Progress Report No. 3, March 1997

Accomplishments

- Over 50% VOC is removed when OSB or particle is steamed at 170°C for 30 minutes. Much lower removal occurs at temperatures approximating 120°C.
- RF treatment of (2 in. x 4 in. x 48 in.) softwood lumber for 20 minutes results in a maximum of 68% VOC removal. The process has commercial potential.
- Transport of moisture in wood is greatest in the transverse surface, followed by the tangential and radial faces.
- Work on the seasonal influence of VOC components in wood has been initiated.

Apparatus for VOC extraction in a low head space environment

VOC extraction from particle and OSB with steam was conducted with the apparatus illustrated in Figure 1, constructed especially for this application. The unit is a 60 cm long by 10 cm diameter stainless steel pressure vessel. Different steam temperatures and treatment times were tested for both OSB and particle. Each experiment was conducted by loading 200 g. of flakes or 400 g. of particle into the vessel, which was then sealed. Thermocouples were positioned, and heating tapes activated in order to heat the exterior of the vessel to minimize steam condensation. Ambient pressure steam was injected into the vessel for 3 minutes, and the vessel was sealed by closing the needle valve. The temperature was brought up to the desired set point which was controlled by adjusting the current to the heating tapes. After steam treatment, the vapor inside the vessel was released into 100 mL of methanol for VOC analysis by gc, and the vessel flushed with fresh steam for 30 seconds.

Steam-induced extraction of VOC from OSB

The OSB steamed in the Figure 1 apparatus was heated in the tube furnace at 130°C and the VOCs measured. Two to four runs were made from each batch of steamed flakes. Results from flakes steamed at high temperature (>170°C) are presented in Table 1. The difference between the control (no steam) and sample runs reflects the VOC removed by steam. Over 50% VOC was removed after 30 minutes of steaming. Data are presented for both 30 and 60 minute treatments. The wood is dry at 30 minutes or less, and the 60-minute reflects an over-dried situation. The last column is the pinene recovered in the

Figure 1: Schematic of a VOC extraction unit.

methanol trap (as measured by gc) as a percentage of total VOC (pinene and other components) lost from the wood. Despite the high variability, it is clear that a substantial fraction of the VOCs released can be recovered. One anomaly was noted: no VOC was lost from samples 151-5 through 151-8 in Table 1, and we are unable to explain this outcome. About 10-25% by weight of moisture was gained by the wood, but this is probably an artifact in that the moisture was deposited on the wood surface, as opposed to being absorbed by the furnish. The pressure within the cylinder was determined from steam tables using the temperature measured within the cylinder. Steaming at low temperature (116°C) removes much less VOC, if any, as shown in Table 2. Clearly, the steam must be at high temperature in order to effect VOC removal. We are presently working on a simple VOC collection system, after which we will explore commercial feasibility.

VOC profiles from steamed and control furnishes are compared in Figures 2 and 3. Signal intensities are much weaker for the latter, since VOC was removed during steaming. The delay in the second signal could well be an artifact, since the furnish picked up water during steaming, and the delay may reflect evaporation of this material.

Steam-induced extraction of VOC from particle

Particle was first steamed, and then dried in the tube furnace at 130°C for 60 minutes, as above. Over 50% of the VOC was removed during steaming at high temperature as shown in Table 3. Decreasing steam treatment from 30 to 15 minutes decreased VOC removal by about 10%. On the other hand, increasing steaming time from 30 to 60 minutes did not increase the VOCs extracted to any substantial extent, but the furnish turned noticeably darker. As with OSB, much less VOC was lost during steaming at lower temperature as shown in Table 4. Typical VOC profiles are illustrated in Figures 4-6. Note that the intensity of the signals drops with increasing steaming temperature.

Figure 4: VOCs from run 153-3(control)

Figure 5: VOCs from run 153-5 (steamed at 179°C)

Figure 6: VOCs from run 160-3 (steamed at 119°C)

The effect of re-steaming once-steamed wood was determined by first steaming at 179°C for 30 minutes, allowing the sample to cool, and then steaming it again for another 30 minutes at 173°C. This wood was now dried in the tube furnace, and the VOCs measured are listed in Table 5. Although considerable additional VOC was lost, the wood particles darkened after the second steam treatment.

VOC steam extraction of wood particles at atmospheric pressure

The previous experiments were conducted under pressure since the steam was introduced under atmospheric pressure, and the sealed unit was then heated. In order to separate the effects of temperature and pressure, a needle valve was attached to the vessel as shown in Figure 7. Particle was then steamed at about 167°C for 10 minutes under sealed conditions (with the valve closed), and then for 20 minutes with the needle valve slightly open. Vapor released during steaming was led to a methanol trap. The steamed wood was then heated in the tube furnace and the VOCs measured. The trap methanol was analyzed for pinene. The results of these experiments are designated in Table 6 as the series 177 measurements.

¹ sealed for the first 10 minutes					

Substantial VOC removal occurred during steaming. A possible mechanism for the low VOC recovery is condensation in the uninsulated, unheated viton tube stretching from the needle valve to the methanol trap. Runs were also made where the needle valve was opened partially immediately after steam-charging was complete, i.e. the material was steamed continuously at atmospheric pressure. The results, designated as the 178 series in Table 6 show VOC removal of about 60%. These results demonstrate that high temperature, and not high pressure, is key to VOC extraction.

RF treatment of lumber

In our previous report we showed that brief RF treatment of lumber in a low-headspace environment removed a large proportion of the VOC and very little water. However, Mississippi State University's kiln is too small to accommodate commercial 2 in x 4 in x 48 in sizes, and samples are split in half prior to drying. The question then arises as to whether VOC extraction with RF would also work with these larger samples. To simulate larger samples, freshly cut commercial 2 in x 4 in x 23 in pieces of lumber were dipped in melted paraffin to seal the end grain, and each piece was then wrapped in polyethylene film for RF treatment. One cut section was set aside as a control, and the other irradiated in a Strayfield unit at Georgia Power's Technology Application Center, at a power level of 0.8 amps for 6, 10, and 20 minutes. The irradiated samples were then dried at Mississippi State, and the emissions are provided in Table 7. The control (un-irradiated) samples were dried as a group, since no major differences were expected among them. The Table 7 results confirm our previous findings in that RF removes VOCs even from these partially sealed samples. Hence, low-headspace RF should be able to extract VOCs from commercial sizes of lumber. We are presently working on a simple collection system, and we expect the method to have commercial potential. We anticipate filing for a patent.

Diffusion of water in wood

The relative drying rates of the transverse, tangential, and radial faces of wood were determined since work in our parallel EPRI project indicates that VOC release is related to the loss of water in wood. The tangential plane faces the outer portion of the wood (Figure 8). The radial face creates a plane reaching from the outer portion of the tree towards the inner core. The transverse, or cross section, is the face exhibiting growth rings. The sample cubes for the water diffusion in wood experiments were cut so all three faces were present in equal dimensions of 20 mm per side with faces appearing on the opposite sides of the cube. Five cubes and two moisture sections were taken from each of 3 boards, yielding a total of 15 sample cubes. An epoxy coating material was then applied to the cubes in the five groups to limit the transport of water through the epoxied face as shown in Table 8.

Table 8: Drying rates as a function of surface orientation					
treatment no.	transverse	radial	tangential	MC change, % / min (r^2)	proportional drying ratio
1	coated	coated	coated	0.588 (0.95)	0.31
2	open	coated	coated	1.459 (0.88)	0.78
3	coated	open	coated	0.715 (0.90)	0.38
4	coated	coated	open	0.929 (0.88)	0.49
5	open	open	open	1.881 (0.86)	1.00

Figure: 8: Cross-section of tree naming the three planes; (1) tangential, (2) radial, and (3) transverse (cross section)

Treatment 1 was the control for the coating which indicated the resistance to water loss provided by the coating. The coating was applied to two faces of each cube for treatments 2-4; hence, water could only be lost through the open face. Finally, treatment 5 was left open. The coated cubes were reweighed and recorded as the adjusted green weight. The cubes were placed in a 120°C oven and weighed every 20 minutes until each cube reached its calculated weight at the fiber saturation point, or approximately 30% moisture content. Moisture contents were calculated for each interval, and linear regressions performed to determine drying rates for each treatment group. The results indicate that epoxy reduces the flow by a factor of 3.24; therefore the surfaces coated with epoxy emit vapor at 31% of normal flow.

Clearly, the high-temperature drying rates are different for the three primary wood

faces, with the transverse surface experiencing the greatest change in moisture content. At the start of a kiln cycle, there is a large drop in wood MC as the water near the ends moves out via capillary action. This phenomenon was demonstrated with the epoxy and cubes; the cubes with the transverse surface exposed dried quickly. At the start of a kiln cycle there is also a peak in the amount of VOC emissions observed from the wood.

Seasonal variation of monoterpenes and resin acids in Southern Yellow Pine

Samples were collected from twelve marked southern yellow pines (SYP) located in Moorehead Bottom on the MSU forest during February 1997. The circumference of the trees ranged between 44 and 57 inches, and increment cores were collected at a height of approximately 42 inches. A 12 inch increment borer with a core diameter of 0.200 inches was used for sample collection. The cores were divided into three four inch sections, with the first four inches being the inside sample, the second four inches being the middle sample and the last four inches being the outside sample.

Samples were prepared by adding 5 ml of methylene chloride to weighed cores and sonicating overnight. Diphenyl methane (internal standard) was added to each sample, which was analyzed for monoterpenes, 4-allylanisole, and resin acids on a Varian 3600 gas chromatograph equipped with a J&W DB-5 30 meter capillary column and a flame ionization detector. Table 9 contains preliminary results on a dry basis. Monthly sample collection will continue. The extraction procedure will be modified to prevent monoterpene loss during extraction.
