Exploring the $^{18}\text{F}(p,\gamma)^{19}\text{Ne}$ Gateway to the Formation of Heavy Elements in Hot Stars.

$^1$Argonne National Laboratory; $^2$Hebrew University, Jerusalem; $^3$University of Wisconsin, Madison, WI; $^4$Northwestern University, Evanston, IL

Abstract

An upper limit to the production of $^{19}\text{Ne}$ through the $^{18}\text{F}(p,\gamma)$ reaction at the recently discovered s-wave resonance has been determined. The limit implies that in a hot stellar environment ($T_9 > 0.5$) this reaction is not a significant gateway from the hot CNO cycle towards the production of heavier elements in stars.

The isotope $^{18}\text{F}$ ($T_{1/2}=110\text{ min}$) plays an important role in our understanding of explosive nucleosynthesis. $^{18}\text{F}$ is produced in the hot CNO cycle [1] and is the stepping stone to the formation of $^{19}$Ne which in turn is the gateway to the rp process [2] where in a series of $(p,\gamma)$ reactions nuclei up to $^{56}\text{Ni}$ and beyond are produced. In a hot stellar environment $^{18}$Ne can be generated either via the $^{18}$F$(p,\gamma)^{19}$Ne reaction or through radiative capture of $^{4}\text{He}$ on $^{15}$O with $^{15}$O produced via the $^{18}$F$(p,\alpha)$ reaction. As pointed out in Ref. 3 the $^{18}$F$(p,\alpha)$ and $^{18}$F$(p,\gamma)$ reactions are also important for controlling the production of the rare oxygen isotope $^{18}$O. The positive Q-value for the $(p,\alpha)$ reaction on $^{18}$F is the reason that no OF cycle exists in nature, since it allows a breakout from the cyclic reaction path $^{16}$O$(p,\gamma)^{17}$F$(\beta^+)^{17}$O$(p,\gamma)^{18}$F$(p,\gamma)^{18}$Ne$(\beta^+)^{19}$F$(p,\alpha)^{16}$O towards $^{15}$O before the final $^{19}$F$(p,\alpha)^{16}$O reaction is reached.

Calculations of the astrophysical reaction rates [4-6] for the $^{18}$F$(p,\alpha)^{15}$O and $^{18}$F$(p,\gamma)^{19}$Ne reactions have been published over the last 30 years. The spin values for the levels used in these computations were taken mainly from the mirror nucleus $^{19}$F. No s-wave resonance was included since no $\ell_p=0$ state in $^{19}$Ne or $^{18}$F was expected at the relevant excitation energy of $\sim 7\text{ MeV}$. It was therefore a surprise when in two recent experiments [7,8] evidence for a $3/2^+$ $(\ell_p=0)$ state in $^{19}$Ne was found which dominates the astrophysical reaction rate in $^{18}$F$(p,\alpha)^{15}$O at temperatures $T_\beta > 0.5$ [9]. Such an s-wave resonance could also play an important role for producing $^{19}$Ne through proton capture and for this reason we have carried out the first investigation of the $p(^{18}\text{F},^{19}\text{Ne})\gamma$ reaction.

The experiment was performed at the ATLAS accelerator system of Argonne National Laboratory using a two-accelerator method for generating the radioactive $^{18}$F ion beam [10,11]. The $^{18}$F material was produced at the cyclotron of the University of Wisconsin via the $^{18}$O$(p,n)^{18}$F reaction, flown to Argonne National Laboratory and installed in the negative ion source of the ATLAS tandem injector.

Because of the relatively small cross sections (typically of the order of tens of $\mu$b) and the low $\gamma$-detection efficiency ($<1\%$), measurements of $(p,\gamma)$ cross sections usually require high beam intensities. In order to compensate for the low intensities available with today's radioactive ion beams, new techniques with considerably higher detection efficiencies are needed. An additional difficulty in experiments with radioactive $^{18}$F beams is the presence of a strong contaminant from the isobar $^{18}$O.
To improve the detection efficiency for radiative capture reactions we have used the Fragment Mass Analyzer (FMA) [12] installed at the ATLAS accelerator. The FMA is a combination of one magnetic and two electric dipoles which disperse the particles according to \( p/q \) and \( E/q \), respectively. Since the electric rigidity of the \((p,\gamma)\) reaction products is lower than that of the beam particles by about 5\%, the primary beam is stopped at a collimator located after the first electric dipole. The subsequent magnetic and electric dipoles provide for additional suppression of scattered beam particles and for the transport of the reaction products to the focal plane of the FMA where the ions are dispersed by \( m/q \) and detected in a position-sensitive parallel-grid avalanche counter. This detector is followed by a large-volume ionization chamber for \( Z \) identification. With this arrangement, a suppression factor for the incident beam relative to the \((p,\gamma)\) reaction products of \( 10^{12} \) is achieved. Details of the experimental techniques will be published in a forthcoming paper [13]. A similar principle, involving a Wien filter combined with an additional magnetic dipole [14], has been used previously for measurements with stable beams.

The efficiency of the FMA and its detector system for radiative capture reactions was determined by measuring an excitation function for the \( p^{(18}\text{O},^{19}\text{F})\gamma \) reaction around the \( \ell_{p}=0 \) resonance in \( ^{19}\text{F} \) at \( E_{cm}=799 \) keV [15]. Beams of \(< 0.5 \) pA of 13-17 MeV \( ^{18}\text{O} \) from the tandem accelerator were used on 80-100 \( \mu \)g/cm\(^2\) \( \text{CH}_2 \) targets. In order to minimize beam induced changes in target thickness, a target wobbler was used that distributed the 3 mm beam spot over a \( \sim 1 \) cm diameter ring. The hydrogen content of the target was monitored by measuring the recoil proton yield in the course of the experiment in two monitor detectors mounted at scattering angles of \( \pm 30^\circ \).

Figure 1a shows a \( \Delta E-E_{res} \) spectrum measured in the ionization chamber at an \( ^{18}\text{O} \) energy of 16 MeV. The field settings of the FMA were chosen to detect the \( ^{19}\text{F}^{7+} \) reaction products originating from the \( ^{18}\text{O}(p,\gamma) \) reaction. The \( ^{18}\text{O} \) particles originate from scattering of the incident beam at various places inside the FMA. The solid lines are the result of a simulation of \( ^{19}\text{F} \) and \( ^{18}\text{O} \) particles traversing the ionization chamber. They are in excellent agreement with the measured data.

Figure 1b shows the measured cross sections (solid points) as function of the center-of-mass energy in comparison with the results obtained in Ref.16. The over-
all efficiency for detecting the recoil $^{19}$F particles is $30 \pm 3\%$. The fraction of the recoiling $^{19}$F ions in the $7^+$ charge state ($f_q = 55\%$) was determined by measuring a charge state distribution of $^{19}$F at the resonance energy. The remaining part of the overall efficiency is due to the acceptance limitations induced by a 1.7 cm wide collimator that was installed after the first electric dipole and to small angle scattering of the particles in the focal plane detector.

A comparison of this excitation function with the results obtained previously[16] shows good agreement. The hatched area in Fig.1b was obtained by averaging a Breit-Wigner resonance with parameters from Ref. 16 over the target thickness of 55 keV. The cross section off resonance ($\sim 20 \mu$b) is dominated by recoil $^{19}$F ions from a small fluorine impurity in the target. This is a general problem for radiative capture measurements in inverse kinematics, if they result in stable reaction products that may be present as trace impurities in either beam or target. Since $^{19}$Ne has a halflife of only 17.2 s this is not a problem for the $^{18}$F(p,$\gamma$)$^{19}$Ne experiment.

The runs with $^{18}$F beams were performed at a bombarding energy of $E_{cm} = 670$ keV, i.e. slightly above the s-wave resonance found in the $^{18}$F(p,$\alpha$)$^{15}$O reaction such that the resonance would fall within the energy range covered by the target thickness. The integrated $^{18}$F charge was determined by collecting elastically scattered $^{18}$F particles on a circular aperture in the angular range $\Theta_{lab} = 3.6-10^\circ$ and measuring the $\beta^+$ activity on the aperture off-line after each run. The time profile of the $^{18}$F exposure during the measurement and the cumulative $^{18}$F activity was also monitored continuously by measuring the $\beta^+$ annihilation radiation from the collimator after the first electric dipole where the primary $^{18}$F beam was intercepted.

Five runs with different samples of $^{18}$F, each about 300 mCi, were accumulated. The data from these runs were summed and the corresponding $\Delta E$-$E_{res}$ spectrum is shown in Fig.2a. The solid lines are again simulations of the response of the ionization chamber for O, F and Ne ions, respectively. The region where events from the $^{18}$F(p,$\gamma$)$^{19}$Ne$^{7+}$ reaction are expected is marked in the figure. There are three events which fall within this region, all of which are located close to the borderline between the Z=9 and 10 events. These three events have been further analyzed using the additional energy loss signal $\Delta E_1$ from the focal plane detector. Figure 2b shows pulse height spectra for these three events (labelled $^{19}$Ne) and for $^{19}$F and $^{18}$O particles, respectively. As can be seen from Fig.2b the three events have
energy loss values very close to the ones observed for $^{19}$F ions. Approximating the pulse height distributions by Gaussians one can estimate that the probability that three $^{19}$Ne ions giving pulse heights as small or smaller than the observed values is less than 0.003 and we conclude that probably all three of these events are $^{19}$F ions. The cross section corresponding to a single $^{19}$Ne event is calculated to be 42 $\mu$b using the integrated charge of the $^{18}$F beam (2.8 pnC) and the detection efficiency which is based on the the measurement of the $^{18}$O(p,$\gamma$) reaction. Taking 42 $\mu$b as the (1$\sigma$) limit and the widths $\Gamma_p$ and $\Gamma_\gamma$ for the 3/2$^+$ resonance as given in Ref. 9 an upper limit for the resonance strength $\omega_\gamma \leq 740$ meV and the gamma width $\Gamma_\gamma \leq 3$ eV has been calculated. This upper limit for $\Gamma_\gamma$ is comparable to the width obtained for the s-wave resonance populated in the $^{13}$N(p,$\gamma$)$^{14}$O reaction [17] but not as low as the limit obtained recently for the system $^{19}$Ne + p [18] where considerably higher beam currents were available. A gamma width $\Gamma_\gamma = 3$ eV for the 3/2$^+$ state in $^{19}$Ne corresponds to about 2% of the single particle width for an E1 transition and 40% for an M1 transition. Transitions with such strengths have been observed in this mass region [15].

This limit for the radiative strength of the 3/2$^+$ resonance allows us to reach significant conclusions about the production of $^{19}$Ne in the hot CNO cycle. The upper limit of the astrophysical reaction rate for the $^{18}$F(p,$\gamma$)$^{19}$Ne reaction populating the 3/2$^+$ state in $^{19}$Ne as function of $T_\odot$ is shown as the dash-dot line in Fig.3a. Also included (dashed line) is the rate for the $^{18}$F(p,$\alpha$)$^{15}$O reaction which is larger than the corresponding (p,$\gamma$) rate by at least a factor of $10^3$. The estimated upper limits for other states located in this excitation energy region are shown as dotted lines in Fig. 3a. These estimates were reached assuming the same gamma widths $\Gamma_\gamma = 3$ eV and the $\Gamma_p/\Gamma$ values as tabulated in Ref. 9. The upper limit for the total (p,$\gamma$) reaction rate is indicated by the thick solid line. A rough estimate for a lower limit for the (p,$\gamma$) reaction rate may be provided from a calculation of direct proton capture [16] which is shown as a thin solid line in Fig. 3a. The symbols in Fig.3a at $T_\odot = 0.6$ are calculated (p,$\gamma$) reaction rates taken from the literature [4-6] none of which included the new 3/2$^+$ resonance in $^{19}$Ne. While consistent with the results from Ref.5, our upper limit for the reaction rate is smaller than the values from Refs. [4,6] by factors of about 3-4.

The controlling factor for the breakout from the hot CNO cycle to the rp-process is the ratio of the reaction rates $R(^{18}$F(p,$\alpha$))/R(18F(p,$\gamma$)). The region allowed for the ratio $R(^{18}$F(p,$\alpha$))/R(18F(p,$\gamma$)) by the present measurement is given by the two
Due to the large value of the $^{18}\text{F}(p,\alpha)^{15}\text{O}$ reaction rate which above $T_9 > 0.5$ is dominated by the recently discovered $3/2^+$ resonance, and a lack of a strong enhancement of proton capture from this resonance, the ratio of the reaction rates is larger than $\sim 1000$ in this temperature range. This means that at these temperatures the production of $^{19}\text{Ne}$ through the $^{18}\text{F}(p,\gamma)$ reaction can be neglected and the dominant mechanism for generating this isotope is most likely the $^{15}\text{O}(\alpha,\gamma)$ reaction. Also shown by the dashed lines are the results of calculated ratios from Refs. [4-6].

The present work provides the first direct experimental limit for the ratio of the reaction rates between the $^{18}\text{F}(p,\alpha)^{15}\text{O}$ and the $^{18}\text{F}(p,\gamma)^{19}\text{Ne}$ reactions. The large cross section for the first reaction makes the $(p,\gamma)$ route a small branch for the production of $^{19}\text{Ne}$ at temperatures $T_9 > 0.5$, where this nuclide is produced more effectively via the $^{15}\text{O}(\alpha,\gamma)$ reaction.

The use of the Fragment Mass Analyzer for the measurement of radiative capture reactions in inverse kinematics results in a considerable improvement over gamma detection techniques, especially when the reaction products are unstable. Improvements in beam intensity, which should be possible for less chemically reactive elements, should allow the use of thinner targets and thus the measurement of excitation functions in finer steps.

The authors want to thank J. Truran (University of Chicago) for valuable discussions and J. Greene for his help with the target production and the thickness measurements.
