ABSTRACT

Using HeLa cells stably transfected with an HIV-LTR-CAT construct, we demonstrated a peak in CAT induction that occurs in viable (but not necessarily cell-division-competent) cells 24 h following exposure to some cell-killing agents. γ rays were the only cell-killing agent which did not induce HIV transcription; this can be attributed to the fact that γ-ray-induced apoptotic death requires functional p53, which is not present in HeLa cells. For all other agents, HIV-LTR induction was dose-dependent and correlated with the amount of cell killing that occurred in the culture. Doses which caused over 99% cell killing induced HIV-LTR transcription maximally, demonstrating that cells that will go on to die by 14 days are the cells expressing HIV-LTR-CAT.

Abbreviations: HIV-LTR, human immunodeficiency virus long terminal repeat; CAT, chloramphenicol acetyl transferase.
INTRODUCTION

Valerie et al. (1988) described the induction of transcription from the human immunodeficiency virus long terminal repeat (HIV-LTR) following exposure to DNA-damaging agents in HeLa cells stably transfected with a construct containing the chloramphenicol acetyl transferase (CAT) reporter gene driven by the HIV-LTR promoter. Since then, many reports have reproduced and expanded upon those findings, even demonstrating in vivo induction in transgenic mouse systems. Recent work from our laboratory has shown enhanced expression from the HIV promoter following exposure of cells to fission-spectrum neutrons at doses which also induce expression of apoptosis-associated genes. We set out in these experiments to determine whether this HIV-LTR induction was a consequence of DNA damage, as suggested by the initial reports, or whether it was associated with the onset of cell death in general (such as occurs during apoptosis or programmed cell death).

MATERIALS AND METHODS

Cell Lines

HeLa cells stably transfected with HIV-LTR-CAT construct were generously provided by Dr. K. Valerie. Immediate cell death was determined by trypan blue dye exclusion. Colony forming cell assays (14 day) were performed as described.
Cultures showing approximately 80% confluence were used for all experiments reported here.

**CAT Assays**

CAT assays were performed as previously described.\textsuperscript{4,7-9} Previous work has shown that UV exposure does not affect expression of actin genes in HeLa or P3 human cells using doses and conditions described here.\textsuperscript{10}

**Treatments**

Equal numbers and concentrations of HeLa cells stably transfected with the HIV-LTR-CAT construct were exposed in triplicate to varying doses of electric current at the indicated voltages; electroporation was carried out in the presence of PBS. Cells were harvested 24 h following exposure and counted.

For UV exposures, HeLa cells stably transfected with the HIV-LTR-CAT construct were exposed to different doses (as indicated) of UVC (254 nm) germicidal lamp (General Electric GE 30T830W). The irradiations were at a distance of 55.6 cm from the source. The dose-rate for all UVC exposures was Jm\textsuperscript{2}/sec.\textsuperscript{7} The media were removed from the plates. Plates were washed once in PBS prior to UV exposure without plate covers. Cells were harvested 24–180 h following exposure. Equal numbers of viable cells were used in each CAT assay.\textsuperscript{4,7} Conditions for other treatments are as defined in Table 1 and as defined.\textsuperscript{4,7}
RESULTS

Figure 1 details the results of one experiment examining the effects of electroporation of sucrose buffer on the induction of CAT expression driven by HIV-LTR. In this experiment, cells were exposed to differing electric voltage levels (0.1 or 0.3 kV) in phosphate-buffered sucrose. At the same time, each culture was monitored for the number of total viable cells when the total number of input cells for each experimental group was the same. These results demonstrated maximal induction of the LTR-CAT construct at voltages which resulted in maximal cell killing. It should be noted that equal numbers of viable cells only were used for each CAT assay so as to avoid variation caused by the number of dead cells resulting from the treatment conditions. These and all other results are from a single experiment since cpm are not directly comparable from one experiment to the next; all results have been repeated twice after the original observation to confirm validity.

Next, the effects of UV exposure on expression of the CAT reporter gene were examined; Fig. 2 shows results demonstrating induction of CAT following UV exposure. The response peaked at 24 h following exposure and was maintained at high levels even as late as 72 h following exposure; conditions were such that cell death was induced. Again, it should be noted that in these experiments, equal
numbers of viable cells were used in determining the number of cells to be used in each CAT assay. The fact that this response remains high in those cultures in which cell death had been triggered, but not in sublethally treated cultures, further supports the concept that induction of HIV-LTR is associated with cell death rather than with DNA damage.

Figure 3 demonstrates the results of experiments examining UV effects on both colony formation (14-day assay) and CAT expression in the same cell cultures. Cellular colony formation was used as a measure of cell division/propagation capability. The same doses capable of inducing HIV-LTR-CAT in Figure 2 were tested for survival in Figure 3. These experiments demonstrate a correlative relationship between HIV-LTR-mediated CAT expression and the lack of cell survival following UV exposure, i.e., cells that are not able to go on to divide express higher levels of LTR-CAT than those that do go on to divide. CAT is expressed maximally in those cultures for which cell death will be over 99% by 14 days. Fig. 4 similarly examines the effects of multiple UV doses on HIV-LTR-CAT induction. Exposures of 5 J/m² were not additive, and a dose between 5 and 20 J/m² was required for induction of HIV-LTR. These results suggest that HIV-LTR has a threshold UV dose for induction of CAT and that this threshold dose corresponds to a dose at which cell killing is first detectable in these cultures.
Table 1 summarizes the results of a series of experiments from our own published and unpublished work\textsuperscript{4,7} in which various agents were tested under different conditions for their abilities to induce HIV-LTR-CAT expression using the stably transfected cell line reported here. Experiments from this manuscript are included in these results but reflect only a partial collection of results reported in Table 1. These experiments demonstrated that treatments which reduced cell survival in a 14-day colony forming cell assay also induced CAT expression. Treatments which induced HIV-LTR-mediated CAT expression included low pH (6.4), high pH (8.4), electroporation, UV exposure (dose-dependent), cisplatin, methotrexate, and excess heat (700 W [microwave] for 10 s in a small volume of PBS). On the other hand, treatments which had no effect on viability and no effect on HIV-LTR-CAT induction included co-culture with metronidazole (a DNA-damage-inducing drug), vitamin C treatment, microwave exposure in an excess volume of medium to reduce overheating, exposure to electromagnetic fields, heat-shock (10 min at 43°C, 2 h at 39°C), solar radiation, sulindac, and salicylic acid. Other work from our group has documented a failure to induce HIV following γ-ray exposure\textsuperscript{7} and following nutrient arrest (Table 1). This suggests that not all methods of inducing cell death are efficient in inducing HIV.

**DISCUSSION**

These results suggest a potentially causative association between some
forms of cell killing and the induction of HIV expression. Past work has shown the requirement for new protein synthesis for induction of HIV.\textsuperscript{11} We hypothesize that one pathway for inducing cellular death (apoptosis or programmed cell death), which also requires new protein synthesis,\textsuperscript{12,13} causes induction of HIV expression. The fact that this response is not repressed within the first 72 h following UV exposure (Fig. 2) suggests that the HIV inductive response is not capable of being directly repressed by the dying cell.

We propose a model whereby HIV lays dormant in cellular DNA until apoptosis or cell death is naturally induced; this activation of apoptosis then turns on HIV expression so that maximal viral transcription occurs in apoptotic cells. Much work has demonstrated a relationship between HIV and apoptosis,\textsuperscript{11,14–16} with most observations suggesting that HIV itself induces the apoptotic process. Our cell system does not produce active virus, so we cannot examine the possibility that HIV itself induces apoptosis, as shown by others.\textsuperscript{11,14–16} Our data suggest, however, that the cell death/apoptotic response induces HIV. This could explain why HIV is expressed in vivo most commonly in T cells which undergo natural developmental apoptosis in adults. Experiments are underway to introduce the HIV-LTR-CAT expression vector into T-cells to determine whether a similar expression pattern is observed.

Past work has also suggested that UV-induced HIV transcription is
mediated directly by DNA damage.\textsuperscript{11} Our model proposes that one mechanism by which HIV is induced is as a consequence of a cell death response; this response can be induced by a variety of agents, including those which damage DNA (UV, neutrons), those which denature proteins (excess heat; pH variations), and those which disrupt cell signaling (electroporation). The actual intracellular signal that induces programmed cell death responses is not known but may provide important insights for studies of HIV gene regulation. It is interesting that γ-rays have no effect on HIV expression in HeLa cells, a cell line which does not induce functional p53 protein following γ-ray exposure due to presence of the papillomavirus protein E6. HIV induction may be associated with a p53-dependent pathway of cell death/apoptosis. In addition, recent work has demonstrated a requirement for NF-κB in HIV-LTR induction.\textsuperscript{17} Recent work from our own group has demonstrated that salicylic acid (which inhibits NF-KB) but not indomethacin is capable of suppressing the UV-induced response.\textsuperscript{9} The relationship of NF-κB to p53/apoptosis pathways is not yet clearly established but may play a significant role in the DNA damage response of the HIV-LTR.

\textbf{ACKNOWLEDGEMENTS}

The authors wish to thank Kay Bexson for excellent secretarial assistance and Gordon Holmblad for assistance in irradiations.

FIGURE LEGENDS

**Figure 1.** A: Cell survival documents the numbers of viable cells remaining in the culture as determined by trypan blue dye exclusion at the time of cell harvest. The number atop each column indicates the percentage of viable cells remaining in the culture. B: Equal numbers of viable cells were counted and used in the CAT assays for the $^3$H acetylation of chloramphenicol. Assays were performed as described previously (Sellins and Cohen 1987). (10^6 cells/point)

**Figure 2.** HeLa cells stably transfected with the HIV-LTR-CAT construct were exposed to different doses (as indicated) of UVC (254 nm) germicidal lamp. Cells were harvested 24–180 h following exposure. For purpose of graphing cpm of $^3$H-chloramphenicol were corrected by subtracting background. Equal numbers of viable cells were used in each CAT assay (Sellins and Cohen 1987). At the high dose (25 J/m²), there were no viable cells remaining for assay after 96 h post-exposure.

**Figure 3.** HeLa cells stably transfected with HIV-LTR-CAT construct were exposed to doses (J/m²) as indicated of UVC (254 nm) germicidal lamp. From each culture, an equal number of cells for each treatment were used for 14-day colony assays for cell survival determination (A; expressed as the number of
colonies/number of cells plated × 100) and equal numbers of viable cells were
set up in CAT assays for expression studies (B; 10).

Figure 4. HeLa cells stably transfected with HIV-LTR-CAT were exposed at 24-h
intervals to 0, 5 or 10 Jm⁻² UVC (254 nm) germicidal lamp. Cells were
harvested at 24 h and 48 h post-exposure. Equal numbers of viable cells (2 ×
10⁵) were used for CAT assays as described (Sellins and Cohen 1987).
