Abstract

Effects of supersaturated excess vacancies on plastic deformation of Fe-Al were investigated by tensile testing at room temperature three different single crystals (Fe-33, 41 and 44mol.%Al). Critical resolved shear stresses (CRSSs) of slowly-cooled specimens (as-homogenized specimens) and well-annealed specimens (vacancy-eliminated specimens) were almost the same and did not show Al concentration dependence. On the other hand, the CRSS of vacancy-containing specimens (fast-cooled specimens) was significantly higher than that of the others, even for Fe-33mol.%Al, and showed strong Al concentration dependence. The fast-cooled specimens displayed serrated flow behavior during work-hardening at room temperature, and the serrated flow was more intensive at a higher Al composition. Deformation microstructures of Fe-44mol.%Al were examined by TEM, and it was found that dislocations in fast-cooled specimen were inhomogeneously distributed, suggesting jerky motion of slip dislocations. These dislocations were oriented along an unstable direction estimated from dislocation line tension. In addition, there were numerous dislocation loops. A dislocation mechanism of the

excess vacancy strengthening is discussed on the basis of the experimental results.

1. Introduction

It is well-known that excess vacancy strengthening is significant at low temperatures in Fe-Al, particularly in B2-FeAl. Special attention has been paid to this phenomenon since Nagpal and Baker reported the composition and cooling rate dependence of hardness in B2-FeAl [1]. This phenomenon was first reported by Rieu and Goux [2]. They revealed that B2-FeAl quenched rapidly from elevated temperatures retains a high concentration of thermal vacancies, and that the retained excess vacancies enhance hardness [2]. Since the excess vacancy concentration increases with increasing Al concentration, the strength of the iron aluminides exhibits strong composition dependence, if samples are subjected to the same thermal histories [1, 3 - 5]. Furthermore it has been found that there is a linear relationship between the hardness and the square root of vacancy concentration [4].

One of the remaining problems is how Fe-Al is strengthened by excess vacancies. Kimura and Maddin [6] reviewed vacancy strengthening in fcc metals and considered that the strengthening is caused by interaction of dislocations with "observable vacancy clusters" and by super-jog formation due to condensation of vacancies on dislocations. In the case of B2-FeAl, however, the excess vacancy strengthening is likely to occur by mechanism(s) different from that in fcc metals, because (i) FeAl does not exhibit age-hardening but rather softens [2, 3, 7], unlike fcc metals that are hardened primarily by aging rather than by quenching, and (ii) vacancy cluster defects such as prismatic dislocation loops and stacking fault tetrahedra are not usually observed in as-quenched FeAl, so called the observable vacancy clusters. There are a couple of exceptions to the latter, however. Crimp and Vedula [8] investigated the compressive properties of FeAl single crystals strengthened by excess vacancies at room temperature, and found that many dislocation loops are formed by deformation. Morris et al. [9] observed void formation, likely by vacancy agglomeration. Although the formation of these defects can be attributed to excess vacancies, the strengthening mechanism has not been understood yet.

In order to understand the strengthening mechanism(s), it is required to investigate plastic deformation of vacancy-strengthened Fe-Al in more detail. The purpose of this study is to obtain tensile properties of single crystals strengthened by excess vacancies. After deformation, post-mortem deformation microstructures are observed in a transmission electron microscope (TEM), and the strengthening mechanism is discussed.

2. Experimental details

The master Fe-Al alloy ingots were made by arc-melting in an argon atmosphere from 99.99% pure aluminum and iron. Single crystal rods of about 25 mm in diameter were grown from the master ingots by the Bridgman technique. Chemical analysis gave three single crystals of compositions, Fe-33, 41 and 44mol.%Al, respectively. Hereafter, the compositions are described as Fe-33Al, Fe-41Al and Fe-44Al throughout this paper. These crystals were homogenized at 1373 K for 48 h in vacuum, and then slowly cooled to room temperature at the rate of $5 \times 10^{-3} \text{ K} \cdot \text{s}^{-1}$. Oriented tensile specimens were cut from the homogenized crystals by an electro-discharging machine (EDM). The specimen shape and size are described in Fig. 1(a), and the tensile axis is shown in Fig. 1(b). A few specimens of the three single crystals were vacuum-sealed in silica tubes, and re-annealed at 1173 K for 1 h, and then fast cooled by taking the silica tubes out of the furnace. A few specimens of the three single crystals were further annealed at 698 K for 100 h in vacuum to eliminate supersaturated excess vacancies, and then furnace-cooled without controlling the cooling rate. As-homogenized tensile specimens are designated as "Specimen A", fast cooled ones as "Specimen B", and fully annealed ones at 698 K as "Specimen C". The thermal histories mentioned above are shown schematically in Fig. 2. Before tensile tests, specimen surfaces were mechanically polished and electropolished in a 10% perchloric acid-methanol solution at voltage of 10.5 V and temperature of about 248 K.

Tensile tests were conducted using an Instron 8562-type machine in a vacuum better than $2 \times 10^{-3} \text{ Pa}$ at room temperature. All load-displacement data were recorded in two ways with analogue and

digital signals. The displacement was measured with an extensometer equipped outside the furnace. An initial strain rate in the range of 1.6×10^{-2} to $1.6 \times 10^{-6} \text{ s}^{-1}$ was applied. Some specimens were strained to about 4 % at $1.6 \times 10^{-4} \text{ s}^{-1}$, and disks parallel to the $(\bar{1}01)$ plane were sectioned from them by EDM. Thin foils for TEM observation were produced by electropolishing these disks in a Struers Tenupol-3 in a 33 % nitric acid-methanol solution at 4 V and 248 K. TEM observation was performed in a Hitachi H-8100D electron microscope at 200 kV.

3. Results

Figure 3 shows resolved shear stress - strain curves of the three specimens deformed at $1.6 \times 10^{-4} \text{ s}^{-1}$. All of the specimens were deformed to failure. The resolved shear stresses and the shear strains are calculated assuming the $(\bar{1}01)[111]$ primary slip system, which is the most reasonable one according to earlier work [8, 10, 11]. All the as-homogenized and vacancy-eliminated specimens (Specimens A and C) start to work harden immediately after yielding (i.e., no yield-drop). This work-hardening rates gradually accelerate with strain, and merge into a linear stage (stage II). The plastic flow behavior of fast-cooled specimens (Specimens B) is distinctly different from that of Specimens A and C. The CRSSs are increased by fast cooling even in Fe-33Al. However, elongation is reduced significantly, at higher Al concentrations. It should be noted that Specimens B display serrated flow after a discontinuous yielding followed by distinct work-hardening. In Fe-41 and 44Al, this serrated flow behavior continues until the specimens failed, and is more pronounced at the higher Al concentration, as shown in Fig. 4. It is believed that all these differences in Specimens B are attributed to excess vacancies retained by fast-cooling.

Figure 5 shows the variation of CRSS at the strain rate of $1.6 \times 10^{-4} \text{ s}^{-1}$ with Al concentration. While the CRSSs of Specimens C are slightly lower than those of Specimens A, they are essentially independent of Al concentration. On the other hand, the CRSS of Specimens B shows a strong dependence on Al concentration. The difference between CRSS of Specimen B and others is significant

(~50%) at 33mol.%Al. Moreover, the CRSS is nearly four times higher than that of Specimens A and C at 44mol.%Al. These results are in agreement with the Vickers hardnesses reported in previous papers [1, 3 - 5].

Figure 6 shows the variation of work-hardening rate in stage II against Al concentration, at a strain rate of $1.6 \times 10^{-4} \text{ s}^{-1}$. At 33mol.%Al, the work-hardening rate is almost the same in the three Specimens. In the B2 region, the work-hardening rates of Specimens A and C are also almost the same but higher than Fe-33Al. On the other hand, the work-hardening rate of Specimens B is distinctly lower than the others. In particular, the value of Fe-44Al is smaller than that of Fe-41Al. The decrease in work-hardening rate due to excess vacancies was also reported in the earlier studies that were carried out using single crystals under compression [12, 13].

Effects of strain rate on tensile flow properties were also examined. Figure 7 shows resolved shear stress-strain curves of Specimens A and C of Fe-41Al obtained by strain-rate change tests. The initial nominal strain rate is $1.6 \times 10^{-4} \text{ s}^{-1}$. The upward arrows correspond to a ten-fold increase of the cross-head speed (i.e. $\dot{\epsilon} = 1.6 \times 10^{-4} \text{ s}^{-1} \rightarrow 1.6 \times 10^{-5} \text{ s}^{-1}$), and the downward arrows correspond to a ten-fold decrease (i.e. $\dot{\epsilon} = 1.6 \times 10^{-5} \text{ s}^{-1} \rightarrow 1.6 \times 10^{-4} \text{ s}^{-1}$). The dotted curve is the resolved shear stress-strain plot of Specimen C obtained in a normal tensile test without a strain-rate change. When the strain-rate is decreased at the shear strain of 0.05, the flow stress is slightly decreased initially, but it immediately begins to restore itself to give a steady work-hardening. However, by comparing the curve obtained by the strain-rate change test with the dotted curve of Specimen C, it is seen that the incremental rate of increase in flow stress is raised only by the ten-fold decrease of strain-rate. When the strain-rate is increased, the flow stresses show a transient increase, followed by the same work-hardening rate as of the specimen under the constant strain rate (i.e., $\dot{\epsilon} = 1.6 \times 10^{-4} \text{ s}^{-1}$ for the dotted curve). These flow stress changes are observed repeatedly every time the strain-rate is altered. As a result, the flow stress of Specimen C gradually becomes higher as the strain increases. The same trends are seen also in Specimen A. This increase in flow stress by the decrease in strain-rate means a negative strain rate dependence of work-hardening rate.

Figure 8 shows highly magnified resolved shear stress-strain curves of Specimens B of Fe-41Al (Fig. 8(a)) and 44Al (Fig. 8(b)) obtained by strain-rate change tests. The upward and downward arrows have the same meanings as those in Fig. 7. In Specimens B, the transients in flow stress changes are not evident. Furthermore, no apparent change of serrated flow behavior is detected by strain-rate changes. As in Specimens A and C, a negative strain-rate dependence of work-hardening is found in Specimens B.

Figures 9 and 10 show deformation microstructures of Specimens A and B of Fe-44Al strained to about 4 %. The Burgers vectors of dislocations in both the microstructures were identified as $\mathbf{b} = [111]$. The deformation microstructure shown in Fig. 10 is clearly different from that in Fig. 9, where the latter shows no specific predominant dislocation orientations similar to those of slowly-cooled B2 FeAl reported in earlier studies [8, 11, 14]. In Fig. 10, dislocations are inhomogeneously distributed in bundles, and the dislocation bundles are preferentially oriented along a direction about 56° from the $[111]$ direction. In addition, there are numerous nano-size dislocation loops having the Burgers vector parallel to the $[111]$ direction. This inhomogeneous dislocation distribution suggests jerky motion of those dislocations during deformation, which is consistent with the appearance of serrated flow.

4. Discussion

4. 1. Yield Stress

Using positron lifetime spectroscopy, Würschum et al. [15] determined the effective enthalpy for vacancy formation to be $H_v^F = 1.04$ eV and 0.98 eV for Fe-37Al and Fe-39Al, respectively, and estimated the effective enthalpy for vacancy migration to be $H_v^M = 1.7$ eV for both compositions. The anomalous increase in yield stress of B2-FeAl with increasing temperature is attributed directly to thermal vacancies [16], and a complex of a vacancy on the Fe-site and a neighboring Fe antisite atom on the Al-site is suggested as the defect type responsible for the internal friction peak observed in FeAl [17].

In addition, divacancies are expected to play an important role in the interaction of dislocations

with vacancies in B2-FeAl [18]. By using the calculated divacancy binding enthalpy [18] of $H_{2V}^B = 0.5$ eV and assuming a divacancy binding entropy of $S_{2V}^B = 1 k_B$, it is estimated from the positron lifetime data [15] that $H_V^F = 0.89$ eV and $S_V^F = 4.2 k_B$, where k_B is the Boltzmann constant. These are slightly lower than those values mentioned in the prededing paragraph, which do not take divacancies into account [15]. Using the above values, equilibrium mono-vacancy concentration, c_V , defined as n_V/N , are given by,

$$c_V = \exp\left(\frac{S_V^F}{k_B}\right) \exp\left(-\frac{H_V^F}{k_B T}\right) \quad (1)$$

where n_V is the number of mono-vacancies, N the total number of lattice sites, and T the absolute temperature [19]. Equilibrium divacancy concentration, c_{2V} ($\equiv n_{2V}/N$, n_{2V} ; the number of divacancies), can be estimated by the following equation [19],

$$c_{2V} = g \cdot c_V^2 \cdot \exp\left(\frac{H_{2V}^B - TS_{2V}^B}{k_B T}\right) \quad (2)$$

where g is a divacancy configuration factor. In disordered alloys, $g = z/2$, where z is the coordination number of nearest neighbors. In B2-FeAl, thermal divacancies are formed between next-nearest neighbor sites [18, 20, 21], thus $z = 6$ is adopted. Consequently, using eqns. (1) and (2), the equilibrium concentration values are determined as: $c_V \approx 10^{-14}$ for mono-vacancy and $c_{2V} \approx 10^{-19}$ for divacancy at room temperature, and $c_V \approx 0.01$ and $c_{2V} \approx 0.016$ at 1173 K are estimated. These show that the equilibrium concentration of divacancy is higher than that of mono-vacancy at high temperatures (≥ 1073 K).

In B2 structure, the number of lattice sites in the unit volume, N_0 , is $2/a^3$ ($= 6\sqrt{3}/b^3$), thus the number of mono- or divacancies in the unit volume is $2c_{V \text{ or } 2V}/a^3$ ($= 6\sqrt{3}c_{V \text{ or } 2V}/b^3$), where a is the lattice constant, b the length of the Burgers vector. Considering the (110)[$\bar{1}11$] slip, since the interplanar spacing of the (110) plane is $a/\sqrt{2}$, the area of the (110) plane in the unit volume is $\sqrt{2}/a$. The total number of mono- and divacancies is $c = c_V + c_{2V} = 2c/a^3$ in the unit volume. Thus, neglecting the configuration and orientation of divacancies, the vacancy concentration on the (110) plane is $\sqrt{2}c/a^2$ ($=$

$3\sqrt{2}c/b^2$), and the mean distance between vacancies (or divacancies) on the (110) plane, $\bar{l}_0$, is

$$\bar{l}_0 = a/\sqrt{c\sqrt{2}} \quad (= b/\sqrt{3c\sqrt{2}}) \quad (3)$$

As an upper bound, when thermal vacancies at 1173 K are all frozen-in at room temperature, the activation volume of about $9b^3$ for dislocation motion is estimated using eqn. (3). This value is comparable to the activation volume of dislocation motion controlled by the Peierls potential at low temperature in bcc metals.

The critical shear stress required for a dislocation to break away from two obstacles was represented by Fleischer and Hibbard [22] and Friedel [23] as follows;

$$\tau = \frac{\mu b}{\bar{l}_0} \left(\sin \frac{\theta_c}{2} \right)^{\frac{3}{2}} \quad (4)$$

where μ is the shear modulus, and θ_c the critical angle for break-away from pinning points. Using eqn. (3), eqn. (4) is written as

$$\tau \equiv 2\mu \left(\sin \frac{\theta_c}{2} \right)^{\frac{3}{2}} c^{\frac{1}{2}} \quad (5)$$

If the break-away stress given by eqn. (5) is high enough, the stress estimated by eqn. (5) gives the CRSS for B2-FeAl. Eqn. (5) shows that the CRSS is proportional to the square-root of supersaturated vacancy (or divacancy) concentration. This relationship is consistent with that of hardness reported by Pike et al. [4, 5] and the vacancy hardening model at elevated temperatures reported by George and Baker [24].

The experimental results on the CRSSs or yield stresses shown in Figs. 3 and 5 are discussed with the aid of Figure 11 ($\mu = 64.8$ GPa [25, 26]), which shows the break-away stress from the equilibrium concentration of mono- and divacancies as a function of temperature. If one assumes the critical angle for mono-vacancies, to be $\theta_c^v = 5^\circ$, and the pinning force of divacancies is twice that of mono-vacancies, i.e., $F_{2v} = 2F_v$, the critical angle for divacancies is estimated to be $\theta_c^{2v} \approx 10^\circ$. Taking a hypothetical case of excess divacancies at room temperature, quenched-in from 1073 K by an 'infinitely

fast' cooling rate, to represent the fast-cooled Specimen B from 1173 K, the CRSS due to divacancies is estimated to be about 230 MPa. This value is in fair agreement with the experimental value interpolated at Fe-39Al of B2 phase in Fig. 5. In the meantime, the CRSS due to mono-vacancies at 1073 K is 78 MPa. Although the concentration of mono-vacancies ($c_v \approx 4.4 \times 10^{-3}$) is almost the same as that of divacancies ($c_{2v} \approx 4.8 \times 10^{-3}$) at the temperature, breaking away from mono-vacancies is not the rate controlling process in this case. The increase in the CRSS of Specimen B with increasing Al concentration (Fig. 5) is consistent with the decreasing trend of vacancy formation enthalpy found with increasing Al content [15].

4. 2. Work-Hardening Rate

The negative strain-rate sensitivity of work-hardening observed in all three cases (A, B and C) of Fe-41Al and Fe-44Al (Figs. 7 and 8) indicates that the dominant mechanism of work-hardening is due to the interaction of dislocations of the primary $(\bar{1}01)[111]$ slip system with those of the other slip systems. Additionally, serrated flow observed during work-hardening of the fast-cooled specimens suggest that the interaction of dislocations with vacancies and its clusters also contributes significantly to the work-hardening rate at room temperature.

While the elastic interaction between a $(\bar{1}01)[111]$ slip dislocation and a vacancy is attractive toward the compressive zone of the dislocation's pressure field, the dislocation interaction with a divacancy is expected to be anisotropic and relatively more complex because of the preferential alignment of two vacancies at the Fe-site along the $[100]$ direction [27]. Once these vacancies and divacancies in the matrix lattice make direct contacts with a dislocation, these will create jogs on the dislocation and may leave behind dipoles and loops. Therefore, as plastic deformation proceeds, the total number of 'vacant' sites is decreased and the dislocation density is increased. The decrease in work-hardening rate observed between Fe-41Al and Fe-44Al (Fig. 6) suggests that there may be an optimum supersaturation of vacant sites that give rise to the maximum work-hardening.

4. 3. Dislocation Microstructure

According to the earlier analysis of dislocation line tension in elastically anisotropic FeAl [28], the dislocation line of $[111]$ Burgers vector lying on the $(\bar{1}01)$ plane is unstable in the angular range of $47.5^\circ \pm 9.5^\circ$ from the $[111]$ direction. Almost all dislocations in as-homogenized Specimen A (Fig. 9) are out of the unstable range, meaning that the dislocations are arranged along elastically stable orientations. In contrast, however, dislocations in fast-cooled Specimen B (Fig. 10) are preferentially aligned along a direction which makes about 56° from the $[111]$ axis. This is just about 1° within the unstable angular range for a glide loop.

As a large number of vacancies and divacancies are absorbed into a slip dislocation and migrate along the dislocation core by a pipe-diffusion mechanism, a distribution of jogs accumulated along the dislocation will take up a configuration such that the total energy (the elastic line and interaction energies and the core energy) is decreased. In other words, while a perfect glide dislocation of the $(\bar{1}01)[111]$ slip system is unstable at the 56° orientation, the climb component of this dislocation makes the post-mortem TEM result of Fig. 10 a metastable inhomogeneous microstructure, which can be related to the serrated-flow behavior observed in fast-cooled Specimen B. When such a dislocation breaks away from jogs and superjogs under an applied stress, dipoles and loops are created behind the moving dislocation, which will in turn contribute to the work-hardening by dislocation-loop interaction.

5. Conclusions

In this work, the effect of excess vacancies on the room temperature tensile properties of Fe-33, 41 and 44mol.%Al was investigated using single crystals.

1. Significant excess vacancy strengthening was detected over the aluminum composition examined, even in Fe-33mol.%Al. Due to the excess vacancy strengthening, CRSS is increased drastically and

elongation is decreased.

2. Dislocation motion obstructed by excess vacancies is interpreted by the break-away process. In fast-cooled specimen, in which the supersaturation of divacancies is comparable to that of mono-vacancies, dislocation-divacancies interaction plays an important part of the strengthening mechanism.
3. The iron aluminides strengthened by excess vacancies exhibit serrated flow during work hardening. In B2 FeAl, work hardening rate is lowered by excess vacancies.
4. Dislocations microstructure in Fe-44mol.%Al were arranged inhomogeneously in the form of bundle structures. Mixed character is predominant in this microstructure, which is in the unstable range of the dislocation line orientation estimated by the anisotropic line-tension calculation.

Fig. 9. Deformation microstructure of as-homogenized Fe-44mol.%Al single crystal (Specimen A) strained up to about 4%. It was taken in g -3 g weak-beam condition with $g = 121$. The incident beam direction and the normal of the thin foil plane is almost parallel to the $[\bar{1}01]$ direction.

Fig. 10. Deformation microstructure of fast-cooled Fe-44mol.%Al single crystal (Specimen B) strained up to about 4%. It was taken in g -3 g weak-beam condition with $g = 121$. The incident beam direction and the normal of the thin foil plane is almost parallel to the $[\bar{1}01]$ direction.

Fig. 11. Break away stress from the equilibrium concentration of mono- and divacancies as a function of temperature.
