number range by applying the Prandtl-Glauert rule. Volterra's solution to equation (21), (see, e.g., ref. 7, p. 190) which is analogous to the subsonic form given in equation (5), is expressible as

\[
\varphi(x, y, z) = \frac{1}{2\pi} \frac{\partial}{\partial x} \int \left( \frac{\partial \varphi}{\partial y} \frac{\partial \varphi}{\partial y} \right) \ln \frac{z-x_1}{r} \, ds_i
\]

(22)

where, as in the subsonic case, \( ds_i \) is an element of surface area on the airplane or its vortex sheet and \( r = \sqrt{(y-y_1)^2 + (z-z_1)^2}. In
distinction to the subsonic solutions, the area of integration is now the portion of the airplane and its vortex wake within the forecone from the point \( x, y, z \) and \( \partial \varphi/\partial y \) is the derivative along the conormal rather than the normal.

If the conormal and differential area are expressed in terms of the direction cosines and the application of equation (22) is limited to slender configurations, \( n_1 \) can again be neglected relative to unity or \( \sqrt{\alpha^2 + \beta^2} \). Furthermore, the approximation, similar to expression (7) for the subsonic case,

\[
\sqrt{(z-x_1)^2 + r^2} \approx |z-x_1|
\]

is implied. Under these conditions, the potential in the vicinity of slender shapes flying at supersonic speeds can be approximated by the equation

\[
\varphi(x, y, z) = \frac{1}{2\pi} \int \left( \frac{\partial\varphi}{\partial y} - \frac{\partial\varphi}{\partial z} \right) ln |s_i| - \frac{U_0}{4\pi} \sum_{l_i} \int_0^x S''(l_i) \ln \left[ \frac{z-x_1 + \sqrt{(z-x_1)^2 + \beta^2 r_j^2}}{\beta} \right] dx_1
\]

(23)

where, again, \( S''(x) \) must be continuous. Equation (23) differs from equation (14) only by a factor of 2 in the second term and the extent of the \( z_1 \) integration. In the supersonic case the \( z_1 \) integration is carried only to \( x - \beta r_j \), or to \( z \) when \( r_j \) can be neglected, since the original integration area \( r \) included only the points in the forecone from \( x, y, z \) (those two differences were compensating in the derivation of the first integral term). The second term in equation (23) further simplifies in a manner analogous to that used for the simplification of equation (14). For example, the expression for the perturbation potential near a slender configuration having a discontinuity in \( S''(x) \) along the arc \( s_i \) in the plane \( x = l_i \) is given by

\[
\varphi(x, y, z) = \varphi(x, y, z) - \frac{U_0}{2\pi} \int_0^x S''(x) \ln \frac{2|z-x_1|}{\beta} \, dx_1 + \frac{U_0}{4\pi} \int_0^x S''(l_i) \left\{ \ln \left[ \frac{x-x_1 + \beta r_j}{|x-x_1 + \beta r_j|} \right] + \ln \left[ \frac{z-x_1 + \sqrt{(z-x_1)^2 + \beta^2 r_j^2}}{\beta} \right] \right\} dx_1
\]

(24)

where \( S''(x) \) and \( \Delta S''(l_i) \) are defined by equation (18) and \( \varphi(x, y, z) \) is the two-dimensional solution to Laplace's equation defined by equation (17).

The physical significance of equation (24) is analogous to that for equation (20). Before proceeding to the next section, however, two observations regarding these solutions are worth mentioning. In the first place, notice that if discontinuities in \( S''(x) \) occur on the \( x \) axis, as could be the case, for example, at the nose of a pointed body of revolution or at the apex of a triangular wing, and if one is interested in evaluating \( \varphi(x, y, z) \) only on the object's surface, the value of \( r_j \) for such discontinuities would be zero and, if there were no other discontinuities, equations (20) and (24) would be correct if the \( \Delta S''(l_i) \) were set equal to zero and \( S''(x) \) was written simply \( S''(x) \). In the second place, for the supersonic case, only the discontinuities between the nose and the plane \( x \) at which the induced velocities are being calculated, affect the flow there. Hence, unless one is interested in the flow field behind the configuration, any discontinuity at
$x=1$ can always be excluded from equation (24). Taking these observations into account simplifies the treatment of many body-of-revolution and supersonic-wing problems.

### The Reference Coordinate Systems

Equation (2) was developed specifically for the case in which the undisturbed stream at infinity is parallel to the $x$ axis. A coordinate system so oriented is usually referred to as the wind-axes system. (See fig. 2.) When the configuration is tilted with respect to the free-stream vector, however, it is often easier to study the boundary-value problem with axis placed along the center line of the fuselage. Such a coordinate system is usually referred to as the body axes system.

Obviously the wind and body axes differ significantly only by rotations about the $y$ and $z$ axes. When $M_0$ is zero, equation (2) is invariant to such a rotation, but for values of $M_0$ greater than zero this is no longer true. However, when $M_0$ is greater than zero, equation (2) represents the governing differential equation only to a certain order, and, if the magnitude of the rotation is similar to that of the parameters by which the equation is ordered, it is, in this sense, still invariant to rotations about all three axes for both subsonic and supersonic Mach numbers. Thus equation (2) is to the lowest order the governing partial differential equation for both wind and body axes, provided the airplane is slender and the angles of attack and sideslip are small.

Although the partial differential equation is invariant with respect to a small rotation of the coordinate system, the boundary conditions and expression for the pressure coefficient in terms of the perturbation velocities are not.

### The Boundary Conditions

The boundary conditions require that the gradient of the total velocity potential evaluated infinitely far from the aircraft be consistent with a uniform free stream (the direction of which depends on the orientation of the coordinate system) and when evaluated normal to and on the surface of the airplane itself be zero. Let $\Phi(x,y,z)$ denote total velocity potential, $\varphi(x,y,z)$ perturbation velocity potential, and refer the analysis to body axes in a free stream. If the orientation of the free-stream velocity vector to the system of axes is fixed by the angles $\alpha$ and $\gamma$ as shown in figure 2, one can write

$$\Phi(x,y,z) = U_0(x \cos \alpha \cos \gamma + y \sin \gamma + z \cos \gamma \sin \alpha) + \varphi(x,y,z)$$

such that on the aircraft surface

$$U_0(n_1 \cos \alpha \cos \gamma + n_2 \sin \gamma + n_3 \cos \gamma \sin \alpha) + n_1 \varphi_2 + n_2 \varphi_3 + n_3 \varphi_4 = 0$$

$n_1$, $n_2$, and $n_3$ again being the direction cosines of a normal to the airplane surface with respect to the $x$, $y$, and $z$ axes, respectively. By the assumptions basic to the present theory, the latter equation reduces to

$$U_0(n_1 + n_2 \gamma + n_3 \alpha) + \frac{\partial}{\partial n} \varphi(x,y,z) = 0 \quad (25)$$

where, as before, $n$ is the normal to the curve bounding a cross section in the $yz$ plane.

Equation (25), which applies to arbitrary slender shapes, can be simplified for many specific problems. Consider now three types of configurations that lead to such simplifications: first, a surface, such as a wing, which deviates only slightly from a plane; second, a surface which forms a body of revolution; and, third, a surface which is a combination of the above two.

Planar systems.—Let $h(x,y)$ be the distance a surface deviates from the $z=0$ plane, and $s$ be local semi-span. (See fig. 3(a).) Assume that $a/(ds/dz) << 1$ holds; then furthermore, if the inequality $(\partial h/\partial z)/(ds/dz) << 1$ is satisfied, it is consistent with the previous approximations to neglect the $y$ component of the normal along the wing surface and to project the velocity vector represented by the resulting vertical derivative to the upper or lower surface of the $z=0$ plane. In this way equation (25) becomes

$$U_0(n_1 + n_3 \alpha) + n_3 \left( \frac{\partial \varphi}{\partial z} \right)_{z=0} = 0$$

and, since $n_1/n_3 = -\partial h/\partial z$, the boundary conditions for planar problems are expressed by the equation

$$\left( \frac{\partial \varphi}{\partial z} \right)_{z=0} = -U_0 \alpha + U_0 \frac{\partial h}{\partial z} \quad (26)$$

---

* Certain planar systems, such as the canard or canard wing, require more than one plane but the concepts are essentially the same as those presented here.
The rather obvious extension of the above concepts is to apply equation (26) over the winged portion of the configuration and equation (27) over the body. It is then necessary, however, to consider the relative magnitudes of the terms $\partial h/\partial x$, $ds/\partial x$, $dt/\partial x$, and $dR/\partial x$, since they appear in the solutions in various combinations. If the winged portion is to be treated as a planar problem, the magnitude of $\partial h/\partial x$ must be small enough to be neglected in comparison to the leading- and trailing-edge slopes, $ds/\partial x$ and $dt/\partial x$. But this does not imply that $\partial h/\partial x$ can be neglected in comparison to $dR/\partial x$ or that $dR/\partial x$ can be neglected in comparison to either $ds/\partial x$ or $dt/\partial x$. The latter approximations will not, in general, be made.

### THE PRESSURE COEFFICIENT

The expression for the pressure coefficient given by equation (5) is written in terms of velocity components that are referred to the wind axes. Its re-expression in terms of velocities referred to the body axes is readily determined. For the orientation shown in figure 2 (a), the equation becomes

$$C_p = \frac{-2}{U_0^2} \left( \phi_x + \gamma \phi_y + \alpha \phi_z \right) - \frac{1}{U_0^2} \left( \phi_x^2 + \phi_y^2 \right)$$

Equation (28) can be used, in general, to evaluate the pressure in a perturbation velocity field that is referred to the body axes. If the interest is limited to the pressure on the surface of the aircraft, however, certain simplifications can be made. For example, consider the configuration illustrated in figure 3 (c) consisting of a sweptback wing mounted on a body of revolution. For simplicity, let $\gamma = 0$. Applying the boundary conditions given by equations (26) and (27), one can show that on the surface of the wing

$$C_p = -\left[ \frac{2\phi_x}{U_0} + \left( \frac{\phi_x}{U_0} \right)^2 \right]_{z=0} + \alpha^2 \left( \frac{\partial h}{\partial x} \right)^2$$

and on the surface of the body

$$C_p = -\left[ \frac{2\phi_x}{U_0} + \left( \frac{\phi_x}{U_0} \right)^2 \left( U_0 \sin \theta - \frac{1}{R} \phi_z \right) \right]_{z=0} + \alpha^2 \left( \frac{dR}{dz} \right)^2$$

These solutions can be simplified further by considering the detailed nature of the perturbation velocity field induced by shapes such as that shown in figure 3 (c). For example, if $S''(x)$ is continuous, the results given by equations (20) and (24) can be expressed in the form

$$\phi(x,y,z) = \phi_0(x,y,z) + A(x)$$

where the expression for $A(x)$ depends on whether the speed is subsonic or supersonic. Further, for the particular configurations being considered, the expression for $\phi_0(x,y,z)$ can be written in the general form

$$\phi_0(x,y,z) = \alpha \phi_0(t,s,R,y,z) + \frac{\partial h}{\partial z} \phi_0(t,s,R,y,z) + \frac{dR}{dz} \phi_0(t,s,R,y,z)$$

since the dependency on $z$ can enter only through the boundary conditions which, in turn, are specified by the body radius $R(z)$, the wing thickness, $h(x,y)$, and the lateral
distances from the center line to the trailing edge and leading edge, \(t(z)\) and \(s(z)\), respectively. The term \(\alpha \varphi_a\) will be referred to as the potential due to angle of attack, since it vanishes when the angle of attack vanishes and increases linearly with increasing \(\alpha\); the term \((dR/dz)\varphi_a+(dR/dx)\varphi_e\) will be referred to as the potential due to thickness, since it exists when the angle of attack is zero, does not change with angle-of-attack change, and vanishes when the thicknesses of the wing and body do not vary with \(z\).

By breaking \(\varphi_e\) down into its component parts as in equation (31), it has been ordered in that the magnitudes of the terms on the right-hand side of equation (31) are controlled by the coefficients of the \(\varphi\)’s, and the derivatives of \(\varphi_a\), \(\varphi_e\), and \(\varphi_s\) with respect to \(z\), \(t\), \(R\), \(y\), and \(z\) can all be considered equal. Since \(\alpha\) and \(dR/dz\) are negligible relative to \(dt/dx\) and \(ds/dx\) (as was pointed out in the discussion of the boundary conditions for interference problems), equations (29a) and (29b) can be written:

On the surface of the wing:

\[
\varphi_a = -\left\{ \frac{2}{U_0} \frac{\partial \varphi_e}{\partial x} \right\}_{s} \Delta R \left[ \frac{2}{U_0} \frac{\partial \varphi_e}{\partial y} \right] \right\}_{x=0} (32a)
\]

On the surface of the body:

\[
\varphi_s = -\left\{ \frac{2}{U_0} \frac{\partial \varphi_e}{\partial x} + \frac{1}{U_0 R^2} \frac{dR}{dx} \left[ \frac{2}{U_0} \frac{\partial \varphi_e}{\partial y} \right] \right\}_{s} \Delta R \left[ \frac{2}{U_0} \frac{\partial \varphi_e}{\partial y} \right] \right\}_{x=0} (32b)
\]

If the body is a cylinder so that its radius does not vary with \(z\), the pressure coefficient reduces to

\[
\varphi_a = -\left\{ \frac{2}{U_0} \frac{\partial \varphi_e}{\partial x} \right\}_{s} \Delta R \left[ \frac{2}{U_0} \frac{\partial \varphi_e}{\partial y} \right] \right\}_{x=0} (33)
\]

LOADING COEFFICIENT

By definition the loading coefficient is

\[
\frac{\Delta p}{q} = (C_p)_U - (C_p)_L (34)
\]

where the subscripts \(L\) and \(U\) refer to the upper and lower surfaces of the airplane, respectively. It is immediately apparent from an inspection of equations (34) and (30) that the loading is not affected by \(A(x)\). Hence, the lift, pitching moment, rolling moment, and induced drag for slender shapes having a continuous variation of \(S''(x)\) can all be expressed entirely in terms of \(\varphi_e(x,y,z)\).

Consider again the type of shapes represented in figure (3c) and let there be no discontinuities in \(S''(x)\). The velocity potential \(\varphi_e\) for such a class of configurations has been expressed in equation (31) as the sum of three potentials: one due to angle of attack, one due to the thickness of the wing, and one due to the thickness of the body. It is now useful to remark that \(\varphi_a\) has odd symmetry with reference to the \(z=0\) plane and \(\varphi_e\) and \(\varphi_s\) have even symmetry.

Placing equations (32a) and (32b) into equation (34) and using these properties, one finds

\[
\left( \frac{\Delta p}{q} \right)_{\text{wing}} = \frac{2}{U_0} \left[ \frac{\partial \varphi_e}{\partial x} + \frac{1}{U_0 R^2} \frac{dR}{dx} \left( \frac{\partial \varphi_e}{\partial y} \right) \right]_{x=0} (35a)
\]

and

\[
\left( \frac{\Delta p}{q} \right)_{\text{body}} = \frac{2}{U_0} \left[ \frac{\partial \varphi_e}{\partial x} + \frac{1}{U_0 R^2} \frac{dR}{dx} \left( \frac{\partial \varphi_e}{\partial y} \right) \right]_{x=0} (35b)
\]

where \(\Delta\) indicates the difference between a quantity on vertically opposed points of the upper and lower surface of the airplane.

It is apparent from the last two equations that, in general, the angle-of-attack and thickness solutions have a coupling effect on the loading coefficient and therefore their contribution to the load distribution cannot be treated separately. It is also important to notice the two special cases in which the coupling effects vanish; namely, a body of revolution without wings, and an airplane with a cylindrical body between the foremost and rearmost extent of the wing. In the former case the term \(\partial \varphi_e/\partial \theta\) is zero and in the latter \(dR/dx\) is zero. In both these cases the equation for the loading coefficient is

\[
\frac{\Delta p}{q} = \frac{2}{U_0} \frac{\partial \varphi_e}{\partial x} (36)
\]

THE TOTAL LIFT

Total lift can be obtained, of course, by integrating the loading coefficient over the aircraft surface. A much simpler way of finding the lift, however, can be derived from a momentum balance. Thus, by momentum considerations it is possible to show that the vectorial force \(F\) on a body inside a control surface \(S\) is given by the surface integral

\[
F = -\int_S \int (p-p_0) dS - \int_S \int \rho \left( \nabla \cdot \mathbf{v} \right) n dS
\]

where vector notation is used, the 0 subscript indicates free-stream conditions, \(p\) and \(\rho\) are the local static pressure and density, and \(\mathbf{v}\) is the local velocity vector. Let the surface \(S\) be a cylinder of infinite radius and two \(yz\) planes closing the cylinder be located infinitely far ahead of and behind the airplane. Then the lift force is given to the lowest order by

\[
L = \frac{\partial}{\partial x} \int_S \int \rho \mathbf{U} \mathbf{v} dy dz dy dz
\]

which reduces to

\[
L = - \rho U_0 \int_S \int (\partial \mathbf{v}/\partial x) dy dz dy dz
\]

This can be simplified since \(\mathbf{v} = \partial \varphi_e/\partial x\) and \(\partial \varphi_e/\partial x\) is the same as the jump in the potential evaluated at the airplane trailing edge. Thus the expression for lift becomes

\[
L = \rho U_0 \int_{\text{trailing edge}} (\partial \varphi_e/\partial x) dy
\]
Equation (37) applies to all slender shapes. In special cases represented by figure 3 (c), thickness effects always have even symmetry with respect to the \( z=0 \) plane, and it follows that the total lift and the vortex distribution in the wake of such configurations are affected only by the part of the potential due to angle of attack, even though the detailed load distribution depends upon both thickness and angle-of-attack solutions.

**EXAMPLES**

**PRESSURE ON A TRIANGULAR WING WITH ELLIPTIC CROSS SECTION**

It is of interest to calculate, by equation (24), the pressure on nonlifting wings of triangular plan form and elliptic cross section flying at supersonic speeds, since examples of this type have been solved without restriction to slender-wing theory. It is proposed, therefore, to study two cases given first by Squire (ref. 8) and then to compare the analytical results.

Let the wing be placed at zero angle of attack in a supersonic free stream of Mach number \( M_0 \). Consider first the thickness distribution for which the ordinate of the upper surface is

\[
h(x,y) = \frac{t}{2mz_0} \sqrt{m^2 x^2 - y^2}
\]

where \( z_0 \) is the root chord, \( t \) is wing thickness at \( z=z_0 \), and \( m \) is the tangent of the semiapex angle of the plan form. The flow is supersonic, so it is unnecessary to consider closure.

It follows from equation (38) that the elliptic section in the plane \( X=x_1 \) has major and minor semi-axes equal to \( nz_0 \) and \( t_0/2c_0 \) respectively. The cross-sectional area and the surface slope are, therefore,

\[
S(z) = \pi t z_0^2 / 2c_0, \quad \partial h / \partial x = t mx / 2c_0 \sqrt{m^2 x^2 - y^2}
\]

Since attention is confined to symmetric nonlifting wings, the boundary conditions are planar and are expressed by equation (26) for \( \alpha=0 \). Further, the solution is given in terms of these boundary values by equation (29) wherein \( \partial \rho / \partial n \) \( \alpha \rightarrow \infty \) becomes \( U_0 \partial h / \partial x \) and \( \partial \rho / \partial n \) \( \alpha \rightarrow 0 \) is zero by symmetry. Let us first study the flow on the surface of the wing. Then, although \( S''(z) \) is discontinuous at the origin, we can still write the equation for \( \varphi(x, y, z) \) in the form (see the discussion preceding equation (24))

\[
\frac{1}{U_0} \varphi(x,y,0) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{dh}{dx} \ln |y-y_1| dy_1 - \frac{1}{2} \int_0^\infty S''(z) \ln \frac{2(z-x)}{\beta} dz_1
\]

Since

\[
\frac{1}{\pi} \int_{-\infty}^{\infty} \frac{txz ln |y-y_1| dy_1}{2c_0 \sqrt{m^2 x^2 - y^2}} = \frac{mtz}{2c_0} \ln \frac{mz}{2}; \quad |y| < mz
\]

the expression for perturbation potential becomes

\[
\frac{1}{U_0} \varphi(x,y,0) = \frac{tmz}{2c_0} \left(1 - \ln \frac{4m \beta}{m} \right); \quad |y| < mz
\]

From equation (32a), wherein \( dR/dx \) is, of course, zero since there is no body, the pressure coefficient on the wing is

\[
C_p = \frac{tmz}{c_0} \left(\ln \frac{4}{m \beta} - 1\right); \quad |y| < mz
\]

Hence, the pressure distribution on the wing is uniform. Analysis not limited by the assumption of slenderness yields for pressure coefficient on the wing

\[
C_p = \frac{tmz}{c_0} \left(\frac{K-E}{\sqrt{1-\beta^2m^2}}\right)
\]

where \( K \) and \( E \) are complete elliptic integrals with modulus \( \sqrt{1-\beta^2m^2} \). Since for values of the modulus near one the asymptotic relations

\[
K = \ln \frac{4}{m \beta}; \quad E \approx 1
\]

apply, the pressure coefficient in slender-wing theory is seen to be a first-order approximation.

If one is interested in the pressure coefficient in the \( z=0 \) plane but off (although still in the vicinity of) the wing, the discontinuity in \( S''(z) \) at the origin should be considered. In such a case, since \( \Delta S''(0) \) is \( \pi t m / c_0 \) and \( S''(z) \) is zero, equation (24) becomes

\[
\frac{1}{U_0} \varphi(x,y,0) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{dh}{dx} \ln |y-y_1| dy_1 - \frac{tmz}{2c_0} \ln \left[ \frac{x-x_1 + \sqrt{(x-x_1)^2 - \beta^2y^2}}{\beta} \right] dz_1
\]

Since

\[
\frac{1}{\pi} \int_{-\infty}^{\infty} \frac{tmz ln |y-y_1| dy_1}{2c_0 \sqrt{m^2 x^2 - y^2}} = \frac{mtz}{2c_0} \ln \frac{|y| + \sqrt{y^2 - m^2 x^2}}{2}; \quad |y| > mz
\]

one can show the expression for the pressure coefficient off, but in the plane of, the wing is

\[
C_p = \frac{tmz}{c_0} \left[\frac{|y|}{\sqrt{y^2 - m^2 x^2}} - \ln \frac{2(x + \sqrt{x^2 - \beta^2y^2}) - 1}{\beta(|y| + \sqrt{y^2 - m^2 x^2})} - 1\right]; \quad |y| > mz
\]

(40)

Notice that the pressure has a square-root singularity along the wing leading edges, a result consistent with the exact linearized-theory solution. The pressure along the Mach cone from the wing apex, which is zero according to linearized theory, is not zero according to equation (40) but its magnitude is of the order \( (m \beta)^2 \) which, in keeping with the assumptions of slender-airplane theory, is negligible.

Squire has also considered the wing with ordinates given by

\[
k(x,y) = \frac{tx}{2c_0 m} \sqrt{m^2 x^2 - y^2}
\]

The lateral section is again elliptic, with semimajor and semiminor axes equal to \( mz \) and \( tz_0 / 2c_0 \). Cross-sectional area and surface slope are, respectively,

\[
S(z) = \frac{\pi mtz^2}{2c_0^2}; \quad \frac{\partial h}{\partial x} = \frac{1}{2mz_0} \frac{2mz^2 - y^2}{\sqrt{m^2 z^2 - y^2}}
\]

By direct integration it can be shown that on the wing

\[
C_p = \frac{mtz}{c_0} \left[3ln \frac{4}{m \beta} - 4\right]
\]

(42)
Analysis not limited to slender wings yields the expression

\[ C_s = \frac{mz}{c_0^2(1 - \beta^2 m^2)} \left[ (3 - \beta^2 m^2) K - (4 - 2\beta^2 m^2) E \right] \]

and again the results are in agreement if higher-order terms in \( \beta m \) are neglected.

A study of generalized conical flow fields in linearized supersonic theory reveals that the linear pressure distribution in the above problem can also be obtained on a wing with thickness specified by the relation

\[ h(x,y) = k \cosh^{-1} \left( \frac{mz}{y} \right) \]

where \( k \) is a constant that can be related to the maximum thickness ratio (attained along the line \( mz/y = 1.31 \)) of the wing. The cross-sectional area and surface slope are, respectively,

\[ S(z) = \frac{\pi kmz^2}{3}, \quad \frac{\partial h}{\partial x} = \frac{k y^2}{m \sqrt{m^2 z^2 - y^2}} \]

and pressure coefficient on the wing is

\[ C_p = 2kmz \left( \ln \frac{4}{\beta m} - 2 \right) \]

The latter expression agrees to the first order in \( \beta m \) with the general linearized solution for such a wing presented in reference 9. Slender-wing theory thus retains the property of the more general linear theory in that a given pressure distribution does not necessarily yield a unique thickness distribution.

**Supersonic Drag of Wings at Zero Incidence**

The general expression for the supersonic drag of a slender aerodynamic shape has been derived by Ward (ref. 3) through the use of momentum methods. It is also possible to obtain these results by direct integration of the product of pressure and surface slope over the specified surface; the analysis, however, requires rather careful attention to orders of integration, when planar problems are involved. Consider, for example, the drag of a wing at zero incidence and with a specified thickness distribution \( \epsilon = \pm h(x,y) \). The drag of the wing is expressible in the form

\[ D = D_e + 2q \int \left[ C_{re} \frac{\partial h}{\partial x} \, dz \, dy \right] \]

where the first term includes possible contributions to the drag that result from a finite leading-edge radius of curvature. From reference 10, this drag per unit of span is, in slender-wing theory,

\[ \frac{dD_e}{dy} = \pi q \rho \frac{1}{2} \left( \frac{dz}{dx} \right)^2 \]

where \( r_e \) is the radius of curvature normal to the wing leading edge and \( \theta \) is the local semispan. If the ordinate of the wing, in the vicinity of the leading edge, is

\[ z = f(\theta, \eta) \sqrt{\rho + \eta} \]

the final expression for the drag of the wing is then

\[ D = D_e + \pi q \rho \frac{1}{2} \left( \frac{dz}{dx} \right)^2 \]

\[ \frac{dD_e}{dy} = \pi q \rho \frac{1}{2} \left( \frac{dz}{dx} \right)^2 \]

Assuming the wing is pointed and the only discontinuity in the interval \( 0 \leq z < \ell \) occurs at the origin, the potential of the wing, evaluated in the plane of the wing, is given by

\[ \varphi(x,y,z) = \frac{U_0}{\pi} \int_{-\infty}^{z} \frac{\partial h}{\partial x} \ln |y-y_1| \, dy_1 - \frac{U_0}{2\pi} \int_{-\infty}^{z} \frac{\partial h}{\partial x} \ln \left( \frac{z-x_1}{z-x} \right) \, dx_1 \]

and, since pressure coefficient in the planar case is directly proportional to the streamwise gradient of \( \varphi \), the contribution of each of the terms on the right-hand side of equation (45) can be calculated separately in equation (43). The second and third terms offer no difficulty but simplification of the expression resulting from the first term necessitates an inversion of order of integration and, if the leading edge has a finite radius of curvature, such an inversion cannot be carried out in the conventional manner. However, a method by means of which such an inversion can be carried out is presented in reference 11. Thus, set

\[ I_1 = \int_0^{\pi} d\epsilon \int_0^{\pi} d\theta \left( \frac{dz}{dx} \right)^2 \frac{\partial h}{\partial x} \ln \left( \frac{\epsilon - \eta}{\epsilon + \eta} \right) \]

where \( \int \) refers to the “finite part” of the integral and the notation \( \int d\epsilon \int d\theta \), signifies that the \( \epsilon \) integration must be performed first. Then if

\[ \varphi(x,y,z) = f(\epsilon, \theta) \sqrt{\rho - \eta} \]

it can be shown that

\[ I_1 - I_2 = \frac{\pi^2}{4} \left( \frac{dz}{dx} \right)^2 f(\epsilon, \theta) \]

Detailed analysis reveals that the residual term (i.e., the value of \( I_1 - I_2 \)) yields a drag component that is equal in magnitude but opposite in sign to \( D_e \).

The final expression for the drag of the wing is then

\[ \frac{dD_e}{dy} = \pi q \rho \frac{1}{2} \left( \frac{dz}{dx} \right)^2 \]

where \( r_e \) is the radius of curvature normal to the wing leading edge and \( \theta \) is the local semispan. If the ordinate of the wing, in the vicinity of the leading edge, is

\[ z = f(\theta, \eta) \sqrt{\rho + \eta} \]

As a particular example, consider the wing-like surface of triangular plan form (ref. 8) which results from a combina-

---

1 For a definition of the finite-part integration technique as used here, see reference 11.
tion of the surfaces specified in equations (38) and (41) and has ordinates given by the expression

$$h_w(x, y) = \frac{2y}{m c_\infty} (c_0 - x) \sqrt{m^2 x^2 - y^2}$$  \hspace{1cm} (47)

This wing has rounded leading edges and a finite trailing-edge angle, and from equation (46) its drag coefficient based on wing area is found to be

$$C_d = -2m \pi \left( \frac{L}{c_0} \right)^2 \left( 1 + \ln \frac{\beta m}{4} \right)$$  \hspace{1cm} (48)

It is apparent from equation (46) that, for the type of wing considered, wing drag varies with Mach number so long as the streamwise gradient of area is finite at the rear of the wing; conversely, there is no dependence on Mach number when the gradient of area vanishes there. For example, a wing with an elliptic plan form and biconvex sections satisfies the latter condition, and its drag coefficient based on wing area is

$$C_d = 2 \frac{b}{a} \left( \frac{t}{a} \right)^2$$  \hspace{1cm} (49)

where $t$ is total maximum thickness, $a$ is the semiaxis of the elliptic plan form in the stream direction, and $b$ is the semiaxis measured normal to the stream direction.

A comparison between the values of $C_d$ given by slender-airplane theory for the Squire wing (eq. (48)) and the elliptic lens (eq. (49)) and the exact thin-airfoil-theory values $^6$ for the same wings is shown in figure 4.

![Figure 4](image)

**Figure 4.**—Comparison of slender-airplane theory with exact thin-airfoil theory results for two wings in supersonic flight.
THE CALCULATION OF PRESSURE ON SLENDER AIRPLANES IN SUNSONIC AND SUPERSONIC FLOW
