Abstract

We present the Cherenkov Ring Imaging Detector in the endcap regions of the SLD detector and report initial performance. The endcap CRID was completed and commissioned in 1993 and is fully operational for the 1994 run. First Cherenkov rings have been observed. The endcap CRID detectors and fluid systems are described and initial operational experience is discussed.

I. INTRODUCTION

The SLC Large Detector (SLD) experiment at the SLAC Linear Collider (SLC) is equipped with Cherenkov Ring Imaging Detectors (CRIDs) in both barrel and endcap regions to provide particle identification over a broad momentum range. The barrel CRID has been fully operational since 1992, whereas the endcap CRID was completed and commissioned during the 1993 run. The 1994 run is

currently underway with a fully operational particle identification system. In this paper, we present the endcap CRID and discuss performance of this new detector system.

Relativistic charged particles traversing the CRID gas radiator emit Cherenkov photons at an angle with respect to the particle direction. This angle depends on the particle velocity and thus, when combined with an independent measurement of the particle momentum, provides effective separation between different particle species. Cherenkov radiation is focussed by spherical mirrors onto Time Projection Chambers (TPCs) where individual photons ionize Tetrakis(diMethylAmino)Ethylene (TMAE) molecules. Electrons produced in this photo-ionization process then drift in a uniform electric field to MultiWire Proportional Chambers (MWPCs) where they are recorded. The MWPCs are designed to be sensitive to single electrons.

The design of the endcap CRID is similar to that of the barrel CRID [1], but the design of the TPCs had to be modified because the photo-electrons drift perpendicular to the 0.6 Tesla magnetic field of SLD. The resulting non-zero Lorentz angle (θ_L) required a special design for the MWPC focussing structure. Furthermore, a decision was made not to build a liquid radiator system. This simplified the TPC design by allowing the use of rectangular TPCs, spaced in azimuth, and equipped with quartz windows on one side only to detect Cherenkov radiation emitted in a gas radiator. With such a system, medium to high momen-

turn particles can be identified. The momentum threshold for pions is 2.5 GeV/c and $\pi/K/p$ separation can be achieved for momenta up to about 30 GeV/c.

II. GENERAL DESCRIPTION

The endcap CRID comprises two 2650 liter vessels located on either side of the SLC interaction point, with each vessel located between inner and outer endcap drift chambers as shown in Fig. 1. This detector system covers forward angular regions from 10° to 35° , and from 145° to 170° with respect to the SLC beamline.

The vessels span the Z-axis (along the beamline) from 124 to 196 cm, and extend from 20 to 146 cm in radius. Each vessel is organized into 10 azimuthal sectors and is equipped with a TPC in every other sector.

The basic elements of the endcap CRID are shown in Figs. 2 and 3. The TPCs consist of drift box and MWPC sections. The active area of a drift box is 43.2 cm wide and 28.0 cm along the drift field direction. Individual drift boxes are constructed with G10 backing and sides supporting a fused silica quartz window facing the mirrors. The drift box sensitive volume thickness is 5.15 cm at the high voltage end (radius = 54.6 cm) and 5.60 cm at the MWPC end (radius = 83.0 cm), due to the 0.9° taper of the 4 mm-thick quartz window. As a result of the taper, photo-electrons drift away from the quartz window, thus minimizing losses and possible distortion effects. Cherenkov radiation is focussed onto the drift boxes by an

array of 60 spherical mirrors in each vessel. The mirrors are attached, in groups of six, to ladders mounted on the back plane of the vessels. For sectors without a TPC, the mirrors are oriented in such a way as to focus light on one of the neighboring drift boxes.

The high voltage end of the drift box is kept at a potential of -15 kV which is degraded to ground via a resistor chain to provide a uniform 400 V/cm electric field. Field uniformity is guaranteed by a series of thin conducting strips precisely located on both sides of the quartz window and G10 surfaces, as well as by an external field cage (see Fig. 2). The electrostatics design closely follows that used in the barrel CRID [2].

Each MWPC contains 128 thin carbon wires (7 μ m diameter) enclosed in a focussing assembly with a wire spacing of 0.3505 cm. The wire length is 6.8 cm. The focussing structure (Fig. 4) includes two layers of etched copper sheets which provide focussing and serve as blinds to prevent UV avalanche photons from reaching the drift box volume where they would otherwise ionize TMAE. Pairs of transverse focus rods, located between the two blinds, provide a transverse electric field to correct the electron trajectories for the non-zero Lorentz angle; $\theta_L \approx 10^\circ$ for the drift gas chosen. Cylindrical support rods made of G10 are placed between each layer of the focussing structure to prevent the blinds from buckling. This might occur due to the different coefficients of thermal expansion of the various materials. The diameter of the three support rods varies between 0.79 mm and 2.38 mm. The larger rod produces a "shadow" in the center of the anode wires. The cathode is kept at -1.5 kV, yielding an average gain of $\sim 3 \times 10^5$ for single photo-electron avalanches, with TMAE present in the drift gas. The high resistivity ($R \approx 29$ k Ω) anode wires are read out on both ends to provide a measurement of the hit coordinate along the wire direction via charge division. The other two hit coordinates are reconstructed from the recorded drift time and the wire number

Figure 5: Drift gas delivery system.

of the hit.

Every TPC is equipped with 19 UV fiber fiducials whose positions on the quartz window are known. These fibers are used in various calibration and monitoring tasks: Lorentz angle and drift velocity measurements, study of electric field distortions and charge division resolution.

III. FLUID SYSTEMS

There are two main fluid systems: the drift gas and the radiator gas systems.

The essential features of the drift gas system are shown in Fig. 5. In order to decrease the electron drift velocity, and thus reduce the magnitude of the Lorentz angle, CO₂ is added to the C₂H₆-based drift gas to form a C₂H₆/CO₂ 85%/15% mixture. The resulting drift gas has good UV transparency in the useful range $\lambda \approx 1600 - 2100$ Å and provides sufficient gain for single electron detection while maintaining proper quenching in the presence of TMAE. Other important properties of the gas mixture are its small diffusion coefficient to preserve good spatial resolution, and its long electron attenuation length to guarantee high detection efficiency.

The C₂H₆ and CO₂ gas supplies are separately filtered through 13X and 3A molecular sieves² respectively, fol-

Figure 7: Transparency measurements in 1 cm of liquid C_4F_{10} kept inside a cell equipped with quartz windows, before (dashed line) and after purification (solid line).

lowed by Oxisorb³ filters before being mixed. The mixture is then sent to two separate gas racks, one for each endcap, where a small amount of the photo-sensitive agent TMAE is added by bubbling through liquid TMAE maintained at 22° C.⁴ At this temperature, the TMAE concentration is 0.05%. TMAE⁵ undergoes an extensive purification procedure [3] before being used in the drift gas system.

The gas mixture flows through the drift boxes at the rate of 0.6 l/min per endcap which corresponds to a volume change in the drift boxes every hour. The drift box pressure relative to the vessel is typically 0.4 Torr. A dedicated device is used to continuously monitor the average attenuation length of electrons in the drift gas mixture.

For gas radiator fluid, we opted for C_4F_{10} ⁶ rather than C_5F_{12} as used in the barrel CRID.⁷ Some advantages of C_4F_{10} are its lower condensation point (−2°C) and higher transparency in the range $\lambda \approx 1600 - 1800$ Å, where the quantum efficiency of TMAE is the highest. However, the index of refraction for C_4F_{10} ($n = 1.00153$ at $\lambda = 1770$ Å) is slightly lower than for C_5F_{12} , resulting in momentum thresholds ~ 6% higher: 2.5 GeV/c for pions, 8.9 GeV/c for kaons, and 17.0 GeV/c for protons. The choice of C_4F_{10}

as a gas radiator is appropriate due to its low chromatic dispersion in the relevant photon energy range ($dn/dE = 53 \times 10^{-6} \text{ eV}^{-1}$ in the range 6.5 to 7.5 eV [4]).

The radiator gas system (Fig. 6) is a closed loop system which maintains the vessel pressure constant by controlling the C_4F_{10} vapor pressure inside a condensing tank. Stable operation of the radiator gas system has been achieved for flows up to 2.5 l/min in each endcap, which corresponds to a volume change every 18 hours. The C_4F_{10} gas is recovered via a condensing tank inside a commercial freezer. The condensing tank effective temperature must be maintained constant to about 0.01° C to keep the C_4F_{10} pressure constant to 0.2 Torr. The C_4F_{10} effective temperature inside the tank is controlled by four Kapton foil heaters (total power = 300 W) which are continuously immersed in the liquid. Input to the controller is provided by differential pressure transducers⁸ which measure the pressure inside each endcap vessel with respect to atmospheric pressure.

Stability is maintained within ± 0.02 Torr for flows up to 2.5 l/min in each endcap. A microprocessor is used to control the freezer compressor and the condensing tank bubbler based on the duty cycle of the heaters. This addition is necessary to achieve long term stability for flows greater than 1 l/min in each endcap. Some instabilities may occur due to the collection of nitrogen and other gases that slowly leak into the system, do not condense in the tank, and accumulate until purged by the bubbler.

As the condensing tank fills up, liquid level indicators act as a trigger to pump out some of the liquid into Buffer Tank A. Liquid in that tank is continuously circulated through Silica Gel⁹ and Ridox¹⁰ filters for purification. As indicated in Fig. 7, purification tests show dramatic improve-

ment in the UV transparency of liquid C_4F_{10} after several passes through this filter combination. A small fraction of the liquid is transferred from the purification loop into Buffer Tank B for a final pass through a separate set of filters before being sent to the vessels in the gas phase.

The C_4F_{10} UV transparency is measured with a monochromator at different stages of the recovery and filtering system (see Fig. 6). A sonar system inside the vessels monitors the gas composition at three different heights.

The overall performance of the endcap CRID can be characterized by the quantity N_0 , defined as $\alpha/(hc) \int \epsilon dE$, where ϵ represents the overall efficiency for single photon detection as a function of photon energy E . We estimate N_0 to be approximately 70 cm^{-1} by taking the following measured quantities into account: TMAE quantum efficiency [5], quartz window and C_4F_{10} radiator gas transparencies, and mirror reflectivity (see Fig. 8). This N_0 estimate also includes a 68% efficiency for detection of single photo-electrons corresponding to losses due to: field-shaping strips and field cage wires (14%), photon conversion length (10%), MWPC efficiency (10%), and electron attenuation in the drift box (2%). As a result, the expected average number of photo-electrons per Cherenkov ring is estimated to be 9–10 for an average radiator thickness of 45 cm. Improvements at the level of $\sim 10\%$ may be possible by increasing the C_4F_{10} flow rate to improve UV transparency at shorter wavelength, and by increasing the amount of TMAE to reduce the photon conversion length. As can be seen in Fig. 8, the limiting factor at short wavelength comes from the quartz transparency rather than that of the radiator gas.

Figure 9: Drift velocity measurement as a function of time.

A dedicated MicroVAX computer is used for slow monitoring, time histories, and temperature control. The vessel temperature and the external plumbing temperatures are monitored and maintained at $\sim 30^\circ\text{C}$. This elevated temperature is required to prevent TMAE from condensing. The water vapor and oxygen content of the drift and purge gases are monitored. Many other parameters are continuously monitored, including gas flow, drift box and vessel pressure, temperature sensors, heaters, radiator gas sonar velocity, drift gas composition, and cathode current.

IV. EXPERIMENTAL PERFORMANCE

Early data analysis results from the 1993 and 1994 SLD runs are presented below. Particle identification performance at the design level requires spatial resolution of 1 mm along the drift field and wire number directions, and 2 mm along the charge division direction. In order to achieve these resolutions, it is necessary to measure the Lorentz angle, the electron drift velocity, and the timing offset accurately each run (a typical run lasts 2–4 hours).

The average conversion length during operation with 22°C TMAE is measured to be $2.1 \pm 0.4 \text{ cm}$, consistent with expectations (see for example Ref. [1]).

The electron drift velocity is measured on an hourly basis using hits from the UV fiber fiducials. Figure 9 shows a typical time dependence for measurements taken over a period of a few days. Velocities are determined to better than $\pm 0.5\%$. The magnitude of the Lorentz angle is measured on a run by run basis with an average value $\langle \theta_L \rangle = 9.65^\circ$ and root mean square (RMS) value of 0.24° , see Fig. 10. The above measurements allow hit reconstruction with a spatial resolution at the 1 mm level or better along the drift field and wire number directions.

The UV fiber fiducials have also been used in a preliminary analysis of the charge division coordinate resolution. UV fibers shining across the wire plane are expected to

Figure 10: Distribution of the Lorentz angle measured on a run by run basis.

produce hits localized along that coordinate axis. By selecting hits within 2 cm of the quartz window and fitting the charge division coordinate distribution to a Gaussian for each wire, the preliminary average resolution is determined to be 2.3 mm with an RMS value of 0.7 mm.

Another aspect of the above calibration process is that of timing offsets. These are monitored by fitting the drift time distribution to determine the time corresponding to the physical end of the TPC. These fits require prior knowledge of the Lorentz angle, the drift velocity and the length of the TPC. The RMS value for the measured timing offset is determined to be 0.3 mm. All of the above procedures have been automated and reside in the off-line analysis.

Finally, the data were examined for the existence of Cherenkov rings in both cosmic ray and colliding beam runs. An example of a ring is shown in Fig. 11 along with a suggestive circle of 2.5 cm radius which corresponds to the radius expected for a $\beta \approx 1$ particle. Figure 11 also shows that good spatial resolution has been achieved.

V. CONCLUSIONS

The endcap Cherenkov Ring Imaging Detector has been recently completed and is currently fully operational. Issues specific to the endcap regions have been dealt with successfully. In particular, the 10° Lorentz angle required a special design for the MultiWire Proportional Chamber focussing structure. Initial performance indicates that the required 1 mm resolution in the hit reconstruction along the drift field direction and along the wire number direction can be achieved. First Cherenkov rings have been observed and work is underway to extract information from the tracking systems for ring-finding and alignment purposes.

Figure 11: Example of a Cherenkov ring displayed in the TPC coordinate system. All hits are shown. The dashed circle of 2.5 cm radius is not the result of a fit but serves as a reference.
