INTRODUCTION

PROGRAM OBJECTIVES

The overall objective of this program is to develop regenerable sorbents for hydrogen sulfide removal from coal-derived fuel gases in the temperature range 343-538 °C (650-1000 °F). Two categories of reactor configurations are being considered: fixed-bed/moving-bed reactors and fluidized-bed (bubbling and circulating) reactors. In addition, a cost assessment and a market plan for large-scale fabrication of sorbents will be developed. As an optional task, a long-term bench-scale testing (100 cycles) of the best fixed-bed/moving-bed and fluidized-bed sorbents will be conducted.

The sorbents will have chemical characteristics that permit cyclic regeneration over many cycles without a drastic loss of activity. They must also have physical characteristics that are compatible with the selected reactor, e.g., fixed vs fluidized bed, and which remain acceptable during absorption and regeneration. The sorbents must be capable of reducing the hydrogen sulfide level in the fuel gas to less than 20 ppmv in the specified temperature range and pressures in the range of 1 to 20 atmospheres.

PROJECT DESCRIPTION

The proposed program is divided into several tasks:

Task 1 – NEPA Report

Task 2 – Sorbent Preparation

Task 3 – Provision of Bench Unit

Task 4 – Bench Testing

Task 5 – Sorbent Cost Assessment

Task 6 – Topical Report

Task 7 – Market Plan

Task 8 – Long-Term Testing (option)

In Task 1, the information required for preparation of a NEPA report by DOE will be provided. In Task 2, several sorbents suitable for fixed-, moving-, and fluidized-bed applications will be fabricated. Three classes of materials will be used: zinc-based materials (e.g., zinc titanates), advanced metal oxide (non-zinc) materials, and proprietary materials. Selection will be based on thermodynamic and laboratory evaluation of powder materials. GE-CRD, IGT, and Prof. M. Flytzani-Stephanopoulos (consultant, Tufts University) will be responsible for identifying and screening the chemical compositions of the sorbents. Pelletization (for moving/fixed beds) and granulation (for fluidized beds) will then be

conducted on the promising materials using suitable binders and pore formers. Standard techniques (extrusion and calcination) as well as novel techniques (solution precipitation or sol/gel formation) will be used to modify the morphology of the formed materials. GE-CRD will focus on moving/fixed-bed applications, while IGT will focus on fluidized-bed applications. Commercial sorbent and catalyst developers will pelletize or agglomerate the final formulations for bench testing according to recommendations by GE-CRD and IGT. In Task 3, the moving/fixed-bed bench reactor at GE-CRD and the fluidized-bed reactor at IGT will be refurbished for use. In Task 4, the eight most promising sorbents that passed screening under Task 2 will be tested for ten cycles of absorption and regeneration each in the GE-CRD moving/fixed-bed bench reactor and IGT fluidized-bed reactor, and the properties of the used materials will be compared against those of the fresh sorbents. In Task 5, a sorbent cost assessment will be performed to determine costs and sensitivity of costs for raw materials, fabrication, disposal, or recycle. In Task 6, a Topical Report will be prepared summarizing the results obtained in the program. In Task 7, a Market Plan will be developed jointly with the commercial sorbent manufacturers and users to develop a strategy for commercialization, teaming/licensing approaches, and benefits to IGCC technologies.

Finally as an optional task, Task 8 will test a minimum of two formulations, one for moving/fixed-bed systems and the other for fluidized-bed systems for long-term (at least 100 cycles) durability and chemical reactivity in the corresponding bench-scale reactor configurations.

Background information

U.S. coals have a very variable sulfur content: low in the eastern (Appalachian) fields and in the western sub-bituminous deposits, and high in the mid-western basin deposits. The major reserves that are most readily accessible to industry and population centers are the midwestern coals of Illinois, Western Kentucky, Indiana, and Iowa. Unfortunately, these coals have sulfur levels that are too high for direct utilization. Therefore, sulfur removal must be accomplished prior to combustion, during combustion, or by post-combustion processing of the exhaust stream. With the ever increasing limitations on SO₂ emissions, even most low sulfur coals will eventually require some treatment at sometime in their utilization. The sulfur in coal is typically about equally divided between its occurrence as the mineral component (pyrite-FeS₂) or as a sulfur-containing compound in the organic portion. Of these, the inorganic component is most readily removed via fine grinding, for liberation and separation via physical techniques. Current coal gasification technology relies on removal of some of the relatively easy inorganic fraction during coal cleaning (ash removal) and anticipates that the major removal will occur during or after gasification.

Coal gas desulfurization to sufficiently low levels at elevated temperatures is now recognized as crucial to efficient and economic coal utilization in Integrated Gasification-Combined Cycle (IGCC) systems. The implementation of hot coal gas desulfurization heavily relies on the development of regenerable sorbent materials that have high sulfur capacity and can efficiently remove H₂S (from several thousand ppmv levels down to a few ppmv) over many cycles of sulfidation/regeneration. Structural stability and good mechanical strength are also

desirable features in a sorbent. Not surprisingly, only a few metal oxides can meet these stringent requirements.

The research and development for high-temperature desulfurization of fuel gases has been sponsored primarily by the Morgantown Energy Technology Center (METC) of the United States Department of Energy (U.S. DOE). Over the last decade a number of studies have been reported on high-temperature H_2S removal, primarily using various transition metal oxides as regenerable sorbents.¹⁻⁵ The sorbent most intensively studied is iron oxide, which yields equilibrium H_2S concentrations in the few hundred ppm range for a composition representative of low Btu coal-derived gas and temperatures of above $500^\circ C$. While the sulfidation kinetics of iron oxide are very good³, this sorbent cannot be used for single-stage coal gas desulfurization to reduce the H_2S content of the fuel gas down to a few ppm of sulfur.

Zinc oxide has been used as a non-regenerable sorbent in "guard beds" protecting catalyst beds from trace sulfur impurities. More recently, zinc oxide has also been investigated as a regenerable sorbent.⁴⁻⁸ The thermodynamic equilibrium for sulfidation of ZnO is quite favorable, yielding desulfurization down to a few ppm H_2S . The sulfidation kinetics of ZnO , however, are much slower⁹ compared to those of iron oxide, and the regenerability of ZnO is restricted by the loss of surface area at high temperatures and the formation of zinc sulfate at low regeneration temperatures.

Reduction and sulfidation take place simultaneously when the sorbent is contacted with the hot fuel gas. Regeneration can be conducted with air or air-steam mixtures. When reaction and diffusion rates are sufficiently rapid, the sorbent sulfur capacity and the extent of desulfurization are determined by thermodynamics alone. With many sorbents, however, the rates of reaction, pore diffusion, or diffusion in the product layer, limit sorbent capacity and the extent of cleanup under practical conditions. Such is the case with some commercial ZnO sorbents where the reported conversions at breakthrough have been less than 20% in packed bed applications. The larger molar volume of the product solid ($ZnS = 24.4 \text{ cm}^3/\text{mol}$) compared to that of the reactant solid ($ZnO = 14.4 \text{ cm}^3/\text{mol}$) causes pore plugging, limiting access to the interior of the sorbent.

In recent years it has been shown that certain mixed oxides have superior properties compared to single oxides for hot gas cleanup.^{6-8,10-16} A compound of zinc and iron oxides, zinc ferrite, $ZnFe_2O_4$, developed by DOE/METC has reached pilot-stage (testing) for desulfurization of low-Btu gases.¹⁷⁻¹⁹ However, physical durability of the zinc ferrite sorbent in long-term testing appears to be inadequate for IGCC application.

Because of the apparent limitations of the zinc ferrite sorbent, many investigators have been conducting research to develop a superior mixed metal oxide sorbent.^{6-8,11-13,20-26}

Work on zinc titanates such as $ZnTiO_3$, Zn_2TiO_4 , and $Zn_2Ti_3O_8$ ^{6-8,24} has shown that titanium oxide is a better alternative to iron oxide additives in terms of the higher stability of the titanates over the ferrite compounds of zinc, and their similar sulfidation equilibria. With zinc titanates, the sulfidation temperature has been shown to extend to $700^\circ C$ and sintering of the ZnO was greatly reduced. Although zinc titanate has also shown better attrition resistance than zinc ferrite in pilot tests, this sorbent also suffers gradual loss of reactivity in

long-term cyclic operation, resulting in high fresh sorbent makeup rate to maintain the desired level of desulfurization^{27,28}. Other mixed metal oxides such as copper-based and cobalt-based sorbents have also been investigated²⁹⁻³²; however, the research has been limited to laboratory-scale equipment.

Although higher temperature application offers better overall process efficiency, the stringent requirement for sulfur removal efficiency at temperatures above 538°C (1000°F) limits the choice of the sorbents to a few metal oxides (based on thermodynamic equilibrium), that have been shown to have other limitations as described earlier. The thermodynamic equilibria of many metal oxides significantly improve as the temperature decreases, making many metal oxide sorbents suitable for hot gas cleanup application in the temperature range of 343°-538°C (650° to 1000°F). Although the initial chemical reactivities of the sorbents generally decrease with decreasing temperature, the lower thermal stress incurred can lead to better sorbent reactivity after a large number of cycles, reducing the sorbent replacement cost. In general, the benefit to be gained by lower temperature application may outweigh the slight loss of efficiency due to lower temperature application, resulting in lower overall cost of electricity. However, no extensive study has been done on the development of advanced sorbents for the lower temperature application.

Moving-Bed Applications

Moving-bed systems are under development at GE³³. Although the sorbent materials move slowly between the absorber and regenerator vessels, the level of deterioration at process conditions requires the material to be mechanically durable. Sorbent formulations prepared for moving-bed systems must have mechanical durability and exhibit satisfactory desulfurization kinetics at 538 °C (1000 °F)³⁴; however, larger-scale demonstration systems such as the Tampa Electric Co.'s Polk Station will operate at lower temperatures, close to 482 °C (800-900 °F). Hence, development of sorbents with reactivity in this middle temperature range of 343 to 538 °C (650-1000 °F) is important for moving-bed systems.

Fluidized-Bed Applications

Although the fixed-bed approach using metal oxides has been shown to reduce the H₂S content of the cleaned gas to very low levels, the operation is not continuous, it suffers from operational problems, and requires large-scale high temperature valves. To overcome these problems, US DOE has sponsored fluidized-bed as well as moving-and fixed-bed hot gas desulfurization research in recent years. The fluidized-bed approach offers advantages over the moving- and fixed-bed reactors because of its ability to control the reactor temperature during the highly exothermic regeneration step.

The key characteristic of concern in the fluidized-bed application is maintenance of the physical integrity of the sorbent during the chemical transformations associated with absorption-regeneration. Testing appears to verify that excessive attrition results primarily from the changes in composition during transformation and not from mechanical forces^{27,28}. The extreme temperature and severe chemical conditions of air/steam regeneration are deleterious to many inorganic support materials and sorbent compounds. A sorbent suitable for fluidized-bed application must, therefore, have both good thermodynamic equilibrium and

initial chemical reactivity in the range of 343 °C -538 °C, as well as acceptable long-term physical and chemical durability with a reasonable cost of production.

PROGRAM DESCRIPTION BY TASK

Task 1 — NEPA Report

The NEPA reports from GE-CRD and IGT were submitted to DOE as per contract requirements.

Task 2 — Sorbent Preparation and Characterization

A review of previous work available in the literature on high-temperature sorbents was performed, and results were evaluated in view of the program objectives considering that most of these previous studies concentrated in the range 1000-1300 °F sulfidation, rather than 650-1000 °F. Consequently, some materials that were not as reactive in the upper temperature range may show reactivity enough to be competitive in the lower temperature range.

Thermodynamic Calculations

The thermodynamic H_2S equilibrium concentrations in simulated fuel gases (U-GAS and Texaco) for a number of potential metal oxides were calculated at elevated temperatures (i.e., 350°-550°C) and pressure (20 bar). The metal oxides considered for this analysis included copper, zinc, iron, nickel, tin, cobalt, molybdenum, manganese, and tungsten. The number of moles of the fuel gas and the solid oxides were selected to correspond to 50% sorbent conversion during sulfidation. Based on the available data, certain restrictions were imposed on formation of a number of species so as to better simulate the actual environment.

The results of these analyses are presented in Figure 1 and Figure 2 for the U-GAS and Texaco fuel gases respectively, indicating that the calculated H_2S equilibrium is not significantly affected by the fuel gas composition. Furthermore, because of the lower temperature range (e.g., 350°-550°C), a large number of metal oxides are capable of reducing the H_2S level of the fuel gases to below 20 ppmv for IGCC application. It should be noted that the H_2S equilibrium for copper oxide is the lowest (e.g., below 0.1ppmv) if reduction to metallic copper is prevented while in the reduced form, metallic copper is still an acceptable candidate below 400°C.

Figure 1. H_2S equilibrium concentration in fuel gas (U-GAS) with various oxides

Figure 2. H_2S equilibrium concentration in fuel gas (Texaco) with various oxides

Phase stability diagrams for reducing gas atmospheres (i.e., coal gases) and oxidizing gas atmospheres (i.e., regeneration gases) have been constructed using algorithms that predict the stability of chemical species based on minimization of the Gibbs free energy of the system. The phase stability of metals under regeneration gases containing SO_2 and O_2 is important because spalling and pellet deterioration occurs more often as a result of metal sulfate formation. Figure 3 shows the stability of copper and molybdenum as a function of the log partial pressure of O_2 and SO_2 . For gas compositions containing approximately 0.02 atm of O_2 and 0.5 to 0.1 atm SO_2 , (typical of atmospheric regeneration gases in the moving-bed system) the thermodynamically stable phase of copper is copper sulfate, while the thermodynamically stable form of molybdenum is the oxide. For most pure oxides, including zinc oxide, the metal sulfate is the stable form under oxidizing gas conditions at temperatures around 500-700 °C, depending on SO_2 and O_2 concentration. Of course, thermodynamic predictions do not take into account the rate of approach to equilibrium (i.e., kinetic rates) and hence experimental data is still needed to confirm the extent of formation of the predicted species. Nevertheless, thermodynamics allows the investigator to determine if formation of certain compounds is favored. Other phase stability diagrams are presented in Appendix A.

Preparation and Characterization of Sorbents for Fluidized Beds at IGT

Sorbent Screening

A large number of sorbent formulations were prepared and tested in a fixed-bed reactor to identify the most promising sorbent formulations for high pressure fluidized-bed application in the range of 343°-538°C. Desirable characteristics of hot gas cleanup sorbents include:

- Favorable sulfidation equilibrium
- High sorbent capacity
- Good reactivity toward H₂S
- Ease of regenerability
- Good attrition resistance
- Acceptable and stable reactivity in the cyclic process.

The initial principal criteria used for sorbent formulation was based on thermodynamic equilibrium which limits the choice of the active sorbent metals to those that can meet the stringent requirement of removing H₂S to below 20 ppmv. Although high sorbent capacity and high initial reactivity are desired, these factors are not deemed crucial in developing a sorbent that will have acceptable long-term physical and chemical durability. These factors generally translate into lower sorbent circulation rates and smaller reactor size. However, this affects the "fixed-cost" of hot gas cleanup; and does not significantly affect the overall cost of hot gas cleanup as long as certain minimum requirements (listed above) are met. The overall mechanical strength and stable reactivity of the sorbent generally affect the "variable cost" of hot gas cleanup, and are the most significant factors contributing to the overall cost of hot gas cleanup.

In a fluidized-bed hot gas cleanup process, given the cost of metal oxides, the sorbents are expected to last over a very large number (i.e., >1000) cycles. However, the reactivity of the sorbent slowly decreases in the cyclic process because of gradual physical and

chemical deterioration. For a given reactor configuration, a minimum level of sorbent reactivity should be maintained for successful desulfurization of the fuel gas. Also, because of attrition in the fluidized bed, a certain fraction of the sorbent is generally lost or removed from the system (because of small particle size and lack of retention in the fluidized bed.) This requires that a fraction of the sorbent bed be replaced with fresh, high reactivity sorbent. Ideally, the rate of fresh makeup for maintaining sorbent reactivity should match the rate of sorbent loss due to attrition and elutriation. Therefore, these factors are the most important that should be considered during formulation of the sorbent, as long as a certain level of overall initial effective capacity can be attained.

The overall effective capacity is equal to the theoretical sorbent capacity times the sorbent conversion at breakthrough. Therefore, a sorbent with a lower theoretical capacity for sulfur but much higher reactivity may have equivalent overall effective capacity to a sorbent with higher theoretical capacity but lower reactivity. However, if the higher reactivity of a sorbent with a lower theoretical capacity can be maintained or stabilized over a very large number of cycles, then the fresh sorbent makeup rate can be reduced and therefore the overall cost of hot gas cleanup is reduced. The technique of stabilizing catalysts by the use of low metal loadings (by dispersing metal oxides with dispersants/supports, for instance) is utilized in high temperature catalyst formulations where reactivity maintenance is critical. This technique can also be applied to high temperature reactive sorbents.

Primary efforts concentrated on preparing sorbents with higher levels of reactive metal oxide dispersion that have higher and stable reactivity as well as higher mechanical strength and durability. This was accomplished by the use of refractory supports/dispersants which are themselves highly resistant to sintering and deterioration. These low theoretical capacity/highly dispersed metal oxide sorbent formulations are considered to have a higher probability for maintaining stability at elevated temperatures over a large number of sulfidation-regeneration cycles. If promising dispersed metal oxide sorbents are developed, then the next step can include increasing the metal loading (concentration) of these sorbents to obtain higher theoretical sulfur capacity. Secondary efforts included preparing sorbents with higher theoretical sulfur capacities and higher mechanical strength for fixed-bed testing at the lower temperatures of interest in this program.

Sorbent Preparation

A systematic approach was used to prepare and screen the sorbents for fixed-bed testing. Formulation parameters considered in preparing the sorbents included sorbent composition, preparation technique and induration conditions.

Sorbent compositions were first selected from the three functional groups shown in Table 1. Commercially available sorbents of similar relative compositions were also included. The dispersants/supports shown here are expected to provide adequate structural strength and sintering resistance to reduce attrition and retain the reactivity of the sorbent.

Table 1. Relative compositions of metal oxide formulations

Main Component	Secondary Component	Structural Component
Cu, Fe, Zn, Mn	Cu, Fe, Mn, Cr, Ce, Co, Mo	TiO ₂ , ZrO ₂ , Binders

After preparing the sorbents their mechanical strengths were compared with that of United Catalyst zinc titanate sorbent (UCI-4), considered here to be the baseline sorbent for mechanical strength. This sorbent has been shown in previous studies to have adequate attrition resistance for fluidized-bed use. If the mechanical strengths of the prepared sorbents were not at least comparable to that of the UCI zinc titanate, the sorbent formulation was modified and the above step was repeated. Formulation modification included first changing the induration conditions, followed, if necessary, by changing the preparation technique and lastly the sorbent composition.

Over 70 sorbent formulations representing various compositions, preparation techniques and induration conditions have been prepared. Of these, 17 had mechanical strength equal to or better than that of the UCI zinc titanate sorbent. These were tested in a fixed-bed for H₂S removal efficiency and reactivity towards H₂S.

Preliminary Sulfidation-Regeneration Testing

Preliminary sorbent testing included determination of the sulfidation reactivity and effective capacity of the sorbents prepared above to identify potential candidate sorbents for high pressure fluidized-bed application. Sorbent sulfidation-regeneration testing was carried out in a quartz fixed-bed reactor system at approximately one atmosphere pressure and temperatures of 350°-550°C using a simulated coal derived-fuel gas mixture (Table 2) at a space velocity of 2000 hr⁻¹. The average particle size of the sorbents tested is approximately 550 micron. Sulfided sorbents were regenerated using nitrogen-air mixtures at temperatures of 650°-750 °C. The extent of desulfurization was determined by analyzing the reactor exit gas for H₂S and SO₂ with a dedicated gas chromatograph.

Table 2. Sulfidation feed gas mixture composition

Component	Composition, mol%
H ₂ S	0.5-2
H ₂	10
CO	20
CO ₂	10
H ₂ O	10
N ₂	48-49.5

Table 3 summarizes the results of the fixed-bed testing of the 17 sorbents. Initial testing included two bulk copper-chromite sorbents (CuCr-1 and CuCr-2) and the UCI-4 sorbent which were tested at IGT and were shown (in earlier programs supported by the Illinois Clean Coal Institute and Enviropower, Inc.) to be highly efficient desulfurization sorbents

at higher temperatures (550°-850°C). The CuCr-1 and CuCr-2 sorbents were previously prepared at IGT using a general method for synthesizing highly porous bulk mixed oxides. CuCr-1, a chromium-rich and CuCr-2, a copper-rich copper chromite, contain about 10 % and 25 % copper, respectively.

The results of the sulfidation testing of the CuCr-2 and UCI-4 sorbents, with higher theoretical sulfur capacities, and CuCr-1 sorbent, with a lower theoretical capacity, demonstrate that higher metal oxide dispersion can have a highly beneficial effect on the reactivity of the sorbent

The H₂S breakthrough curves for the CuCr-1 and CuCr-2 sorbents are shown in Figure 4 and Figure 5. Sorbent conversion is based on the assumption that the active sulfide phase produced during sulfidation is the one that is the most thermodynamically stable (i.e., Cu₂S or ZnS). Conversions greater than a value of one indicate the presence of other sulfided species. The desulfurization data for CuCr-1 and CuCr-2 at 750 °C, obtained in a previous program, were included in these figures to extend the temperature range for comparison purposes. The prebreakthrough H₂S exit gas concentrations range from less than 1 to about 5 ppmv and are significantly lower than those predicted for the elemental Cu-H₂S equilibrium. These lower levels generally correspond to the copper oxide-H₂S equilibrium, suggesting that the copper in the compound oxide was not completely reduced to elemental copper by the fuel gas during sulfidation reaction. It is believed that this is probably due to either chemical and/or physical mechanisms, whereby compound formation, such as surface spinels or surface adsorption, may retard the complete reduction to metallic copper.

The rate of sulfidation of sorbents in the form of compounds, such as the copper chromite spinels used here, is generally expected to be lower compared to the rate of sulfidation of pure metal oxides. However, the sharp rise in the H₂S breakthrough curves and the high sorbent conversions observed in these tests indicate that overall reaction rate involving copper chromite compound is sufficiently high at temperatures above 450°C.

The H₂S prebreakthrough levels for the higher theoretical sulfur capacity UCI-4 sorbent (Figure 6), ranging from about 10-20 ppmv, are considerably higher than those obtained with the copper chromite sorbents. The gradually increasing H₂S prebreakthrough levels and very low sorbent conversions indicate a much lower reactivity compared to the lower capacity sorbents.

The maximum effective conversion as a function of temperature for the CuCr-1, CuCr-2 and UCI-4 sorbents is summarized in Figure 7. This parameter was determined at a target H₂S exit gas concentration of 20 ppmv. The effective maximum conversion of the CuCr-2 sorbent is lower than that of the CuCr-1 sorbent throughout the entire temperature range studied, clearly indicating the beneficial effects of dispersion on enhancing reactivity. The effective conversion of the zinc titanate sorbent is lower than that of the copper chromite sorbents and decreases with decreasing temperature at about the same rate as that of the CuCr-2 sorbent.

Another indication of the higher reactivity of the highly dispersed copper chromite sorbent is shown in Figure 8, which shows the effect of temperature on the maximum space velocity. At 500 °C, the CuCr-1 sorbent is capable of reducing the H₂S content of the fuel gas to below 20 ppmv at space velocities as high as 15,000 hr⁻¹, which is significantly higher than the maximum space velocity for the CuCr-2 and UCI-4 sorbents.

Figure 9, which shows the effect of temperature on the maximum effective sulfur capacity, indicates that, although the chromium-rich copper chromite sorbent has a much lower theoretical sulfur capacity than that of the CuCr-2 or UCI zinc titanate sorbents, it has comparable effective sulfur capacities at temperatures around 450 °C. Neither of the copper chromite sorbents appeared to have sufficient mechanical durability for fluidized-bed application so no further testing of these sorbents was undertaken.

Sufficient reactivity and mechanical strength was indicated for 10 of the sorbents tested in the first round to warrant further sulfidation-regeneration testing. The sorbents selected and results of the second cycle testing for these 10 sorbents are summarized in Table 4. Higher levels of conversion at H₂S breakthrough approaching and in some cases surpassing 100% utilization of the sorbent were obtained for the more highly dispersed (lower theoretical sulfur capacity) sorbents at temperatures as low as 350 °C. Again, conversion in excess of 100% is attributed to formation of different forms of sulfides.

Table 3. Summary of sorbent performance in first cycle

			Sorbent Fractional Conversion at H ₂ S Breakthrough of	
Sorbent	Temp., °C	No. of Cycles	20 ppmv	100 ppmv
CuCr-1	350	1	0.04	0.07

IGTSS-55	538	3	0.26	0.26
IGTSS-57	450	2	0.12	0.75

The sorbents that show lower conversion at breakthrough in Table 4 also have higher theoretical sulfur capacities. Some of these sorbents required higher desulfurization temperatures to reduce the H₂S in the exit gas to less than 20 ppmv.

Table 4. Summary of sorbent performance in first and second cycles

Sorbent	Temperature, °C	Sorbent Fractional Conversion at H ₂ S Breakthrough of 20 ppmv	
		Cycle 1	Cycle 2
IGTSS-1	350	1.08	1.13
IGTSS-2	350	0.98	0.12
IGTSS-3	350	0.54	0.19
IGTSS-5	450	0.50	0.15
IGTSS-6	350	0.83	0.77
IGTSS-10	350	0.86	0.03
IGTSS-11	450	1.00	0.67
IGTSS-27	450	0.22	0.18
IGTSS-57	450	0.12	0.54
IGTSS-55	538	0.26	0.30

Based on the results of the second cycle testing, additional sulfidation-regeneration cycles were performed on seven of these sorbents, IGTSS-1, SS-6, SS-11, SS-57, SS-5, SS-55. The results of these tests are summarized in Figure 10-Figure 16. As indicated in Figure 10, high levels of sorbent conversions were obtained at 350°C in the first 10 cycles for sorbent IGTSS-1. The H₂S breakthrough profiles for this sorbent (Figure 11) also indicate very high levels of desulfurization (<10 ppmv H₂S). The very sharp rise in the H₂S breakthrough curves at high levels of sorbent utilization indicates that the reactivity of this sorbent towards H₂S is very high. IGTSS-1 is significantly more reactive at 350 °C than either the CuCr-1 or zinc titanate sorbents tested. However, an examination of the sorbent after the 15th cycle revealed that it had disintegrated which may explain the rapid decline in reactivity and conversion after the 10th cycle.

Based on the excellent performance of IGTSS-1 during the initial 10 cycles, a stronger version of this sorbent, IGTSS-11, was formulated and tested. The sorbent conversions are relatively high and constant over the 13 cycles tested at 450°C as shown in Figure 12. The H₂S breakthrough curves (Figure 13) indicate that this sorbent can reduce H₂S to below 10 ppmv. No loss of strength was observed after 13 cycles. Based on its mechanical strength and reactivity, this sorbent is considered a candidate for fluidized-bed reactor testing at 450°C.

The conversions for sorbent IGTSS-6 at 350°C, shown in Figure 14, indicate a relatively stable reactivity for this sorbent over 10 cycles. The H₂S breakthrough curves for this

sorbent (Figure 15) indicate very low H_2S prebreakthrough levels of below 5 ppm. Examination of the sorbent after the 10th cycle indicated no apparent loss of sorbent strength. The apparent loss of reactivity in some of the cycles is probably due to the changing sulfidation-regeneration conditions used during this series of tests. If this sorbent can maintain this level of conversion and maintain its mechanical strength for few additional cycles it will be considered a candidate for fluidized-bed reactor testing at 350°C.

Fixed-bed testing was also conducted on three sorbents with higher theoretical sulfur capacities. The results are summarized in Figure 16. A total conversion of nearly 47% at breakthrough was attained with sorbent IGTSS-57 in the second cycle at 450°C. This increase in capacity over that seen in the first cycle is possibly due to a change in the oxidation state of the sorbent as a result of its method of preparation. IGTSS-5, also tested at 450°C, shows a marked reduction in conversion after the first cycle, but a more stable performance in the next five cycles. IGTSS-55 indicates a conversion of about 35% after 3 cycles at a temperature of 538°C and is considered a candidate for fluidized-bed reactor testing at 538°C. Additional fixed-bed testing will be conducted with each of these three sorbents.

Conclusions of Sorbent testing at IGT

This investigation has demonstrated that:

- Based on thermodynamic calculations, at 350°-538°C, a large number of metal oxides are capable of reducing the H_2S level of coal-derived fuel gases to below 20 ppmv for IGCC application
- Sorbents with lower theoretical capacities for sulfur but much higher reactivities can have equivalent overall effective capacities as sorbents with higher theoretical capacities but lower reactivities.
- Three sorbents, IGTSS-6, IGTSS-11 and IGTSS-55 have been developed that have sufficient reactivity and mechanical strength for fluidized-bed reactor testing at 350°, 450°, and 538° C, respectively.

Future work at IGT

Sorbents IGTSS-5, SS-6, SS-11, SS-55 and SS-57 will be further evaluated for other important characteristics, such as sorbent regenerability and mechanical durability, in multicycle sulfidation-regeneration tests. Secondary components may be added to enhance desulfurization reactivity, chemical stability, porosity and/or maintain mechanical durability, as needed.

Additional sorbent formulations will be prepared and further screening of metal oxide formulations in Table 1 will be performed.

The most reactive and mechanically durable sorbent formulation will be produced in a form and quantity suitable for fluidized-bed testing in the bench-scale desulfurization test unit.

Task 3 — Provision of Bench-Scale Reactor

Modifications to the existing bench-scale units at GE-CRD and IGT were conducted during the current reporting period. Several expendable and non-consumable items were purchased for use in sorbent screening or bench-scale testing at GE-CRD and IGT.

Task 4 — Bench-Scale Testing

Task 5 — Sorbent Cost Assessment

No effort has been spent during the current reporting period.

Task 6 — Topical Report

No effort has been spent during the current reporting period.

Task 7 — Market Plan

No effort has been spent during the current reporting period.

Task 8 — Long-Term Testing (Optional)

No effort has been spent during the current reporting period.
