### ABSTRACT

The epitaxial growth of  $\text{CeO}_2$  on various (001) metal surfaces using pulsed-laser deposition is discussed. In particular, the growth of (001)  $\text{CeO}_2$  on (001) Pd, Ag, and Ni is described. Emphasis is given to the specific deposition conditions which successfully alleviate the formation of native oxides at the metal/metal oxide interface. The control of the epitaxial relationships between the oriented oxides films and the underlying noble and oxidizing metal surfaces is addressed. In addition, recent use of these heterostructures in the epitaxial growth of high temperature superconducting films on biaxially-textured metal substrates for superconducting wire development is described.

### INTRODUCTION

The growth of epitaxial metal oxide/metal thin-film heterostructures is important for many applications involving superconducting and ferroelectric oxide materials. For example, recent efforts to utilize thermo-mechanically processed metal tapes as substrates for long-length cuprate superconductors has defined a viable route for producing high-current superconducting wires for operation at 77 K.[1] In addition, many ferroelectric device structures have a metal / oxide interface at the electrode/ferroelectric boundary. The metal / oxide interfaces created in these structures often present special challenges involving chemical reactivity, lattice mismatch, and thermal expansion mismatch. In addition, the formation of native oxides on the metal surface prior to or during deposition represents a significant obstacle to achieving epitaxial growth. The utilization of these structures will require the development of deposition techniques that can circumvent these difficulties, as well as an understanding of these interfaces, both during epitaxy and after formation.

In this paper, we describe the epitaxial growth and properties of ceria on (001) Ag, Pd, and Ni surfaces using pulsed-laser deposition. These materials are often utilized as buffer layers in high-temperature superconducting film applications, and possess structural and chemical properties that are similar to many ferroelectric oxides. The epitaxial relationships between the oriented  $\text{CeO}_2$  oxides films and the underlying noble and oxidizing metal surfaces is addressed.

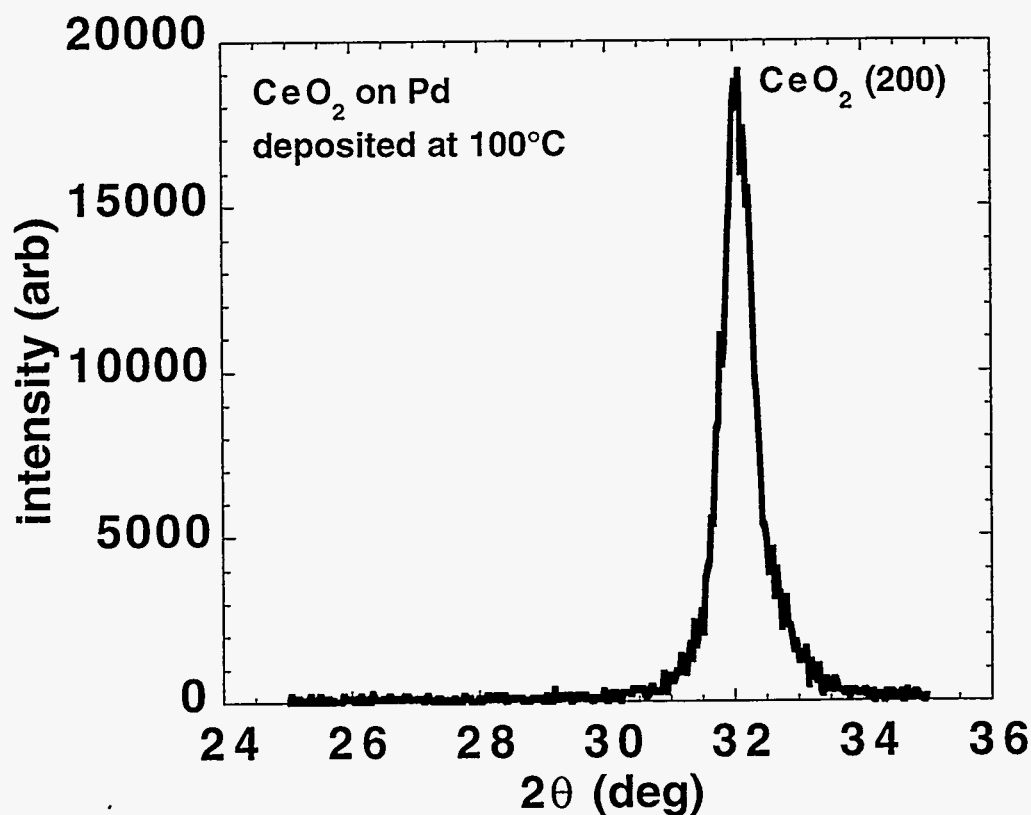

Fig. 1. X-ray diffraction pattern for a CeO<sub>2</sub> film deposited on (001) Pd at 100°C.

## EXPERIMENT

The CeO<sub>2</sub> films were deposited in a multi-target pulsed-laser deposition system. The base pressure of the vacuum system was  $\sim 4 \times 10^{-6}$  Torr. Stoichiometric polycrystalline oxide disks were used as the ablation targets. A KrF (248 nm) excimer laser was used as the ablation source with a laser energy density of  $\sim 4$  J/cm<sup>2</sup>. The laser repetition rate was 3.3 Hz, with a deposition thickness per laser shot of  $\sim 0.5$  Å. Typically, the final CeO<sub>2</sub> film thickness was  $\sim 500$  nm, although some multilayer structures consisted of much thinner individual layer thicknesses. The substrates used in this study were biaxially-textured (001) Ni tapes, formed by cold-rolling and annealing pure Ni.[1] The resulting in-plane and out-of-plane crystallographic alignment was FWHM  $\sim 8^\circ$  as determined by four-circle x-ray diffraction. The surfaces of the as-rolled and annealed Ni substrates were quite smooth due to the use of highly polished rollers, and required no additional polishing. For the epitaxial growth of oxides on (001) noble metal surfaces, an epitaxial layers of either Pd and Ag was sputter- or electron-beam deposited onto the (001) Ni surface.

## EPITAXIAL CeO<sub>2</sub> ON NOBLE METALS

The epitaxial growth of oxides on noble metals is the simplest case to consider, as there are no stable native oxides on the surface to interfere with epitaxy. For the growth of CeO<sub>2</sub> on Pd and Ag using PLD, the range of deposition conditions in which (001) oxide epitaxy is realized differs for the two substrate materials. For the case of (001) Pd, epitaxial growth of (001) CeO<sub>2</sub> is observed at substrate temperatures ranging from room temperature up to 300°C, with the best results obtained at 100°C. Figure 1 shows the x-ray diffraction 2θ-scan of a CeO<sub>2</sub> film grown on a (001) Pd surface at a substrate temperature of 100°C. The film was in-plane aligned with the CeO<sub>2</sub> [100] axes rotated 45° with respect to the Pd [100]. For consistent (001)-oriented CeO<sub>2</sub> film growth at low temperature, the initial 100 Å was deposited in vacuum ( $P_{\text{background}} < 5 \times 10^{-6}$  Torr), with the remaining majority of the film deposited in an oxygen pressure of  $\sim 4 \times 10^{-4}$  Torr. In situ at 500°C yielded similar results without the initial vacuum deposition.

We have also investigated the growth of (001) CeO<sub>2</sub> on (100) Ag. Unlike the case with Pd, the growth of (001) CeO<sub>2</sub> on (001) Ag required a deposition temperature of at least 600 °C in order to achieve good epitaxy. X-ray diffraction scans for CeO<sub>2</sub> films grown at 600–750°C, show only the (001) orientation. Although not shown, scanning electron microscopy images of CeO<sub>2</sub> films grown on Ag at elevated temperature show only partial surface coverage, presumably an effect stemming from the high vapor pressure of the substrate. As with Pd, the CeO<sub>2</sub> film on Ag was in-plane aligned with the CeO<sub>2</sub> (100) axes rotated 45° with respect to the Ag (001). Previous work reported similar results for the epitaxial growth of YBa<sub>2</sub>Cu<sub>3</sub>O<sub>7</sub> directly on single crystal Ag.[2]

## EPITAXIAL OXIDE ON (001) Ni

The epitaxial growth of an oxide on the surface of an oxidizing metal is significantly complicated by the crystal structure and orientation of the native oxide. For example, the oxidation of a (001) Ni surface typically results in the formation of (111)-oriented NiO.[3] Subsequent growth of another oxide results in a similar (111) orientation. Obviously, it is imperative that the native oxide be removed prior to epitaxial growth. For some metals, such as Ni, an effective approach for the removal of the native oxide achieving this is to heat the metal in the presence of hydrogen gas. This results in the reduction of the NiO, and enables the formation of a (001)-oriented epitaxial oxide on the (001) Ni surface. Fig. 2 shows x-ray diffraction 0–20 scans for CeO<sub>2</sub> films grown on (001) Ni substrates in which a 4% H<sub>2</sub>/ Ar mixture was introduced as a background gas during the pulsed-laser deposition. The Ni substrates were annealed at 900°C in a 4% H<sub>2</sub>/Ar gas mixture prior to film growth to reduce any NiO initially on the substrate surface. Deposition was carried out at a substrate temperature of 750°C. Consistent (001)-oriented epitaxial growth of CeO<sub>2</sub> was achieved only if the oxide growth was initiated in the presence of the H<sub>2</sub> / Ar mixture. This clearly shows that the nucleation of

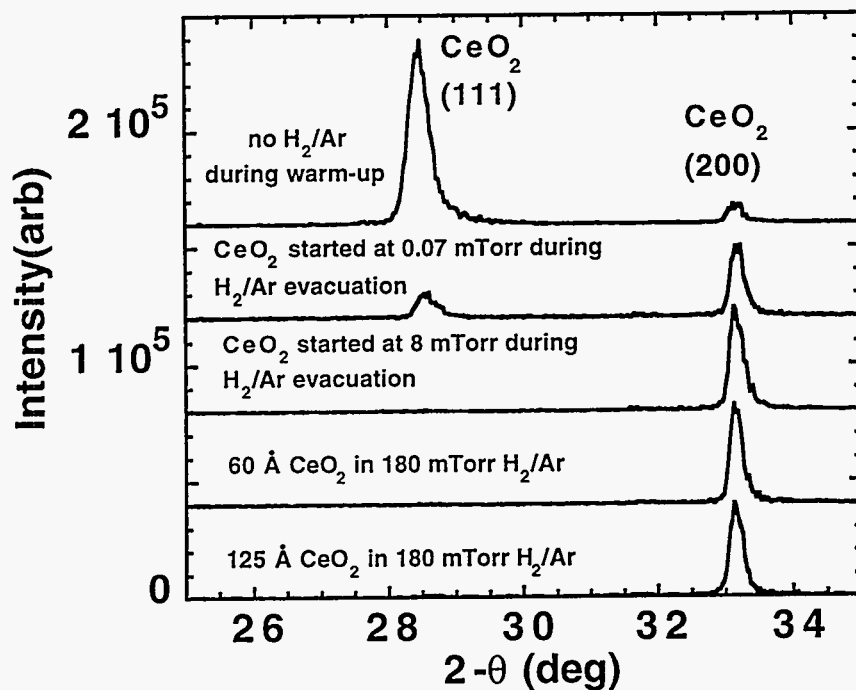

Fig. 2. X-ray diffraction patterns for CeO<sub>2</sub> films grown on (001) Ni with and without a 4% H<sub>2</sub> / Ar background gas during the initial nucleation of the film. Growth temperature was 750°C.

Fig. 3. X-ray diffraction patterns for CeO<sub>2</sub> / YSZ bilayers grown on (001) Ni. The initial CeO<sub>2</sub> layer was nucleated in the presence of the 4% H<sub>2</sub>/Ar mixture.

Fig. 6 Electron back-scattered pattern of a  $\text{CeO}_2$  / YSZ bilayer grown on (001) Ni. The continuous shading indicates a point-to-point crystallographic change of less than  $1^\circ$ . The four distinct shaded regions represent nickel grains in the substrate. The dimensions of the image is  $80 \times 80 \mu\text{m}^2$ .

the  $\text{CeO}_2$  layer in the presence of  $\text{H}_2$  results in the formation of (001)  $\text{CeO}_2$ , with subsequent growth in either vacuum or a background of oxygen maintains this orientation. For all of the films represented in the figure, the total  $\text{CeO}_2$  layer thickness is  $\sim 500$  nm. Note that the presence of  $\text{H}_2$  has little effect on the  $\text{CeO}_2$ , as the Ce-O bond energy is relatively high.

In some cases, the growth of (001)-oriented  $\text{CeO}_2$  can be used as a nucleation layer for subsequent growth of other oxides that are difficult to grow directly on the Ni surface. Figure 4 illustrates the case where (001)-oriented yttria-stabilized zirconia (YSZ) is grown on (001) Ni with a  $\text{CeO}_2$  nucleation layer. For these multilayer structures, the thickness of the  $\text{CeO}_2$  layer that was deposited on the (001) Ni surface in the presence of the  $\text{H}_2$  / Ar mixture is varied. Subsequent deposition of YSZ results in a (001) orientation

orientation. The film growth was carried out at a substrate temperature of 750°C, with an oxygen background pressure of  $4 \times 10^{-4}$  Torr for the YSZ growth. Note that the CeO<sub>2</sub> nucleation layer can be quite thin, with only complete surface coverage necessary for subsequent (001)-oriented YSZ growth. The degree of in-plane and out-of-plane alignment of this multilayer structure is illustrated in the electron back-scattered pattern shown in Fig. 5. The various shadings indicate regions of the YSZ layer that are aligned to within 1°. The four distinct regions of orientation represent four large Ni grains within the rolled-textured substrate. The similar shading of the YSZ film within a Ni grain shows that the YSZ is epitaxial with respect to the (001) Ni substrate due to the intermediate CeO<sub>2</sub> nucleation layer.

## CONCLUSIONS

We have investigated the epitaxial growth of CeO<sub>2</sub> on various (001)-oriented metals using pulsed-laser deposition. The epitaxial relationships between CeO<sub>2</sub> films and the underlying noble and oxidizing metal surfaces was addressed, along with the deposition conditions necessary to realize these structures. Clearly, the epitaxial growth of various oxide thin films on metals, along with the resulting heterostructures and interfaces, will continue to be an important area of research for oxide thin-film devices.
