ABSTRACT

The J-integral fracture methodology was applied to evaluate the stability of postulated flaws in mild steel storage tanks. The material properties and the J-resistance ($J_R$) curve were obtained from the archival A285 Grade B carbon steel test data. The J-integral calculation is based on the center-cracked panel solution of Shih and Hutchinson (1976). A curvature correction was applied to account for the cylindrical shell configuration. A finite element analysis of an arbitrary flaw in the storage tank geometry demonstrated that the approximate solution is adequate.

INTRODUCTION

Mild steel storage tanks are widely used in the petrochemical and nuclear industry. The A285 Grade B carbon steel is one of the commonly used materials of construction in such tanks. A key element in assessing the fitness-for-service of aged mild steel storage tanks is the flaw stability analysis. In applications where the normal operating temperature of the tanks is 70°F and above, the material of construction (A285 Grade B carbon steel) falls in the upper transition region where ductile crack growth occurs. The most appropriate fracture mechanics methodology to evaluate such structures is the J-integral based elastic-plastic fracture analysis in which stable tearing is taken into consideration. This approach best represents the actual material behavior. This paper presents the J-T flaw stability methodology and the results of the analyses, where $T$ is the tearing modulus.

The analyses utilize the comprehensive materials property database for A285 carbon steel. The mechanical and fracture properties including the effect of age related degradation on the properties have been assimilated and discussed by Sindelar, Lam, Caskey, and Woo (1999). The flaw stability evaluation for the mild steel storage tank presented in this paper utilizes the lower bound $J_R$ curve from the above referenced paper. This lower bound curve is considered to provide a conservative analysis when applied to tanks where the minimum operating temperature is higher than the test temperature of 40°F. Both temperatures are within the regime where crack extension is stable, crack advance proceeds by ductile tearing, and where toughness or resistance to ductile crack propagation increases as the temperature rises. Therefore, fracture resistance at the tank operating temperature would be greater than that obtained at 40°F.

The analytical solution for a center-cracked panel developed by Shin and Hutchinson (1976) was primarily used to evaluate the J-integral values under applied load. The J-integral calculation and curvature correction procedure developed by Lam, Sindelar, and Awadalla (1993) was used to account for the tank geometry. The stress intensity factor due to residual stress was also included. The J-integral value at which flaw instability occurs is taken from the lower bound specimen data for $J_R$ curve when the crack extension reached 1.5 millimeters and was well within the stable growth regime. The instability crack length corresponding to this critical J value versus applied load can therefore be obtained.

A finite element analysis for an arbitrary flaw in tank geometry has been performed. The analysis demonstrated that the center-cracked panel solution is adequate for the flaw stability analysis of this type of mild steel storage tanks.

J-T FLAW STABILITY METHODOLOGY

J-T Analysis of Flaw Stability

The tearing stability of the material is characterized by the tearing modulus ($T$), which is defined by:
where $J$ is the value of $J$-integral, $\sigma$ can be the 0.2% yield stress, $E$ is the Young’s modulus, and $da$ is an incremental crack extension. Instability flaw lengths are based on the loading conditions and calculated stresses and are determined by an elastic-plastic $J$-integral or $J$-$T$ analysis. The crack growth ($J \geq J_c$) is stable if $T < T_R$, where $T_R$ is the tearing modulus of the material. As schematically shown in Figure 1, the intersection point of the applied $J$-$T$ curve and the material $J$-$T$ curve will determine the crack growth stability limit.

![FIGURE 1 – J-T METHODOLOGY FOR INSTABILITY CRACK LENGTH](image)

**Development of Material J-T for Flaw Stability Analysis**

The $J_R$ curves were developed from the 0.4C(T) fracture toughness tests of the A285 (Sindelar et al., 1999). A lower bound $J_R$ curve for A285 compact tension specimen tests is shown in Figure 2. The material $J_R$ curve was obtained from a power law fit to the experimental data:

$$J = C(\Delta a)^n$$

where $\Delta a$ is the crack extension. The material parameters $C$ and $n$ are determined through curve fitting. For this lower bound curve in Figure 2, $C = 328.1$ and $n = 0.6578$. It should be noted that the last data point represents the termination of the compact tension test, rather than the rupture failure of the specimen. The power law formulation of the $J(\Delta a)$ obtained from material testing can be plotted with its tearing modulus, $T(\Delta a)$, to produce the material $J$-$T$ curve.

![FIGURE 2 - LOWER BOUND J_R CURVE FOR A285 CARBON STEEL PIPING MATERIAL](image)

**Determination of $J$-$\Delta a$ Cut-off for $J$-controlled Growth in C(T) Specimens**

Stable crack growth occurs under conditions where additional deformation is needed to maintain the appropriate level of strain concentration at the crack tip (Hutchinson and Paris, 1979). The $J$-integral is an appropriate parameter for characterizing crack growth provided increments in the strain field that are proportional to applied load are greater than increments which are nonproportional to the applied load. These conditions may be expressed as,

$$(\Delta J/\Delta a)(b/J) \equiv \omega > > 1,$$

where $b$ is the uncracked ligament size.

Crack extension in C(T) specimens generally limits (in ASTM standards E399, E813, and E1152) the region of the plastically blunted crack tip in relation to the in-plane dimension of the specimen (remaining ligament). Tough materials (large $J$ value) such as austenitic stainless steels or carbon steels do not generally meet the criteria when tested above the nil-ductility transition temperature (NDTT) for small planforms. Data at high crack extension from these specimens can be applied in elastic-plastic fracture analyses if $J$-controlled growth can be established.

A program to measure the fracture toughness of austenitic stainless steel was completed in the early 1990’s. Test results from the program can be applied to evaluate $J$-controlled growth in the 0.394T planform specimen from the carbon steel test program. The measurement of an austenitic stainless steel specimen in both the large planform (0.394X1T, the width of the specimen is 2 inches measured from the load line to the back face of the specimen) and small planform (0.394T, the width of the specimen is 0.788 inches measured from the load line to the back face of the specimen) allows a direct comparison of $J$ (deformation theory) versus crack extension. Deviation of the small specimen $J_R$ curve from the large specimen curve would indicate the point ($\Delta a$) at which the toughness (defined by the deformation theory) is changing due to size effects. It was found that the $J$ values from the small planform deviate markedly from the large planform values at crack extensions greater than 3 millimeters. Above this point, the $J$ values from the small planform specimen are lower (conservative) compared to the large planform results. The point of deviation between the large and small planform results is suggested to indicate the limit of validity of $J$ deformation theory for the 0.4T planform specimen. For the lower bound carbon steel specimen (Fig. 2), the value of the $\omega$ factor is 1.5 at 3-millimeter crack extension for this 0.4T planform. Note that the value of $\omega$ is significantly less than the proposed value ($\omega > > 1$).

In some applications including the present case, the material J-T curve does not intersect with the applied J-T curve, unless the material J-T curve is extrapolated extensively. Under these circumstances, a cut-off J value is conservatively used (rather than extrapolation) to determine the instability crack length. Therefore, in the current flaw stability analysis, a cut-off J-integral value as shown in Figure 2 is taken as 450 kJ/m² which corresponds to a crack extension at about 1.5 millimeters in a 0.4T planform (Sindelar et al., 1999).
The Ramberg-Osgood power law for stress and strain can be expressed as \( \varepsilon = \frac{\sigma}{\sigma_0} + \alpha \left( \frac{\sigma}{\sigma_0} \right)^n \), where \( \sigma_0 \) is the 0.2% yield stress and \( \varepsilon_0 \) is the corresponding elastic strain. Figure 3 shows a uniaxial tension test result for a specimen representing a material property lower bound, based on its \( J_0 \) curve and \( J_c \) value (Fig. 2). The true stress-true strain curve is characterized with \( \alpha=17.176 \) and \( n=3.585 \) (Sindelar, et al., 1999).

\[ \sigma = \frac{P}{\varepsilon_0} \left( 1 - \frac{a}{b} \right) = \frac{2b - a}{b - a_{eff}}. \]

Note that the total J-integral can be composed of two parts, the elastic portion (\( J_{el}^{pl} \)) and a plastic portion (\( J_{pl}^{pl} \)). Therefore,

\[ J_{el}^{pl} = \psi \sigma \varepsilon_0 \left( \frac{P}{P_o} \right)^{\frac{a_{eff}}{b}} \left( \frac{a_{eff}}{b} \right)^{n-1} \]

\[ J_{pl}^{pl} = \alpha \sigma \varepsilon_0 \left( \frac{P}{P_o} \right)^{\frac{a}{b}} \left( \frac{a}{b} \right)^{n-1} \]

where \( a \) is the half crack length, \( b \) is the half specimen width, \( \varepsilon_0 = \sigma_0 / E \),

\[ a_{eff} = a + \phi \varepsilon_0, \quad P \leq P_o \] (Kumar and Shih, 1980),

\[ a_{eff} = (a_{eff})_{ref}, \quad P > P_o \]

\[ \phi = \frac{1}{1 + \left( \psi / \alpha \right)^n} \]

\[ P_o = 2(b-a)\sigma_0 \] is the lower bound limit load.

\( P = 2b\sigma^* \) is the applied load corresponding to a remote stress \( \sigma^* \).

\[ r_y = \frac{1}{2\pi} \left( \frac{n - 1}{n + 1} \right) \left( \frac{K}{\sigma_o} \right)^2 = \frac{a}{2\pi} \left( \frac{n - 1}{n + 1} \right) \left( \frac{P}{P_o} \right)^2 \frac{g_1(b, 1)}{g_1(a, 1)} \]

for plane stress.

\[ \psi = \frac{a_{eff}}{b - a_{eff}}. \]

and

\[ g_1 \left( \frac{a}{b} \right) = \pi \left[ 1 - 0.5 \frac{a}{b} - 0.37 \left( \frac{a}{b} \right)^2 - 0.044 \left( \frac{a}{b} \right)^3 \right]. \]

For this material, the values for \( g_1(a/b, n=3.585) \) can be calculated according the procedure outlined in Shih and Hutchinson (1976):

- \( a/b \)
- \( g_1(a/b, n=3.585) \)
- 0: 6.133
- 1/8: 4.152
- 1/4: 3.156
- 1/2: 1.984
- 3/4: 1.385
- 1: 0.916

A simpler solution for an infinite plate can also be found in Shih and Hutchinson (1976). That solution is also adequate for this type of large tank geometry (the radius to thickness ratio is greater than 800).

**Curvature Correction**

This analytic solution (\( J_{pl}^{pl} \)) provides a basis for constructing an approximate solution (\( J_{cur}^{pl} \)) for the sidewall of a storage tank by the application of a curvature correction factor (Lam, Sindelar, and Awadalla, 1993). The correction factors (\( Y \)) can be derived from a linear elastic stress intensity factor (K) solution of Tada, Paris, and Irwin (1973). Assumptions have been made: 1) The correction factor for J-integral is \( Y \) since elastic J-integral is proportional to \( K \); and 2) Same correction factor is applied to the elastic portion of J-integral as well as to its plastic portion (\( J_{el}^{pl} = Y J_{el}^{pl} \) and \( J_{pl}^{pl} = Y J_{pl}^{pl} \)).

For an axial flaw opened by a hoop stress(\( \sigma_h \)), the stress intensity factor for a crack with length \( 2a \) in a cylinder with mean radius \( R \) and thickness \( t \) is (Tada et al. 1973)

\[ K_1 = \sigma_h \sqrt{\pi a} Y_1(\lambda), \text{ where } \lambda = \frac{R}{t}. \]

Therefore, the correction factor for an axial crack is

\[ Y_1(\lambda) = \sqrt{1 + 1.25 \lambda^2} \text{ for } 0 < \lambda < 1 \text{ or } Y_1(\lambda) = 0.6 + 0.9 \lambda, \text{ for } 1 < \lambda < 5. \]

For a circumferential crack with length \( 2a \) or angle \( \theta \) subjected to a longitudinal stress \( \sigma_l \), the stress intensity factors are (Tada et al. 1973)

\[ K_1 = \sigma_l \sqrt{\pi R} Y_2(\lambda \text{ or } \theta), \text{ where } \]

\[ Y_2(\lambda) = \sqrt{1 + 0.3225 \lambda^2} \text{ for } 0 < \lambda < 1, \]

\[ Y_2(\lambda) = 0.9 + 0.25 \lambda, \text{ for } 1 < \lambda < 5, \]

and
\[
Y_2(\theta) = \sqrt{\frac{\pi}{\lambda}} f(\theta), \text{ for } \lambda > 5,
\]
in which
\[
\eta^2 = \frac{t}{\sqrt{12 (1 - \nu^2)}}
\]
and
\[
f(\theta) = \theta + \frac{1 - \theta \cot \theta}{2 \cot \theta + \sqrt{2 \cot (\theta/2)}}
\]

**Procedure of Combining J-integral Solutions**

(1) For a given applied remote stress, calculate the CCP solution of Shih and Hutchinson for various crack lengths. The J-integral \((J_{\text{ccp}})\) is composed of an elastic portion \((J_{\text{el, ccp}})\) and a plastic portion \((J_{\text{pl, ccp}})\), that is, \(J_{\text{ccp}} = J_{\text{el, ccp}} + J_{\text{pl, ccp}}\).

(2) The plastic zone size correction (or small scale yielding correction) is applied to \(J_{\text{el, ccp}}\) (Kumar and Shih, 1980).

(3) The CCP plate solution is corrected for the curvature of the shell or cylindrical structure. The approximated J-integral values for the tank shell \((J_{\text{el, cur}}\) and \(J_{\text{pl, cur}}\)) are
\[
J_{\text{el, cur}} = Y_2 J_{\text{el, ccp}} \quad \text{and} \quad J_{\text{pl, cur}} = Y_2 J_{\text{pl, ccp}},
\]
respectively.

(4) The contributions of fracture parameters from the other sources, such as thermal stress or residual stress, can be combined in the sense of linear elastic fracture mechanics. The elastic portion of J-integral \((J_{\text{el, cur}})\) in (4) above is first converted to \(K_{I, \text{appl}}\), the Mode I stress intensity factor due to applied load:
\[
K_{I, \text{appl}} = E \sqrt{J_{\text{el, cur}}}, \text{ for the plane stress condition.}
\]

(5) A residual stress contribution can be included in the J-integral solution using the formula advanced by Green and Knowles (1994). The residual stress distribution is a self-equilibrium, symmetric pattern with maximum tension (+\(\sigma\)) on the edges and maximum compression (-\(\sigma\)) in the mid-section of the plate. The through-thickness variation from tension-compression-tension is assumed to be a cosine shape. The \(\sigma\) value is taken to be the yield stress of the base metal. The maximum stress intensity factor is \(K_{I, \text{max}} = 0.43 \sigma \sqrt{\pi t}\). Note that \(K_{I, \text{res}}\) is saturated to a maximum value when the crack is extended in length only a fraction of the plate thickness. Therefore, the residual stress of this type is not subject to curvature correction.

(6) The total elastic portion of J is calculated as
\[
J_{\text{el}} = \frac{1}{E} K_{I, \text{appl}}^2 + K_{I, \text{max}}^2.
\]

(7) The plastic portion of J remains unchanged, that is, \(J_{\text{pl}} = J_{\text{pl, cur}}\).

(8) Finally, the total J-integral of the crack is \(J = J_{\text{el}} + J_{\text{pl}}\).

Based on the calculation procedure described above, the instability crack length as a function of applied stress is shown in Figure 4. The remote applied stress is perpendicular to the crack and is up to the yield stress of the material (256 MPa or 37.1 ksi). Both solutions for an axial crack (2b is the height of the storage tank) and for a circumferential crack (2b is the circumference of the storage tank) are presented.

**FINITE ELEMENT ANALYSIS OF AN ARBITRARY FLAW IN A STORAGE TANK**

As a demonstration of the J-Integral fracture methodology applied to a flaw in a tank and to validate the application of the CCP solution to the tank configuration, a finite element analysis was performed for an arbitrary flaw in storage tank geometry. This flaw has an arc length of about 16 inches (the projection length is about 13 inches perpendicular to the direction of the applied stress).

The finite element region was chosen such that the flaw is away from the edges of the model to minimize the boundary effects. The mesh shown in Figure 5 was generated with MSC/PATRAN (1996), a finite element analysis pre/post-processor. The near crack tip elements were refined for accurately evaluating the J-integral. In addition, it was designed for a potential crack extension analysis for the right-end crack tip.
This finite element model contains 2096 four-noded plane stress elements with 2192 nodes before the multi-point constraints are applied (for example, for zipping the nodes ahead of the crack tip in the direction of crack growth). The true stress-true strain curve is characterized by the Ramberg-Osgood power law. The mechanical properties for input to the finite element program are: The Young’s modulus is 208 GPa, the Poisson’s ratio is 0.333, the yield stress is 256 MPa, and the Ramberg-Osgood parameters $\alpha$ and $n$ are, respectively, 17.176 and 3.585 (Fig. 3).

The ABAQUS finite element program (1998) was used for the analysis. Because the radius to thickness ratio is extremely large (> 800), the curvature effect of the tank is then insignificant and the plane stress elements were used for calculation. The J-integral values were obtained at each load level up to the yield stress (256 MPa or 37.1 ksi) as shown in Figure 6. It can be seen that the cut-off J (450 kJ/m$^2$) corresponds to an applied stress level equal to 58% of the yield stress, or 150 MPa (22 ksi). This stress level is equivalent to an instability flaw size about 10-inch long according to Figure 4 which was based on CCP solution. This demonstrates that the CCP solutions are adequate for approximating J-integral solutions for a complex flaw configuration in storage tanks. Furthermore, it provides a methodology for assessing the fitness-for-service of the existing storage tanks for known loading conditions and safety margins.

![J-integral solution for an arbitrary crack](image)

**CONCLUSION**

Elastic-plastic fracture methodology based on J-integral was used to investigate the flaw stability in mild steel storage tanks. Finite element analysis of an arbitrary flaw in tank geometry showed that the analytical solution for a center-cracked panel is appropriate and adequate. Because the material and the applied J-T curves do not intersect unless by extrapolation, a conservative, cut-off J value corresponding to 1.5-millimeter stable crack growth was used to define the instability crack length. The resulting relationship between the instability flaw size and the applied stress can be used to provide guidelines for assessing the fitness-for-service of existing storage tanks for known loading conditions and safety margins.
