Abstract

We present the results of calculation of transverse mode coupling instability (TMCI) thresholds for Very Large Hadron Collider (VLHC). The estimates are done with use of conventional approach and more sophisticated mode dynamics analysis. We found the RF system parameters which allows to get appropriate TMCI threshold number of particles per bunch and attain high luminosity of the collider. Alternative ways to raise the threshold are briefly discussed.

1 Introduction

The Very Large Hadron Collider (VLHC) [1] will have large circumference, that leads to domination of transverse instabilities in beam dynamics problems [2, 3]. Consideration done by J. Rogers [2] concludes that dominant single bunch effect is the transverse mode coupling instability (TMCI) driven by a broadband impedance. We redo estimates of the impedance budget and the TMCI threshold using conventional approach and discuss observations at the Tevatron in Section 2. As most of the impedance comes from resistive wall fields which are not constant over longitudinal coordinate in a bunch s , then more sophisticated analysis is done in Section 3 with means of the method developed in [5]. We study dependence of the beam eigenfrequencies versus current and modes coupling in the VLHC low-field option. In Section 4 we consider possible ways to increase the threshold in the VLHC.

2 Rough estimates

Basically, the TMCI (or “strong head-tail instability”) appears due to defocusing effect of the wake fields induced by the head of the bunch on the bunch tail particles. In the presence of synchrotron motion, there is a permanent exchange of head and tail particles that helps to avoid the instability. The instability was observed at many electron storage rings which usually tend to increase the synchrotron tune ν_s in order to stabilize the TMCI. To date there is no solid evidence of the “strong-head tail” instability in proton machines [4]. Nonetheless, it is expected the proton TMCI will be important at injection into the SPS, when it works with LHC parameters and in the VLHC. We have

to note that for existing proton accelerators, stabilizing processes other than the synchrotron mixing can play important role, for example, incoherent tune spread due to direct space charge and/or broad-band impedance, or other sources of possible Landau damping. They are not yet analyzed properly, and, therefore, it is not clear will they distort the picture of the TMCI at the VLHC or not.

After these precautions, we start with routine analysis of the mode coupling phenomena.

The transverse mode-coupling instability leads to fast beam break-up, and, therefore, sets strong constraint on a broad band transverse impedance $Z_{\perp}$. The threshold number of particles per bunch N_p can be estimated as [6]:

$$N_p^{th} = \frac{32\pi^{3/2}(E/e)\sigma_s\nu_s}{3ec\text{Im} \langle Z_{\perp}\beta_{\perp} \rangle} \quad (1)$$

where brackets $\langle \dots \rangle$ mean averaging with the beta-function at locations of the impedance sources.

As it was pointed out in [2], transverse broad band impedance in the low-field VLHC is dominated by resistive wall impedance. The latter can be estimated for round vacuum chamber with radius a as:

$$Z_{\perp}(\omega) = (1 - i)\frac{Z_0\delta R}{a^3}, \quad (2)$$

where R is the radius of the machine, $Z_0 = 377\Omega$ is the vacuum impedance, $\delta = c/\sqrt{2\pi\sigma\omega}$ is the skin depth at frequency ω , σ is the wall conductivity.

As the impedance depends on frequency, its effective value integrated over the bunch spectrum is used¹:

$$Z_{\perp} = \frac{\sum_n Z_{\perp}(\omega = n\omega_0)e^{-(n\omega_0\sigma_s/c)^2}}{\sum_n e^{-(n\omega_0\sigma_s/c)^2}}. \quad (3)$$

where $\omega_0 = c/R$ and σ_s is the rms bunch length. Using (2, 3) one finds that

$$Z_{\perp}^{RW} = \frac{\Gamma(1/4)}{\sqrt{\pi}} Z_{\perp}(\omega = c/\sigma_s) = 2.05 Z_{\perp}(\omega = c/\sigma_s). \quad (4)$$

For $\sigma_s = 10$ cm long bunches in *Al* vacuum chamber with conductivity of $\sigma = 3.2 \cdot 10^{17} \text{c}^{-1}$ the skin depth at $\omega = c/\sigma_s = 3$ GHz is about $3.86 \mu\text{m}$.

For other than round vacuum chambers, a geometry factor can be introduced. For example, it is equal to $R_G \approx 0.84$ for elliptical vacuum chamber with minor half-aperture a two times less than the major one [7], i.e.

$$\text{Im}Z_{\perp}^{eff} \approx 2.05 \cdot 0.84 \frac{Z_0 R \delta(\omega = c/\sigma_s)}{a^3} = 1.72 \frac{Z_0 R \delta(\omega = c/\sigma_s)}{a^3}. \quad (5)$$

Additional wide-band impedance of the ring can be estimated as a sum of impedances of its components, such as bellows, BPMs, kickers, vacuum ports, tapers, etc. Most of these elements are discontinuities having resonant frequencies much higher than the frequencies within the bunch spectrum, and, therefore, they give rise to a mostly inductive impedance. At this stage of the VLHC ring design we restrict ourselves with rough estimate, based on assumption that for every half FODO cell

¹as will be discussed in the next section, this is the point of some uncertainty in the impedance estimates

length of $L = 250\text{m}$, there are some discontinuities like aperture increase $\Delta = 0.5\text{mm}$ and total length of about $g = 10\text{cm}$, then

$$\text{Im}Z_{\perp} = \left(\frac{Z}{n}\right) \cdot \frac{2R}{a^2} = -\frac{2R}{a^2} \cdot \frac{Z_0 g \Delta}{2\pi R a} \times N_{\text{elements}}, \quad N_{\text{elements}} = 2\pi R/L. \quad (6)$$

Resulting impedance budgets for low-field and high-field options of the VLHC (some parameters are taken from [2]), 3 TeV low-field injector with $C = 34\text{ km}$ (with $L \simeq 86\text{m}$) and for the LHC [8] are presented in Table 1.

Table 1 also presents the threshold bunch population for these machines at their injection energies where the TMCI is expected to be more dangerous.

For the low-field option of the VLHC the bunch intensity threshold determined by the TMCI (mostly due to resistive walls) is equal to:

$$N_{th} \approx 3.87 \cdot 10^{10} \cdot \sqrt{\frac{\sigma_s}{10\text{cm}}} \cdot \frac{E}{3\text{TeV}} \cdot \frac{\nu_s}{0.01} \cdot \left(\frac{a}{0.9\text{cm}}\right)^3 \cdot \frac{550\text{km}}{C} \cdot \frac{320\text{m}}{<\beta>}. \quad (7)$$

For example, one can expect that due to 4 times smaller beta-function and seven times longer bunch length, the threshold in 3 TeV ring built with the same low-field magnet technology will be about 10 times the threshold of the 50 TeV collider ring as long as acceleration ratio (top energy divided by injection energy) and ν_s are the same for both rings.

It is useful to apply the above consideration to the Tevatron ring (see also Table 1). Assuming stainless steel *round* vacuum chamber with $a = 3.5\text{cm}$, resistivity of $\rho = 7.4 \cdot 10^{-7} \Omega\text{m}$, the rms bunch length of about 0.5 m and synchrotron tune 0.002 at the injection energy of 150 GeV, $<\beta> \approx 50\text{ m}$, one gets

$$N_{th}^{TeV} \approx 4.6 \cdot 10^{12}, \quad (8)$$

that corresponds to effective resistive wall broadband impedance of about $0.8\text{ M}\Omega/\text{m}$. Detailed estimate of the impedance made by K.Y.Ng [9] gives total transverse impedance about 3-4 times larger. There are some experimental evidences of the longitudinal broadband impedance as large as $(Z/n)^{TeV} \sim 10\Omega$ [10]. From that one can estimate the transverse broadband impedance as $Z_{\perp} = 2R(Z/n)/a^2 = 10\text{ M}\Omega/\text{m}^2$. For the given spread of the impedance of (3-10) $\text{M}\Omega/\text{m}$ we get the threshold bunch populations of $N_{th}^{TeV} = (3.7 - 12) \cdot 10^{11}$. Particle production at the Tevatron limits maximum bunch population at the Tevatron at the level of about $3 \cdot 10^{11}$, and that probably explains why the TMCI was not observed at the Tevatron. As we mentioned at the beginning of this Section, there is other factor which may play role and increase the TMCI threshold - the spread of betatron tunes within the bunch. Such a spread takes place along the bunch (due to direct space-charge or/and broad-band impedance) as well as across the bunch (due to direct space charge, octupole magnets, beam-beam interaction, etc.) It is not clear now which of the spreads may lead to more effective stabilization. Recent numerical studies [11] of the TMCI with direct space charge tune shift δQ_{sc} have shown that the threshold grows approximately as $\mathcal{R} = 1 + \Delta Q_{sc}/\nu_s$. For the Tevatron at injection

$$\Delta Q_{sc} = \frac{N_p r_p R}{2\sqrt{2\pi}\sigma_s \epsilon_N \gamma^2} \approx 0.001,$$

²in the estimate we used $a = 4.5\text{ cm}$, i.e. somewhat larger than for the vacuum chamber, because the aperture is larger in the Tevatron injection and abort kickers which are thought to contribute significantly into the broad-band impedance.

(here $\epsilon_N \approx 4 \cdot 10^{-6}$ m is the rms normalized emittance, $r_p = 1.53 \cdot 10^{-18}$ m is the proton classical radius, and we took $N_p = 3 \cdot 10^{11}$) that may give additional 50% of the threshold increase. The direct space charge tune shift and tune spread are negligible at high energies (e.g. for all machines we considered above except 3TeV low-field injector ring with 150 GeV injection energy - the protons will come from the Fermilab Main Injector). It would be of interest to observe the TMCI at the Tevatron, for example, by increasing the transverse broad-band impedance of the ring and to study the tune shift and the coupling of the transverse modes.

Table 1: Broadband Impedance Model and Threshold Bunch Intensities
(L-F is for low-field VLHC option, H-F - high-field option,
3TI - 3 TeV low-field VLHC injector ring, TEV is for the Tevatron)

3 Mode coupling simulations

As we know from preceding section, the most of the transverse impedance comes from the resistive wall fields. These fields are not constant over the bunch longitudinal coordinate s . E.g., the corresponding wake-function is given by [12]:

$$W(s) = -\frac{2C}{\pi a^3} \sqrt{\frac{c}{\sigma s}}, \quad (9)$$

One can see, that the wake field has a singularity $\propto 1/\sqrt{s}$. That plays certain role in excitation and coupling of particular modes, and the averaging over the bunch spectrum is not completely correct: in fact, such averaging should be performed over different modes of transverse motion, which are not known *a priori*. We used different approach to pursue the problem, following the method developed in [5].

Figure 1: Eigentunes (vertical axis) versus number of protons per bunch (horizontal axis). The fractional part of the betatron tune is 0.1; upper lines present real part, and lower ones - imaginary part of eigentunes.

In our simulations, the bunch is divided into 4 radial and 5 azimuthal parts, so it is possible to see the behavior of the first 4 radial and 5 azimuthal modes. It gives about few percent deviation from the exact threshold current value for the first (0,+1,-1) modes coupling (see details in [5]). The integrated wake kick Eq.(9) is applied once over the revolution period, that is a good approximation while the tune shifts due to impedance and synchrotron tune are much less than 1. The rest of the lattice is presented as a linear transform matrix. Total transformation matrices including the kick are different for different modes. Eigenvalues (eigentunes) of these modes can be calculated numerically.

In Fig.(1) one can see the eigentunes versus number of protons per bunch. The parameters used in this simulation are $\langle \beta \rangle = 600\text{m}$, $\nu_s = 0.01$, $\sigma_s = 0.1\text{m}$, $E = 3\text{TeV}$, $C = 550\text{km}$. The fractional part of the betatron tune is equal to $\nu_\beta = 0.1$. We found that being far from low-order resonances, the tune is not significant for the threshold estimations. There is a number of "radial" eigentunes with zero "azimuthal" number around the betatron frequency at $\nu_\beta \pm \nu_s, \pm 2\nu_s$. All these modes for small current have zero oscillations of the dipole moment over the angle in synchrotron phase space, and they have different dependence on the dipole moment over the synchrotron amplitude ("radius" in synchrotron phase space). For each synchrotron sideband, there are several higher "azimuthal" modes, whose tunes for small current are different from the betatron tune on a particular integer number of synchrotron tunes. This number means the eigenmode variation numbers over the angle in the synchrotron phase space. As in the case of "zero" azimuthal modes, there are a lot of "radial" modes for every azimuthal number.

With chosen parameters, the first merging of some "zero" radial mode and some "-1" radial mode occurs for the number of protons in bunch equal to $1.2 \cdot 10^{10}$. The next merging occurs for approximately triple current ("0" radial and "+1" radial modes). In both cases a pair of the modes with equal real parts of the tune and with opposite imaginary parts of the tune appears; this, evidently, gives unstable motion of the bunch.

Let us take into account the reduction factor of $R_G = 0.84$ due to the beam pipe ellipticity, and present the threshold obtained in the same form as Eq.(7):

$$N_{th} \approx 2.7 \cdot 10^{10} \cdot \sqrt{\frac{\sigma_s}{.1\text{m}}} \cdot \frac{E}{3\text{TeV}} \cdot \frac{\nu_s}{0.01} \cdot \left(\frac{a}{0.9\text{cm}}\right)^3 \cdot \frac{550\text{km}}{C} \cdot \frac{320\text{m}}{\langle \beta \rangle}, \quad (10)$$

This value is about 0.7 times the value we got with straightforward estimates above. Again, worrisome intensity limitation in the VLHC occurs at the injection energy.

4 Luminosity and safety factor.

Now we can estimate luminosity of the low-field VLHC under assumption that the number of particles per bunch N_p remains the same during the acceleration, normalized transverse emittance $\epsilon_n = 2.5\text{mm} \cdot \text{mrad}$ (or 95% emittance of $15\pi \text{ mm} \cdot \text{mrad}$), beta-function at the interaction point of $\beta^* = 10\text{cm}$, revolution frequency $f_0 = 0.5 \text{ kHz}$, and the collision energy of 50 TeV ($\gamma_p = 5.1 \cdot 10^4$):

$$\mathcal{L} = f_0 N_b \frac{N_p^2 \gamma_p}{4\pi \epsilon_n \beta^*} \mathcal{F}\left(\frac{\sigma_s}{\beta^*}\right), \quad (11)$$

where the geometrical luminosity reduction factor for round beams is $\mathcal{F}(x) = \mathcal{L}(\sigma_s)/\mathcal{L}(0) =$

$\sqrt{\pi}xe^{x^2}\text{erfc}(x)$, $x \equiv \beta^*/\sigma_s$. For 7 cm rms bunch length it leads to $\mathcal{F} \approx 0.82$ and one gets the luminosity of

$$\mathcal{L}/10^{34}[s^{-1}cm^{-2}] = 0.73 \cdot \frac{N_b}{10^5} \cdot \left(\frac{N_p}{10^{10}}\right)^2. \quad (12)$$

Number of interactions per crossing due to inelastic interaction of protons with 132mb cross section is about

$$n_{int} = 28 \cdot (\mathcal{L}/10^{34}) \cdot \frac{10^5}{N_b}. \quad (13)$$

One can see, from this formula, that, for the same luminosity, larger number of bunches is preferable in order to decrease the number of particles per bunch and n_{int} . The same preference occurs for the parameter of the beam-beam interaction:

$$\xi = \frac{r_p N_p}{4\pi\epsilon_n} \approx 0.0005 \cdot \frac{N_p}{10^{10}}, \quad (14)$$

although the bunch intensity limitation due to the TMCI at the injection appears well before beam-beam effects would be of importance.

Let us choose for definiteness the frequency of the RF accelerating cavities to be $f_{RF} = 500$ MHz³, it is equal to $h = 9 \cdot 10^5$ harmonics of the revolution frequency. If one fills every 9th bucket then number of bunches is $N_b = 10^5$ and bunch spacing is 18 ns.

Other parameters of the collider are as follow: the half FODO cell length $L = 250$ m, betatron phase advance per cell $\psi = 90^\circ$, average beta-function $\langle \beta \rangle = 318$ m, tune of the 554km-long machine is about $\nu \approx 275$ that yields a momentum compaction factor $\alpha \approx 1/\nu_x^2 = 1.3 \cdot 10^{-5}$.

In order to have synchrotron tune at the injection (at 3 TeV) of

$$\nu_s = \sqrt{\frac{\alpha h e V_0}{2\pi E_{inj}}} = 0.01,$$

one needs to have the total RF voltage of $V_0 = 160$ MV. That value correspond to some 10 minutes ramp of the proton energy from 3 TeV to 50 TeV. With $V_0 = 640$ MV RF voltage, the ramp is four times faster and the synchrotron tune is 0.02.

Using all parameters presented above and Equation (10), we can calculate a *safety factor* of $S = N_{th}/N_p$ versus luminosity (see Fig.2):

$$S = \frac{1.79}{\sqrt{\mathcal{L}/10^{34}}} \quad \text{at } V_0 = 160 \text{ MV},$$

and

$$S = \frac{3.01}{\sqrt{\mathcal{L}/10^{34}}} \quad \text{at } V_0 = 640 \text{ MV}.$$

For example, the safety factor of $S = 2$ corresponds to $\mathcal{L} = 8 \cdot 10^{33} s^{-1}cm^{-2}$ with $V_0 = 160$ MV and $\mathcal{L} = 2.26 \cdot 10^{34} s^{-1}cm^{-2}$ with $V_0 = 640$ MV at the injection.

³powerful DC klystrons are available for such frequency at present time, both normal- and super-conducting RF technologies at this frequency are well developed for electron-positron storage rings

Figure 2: Safety factor $S = N_{th}/N_p$ vs luminosity. RF voltage at injection is 160 MV (solid line) and 640 MV (dashed line).

The scaling of the safety factor S for fixed luminosity is:

$$S \propto a^3 f_{RF}^{7/8} V_0^{3/8} \langle \beta \rangle^{1/4} A^{1/4}.$$

Thus, the most attractive ways are to increase the dipole magnet aperture or the RF frequency. Unfortunately, there is not too much freedom to vary these parameters, and therefore, it would be very useful to consider other ways of improvement.

5 Ways to increase the TMCI threshold.

There were several attempts in the past to increase the TMCI threshold with use of a feedback system. A resistive feedback doubles the threshold in PEP (see [13] and references therein) and in VEPP-4M storage rings [14]. Sophisticated reactive feedback (oscillator-like) was tested at LEP (CERN) and raised the threshold by 5% [15]. The conventional feedback at LEP didn't help for several reasons. Due to noises (or due to some other reasons) it didn't work in essentially resistive variant, but for reactive regime of work the "-1" mode became unstable. The calculations also gave the instability of "+1" azimuthal mode for near-threshold current.

The difference for situation with the TMCI at LEP in comparison with the other machines is its large synchrotron tune and large impedance between pickup and kicker. The VLHC parameters

are closer to the VEPP-4M parameters, than to the LEP ones due to the fact, that their synchrotron tunes are of the same order. So, it can be assumed, that conventional feedback has to help at VLHC, as it does at the VEPP-4M collider. Special variants of feedbacks may also help to damp the TMCI [5].

One more opportunity to counteract effectively the TMCI was considered recently in Ref.[16]. Introduction of a correlated tune spread from head to tail of the bunch using RF quadrupoles has shown significant increase of the threshold if the spread is several times the synchrotron tune ν_s . The idea is similar to the BNS-damping in linear electron-positron colliders [17] which was experimentally proven as an effective way to counteract beam break-up in SLAC Linear Collider.

Acknowledgments

We sincerely acknowledge useful comments of Gerry Jackson, John Marriner and Glenn Goderre on the Tevatron parameters and the TMCI experience at hadron machines. We thank K.Y.Ng for providing us with the Tevatron broad band impedance estimates.
