Abstract

Fracture toughness values for A533-B reactor pressure vessel (RPV) steel obtained from test programs at Oak Ridge National Laboratory (ORNL) and University of Kansas (KU) are interpreted using the J-A₂ analytical model. The analytical model is based on the critical stress concept and takes into consideration the constraint effect using the second parameter A₂ in addition to the generally accepted first parameter J which represents the loading level. It is demonstrated that with the constraint level included in the model effects of crack depth (shallow vs. deep), specimen size (small vs. large), and loading type (uniaxial vs. biaxial) on the fracture toughness from the test programs can be interpreted and predicted.

Introduction

Constraint effect in fracture is qualitatively referred to as the dependence of fracture toughness of materials upon the specimen thickness, in-plane geometry and loading configuration. To understand this fracture behavior considerable effort has been devoted to tests and development of analytical models in recent years. While tests attempt to simulate the actual structural loading and geometric situations as closely as possible, analytical models serve to interpret and predict the fracture of test specimens of different geometries. More importantly, any analytical model validated by existing test data will provide a quantitative tool to be utilized to predict the fracture behavior of actual structures such as nuclear reactor vessels under realistic loading conditions.

To prevent fracture of nuclear RPV, fracture mechanics methodologies are generally applied to evaluate the structural integrity of the vessels. As more nuclear power plants become aged and reactor vessel steels get further embrittled, structural integrity of reactor vessel has become an extremely important and timely issue. The Nuclear Regulatory Commission (NRC) has commissioned Oak Ridge National Laboratory to conduct a series of tests and modeling in an attempt to investigate the fracture behavior of reactor vessel steels. In particular, the constraint issue has been studied extensively. It has been reported that specimens with shallow cracks produce high toughness values compared to deep or standard ASTM fracture test specimens [see, e.g. 1-3]; small specimens yield high toughness values compared to large specimens [4]; and biaxially loaded specimens that simulate a crack in RPV wall subjected to thermal shock loads experience low toughness values compared to uniaxially loaded specimens [5-8].

In this paper, experimental data from ORNL [1,5] and KU [2] are interpreted using the J-A₂ analytical model developed by Chao, et al. [9] and Chao and Ji [10]. These experimental data are from the material, A533-B RPV steel, tested at different temperatures. Our analysis used the data tested at about -40 °C which is at the lower portion of the ductile-to-brittle transition curve of the material. In both [1] and [2], toughness values are obtained for shallow ($a/w=0.1$) and deep ($a/w=0.5$) single-edge-notch-bend (SENB) crack specimens. The KU tests [2] used the broken specimens from ORNL and thus are smaller in size. In [5], the fracture toughness values are obtained by testing a six-point-bend cruciform specimen under either uniaxial or biaxial loads. Using these data, this paper is able to address the constraint issues in specimen size (KU vs. ORNL), crack depth ($a/w=0.1$ vs. 0.5), and loading configurations (uniaxial vs. biaxial) using the J-A₂ model.

The theoretical background of the J-A₂ methodology is briefly reviewed in the next section. Detailed specimen dimensions and loading configurations from [1,2,5] are presented then. The KU test data [2] are used to construct the failure curve in the J-A₂ space for the RPV steel, A533-B. Using this material failure curve and numerical finite element analysis, fracture toughness values reported in [1,5] are *predicted*. Good agreement between the predicted values and the test results is obtained. Discussion and comments are provided to conclude the paper.

Theoretical background

For structural steels fracturing at lower shelf and lower portion of the ductile-to-brittle transition temperature, the predominant mode of fracture is cleavage. It is generally recognized that a cleavage fracture event initiates when a critical tensile stress σ_c is attained at a critical distance r_c ahead of the crack tip, or the RKR model [11-13]. A large scatter in the toughness data observed in experiments for cleavage fracture could be due to a combination of statistical sampling [14] and constraint effects. In this paper, the constraint effect on the fracture toughness is investigated. Referring to fig.1, if the critical stress σ_c can be represented by the well known asymptotic solution, HRR fields, after Hutchinson [15,16] and Rice and Rosengren [17], the fracture can be well characterized by a single parameter J since the strength of the HRR solution is uniquely governed by J. Note that the HRR solution is valid as $r \rightarrow 0$. Only under stringent conditions, a structure or specimen can possess a stress at a finite distance r_c close to the HRR stress. This is indeed the underlying principle for the severe size requirements by ASTM for fracture toughness testing. In the general case, the critical stress at the finite distance r_c deviates a certain amount from the HRR stress. When this deviation is large, a single parameter, J or CTOD (crack tip opening displacement), is insufficient to characterize the fracture event. This is the fundamental reason for the constraint effect in fracture.

To quantify the stress at a finite distance r_c (in contrast to $r \rightarrow 0$) ahead of the crack tip, it is nature to examine the analytical asymptotic solutions including higher order terms. Li and Wang [18] presented a procedure for determining the second term in the asymptotic expansion. Sharma and Aravas [19] completed the second order analysis using a somewhat different method than used by Li and Wang [18]. Recent results by Xia, et al. [20] include higher order terms. O'Dowd and Shih [21-23] introduced a Q-stress term to collectively represent all the higher order terms for the stress fields. Note that these analyses [18-23] are for plane strain, Mode I conditions. A more complete theoretical asymptotic analysis including higher order terms for the stress and deformation fields around a crack tip embedded in Ramberg-Osgood nonlinear materials for Mode I and Mode

II under either plane stress or plane strain conditions are developed by Yang, et al. [24,25]. It is shown that the stress field at a crack tip can be written as

$$\begin{aligned}\bar{\sigma}_{ij} &= \sum_{\beta=1}^{\infty} \bar{A}_{\beta} \bar{r}^{s_{\beta}} \bar{\sigma}_{ij}^{(\beta)}(\theta) \\ &= \bar{A}_1 \bar{r}^{s_1} \bar{\sigma}_{ij}^{(1)}(\theta) + \bar{A}_2 \bar{r}^{s_2} \bar{\sigma}_{ij}^{(2)}(\theta) + \bar{A}_3 \bar{r}^{s_3} \bar{\sigma}_{ij}^{(3)}(\theta) + \dots\end{aligned}\quad (1)$$

where $\bar{\sigma}_{ij} = \sigma_{ij}/\sigma_0$, $\bar{r} = r/L$, L is a crack characteristic length, β is a positive integer, $\bar{A}_{\beta}$ is the amplitude, s_{β} is the stress exponent, and $\bar{\sigma}_{ij}^{(\beta)}(\theta)$ is the dimensionless angular distribution of stress of the β -th term in the series expansion. Note that $i,j=1,2,3$ in the above equation and it is understood that they represent r,θ,z in a cylindrical coordinate system with the origin at the crack tip.

It is further demonstrated by Chao, et al. [9] and Yang, et al. [24] that for Mode I under plane strain conditions the first three terms from the series solution can be used to characterize the stress $\sigma_{ij}(r,\theta)$ in the crack tip region well beyond $r/(J/\sigma_0) = 5$. Retaining the first three terms from the infinite series eqn.(1) is sufficient because of the similarity of the angular distributions of each stress component for $\beta \geq 3$. Consequently, a third term ($\beta=3$) alone can collectively represent several higher order terms in the series expansion. Thus, using more than three terms in (1) is redundant and using two terms is not sufficient to characterize the stress fields in the range $1 < r/(J/\sigma_0) < 5$ as discussed in [19,25]. The three-term solution for the stress in the θ direction is written as

$$\frac{\sigma_{\theta\theta}}{\sigma_0} = \left(\frac{J}{\alpha \epsilon_0 \sigma_0 I_n L} \right)^{\frac{1}{n+1}} \left[\left(\frac{r}{L} \right)^{s_1} \bar{\sigma}_{\theta\theta}^{(1)}(\theta) + A_2 \left(\frac{r}{L} \right)^{s_2} \bar{\sigma}_{\theta\theta}^{(2)}(\theta) + (A_2)^2 \left(\frac{r}{L} \right)^{s_3} \bar{\sigma}_{\theta\theta}^{(3)}(\theta) \right] \quad (2)$$

where

$$A_2 = \frac{\bar{A}_2}{\bar{A}_1} = \frac{\bar{A}_2}{(\alpha \epsilon_0 \sigma_0 I_n L/J)^{s_1}}$$

n is the strain hardening exponent, α is a material constant used in the Ramberg-Osgood constitutive modeling, (σ_0, ϵ_0) is a reference stress-strain state and I_n is a tabulated function [26]. The first term in eqn.(2) is the HRR solution and the remainder represent the higher order terms in the asymptotic expansion. Note that eqn.(2) has two amplitudes, J and A_2 , while J represents the level of loading A_2 is generally a function of loading level (i.e. J), material constants (i.e. $\alpha, \sigma_0, \epsilon_0, n$), and geometry and loading configuration, or

$$A_2 = f(J; \alpha, \sigma_0, \epsilon_0, n; \text{geometry and loading configuration}) \quad (3)$$

It appears that for common fracture test specimen geometries both the second and the third term in eqn.(2) are negative, i.e. A_2 is a negative quantity, $\tilde{\sigma}_{\theta\theta}^{(2)}$ is positive, and $\tilde{\sigma}_{\theta\theta}^{(3)}$ is negative. Since the first term is always positive, the opening stress in front of a crack tip is thus in general lower than the HRR stress as shown schematically in fig.1. In addition, since the critical distance r_c is believed [11-13] within the range $1 < r_c/(J/\sigma_0) < 5$ for cleavage fracture and the critical stress σ_c in this range can be represented by eqn.(2), fracture event can thus be characterized by these two mechanics parameters J and A_2 . The three-term solution combined with the critical stress criterion for cleavage fracture can therefore be written as

$$\frac{\sigma_c}{\sigma_0} = \left(\frac{J}{\alpha \varepsilon_0 \sigma_0 I_n L} \right)^{\frac{1}{n+1}} \left[\left(\frac{r_c}{L} \right)^{s_1} \tilde{\sigma}_{\theta\theta}^{(1)}(0) + A_2 \left(\frac{r_c}{L} \right)^{s_2} \tilde{\sigma}_{\theta\theta}^{(2)}(0) + (A_2)^2 \left(\frac{r_c}{L} \right)^{s_3} \tilde{\sigma}_{\theta\theta}^{(3)}(0) \right] \quad (4)$$

Note that a critical stress at a critical distance ahead of the crack tip, which represents the material's own resistance to fracture, is used here as the material property for cleavage fracture. Thus, the J - A_2 fracture criterion written as eqn.(4) is based on the RKR model and the critical stress is assumed to be characterized by the three-term series solution. The two *material* parameters, σ_c and r_c , used in the RKR model are now transformed into two *mechanics* parameters, J_c and A_2 , through the mathematical asymptotic solutions, e.g. eqn.(4). Physically, the magnitude of A_2 directly determines the amount of departure of the stress from the HRR stress. For specimens having $A_2 = 0$, the critical stress σ_c is uniquely characterized by the HRR stress. As a consequence, fracture of such specimens is controlled by a single parameter, such as J , or equivalently δ_5 , or CTOD. For general specimen geometry or structures, A_2 provides a quantitative measure of the level of constraint, e.g. small (large) value of $|A_2|$ corresponds to high (low) constraint or high (low) stress triaxiality.

The constraint level A_2 can be determined by either numerical or experimental method. Experimentally, any deformation measurement close to the crack tip, for example, CTOD or strain gage, will yield a displacement or strain value that is a function of J and A_2 . Since J can be obtained by other techniques for the test specimen, A_2 can be determined from that deformation measurement. In this paper A_2 is determined numerically by a point matching technique [24], that is, the opening stress value $\sigma_{\theta\theta}(r, 0^0)$ determined from a finite element analysis (FEA) at a point in front of the crack tip is set equal to the three-term analytical result, e.g. left hand side of eqn.(2). Since J value can be calculated by contour integral, eqn.(2) can be used to determine the A_2 value for this given J and $\sigma_{\theta\theta}$. Table 1 lists the stress exponents of higher order terms and Table 2 provides the dimensionless values of $\tilde{\sigma}_{\theta\theta}^{(\beta)}$ at $\theta=0^0$ for several hardening exponents to use with eqns.(2) and (4).

Table 1 Stress exponents of higher order terms, Mode I, plane strain

n	$s_1 = -1/(n+1)$ (HRR values)	s_2	s_3
3	-0.25	-0.01284	0.2243
4	-0.2	0.03282	0.2656
5	-0.1666	0.05456	0.2758
10	-0.0909	0.06977	0.2304

Table 2 Higher order opening stress values $\tilde{\sigma}_{\theta\theta}^{(\beta)}$ at $\theta=0^\circ$, Mode I, plane strain

n	$\beta = 1$ (HRR values)	$\beta = 2$	$\beta = 3$
3	1.9407	0.2834	-1.2764
4	2.1042	0.3092	-2.1506
5	2.2171	0.3184	-3.2224
10	2.4969	0.3130	-6.4128
13	2.5775	0.3036	-7.2798

Based on the above discussion, Chao, et al. [9] and Chao and Ji [10] proposed a two parameter approach using J and A_2 for the prediction of onset of crack growth in structures. The necessary steps are suggested as follows and demonstrated in fig.2.

- Determine the J_C versus A_2 material failure diagram for the material of interest. This can be accomplished by using laboratory test specimens and obtaining J_C at the onset of crack growth. FEA is then performed to determine the A_2 value corresponding to the loading level J_C . A best fit from the data consisting of (J_C, A_2) to eqn.(4) forms the material failure curve. Note that there are two unknowns σ_C and r_C in eqn.(4). Thus, at least two test data points are required to determine eqn.(4). In addition, the in-plane size requirement as specified in the ASTM standard for the test specimens is not needed since the effect of size and crack depth is represented by the magnitudes of J_C and A_2 .
- For a given crack in a service structure, perform the FEA to determine J and A_2 pairs at different loading levels. Data consisting of (J, A_2) forms the applied loading curve or the crack driving force curve. This crack driving force represents the opening stress ahead of the crack tip as the applied load (or J) is increased. Note that the driving force curve becomes vertical in fig.2 as the loading increases and the crack tip stress state becomes fully plastic. The theoretical background of this behavior can be found in [9].
- Superimpose the two curves obtained in steps (a) and (b). The point of intersection of these two curves determines the failure parameters (J_C, A_2) . The applied load corresponding to this failure J_C is the failure load. A statistical scatter band may be established around the failure curve determined in (a). Thus, a failure load with certain confidence bound can be obtained.

The above procedure has been successfully applied to a series of test data composed of various crack depths [10]. Constraint effects in fracture such as size effect and transferability are also studied in [10]. In the current paper, this procedure is applied to the interpretation and prediction of the test data from KU [2] and ORNL [1,5] for the A533-B RPV steel. The test data show a significant dependence of the fracture toughness values on specimen size, crack depth, and loading configurations.

Material failure curve for A533-B reactor pressure vessel steel

The material used in [1,2,5] is an A533 grade B, Class 1 steel and is typical of a RPV steel. The material was heat-treated to simulate RPV conditions. The mechanical properties are : Young's modules, $E=206,850$ MPa (30,000 ksi); Poisson's ratio, $\nu=0.3$; yield stress, $\sigma_0=452$ MPa (66 ksi) at Temperature -40°C . The stress-strain curve shown in [1] is curve-fit to the Ramberg-Osgood constitutive equation and is shown in fig. 3. The curve fit gives: strain hardening exponent $n=6.3$, $\alpha=2.71$. In addition, $I_n = 4.85$, $\tilde{\sigma}_{\theta\theta}^{(1)}=2.2898$, $\tilde{\sigma}_{\theta\theta}^{(2)}=0.317$, $\tilde{\sigma}_{\theta\theta}^{(3)}=-4.0519$ at $\theta=0^\circ$, $s_1=-0.137$, $s_2=0.05851$, $s_3=0.264$, $\epsilon_0=\sigma_0/E$ and $L=1$ mm. Note that the use of $L=1$ mm is arbitrary as long as it is used for all data studied.

Table 3 lists the specimen geometry and test conditions of A533-B steel from ORNL [1,5] and KU [2]. The average values of the KU test results for $a/w=0.1$ or 0.5 are used here to generate the material failure curve. The finite element program ABAQUS [27] is used and plane strain assumptions are adopted for the models. Deformation theory with the Ramberg-Osgood material is used in the analysis. Following the procedure described in (a), the specimen was loaded until the critical load P_c ($P_c=78.7$ kN and 22.5 kN for $a/w=0.1$ and 0.5 , respectively) is reached. The J value corresponding to this critical load is calculated from the ABAQUS code and designated as J_c . The A_2 value corresponding to this load or J_c is then calculated numerically using the opening stress ahead of the crack tip. These (J_c , A_2) pairs are (539 kN/m, -0.39) and (76 kN/m, -0.27) for $a/w=0.1$ and 0.5 , respectively, and the value of A_2 was determined at $r/(J/\sigma_0)=2$. Substituting these two data points into equation (4) as (J , A_2), the two material fracture parameters are obtained as $\sigma_c=2.23\sigma_0$ and $r_c=1.54$ mm. Knowing these two parameters, equation (4) can be plotted in the J and A_2 space as shown in fig.4. This curve represents the failure curve for A533-B steel assuming that the fracture is controlled by the opening stress ahead of the crack tip, i.e. the RKR model. A flawed structural member made of this material is expected to fail if the point (J , A_2) under a postulated load is located above (or the left) of the material failure curve.

Prediction of ORNL fracture toughness data ----- Size effect

With the failure curve available, we will proceed to *predict* the fracture toughness of the ORNL test specimens reported in [1,5]. The ORNL test specimens have shallow ($a/w=0.1$) and deep ($a/w=0.5$) configurations. They are different from the KU data in the overall size as shown in Table 3. Following the procedure (b) in the "Theoretical background" section, crack driving forces are obtained and plotted in fig.5. Note that since the critical distance is known as $r_c=1.54$ mm, the A_2 value at an applied J was determined at $r_c/(J/\sigma_0)$ from the crack tip. The crack driving force intersects with the material failure curve at $J_c=148$ MPa-mm (kN/m) for shallow crack and 65 MPa-mm (kN/m) for deep crack. Fracture toughness J_c from ORNL tests are plotted on the crack driving forces

shown in fig. 5. Notice that the material failure curve passes right through the scatter band of the test data.

It can be concluded from the prediction demonstrated here that the (J, A_2) fracture criterion can predict the effect of crack depth and specimen size on the fracture toughness values of the A533-B RPV steels.

Prediction of ORNL fracture toughness data ----- Biaxial vs. uniaxial loadings

It has been found that cracks embedded in RPV are subjected to far field biaxial stress fields (i.e. a positive tensile stress parallel to the crack front in addition to the common Mode I loading) under thermal shock loading conditions. ORNL has initiated a comprehensive testing and modeling program to investigate the fracture behavior of RPV steels. A six-point-bend cruciform specimen was designed and tested to apply the biaxial load to the crack specimen. The specimen has $a/w=0.11$, thus a shallow flaw. Three dimensional finite element analysis was performed by ORNL to reveal the crack tip stress fields. Detailed data and testing procedures can be found in [5]. Figure 6 shows the opening stress distributions at the critical loads of the cruciform specimen under uniaxial (three-point-bend) and biaxial (six-point-bend) loading conditions [5]. Since the opening stress ahead of the crack tip is available, we proceeded to use these stresses (i.e. shown in fig.6) with eqn.(4) to calculate the A_2 corresponding to the applied J . The A_2 calculated at various positions are shown in fig.7. Note that the stress distribution shown in fig.6 is determined from finite element analysis using piecewise linear uniaxial material stress-strain curve in contrast to Ramberg-Osgood power law model. This could explain the variation of A_2 with distance from the crack tip. Again, the A_2 value at $r_c = 1.54$ mm is chosen

which corresponds to $r_c/(J/\sigma_0)=2.9$ and 4.1 for uniaxial and biaxial case, respectively. The experimental (J_c, A_2) points, $(246, -0.35)$ for uniaxial and $(167, -0.32)$ for biaxial case, are shown in fig.5. Note that if the failure curve is exact, the experimental data should be located on the curve. As shown in fig.5, the prediction of the fracture toughness from the failure curve is excellent.

It should be noted that the RKR model is based on the failure stress of the material or the resistance of the material to fracture. It should be able to apply to either two-dimensional or three-dimensional cracked geometries. The approximation used here is that the stress distribution in front of the crack tip, i.e. eqn.(4), is from a two-dimensional plane strain solution. However, it has been shown in [9] that J and A_2 can be utilized to characterize the crack tip opening stress in a three-dimensional surface crack. The data shown in fig.5 further indicates that the J - A_2 method may be a useful analytical model to predict fracture in three-dimensional structures.

Discussion and Conclusion

1. The predicted results in this report are excellent. It indicates that the J - A_2 methodology can be effectively used to interpret and predict fracture toughness values under various levels of constraint. It is further demonstrated that test data from small specimens can be utilized to predict fracture of large specimens or structures if the constraint level such as A_2 can be included in the analytical model.
2. The J_c values for the KU data used in this paper are calculated by the domain integral built into the ABAQUS code corresponding to the critical loads [28] applied to the specimens. As shown in Table 3, these J_c values are lower than the J_c reported [2] where they were determined using a formula developed by Gordon and Wang [29] for

load versus CMOD record. The difference could be due to the small size of the KU specimens so that the formula may not be applicable.

3. As stated in "Theoretical background" section, procedure (a), to determine the material failure curve in the (J, A_2) space or to determine σ_c and r_c in eqn.(4), at least two experimental data consisting of (J_c, A_2) are required. Two data points from KU are available and used in this study to determine the failure curve for the RPV A533-B steel. Although it does not seem to affect the predictions reported in this paper, more experimental data that cover a large range of A_2 are recommended to construct the material failure curve to account for the scatter of the experimental data.
4. The physical meaning of r_c should be the distance from the original fatigue crack tip to the cleavage initiation site in front of the crack tip including any stable ductile crack growth. The r_c value obtained from KU data in this paper is 1.54 mm and is used to predict the failure J of the ORNL test data. This value is well within the estimated plastic zone radii of 14 and 9.6 mm for the ORNL uniaxial and biaxial specimens at failure, respectively [5]. However, this value is larger than the measured r_c from post-test fractography studies where 0.13 to 0.22 mm are reported for the cruciform specimens and 0.08 to 1.5 mm for the shallow and deep SENB specimens [5]. It is difficult to judge the accuracy of the obtained $r_c=1.54$ mm value since no fractograph data is reported and only two geometries at this temperature are tested in [2]. In applying the procedure (a), a statistically meaningful r_c could be obtained if more experimental data are used in determining the material failure curve.
5. Note that the J - A_2 fracture criterion is based on the RKR model, that is, the opening stress $\sigma_{\theta\theta}$ ahead of the crack tip controls the cleavage fracture. Therefore, the opening stress, not the applied J , should be used as the crack driving force. For three dimensional (3D) cracked geometry, both J and the opening stress are not uniform along the crack front and the location of maximum J may not coincide with the location of the maximum opening stress (see, e.g. refs. 9 and 30). Under such conditions, the opening stress ahead of the crack tip at the location where $\sigma_{\theta\theta}|_{\theta=0}$ is maximum should be used to interpret the fracture. One possible scenario is shown in fig.8. In fig.8, we assume that point A has maximum J and point B has maximum opening stress along a 3D crack front under an applied load. As the load is increased, the crack driving forces associated with points A and B are depicted in fig.8. In this case, initial fracture will occur at point B instead of A. The fundamental reason for this behavior is that the J - A_2 method uses a critical opening stress as the fracture criterion in contrast to using J as the fracture criterion. The opening stress distribution for the 3D cruciform specimen used in this paper, fig.6, is from the center point of the cruciform specimen where J is maximum [5]. The distribution of the opening stress along the crack front is not reported in [5] and hence the effect due to this cannot be evaluated.
6. In addition to the cruciform specimen tested at ORNL under biaxial load, Battelle Memorial Institute (BMI) also performed biaxial tests on a different specimen geometry made of the same material. The BMI specimen is a double-edge-notch specimen under tension (DEN(T)) with $a/w=0.54$ while the ORNL specimen is primarily SENB (single-edge notch bend) with $a/w=0.11$. The test data by BMI shows only a slight decrease in J_c comparing uniaxial to biaxial results (124.34 to 120.14 kN/m). A quantitative prediction is not possible since no opening stress distribution is available for the BMI test specimen. However, it is attempted here to qualitatively interpret the test results using the J - A_2 model which includes the constraint effect. The BMI's DEN(T) specimen is a lower constraint geometry relative to the ORNL's SENB specimen for the same a/w

ratio and in-plane size [9]. But the BMI specimen is a deep crack ($a/w=0.54$) compared to the ORNL specimen ($a/w=0.11$). It is anticipated that the BMI specimen has a higher constraint than the ORNL specimen considering the combined effect of a/w , geometry and size. Figure 9 shows the predicted J_c values for the two specimens. Since the failure curve is relatively flat on the high constraint side, it is anticipated that the BMI test results should yield only a small deduction in the fracture toughness value comparing uniaxial to biaxial data.

In conclusion, the results shown in this paper indicate that the J-A₂ fracture methodology is a viable analytical model in predicting fracture of RPV steels. Further studies and validations are needed in the interpretation of three-dimensional cracked geometries and extension of the methodology to mixed fracture of cleavage and ductile modes.
