SUMMARY

The current BNFL Inc. flow sheet for pretreating Hanford High-Level tank wastes includes the use of Superlig® 639 (SL-639) in a dual column system for removing technetium-99 (^{99}Tc) from the aqueous fraction of the waste. This sorbent material has been developed and supplied by IBC Advanced Technologies, Inc., American Fork, UT. This report documents the results of testing the SL-639 sorbent with diluted waste ($[\text{Na}^+] \approx 5 \text{ M}$) from Tank 241-AN-107 (an Envelope C waste, abbreviated AN-107) at Battelle Northwest Laboratories (BNW).

The equilibrium behavior was assessed with batch contacts between the sorbent and the waste. Two AN-107 samples were used: 1) an archived sample from previous testing and 2) a more recent sample collected specifically for BNFL. A portion of the archive sample and all of the BNFL sample were treated to remove Sr-90 and transuranic elements (TRU). All samples had also been Cs decontaminated by ion exchange (IX), and were spiked with a technetium-95m ($^{95\text{m}}\text{Tc}$) pertechnetate tracer, $^{95\text{m}}\text{TcO}_4^-$. The TcO_4^- and total Tc K_d values, assumed equal to the $^{95\text{m}}\text{Tc}$ and ^{99}Tc K_d 's, respectively, are shown in Table S1. Values are averages of duplicates, which showed significant scatter. The total Tc K_d for the BNFL sample is much lower than the TcO_4^- K_d , indicating that a large fraction of the ^{99}Tc is not pertechnetate.

Table S1. TcO_4^- and Total Tc K_d Values

Sample	Feed conditions	TcO_4^- K_d (mL/g)/ % Removal (1)	Total Tc K_d (mL/g)/ % Removal (2)
Archive AN-107 (3)	Na = 5.70 M Density = 1.256 g/mL ^{99}Tc = 55 $\mu\text{Ci/L}$ (3.2 mg/L) $\text{NO}_3/\text{Tc} = 6.8 \times 10^4$	350 / 75%	Not Determined
Treated Archive AN-107	Na = 4.70 M Density = 1.226 g/mL ^{99}Tc = 48 $\mu\text{Ci/L}$ (2.8 mg/L) $\text{NO}_3/\text{Tc} = 7.3 \times 10^4$	200 / 66%	Not Determined
BNFL AN-107 (Treated)	Na = 4.84 M Density = 1.241 g/mL ^{99}Tc = 57 $\mu\text{Ci/L}$ (3.3 mg/L) $\text{NO}_3/\text{Tc} = 5.4 \times 10^4$	500 / 80%	22 / 17%
1) Assumed equal to the $^{95\text{m}}\text{Tc}$ K_d . 2) Assumed equal to the ^{99}Tc K_d . 3) Archive and Treated Archive ^{99}Tc and NO_3/Tc estimated from Blanchard et al. (1997) and Hallen, Bredt, Brooks and Jagoda (2000)			

Small column testing was performed using a dual column system. The columns were arranged in series, and each contained a 4.7 mL bed, length/diameter = 6.0. The columns were used in a previous test, but the order was reversed. As a result of the previous test, the lead column at the start of this test was partially loaded and the lag column had been loaded and eluted to $\text{C}/\text{C}_0(^{99}\text{Tc}) = 1\%$. Approximately 0.8 L of the BNFL AN-107 sample was processed in this column test. A $^{95\text{m}}\text{TcO}_4^-$ tracer was used to follow the progress of the test. After elution of the first column with warm (53.5°C) de-ionized water, a second set of tests was performed to investigate the impact on subsequent loading of residual Tc on the column. A Tank AN-107 waste feed simulant and actual

Tank AN-107 waste feed were run through the eluted column to determine the amount of the residual ^{99}Tc that would bleed from the column, and to get an estimate of the fraction of extractable Tc in the waste.

A summary of performance measures from the small column tests is shown in Table S2. The λ value is the number of column volumes processed when C/C_0 reaches 50%, and is a measure of the effective capacity of the resin. The λ value for the $^{95m}\text{TcO}_4^-$ tracer is approximately half that observed in a previous test of Tank 241-AW-101 waste. The initial DF's for the $^{95m}\text{TcO}_4^-$ tracer for the 1st and 2nd columns were much lower than the corresponding values for AW-101 (180 and 433, respectively), reflecting the partial loading of the columns from the previous test.

Results for ^{99}Tc were dramatically different. The concentration of ^{99}Tc in the effluent during "loading" was the same as or higher than in the feed, indicating that ^{99}Tc was actually being eluted during this phase. Thus λ values could not be calculated, and the initial DF's were less than or equal to 1. Approximately 170 bed volumes of the diluted AN-107 feed was processed through the SL-639 columns. The initial ^{99}Tc C/C_0 for the lead column was approximately 144%, and dropped to 126% at the end of the run. The initial ^{99}Tc C/C_0 for the lag column was approximately 98%, and rose to 127% at the end of the run. The difference between the ^{99}Tc and $^{95m}\text{TcO}_4^-$ results is attributed to the high concentration of non-pertechnetate Tc in AN-107 feed. The concentration of ^{99}Tc in the effluent composite is 59.3 $\mu\text{Ci/L}$ (3.47 mg/L), almost 50% higher than the expected average maximum allowed concentration.

Table S2. Summary of Performance Measures from Small Column Tests

Feed	Column Effluent Sampled	Flow rate, BV/hr	λ		Comp DF, $^{95m}\text{TcO}_4^-$	Comp DF, ^{99}Tc	Initial DF	
			$^{95m}\text{TcO}_4^-$ Tracer	^{99}Tc			$^{95m}\text{TcO}_4^-$ Tracer	^{99}Tc
BNFL AN-107	Col 1	6.1	125	(Eluted)	NA	NA	9.9	0.7
BNFL AN-107	Col 2	6.1	NA	(Eluted)	22	0.96	74	1
AN-107 Unspiked Simulant	Col 1, Post-Elution	6.3	NA	NA	NA	NA	20 (rel. to AN-107)	48 (rel. to AN-107)
BNFL AN-107	Col 1, Post-Elution	6.1	NA	NA	NA	NA	19	1.3

Only the lead column was eluted. The peak ^{99}Tc concentration was 27 times the ^{99}Tc concentration in the feed, and was found in the 2nd bed volume. After this the elution proceeded very slowly, requiring 46 BV of eluant (DI water at 50°C) for the ^{99}Tc concentration to drop to $C/C_0 = 0.05$. Tank AN-107 waste feed simulant containing no Tc was subsequently passed through the eluted column. The levels of ^{99}Tc and ^{95m}Tc found in the effluent were 2.5% and 5%, respectively, of that in the actual feed. Actual AN-107 waste feed was then passed through the column, and the ^{99}Tc was found to immediately break through with a C/C_0 of almost 80%. The ^{95m}Tc tracer immediately broke through with an initial C/C_0 of about 5%. Washing of the loaded columns with 0.1 M NaOH was found to elute Tc slightly.

1.0 INTRODUCTION

The current BNFL Inc. flow sheet for pretreating Hanford High-Level tank wastes includes the use of Superlig® 639 (SL-639) in a dual column system for removing technetium-99 (^{99}Tc) from the aqueous fraction of the waste. This material has been developed and supplied by IBC Advanced Technologies, Inc., American Fork, UT.

This report documents the results of testing the SL-639 sorbent with Hanford tank waste samples from Tank 241-AN-107 (the 241 prefix, which is common to all Hanford tanks, will not be used hereafter). Batch contacts were performed with small samples to assess equilibrium behavior and to plan small column tests. A 0.8 L sample of diluted waste (@ 4.8 M Na) was processed in a small column test. The samples had been previously treated to reduce the concentrations of Sr-90 and transuranic (TRU) components and filtered to remove particulates (Hallen, Brooks and Jagoda, 2000; Hallen, Bredt, Brooks and Jagoda, 2000), and processed by IX to remove cesium-137 (Kurath et al., 2000). The Tc removal process steps tested include loading, feed displacement, water rinse, elution, resin regeneration, and subsequent reloading of the eluted column. The Tc removal column system was used in a previous test of Tc removal from Tank AW-101 waste (Envelope A; Blanchard, Kurath and Bontha, 2000); the lead column in this test was already partially loaded from the previous test.

Most of the ^{99}Tc in the liquid fraction of Hanford tank wastes is expected to be present as the pertechnetate anion (TcO_4^-). Analyses of candidate LAW Envelope A and B feed samples indicate that 95% (or greater) of the ^{99}Tc is indeed present as TcO_4^- . However, analyses of candidate LAW Envelope C feed samples (e.g., Tank 241-AN-102 and Tank 241-AN-107 samples) indicates that only 15% to 20% of the ^{99}Tc is present as the TcO_4^- . The BNFL Inc. Waste Treatment Plant (WTP) project uses a sorbent material that selectively removes the TcO_4^- from LAW solutions. Therefore, the amount of Tc separated from LAW Envelope A and B feeds can approach 95% and that from Envelope C feed only ~20%. In order to comply with the ILAW glass product acceptance criteria by averaging 80% removal of the Tc present in the feed, the amount of Envelope C processed by the WTP will be limited. Similarly, the ^{99}Tc concentration in the ILAW glasses produced from Envelope C solutions are expected to exceed 0.1 Ci/m^3 , but the average concentration of Envelope A, B, and C glasses together will be less than 0.1 Ci/m^3 .

The objectives of this work were to:

- Demonstrate the ^{99}Tc decontamination of Envelope C (Tank AN-107) and provide a technetium-decontaminated sample for downstream process testing (i.e. corrosion testing, Low Activity Waste (LAW) melter feed testing and LAW vitrification).
- Demonstrate the effectiveness of all SL-639 process steps including loading, feed displacement, DI water washing, elution, resin regeneration, and subsequent reloading.
- Obtain process performance data for SL-639 at conditions different than those previously tested.
- Obtain process performance data for loading of SL-639 by AN-107 waste following partial loading by AW-101 waste.
- Investigate sorbent/waste chemistry, particularly the differences in the interaction of TcO_4^- and non-pertechnetate Tc with the sorbent.
- Investigate the potential for exchanger fouling.

2.0 EXPERIMENTAL

2.1 Tc Removal Column System

A schematic of the Tc Removal column system is shown in Figure 2.1. The system, which is mounted in a radiological fume hood, consists of 2 small columns containing the sorbent resin, a small metering pump, 3 valves, a pressure gauge and a pressure relief valve. The pump inlet tube was manually switched between the waste feed and various process solutions. Valves 1, 2 and 3 are three-way valves that can be turned to a flow position, a sample position or a no-flow position. Valve 1 is placed at the outlet of the pump and is used to eliminate air from the system, purge the initial volume of the system or isolate the columns from the pump. Valves 2 and 3 are primarily used for obtaining samples and may also be used to isolate the columns from the rest of the system.

The columns are Kontes Chromaflex chromatography columns made of glass with adjustable plungers on the bottom and the top. The inside diameter of the columns is 1.0 cm which corresponds to a volume of 0.785 mL per cm of length. The columns are jacketed with a clear plastic to provide temperature regulation and a safety shield. The connecting tubing is a polyfluorinated plastic with 1/8-in OD and 1/16-in ID. The columns are connected in series with the first column referred to as the lead column and the second column referred to as the lag column. The pump is a FMI piston pump with the flow rate controlled from outside of the hood with a FMI stroke rate controller. The pump was calibrated with the stroke rate controller and can provide pumping rates of approximately 0.5-50 mL/hr. The volume actually pumped is determined using the mass of the fluid and the fluid density.

The pressure relief valve is set at 40 psi, which is below the maximum operating pressure for the columns. The pressure indicated on the pressure gauge remained below 5 psi during the run. The total holdup volume of the system was estimated to be 14 mL (3 BV) with the holdup volume to valve 1 being approximately 2 mL (0.4 BV). The columns were used in a previous test of Tc removal from AW-101 waste (Blanchard, Kurath and Bontha, 2000), but the order was reversed. As a result, the lead column at the start of this test was partially loaded and the lag column had been loaded and eluted to $C/C_0(^{99}\text{Tc}) = 1\%$, where C and C_0 are the concentrations of ^{99}Tc in the effluent and feed, respectively.

2.2 SL-639 Resin and Bed Preparation

The SL-639 resin was supplied by IBC Technologies Inc. (American Fork UT) from batch # 980624001DC. The resin consists of a proprietary organic compound (ligand) attached to spherical styrene beads. The mean diameter of the beads (D_p) is reported by the manufacturer as 0.5 mm. SL-639 functions by extracting the sodium pertechnetate salt-pair (NaTcO_4) from either acidic or basic solutions.

The resin was used for batch contacts with no pre-conditioning. The resin and beds were prepared for the column testing in the previous test of Tc removal from AW-101 (Blanchard, Kurath, and Bontha, 2000). The resin was slurried into the columns in DI water. The bed height was 6.0 cm, giving a bed volume of 4.7 mL, and a length-to-diameter ratio (L/D) of 6. The number of beads per column diameter (1 cm) is approximately 20:1, which is at the low end of the range (20–30) commonly assumed necessary to prevent wall effects during small-scale column testing. (The column size was chosen based on the bed size required for 50% breakthrough given the amount of sample available, and the desired L/D .) The columns were prepared for loading by flushing them with 14.4 BV (67.5 mL) of 1 M NaOH. This was done primarily to flush water from the beds to prevent precipitation of solids on introduction of the feed.

Figure 2.1. Technetium Removal Column System

2.3 Feed Preparation

The first set of batch contacts used a sample of waste from Tank AN-107 (Envelope C) archived after previous testing (Hendrickson et al., 1997). The original sample was removed from Tank AN-107 as a grab sample in January 1997. It was diluted with 0.53 M NaOH to approximately 5 M Na and 0.126 M OH. Particulates were allowed to settle, and the decantate was then Cs decontaminated using a crystalline silicotitanate ion exchanger, IE-911 (UOP). Details may be found in Hendrickson (1997). Several liters of this waste were received in six 1 L bottles in the Shielded Analytical Laboratory (SAL) at the Radiochemical Processing Laboratory (RPL) on May 23, 1997. Several of these bottles were loaded into the SAL hot cells later that summer for archival. This archived material was transferred to the High Level Radiochemistry Facility (HLRF) (also in the RPL) in July 1999, where the [OH⁻] of a subsample was adjusted to approximately 1 M. The subsample was then spiked with Sr(NO₃)₂ and NaMnO₄ to precipitate native Sr and TRU. Development of this Sr/TRU removal method is reported in Hallen, Bryan and Hoopes (2000), and treatment of the archived AN-107 is reported in Hallen, Brooks and Jagoda (2000). Portions of the untreated and treated samples were transferred to a radiological fume hood for batch contact testing. The untreated solution was opaque dark brown. The supernate of the treated sample was clear light brown, and a fine-grained black precipitate had settled to the bottom of the vial. Only the clear supernate was used for the contacts of the treated material. The "untreated archive AN-107" and "treated archive AN-107" samples referred to in this report are subsamples of samples MN-21 and MN-22, respectively, described in Hallen, Brooks and Jagoda, (2000).

Approximately 0.3 μ Ci of ^{95m}Tc ($t_{1/2}$ = 61 days, decays to stable ⁹⁵Mo) was added as ammonium pertechnetate (NH₄TcO₄) in 1 M ammonium hydroxide (NH₄OH) to each of the archive AN-107 samples to act as a tracer for following the removal of TcO₄⁻. A 10- μ L aliquot of the tracer solution was added to each 15 mL sample. The amounts of NH₄TcO₄ and NH₄OH added to the waste are not expected to significantly change the physical or chemical properties of the waste. The amount of ^{95m}Tc added to the waste (1.4E-10 moles) is small relative to the ⁹⁹Tc already in each 15 mL waste sample (approximately 4.8E-7 moles, based on data in Blanchard et al., 1997), and is not expected to change either the TcO₄⁻ K_d or the effective total Tc K_d. The additional ⁹⁵Mo produced by ^{95m}Tc decay is also not expected to change the waste properties. Batch contacts using these samples were performed September 27 - October 1, 1999.

A second sample of waste from Tank AN-107 (Envelope C) was received in the HLRF during the 4th quarter of 1998. The homogenization, dilution, and subsampling are described in Urie et al. (1999). This sample was processed to remove Sr-90 and TRU in September 1999 in the same fashion as the archive sample. The [OH⁻] of the sample was adjusted to approximately 1 M and it was spiked with Sr(NO₃)₂ and NaMnO₄ to precipitate native Sr and TRU. In addition, it was filtered in a single tube cross-flow filter to remove entrained solids using a 0.1 micron sintered metal Mott filter. A complete description may be found in Hallen, Bredt, Brooks and Jagoda (2000). The clarified AN-107 sample was then transferred from the HLRF to the SAL hot cells for Cs IX testing using Superlig® 644. Following Cs IX, described in Kurath et al. (2000), the feed was removed from the hot cell and transferred to a radiological hood containing the Tc removal column system.

A 100-mL aliquot of this feed was set aside, and then approximately 0.5 mCi of ^{95m}Tc was added to the remainder (approx. 1.5 L), to act as a tracer to follow the progress of TcO₄⁻ removal. The tracer was added as NH₄TcO₄ in 1 M NH₄OH. The amounts of NH₄TcO₄ and NH₄OH added to the waste (4E-5 g and 0.875 g) are not expected to significantly change the physical or chemical properties of the waste. The amount of ^{95m}Tc added to the waste (2.2E-05 g) is small relative to the ⁹⁹Tc already in the waste sample (8.4E-03g), and is not expected to change either the TcO₄⁻ K_d or the effective total

Tc K_d . The additional ^{95}Mo produced by decay is also not expected to change the waste properties. Batch contacts with this feed were performed November 8 - 12, 1999. Column tests with this feed were performed November 4 - 11, 1999. The feed is referred to in this report as the "BNFL sample" or "BNFL feed" or "Tc removal feed." The density of this feed was determined with a 25 mL volumetric flask and a 4-place analytical balance.

Based on previous work (Blanchard, Kurath and Bontha, 2000; Blanchard, Lawrence, Kurath and Golcar, 2000), the ^{95m}Tc pertechnetate tracer is expected to remain as TcO_4^- after addition to the waste samples, and not form ^{95m}Tc non-pertechnetate species. Because the amount of the ^{95m}Tc tracer added to the samples is very small relative to the amount of ^{99}Tc already present (less than $1/100^{\text{th}}$ for the archive samples and less than $1/1000^{\text{th}}$ for the BNFL sample) the added tracer is not expected to change the observed K_d 's. It acts only as an indicator of the TcO_4^- K_d .

2.4 Batch Contact Procedure

The batch K_d tests were performed at a phase ratio of approximately 100 (liquid volume to exchanger mass), with 0.05 g of exchanger contacted with 5 mL of solution. The exchanger mass was determined to an accuracy of 0.0001 g. The waste volume was transferred by pipette and the actual volume was determined from the mass difference (0.0001 g accuracy) and the solution density. Agitation was provided by a back-and-forth shaker set at 180 cpm for approximately 96 hours. The temperature was not controlled, and varied between approximately 22.5°C and 25.0°C over the course of the 4-day contacts.

The archive AN-107, treated archive AN-107, and BNFL AN-107 samples were tested. All K_d measurements were made in duplicate and blank samples were used to determine the initial concentration of the species of interest. All solutions were analyzed by gamma spectroscopy to determine the $^{95m}\text{TcO}_4^-$ concentrations and K_d 's. The ^{99}Tc concentrations in the BNFL samples were determined by Inductively Coupled Plasma-Mass Spectroscopy (ICP-MS). The concentrations of various components of the BNFL feed were determined as described in Section 2.5 below.

The batch distribution coefficient, K_d (with units of mL/g), was determined using the following relationship;

$$K_d = \frac{(C_0 - C_1) * V}{C_1 * M * F}$$

where C_0 and C_1 are the initial and final concentrations, respectively, of the species of interest (i.e., $^{95m}\text{TcO}_4^-$ and ^{99}Tc), V is the volume of the liquid sample (mL), M is the mass of resin used for the contact (g), and F is the mass of a sample of dried resin divided by its mass before drying. The resin was sampled for F factor determination at the same time resin samples for the contacts were tared in order to minimize changes due to atmospheric humidity.

2.5 Column Test Procedure and Conditions

The experimental conditions for each process step of the column test are shown in Table 2.1. In general the flow rates were maintained as close as possible to the recommended values but in some steps the total volume of the process solutions was increased in an attempt to ensure adequate flushing of the system, as for instance, in the column preparation with 1.0 M NaOH. Only the lead column was eluted. The bed preparation, loading, feed displacement and regeneration steps were conducted by passing these solutions through both resin beds connected in series. The DI water rinse,

elution and elution rinse were conducted on only the lead column, as were the follow-on tests to reload the eluted column.

Table 2.1. Experimental Conditions

Process step	Solution	Total Vol., BV (mL)	Flow Rate, BV/hr (mL/hr)	Time (hr)
Column prep	1.0 M NaOH	18 (83)	11 (50)	1.67
Loading	AN-107 Feed	170.5 (801.3)	6.1 (28.8)	28.1
Feed displacement	0.1 M NaOH	7.5 (35.1)	3.0 (14.0)	2.5
Rinse (Lead Column)	DI water	2.1 (9.7)	3.1 (14.5)	0.7
Elution (Lead Column)	DI water @ @ 53.5°C	46.1 (216.8)	1.0 (4.8)	45.7
Eluant rinse (Lead Column)	DI water	4.1 (19.2)	6.1 (28.9)	0.7
Regeneration	1.0 M NaOH	6.4 (30.2)	6.4 (30.2)	1.0
Simulant Loading (Lead Column)	AN-107 Simulant (No Tracer)	13.4 (62.8)	6.3 (29.4)	2.1
Feed Displacement (Lead Column)	0.1 M NaOH	4.9 (23.0)	3.7 (17.2)	1.3
Loading (Lead Column)	AN-107 Feed	29.8 (139.9)	6.1 (28.8)	4.9
Regeneration (Lead Column)	1.0 M NaOH	4.6 (21.8)	3.5 (16.4)	1.3

Elution was performed using DI water at 53.5°C. A recirculating water bath was used to circulate heated water through the column jacket, and the feed tube to the column was taped (approx. 12" length) to the much larger tube carrying warm water to the jacket. Although faster than in a previous test using room temperature 0.5 M nitric acid as the eluant, elution was still relatively slow. It was halted when C/C_0 for the $^{95m}\text{TcO}_4^-$ tracer reached 13%, instead of the target 1%, in order to limit the cost of the run, as per discussion with the BNFL Pretreatment Technical Manager (M.E. Johnson). To determine the extent to which the residual Tc on the column would affect the next loading cycle, simulant without the tracer was passed through the column after regeneration. The BNFL actual AN-107 feed (with tracer) was then passed through the column for the same reason and to assess the fraction of pertechnetate Tc.

The adjustable plungers at the top of each column were used to minimize the volume of solution above each of the resin beds. The bed volumes changed less than 0.2 cm (0.16 mL or 3.3 %) during the run. The height of liquid above the beds was kept to less than 0.5 cm (0.4 mL).

The sampling and analysis protocol is shown in Table 2.2. The $\text{TcO}_4^- C/C_0$ was determined in all samples by counting the ^{95m}Tc gamma emission at 205 KeV with a portable gamma spectrometer. The C/C_0 were determined by taking the ratio of the peak areas of the feed and the effluent samples. The feed sample was recounted periodically (at least every 24 hours) to minimize the effects of the ^{95m}Tc decay. This method allowed near real time analysis of the behavior of TcO_4^- in the samples. The

response time was limited by the rate at which samples could be removed from the hood. The ^{99}Tc activities were determined in selected samples by ICP-MS after the run was concluded. ICP was used to determine sodium and other elemental concentrations. Free hydroxide ion concentrations were determined by titration with standard hydrochloric acid solutions. Total inorganic carbon was determined by evolution of CO_2 from an acidified, heated sample, and total organic carbon was determined by evolution of CO_2 from the same sample after subsequent addition of persulfate with heating. A sample of the feed was analyzed for ^{99}Tc by ICP-MS, and for nitrate by IC. Data on other analytes collected during these analyses are also reported.

Table 2.2. Sampling Interval and Analyses

Process Step	Lead Column BV	Lag Column BV	Approx. Sample Vol. (mL)	Analyses
Column prep	-	-	-	-
Loading	Every 10 BV	Every 20 BV	2	ICP-MS
Feed displmt	-	Every 1 BV	5	ICP, ICP-MS, OH
DI water rinse	Every 1 BV	-	5	ICP, ICP-MS, OH
Elution	Every 1 BV	-	5	ICP-MS
Eluant rinse	Every 1 BV	-	5	ICP-MS
Regeneration	-	1 composite	30	ICP, ICP-MS, OH
Sim. Loading	Every 1 BV	-	5	ICP-MS
Feed displmt	Every 1 BV	-	5	ICP-MS
Loading	Every 1 BV	-	5	ICP-MS
Regeneration	Every 1 BV	-	5	ICP-MS
Composite Samples				
Effluent (Initial Loading)	-	1 composite	5	ICP-MS
Eluate	1 composite	-	22	ICP, TIC, TOC, OH ICP-MS, Radchem

During the loading phase, the treated effluent was collected in an effluent bottle except for the small (2 mL) samples that were taken. A composite sample from the effluent bottle was analyzed for ^{99}Tc by ICP-MS. The regenerate was collected in one 30 mL batch. A sample was analyzed for ^{99}Tc , Na and OH. The rest of the samples were collected in approximately 1 BV aliquots. A composite sample of the eluate was prepared and submitted for ICP-MS, ICP, TOC, TIC, OH and various radiochemical analyses (total alpha, Sr-90, GEA).

The λ value, which is the number of column volumes of feed processed when $C/C_0 = 50\%$, may be predicted from a batch contact K_d by the relationship $\lambda = K_d * \rho_B$, where ρ_B is the bed density of the resin in the waste. Since the SL-639 resin did not swell or shrink in any of the solutions processed, ρ_B is equal to its dry bed density, 0.49 g/mL (Kurath et al., 1999). The experimental λ values from breakthrough curves were determined from a linear fit of the breakthrough data plotted on a linear-linear scale. Initial DF's were calculated as C_0/C_1 , where C_1 is the concentration in the first sample collected from each column.

3.0 RESULTS AND DISCUSSION

3.1 Feed Composition

The compositions of the treated and untreated archive AN-107 samples used for batch contacts are shown in Table 3.1. A limited number of analyses were performed, as testing of these samples was primarily in preparation for testing the BNFL AN-107 sample. The ^{99}Tc concentration and the $\text{NO}_3^-/^{99}\text{Tc}$ mole ratio in the untreated archive sample are estimated from previous work with this material (Blanchard et al., 1997). The ^{99}Tc concentration and the $\text{NO}_3^-/^{99}\text{Tc}$ mole ratio in the treated archive sample are estimated based on dilution of, and addition of NO_3^- to, the untreated sample during treatment (Hallen, Brooks and Jagoda, 2000).

The composition of the BNFL Tc removal feed is also shown in Table 3.1. The concentrations of Na and Al were determined by ICP-AES and the values presented in Table 3.1 are averages of the analyses for the filtrate from the Sr/TRU removal process, cesium IX feed, Tc removal feed, Tc removal effluent and sulfate removal feed. The concentrations of K, Cr and P were also determined by ICP and are averages of analyses for the filtrate from the Sr/TRU removal process and the cesium IX feed. Anionic forms for Al, Cr and P are assumed on the basis of waste chemistry. Additional anion concentrations were determined by IC analyses of the feed and effluent for the Tc removal tests. This compilation is assumed valid since the non-radioactive cations and anions indicated are not greatly affected by the Cs and Tc removal processes. The hydroxide (OH^-) concentration is estimated based on data in Urie et al. (1999) corrected for chemical additions during the Sr/TRU precipitation. The feed had a light brown color that has been attributed to the presence of organic compounds. The ^{99}Tc concentration was determined by ICP-MS of the Tc removal feed. Data from individual analyses may be found in Appendix A, Kurath et al. (2000), and Hallen, Bredt, Brooks and Jagoda (2000).

The total anion normality, 4.62 N, is lower than the total cation normality, 4.86 N. This is probably mostly due to the presence of anionic complexants for which analyses were not performed. For example, previous analyses of an AN-107 tank waste grab sample (Campbell et al., 1998) indicate concentrations of acetate and formate of 0.13 mole/kg and 0.12 mole/kg, respectively. Data in the same report indicate concentrations of nitroso-iminodiacetate (NIDA), nitrilotriacetate (NTA), citrate, N-(2-hydroxyethyl)ethylenediaminetriacetate (HEDTA), ethylenediaminetriacetate (ED3A), and ethylenediaminetetraacetate (EDTA) ranging from 1.7×10^{-3} moles/kg (HEDTA) to 3.1×10^{-2} moles/kg (citrate). All of these complexants are expected to be in their anionic form in the waste, and carry full anionic charges of -2 to -4, resulting in normalities 2 to 4 times their observed molarities. The sum of the anionic normality of these species is 0.48 equivalents per kg waste. (See appendix for details.) Campbell et al. (1998) claim 86% of the TOC in the sample was accounted for by their analyses, so there may be more anionic complexants that were not discovered. The feed sample used in this study was treated with permanganate and diluted relative to the sample analyzed by Campbell et al. (1998), so a direct comparison is not appropriate, but the data indicate that the complexants and complexant fragments present in the waste represent a significant contribution to the anionic concentration.

Table 3.1. Composition of Envelope C (AN-107) Tc Removal Feeds

	Archive AN-107 (Untreated)	Treated Archive AN-107	BNFL AN-107 (Treated)
Cations, M			
Na ⁺	5.70	4.70	4.84

1) Determined by ICP. Anionic form is assumed on the basis of waste chemistry. 2) Estimated. See text. 3) Estimated using data from Blanchard et al. (1997) and Hallen, Brooks and Jagoda (2000). 4) N. D. indicates that the concentration of this analyte was not determined. 5) The raw analytical results may be found in the appendix.			

A series of analyses were also performed to determine the fraction of ⁹⁹Tc present as TcO₄⁻ in the archive sample, in the treated archive sample, and in the BNFL sample. The samples were prepared for counting of ⁹⁹Tc in three different ways: 1) extraction of TcO₄⁻ (no oxidation), 2) extraction of TcO₄⁻ following oxidation by Ce(IV)/8 M HNO₃/heating and 3) extraction of TcO₄⁻ following oxidation by potassium permanganate (KMnO₄). The procedures are given in more detail with the raw data in the appendix. Results are shown in Table 3.2.

The treated archive sample used for this analysis was processed differently than that used for the batch contacts. The target concentrations of OH⁻, Sr(NO₃)₂ and NaMnO₄ were slightly lower. Details may be found in Hallen, Brooks and Jagoda (2000). Results in Table 3.2 for the "Archive AN-107" are from the samples designated MR-01 and MR-02 in that report, except they were not acid digested prior to the

indicated analyses. MR-02 is the same as MR-01, but was filtered prior to analysis. Results were within error for these two samples, as well as for a duplicate of MR-01, so all three sets were averaged. Results for "Treated Archive AN-107" are from sample MR-03, prior to acid digestion. Note that MR-03 was diluted relative to the untreated archive samples, so the total Tc concentration should be lower, as observed. The difference is not completely accounted for by the dilution; the remaining Tc loss is probably due to precipitation of some of the non-pertechnetate Tc with the Sr and TRU. Radiochemical analysis of the precipitated solids for the archive sample was not performed, but analysis of precipitated solids from the BNFL AN-107 sample did show significant Tc-99 present (Hallen, Bredt, Brooks and Jagoda, 2000). The "BNFL AN-107" results are from a sample of the same material used for the batch contacts and the column test reported herein. The raw data for all samples may be found in the appendix.

Table 3.2. TcO_4^- and Total Tc Concentrations in Envelope C (AN-107) Tc Removal Feed

	Archive AN-107	Treated Archive AN-107	BNFL AN-107 (Treated)
TcO_4^- , $\mu\text{Ci/L}$ (No Oxidation)	16.5	17.4	13.0
Total Tc, $\mu\text{Ci/L}$ (Ce(IV) Oxidation)	53.0	43.5	36.3
TcO_4^- Percentage	31%	40%	36%
Total Tc, $\mu\text{Ci/L}$ (KMnO_4 Oxidation)	54.6	43.5	38.6
TcO_4^- Percentage	30%	40%	34%

Results using the two different oxidation methods are consistent. The absolute concentration of TcO_4^- in the treated archive sample is slightly higher than in the untreated sample, suggesting that some of the non-pertechnetate was oxidized to TcO_4^- by the permanganate added for the Sr/TRU precipitation. Combined with the apparent precipitation of non-pertechnetate Tc, the percentage of TcO_4^- increases significantly due to the treatment. The lower TcO_4^- percentage found in the (treated) BNFL AN-107 relative to the treated archive sample is consistent with the observation that the non-pertechnetate slowly converts to TcO_4^- if the sample is not located in a high radiation field (i.e., after removal from the tank; Schroeder, 2000). The archive sample was removed from Tank AN-107 approximately 18 months before the BNFL sample.

The total ^{99}Tc concentrations determined for the BNFL AN-107 sample by the two oxidation methods are approximately 34% lower than that determined by ICP-MS (57.1 $\mu\text{Ci/L}$; see Table 3.1 above). Recovery of a matrix spike added to duplicate samples was above 93% in all cases, so the discrepancy is evidently not due to losses during the analytical procedures. It's possible that even these vigorous oxidations did not recover all the ^{99}Tc . In a previous study, the same Ce(IV) oxidation recovered 82% of the Tc found by ICP-MS (Blanchard et al., 1997).

It's also possible that the concentration determined by ICP-MS is higher than the actual. This technique determines the mass of material at a given mass-to-charge ratio (m/z). Ruthenium-99 (^{99}Ru) is one of seven stable, naturally occurring Ru isotopes. If present, it will appear at the same m/z as ^{99}Tc . Examination of the mass spectrum indicated that there were some ruthenium (Ru) isotopes present, but they did not exhibit a natural abundance distribution, so they were assumed to be fission products. Since fission produces only a vanishingly small amount of stable ^{99}Ru , all signal at $m/z=99$ was assumed to be ^{99}Tc . If some natural Ru was present from impurities in another chemical added during processing,

however, there would be ^{99}Ru present that was counted as ^{99}Tc . An error in the ^{99}Tc activity due to this source is expected to be very small, but it allows us to assume that the activity determined this way is an upper bound to the total Tc present. If this higher value of the total Tc is used, the fraction of TcO_4^- present is calculated to be 23%. So taking the true value to be intermediate between this value and those given in Table 3.2, the fraction of TcO_4^- is given as $(29 \pm 10)\%$, where the error estimate is conservative.

3.2 Batch Contacts

Results of the batch contacts are shown in Table 3.3. (The complete data table may be found in the appendix.) The Sr/TRU precipitation used for the treated archive sample and the BNFL sample diluted the ^{99}Tc relative to the archive sample. The use of permanganate (MnO_4^-) for the precipitation is expected to have oxidized various organic and inorganic components. These changes are expected to result in different observed TcO_4^- K_d 's for the three different solutions. However, the relatively large differences between the archive duplicates and between the BNFL duplicates makes it difficult to discern these true differences. The large differences between duplicates are attributed to poor resin/solution contact. This would prevent true equilibrium, and is suspected because transfer of resin beads out of the liquid and onto the sides of the vials or inside of the caps has been previously observed when the resin floats in or on the solution.

At least some of the resin floated in all three solutions. The largest fraction of the resin floated in the treated archive sample, with almost all the resin beads at the surface and the remainder suspended in the liquid. In the untreated archive sample and the BNFL sample most of the resin was suspended in the liquid, with small amounts of resin at the bottom and at the surface. It is not clear why a greater percentage of the resin floated in the treated archive sample (density = 1.226) than in the untreated archive sample (density = 1.256) and the BNFL AN-107 sample (density = 1.241). Vials were checked once or twice daily for resin on the vial sides and cap. None was observed, but it may have occurred between inspections. Transfer of relatively few resin beads to the sides or cap may significantly skew the results due to the small sample of resin used for the contacts. The small resin sample was driven by the required phase ratio and the small amounts of sample available.

The large difference between TcO_4^- removal (measured by the $^{95\text{m}}\text{TcO}_4^-$ tracer) and total Tc removal (measured by ^{99}Tc) in the BNFL sample is easily discerned. The lowest TcO_4^- removal was 64.5%, while the highest total Tc removal was 22.3%. The observed total Tc removal is expected to be an average of the removal of each different Tc species, weighted by the molar amounts of each species. The difference between the TcO_4^- and total Tc results therefore indicates a significant amount of inextractable non-pertechnetate. If the non-pertechnetate is assumed to be completely inextractable, the fraction of non-pertechnetate is calculated to be 79%. The large difference between the K_d 's indicates that it is reasonable to assume that little or none of the $^{95\text{m}}\text{Tc}$ pertechnetate tracer is converted to non-pertechnetate.

The total Tc K_d 's for the BNFL AN-107 sample are very similar to those observed previously at Battelle for untreated samples of the same feed (K_d 's of 13 – 21, representing 11% to 16% removal; Kurath et al., 1999), and are similar to those observed previously at SRTC using a phase ratio of 10 instead of 100 (K_d 's of 4 to 5, representing 27% removal; Hassan, 1997).

Based on these K_d 's the predicted λ value for $^{95\text{m}}\text{TcO}_4^-$ in BNFL AN-107 is between 150 BV and 347 BV. Comparison with the treated archive AN-107 K_d 's suggests it will be closer to 150 BV than to 347 BV. The predicted λ value for ^{99}Tc in BNFL AN-107 is between 6.4 BV and 14.7 BV. This prediction, however, is based on the implicit assumption that all the ^{99}Tc present is extractable, which is not correct. Therefore this prediction is of limited use.

Table 3.3. TcO_4^- and Total Tc K_d Values

Sample	Feed conditions	$\text{TcO}_4^- K_d$ (mL/g)/ % Removal (1)	Total Tc K_d (mL/g)/ % Removal (2)
Archive AN-107 (3)	Na = 5.70 M Density = 1.256 g/mL ^{99}Tc = 55 $\mu\text{Ci/L}$ (3.2 mg/L) $\text{NO}_3^-/\text{Tc} = 6.8 \times 10^4$	257 / 70.5%	Not Determined
Archive AN-107 Dup	Na = 5.70 M Density = 1.256 g/mL ^{99}Tc = 55 $\mu\text{Ci/L}$ (3.2 mg/L) $\text{NO}_3^-/\text{Tc} = 6.8 \times 10^4$	445 / 80.9%	Not Determined
Treated Archive AN-107	Na = 4.70 M Density = 1.226 g/mL ^{99}Tc = 48 $\mu\text{Ci/L}$ (2.8 mg/L) $\text{NO}_3^-/\text{Tc} = 7.3 \times 10^4$	186 / 64.5%	Not Determined
Treated Archive AN-107 Dup	Na = 4.70 M Density = 1.226 g/mL ^{99}Tc = 48 $\mu\text{Ci/L}$ (2.8 mg/L) $\text{NO}_3^-/\text{Tc} = 7.3 \times 10^4$	211 / 67.3%	Not Determined
BNFL AN-107 (Treated)	Na = 4.84 M Density = 1.241 g/mL ^{99}Tc = 57 $\mu\text{Ci/L}$ (3.3 mg/L) $\text{NO}_3^-/\text{Tc} = 5.4 \times 10^4$	708 / 87.0%	30 / 22.3%

<p>1) Assumed equal to the ^{95m}Tc K_d. 2) Assumed equal to the ^{99}Tc K_d. 3) Archive and Treated Archive ^{99}Tc and NO_3^-/Tc estimated from Blanchard et al. (1997) and Hallen, Bredt, Brooks and Jagoda (2000)</p>			

3.3 Column Test: Loading (Breakthrough Curves) and Feed Displacement

Column preparation with 1.0 M NaOH was completed by 11:00 AM on November 3, 1999. The columns were left in 1.0 M NaOH overnight, and column loading with the BNFL AN-107 sample was started at 6:00 AM the next morning. Small samples (about 2 mL) were collected from the lead column every 10 BV of feed and from the lag column every 20 BV of feed. The initial samples were collected from the columns after just 10 BV to determine the maximum decontamination factors (DFs). (The DF of a sample is defined as C_0/C_c .) The loading phase generally went well. A few (less than 50) resin beads were observed to float above the top of the column.

The ^{99}Tc and $^{95\text{m}}\text{TcO}_4^-$ concentrations in the load effluent samples are shown in Figure 3.1 as % C/C_0 vs. the bed volumes of feed processed through each column. The C_0 value for ^{99}Tc was $57.1 \mu\text{Ci/L}$ (3.34 mg/L). The initial $^{95\text{m}}\text{TcO}_4^-$ C_0 was 1820 counts/min/mL of sample. This decayed to 1664 counts/min/mL of sample by the end of the run. The $^{95\text{m}}\text{TcO}_4^-$ C_0 was recounted periodically to account for this decay. The C/C_0 value of 0.70 (i.e., 70%) is marked on the plot. This corresponds to the expected maximum allowed effluent concentration needed to meet the average ^{99}Tc limit in the LAW glass (0.1 Ci/m^3). The % C/C_0 values for ^{99}Tc and $^{95\text{m}}\text{TcO}_4^-$ in the effluent composite are also shown on the plot.

Figure 3.1. ^{99}Tc and $^{95\text{m}}\text{TcO}_4^-$ Breakthrough Curves, First and Second Columns

The $^{95\text{m}}\text{TcO}_4^-$ data form fairly typical breakthrough curves, with the exception that the breakthrough curve for the first column is about 10 percentage points higher than expected for a fresh column. This is attributed to the use of a column that was still partly loaded from a previous run, as described in the experimental section. The breakthrough is comparable to that on the last sample taken from this column at the end of the previous run ($C/C_0 = 14.8\%$). However, a direct comparison cannot be made as the ratios of $^{95\text{m}}\text{Tc}$ to ^{99}Tc are not the same on the column and in the feed due to the decay of the $^{95\text{m}}\text{Tc}$ loaded on the column, and probable differences in the amount of tracer added to the two different feeds. There is a relatively high initial breakthrough on the second column ($C/C_0 = 1.3\%$). This may be due to bleed of residual Tc from the column, which was previously loaded and eluted. For comparison, $C/C_0 = 0.6\%$ on the second column when $C/C_0 = 9\%$ on the first column during the AW-101 test.

In sharp contrast to the $^{95m}\text{TcO}_4^-$ data, the ^{99}Tc data indicate that ^{99}Tc was eluted from the column during the "loading" phase. The initial C/C_0 of approximately 145% decreased over the first 100 BV to approximately 125%, where it levels off. The initial ^{99}Tc C/C_0 for the lag column effluent is slightly less than 100%, then also climbs to approximately 125%. The behavior of the ^{99}Tc is attributed to the presence of a large fraction of non-pertechnetate Tc in the AN-107 feed and to the use of a column that was still partially loaded from a previous run, as described.

The initial DFs for ^{99}Tc for the first and second columns (derived from the ^{99}Tc concentration in the first sample from each column) are 0.7 and 1, respectively. The corresponding initial DFs for TcO_4^- (similarly derived from the $^{95m}\text{TcO}_4^-$ C/C_0 in the first sample from each column) are 9.9 and 74. These were also the maximum DFs observed for $^{95m}\text{TcO}_4^-$.

The λ value is the number of bed volumes of processed feed at which the C/C_0 value reaches 50% (0.5) and is a direct indicator of the effective capacity of the resin. Since the ^{99}Tc C/C_0 was never below 50% for either the lead or lag columns, ^{99}Tc λ values could not be calculated. The $^{95m}\text{TcO}_4^-$ λ value for the lead column is 125. The $^{95m}\text{TcO}_4^-$ breakthrough on the second column at the conclusion of the loading phase was sufficiently low (approximately 25%) that extrapolation to determine the λ value is not practical.

The overall ^{99}Tc DF was 0.96 (^{99}Tc was added to the feed by the process) and the concentration of ^{99}Tc in the effluent composite is $59.3 \mu\text{Ci/L}$ (3.47 mg/L), 1.5 times the expected maximum allowed concentration needed to meet the average ^{99}Tc limit in the Envelope C LAW glass (0.1 Ci/m^3). The overall $^{95m}\text{TcO}_4^-$ DF was 22.5. The corresponding C/C_0 values are shown in Figure 3.1.

The $^{95m}\text{TcO}_4^-$ breakthrough curves for AN-107 are compared to those for AW-101 in Figure 3.2. The affect of the partially loaded lead column on the initial C/C_0 for AN-107 is clear.

Figure 3.2. Comparison of $^{95m}\text{TcO}_4^-$ Breakthrough Curves for AW-101 and AN-107, First and Second Columns

Feed displacement was started immediately after the last load sample was collected. The beds were flushed in series with 7.5 BV of 0.1 M NaOH at 3.0 BV/hr to displace the feed prior to elution. (Direct contact of the feed and the eluant, DI water, would result in precipitation of some of the feed components.) The feed tube was transferred to the feed displacement solution prior to collection of the last load sample to reduce feed holdup in the feed displacement samples. The brown color indicative of feed began to lighten with the 4th feed displacement sample.

The ^{99}Tc and $^{95\text{m}}\text{TcO}_4^-$ concentrations in the feed displacement samples taken after the second column are shown in Figure 3.3 as C/C_0 vs. the bed volumes of feed displacement processed through the columns. The C/C_0 from the last load effluent sample from the second column is also shown on the plot. The $^{95\text{m}}\text{TcO}_4^-$ C/C_0 of the feed displacement samples drop off only slightly (from 25% to 20%) for the first 5 BV. After this the C/C_0 rises significantly, signaling elution. After the second point confirmed that the $^{95\text{m}}\text{TcO}_4^-$ was eluting, the feed displacement was stopped, at $C/C_0 = 55\%$. The subsequent DI rinse was performed only on the first column to minimize this elution.

Figure 3.3. ^{99}Tc and $^{95\text{m}}\text{TcO}_4^-$ C/C_0 for Feed Displacement

The general behavior of ^{99}Tc is similar to $^{95\text{m}}\text{TcO}_4^-$, although the changes are much larger. The ^{99}Tc starts at a much higher C/C_0 (127%), but also drops off only slightly for at least the first 3 BV. At the 5th BV the C/C_0 drops quite strongly to just under 50%, before rising again to almost 75% by the 7th BV. This behavior is attributed to displacement of ^{99}Tc (with the feed) in the first 3 BV to 4 BV, followed by elution of $^{99}\text{TcO}_4^-$ from the bed by the 0.1 M NaOH. The observed elution of both ^{99}Tc and $^{95\text{m}}\text{TcO}_4^-$ with 0.1 M NaOH is consistent with information provided by the resin manufacturer that decreasing the ionic strength of the solution in contact with the SL-639 resin will elute perhenate (ReO_4^-), a surrogate for TcO_4^- , from the resin (King, 1999).

The concentrations of sodium (Na), potassium (K), aluminum (Al) and hydroxide (OH⁻) in the feed displacement are shown in Figure 3.4. The concentrations of Na, K, and Al are indicated on the left hand axis while the OH⁻ concentration is shown on the right hand axis. Both Y-axes are logarithmic scales in order to clearly show the large decreases in the concentrations. The samples were taken at the effluent line from the lag column, after the solutions had passed sequentially through both columns. Analytical results and calculations may be found in the appendix.

Figure 3.4. Component Concentrations in Feed Displacement Samples

The concentrations of the four components do not change between the first and second samples (first three BV) of the feed displacement, but a large decrease in all concentrations is observed in the third sample (5th BV). The displacement of the feed is reasonably sharp, with the concentrations of most components dropping 1.5 to 2 orders of magnitude between the 3rd and 7th bed volumes. The Na and OH⁻ concentrations do not drop as low as the others as they are present in the displacement solution. The feed components (excluding OH) are 66% to 84% reduced in the 5th BV, and 96% to 99% reduced in the 7th BV.

The observed color change in the samples and the behavior of ⁹⁹Tc, ^{95m}TcO₄⁻, and the other feed analytes are all consistent with the conclusion that the first 3 BV to 4 BV consist of feed holdup. This is consistent with the estimated system holdup volume of 3 BV, as stated in Section 2.1. Based on this data, it is recommended that the feed displacement be terminated after the 5th bed volume. Elution continued with

the room temperature DI water rinse (see appendix for data). If a small amount of OH^- can be tolerated in the eluate, it may be desirable to omit the room temperature DI water rinse and proceed directly to the 50°C DI water elution. Assuming 2 BV of 0.1 M NaOH and 50 BV of DI eluate, the OH^- concentration in the eluate would be approximately 0.004 M.

3.4 Column Test: Water Rinse, Elution, Eluant Rinse and Regeneration

The 0.1 M NaOH feed displacement was followed by a room temperature de-ionized (DI) water rinse of 2.1 BV at 3.1 BV/hr (lead column only). The rinse was started on November 8, 1999, 67 hours after the feed displacement. (The column was left in the feed displacement solution over the weekend.) At the completion of the DI water rinse the lead column was eluted with DI water at 53.5°C at a rate of 1 BV/hr. The requested elution temperature was $50(+/- 5)^\circ\text{C}$; the water bath set point was set to 53.5°C to compensate in case the actual bed temperature was lower. As shown below, the bed temperature was most likely at the same temperature ($+/- 0.3^\circ\text{C}$) as the water bath. The water bath reached 50°C within 12 minutes while circulating water through the column jacket. The column was allowed to warm for about 30 minutes before elution was started. The total time between the last rinse sample and the start of the elution was 2 hours 40 minutes. The eluate was collected in 1 BV increments. The elution was stopped at 20 BV for 22 minutes to check the liquid level above the bed. Elution was stopped again at 37 BV for 7.2 hours (overnight) to reduce RCT overtime and expense, and to investigate the effect of allowing the column to stand in DI water at temperature (53.5°C) for an extended period of time. The heater was left on during both breaks.

When the elution was stopped and the lead column had cooled to room temperature (overnight), it was rinsed with room temperature DI water at 6 BV/hr. Samples were collected in 1 BV increments. After 2 BV, the feed tube was transferred to the 1 M NaOH reservoir for the regeneration, but the next 2 BV were collected as DI rinse due to the holdup in the system, giving a total of 4 BV of DI rinse. The regenerate was then immediately collected (both columns) in a 6.4 BV batch. (The flow rate had increased to 6.4 BV/hr.) Collection of the regenerate was complete at 10:15 AM on November 11, 1999.

The $^{95\text{m}}\text{TcO}_4^-$ C/C_0 for each sample was determined soon after collection (generally within an hour). The ^{99}Tc concentrations in selected samples were determined later by ICP-MS. The elution, rinse and regeneration data are shown in Figure 3.5. The Y axis is a logarithmic scale to clearly show the large range of C/C_0 values. (Note these are not $\% \text{C}/\text{C}_0$ values.)

The concentrations of ^{99}Tc and $^{95\text{m}}\text{TcO}_4^-$ jumped sharply from the last room temperature DI rinse sample to peak in the 2nd eluate bed volume at C/C_0 of 27 and 51, respectively. This is probably due both to the higher temperature of the water and to the 2.7 hours during which the loaded column sat in the water eluant. The elution tailed off slowly, however, only dropping to C/C_0 of 0.24 at 22 BV. After a 22-minute break, C/C_0 jumped to about 0.4, and then tailed off slowly again. A larger, sharper rise in C/C_0 was observed following a longer (7.2 hour) break, but again the concentration tailed off very slowly.

Figure 3.5. Elution, Eluant Rinse and Regeneration of Lead Column

The elution was continued for 8 hours after the last break. At that time C/C_0 of the $^{95m}\text{TcO}_4^-$ tracer had dropped to 0.13. Subsequent analysis of ^{99}Tc concentration by ICP-MS indicated that the ^{99}Tc C/C_0 was 0.05 in the last sample. The water bath was turned off, and the column was allowed to cool overnight (about 16 hours), and then rinsed with 4 BV of room temperature DI water at 6.1 BV/hr. This rinse was collected in 1 BV increments. The C/C_0 of both Tc isotopes in the first rinse sample were much lower than in the last elution sample, in spite of standing overnight in contact with the resin. When compared with the rises in C/C_0 seen when the resin stood in contact with warm (50°C) eluant, the drop illustrates the large effect temperature has on the equilibrium of Tc between resin and eluant.

The C/C_0 of both Tc isotopes dropped nearly an order of magnitude over the 4 BV rinse; both were less than 0.01 in the last sample. The concentration of ^{99}Tc in the last elution sample was 2.7 $\mu\text{Ci/L}$ (0.160 mg/L) and 0.26 $\mu\text{Ci/L}$ (0.015 mg/L) in the last rinse sample.

Although the ^{99}Tc and $^{95m}\text{TcO}_4^-$ elution and rinse data track well, at any given point the magnitude of C/C_0 for ^{99}Tc is significantly lower than that for the tracer. This indicates that the ratio of Tc on the column to that in the feed is lower for ^{99}Tc than it is for ^{95m}Tc . This is consistent with the observation that ^{99}Tc did not load on the column while $^{95m}\text{TcO}_4^-$ did. The ^{99}Tc observed to elute is that left from the initial partial loading with AW-101, minus the amount that eluted during the "loading" phase. The $^{95m}\text{TcO}_4^-$ observed to elute is that left from the initial partial loading with AW-101, plus the large amount that loaded during the loading phase. This difference between the ratio of ^{99}Tc to ^{95m}Tc in the feed and on the column is reflected in the elution and rinse C/C_0 values.

The ^{99}Tc concentration in the 6.4 BV regenerate batch was found to be $0.14 \mu\text{Ci/L}$ (0.008 mg/L), for a C/C_0 of 0.003. The $^{99\text{m}}\text{TcO}_4^- C/C_0$ was found to be 0.002. Results of various analyses of a sample of the regenerate are shown in Table 3.4.

Table 3.4. Composition of Regenerate

	Concentration, $\mu\text{g/mL}$	Concentration, M
Na	19200	0.83
K	< 33.8	< $8.6\text{E-}4$
Al	11.2	$4.15\text{E-}4$
OH^-	-	0.85
^{99}Tc	0.008 ($0.14 \mu\text{Ci/L}$)	$8.1\text{E-}8$
Density, g/mL	-	1.04

The temperature of the resin bed during elution was assumed to be $50(\pm 5)^\circ\text{C}$. A thermocouple was subsequently placed at the top of a resin bed and the temperature was measured while the elution conditions were reproduced in order to check this assumption. The thermocouple was a K type enclosed in stainless steel. It was inserted along the long axis of the column and sealed in an elbow at the bottom, allowing flow during temperature measurement. The tip of the thermocouple, where the temperature is measured, was barely visible emerging from the top of the resin bed. This location, where the eluant first contacts the bed, is expected to be the coldest one in the bed. The resin bed used for the loading and elution test had been removed from the column for chemical analysis, so another bed was packed in the column. A shorter resin bed (3.4 cm) was required in order to locate the tip of the thermocouple at the top of the bed. The volume of the bed was therefore only 2.7 mL, about half the size of the bed used for the actual loading and elution test. The temperature at the top of the bed is expected to be independent of the bed volume when the flow rate (in mL/hr) is the same.

A plot of the temperature measured by the thermocouple at the top of the bed during ramp up and elution is shown in Figure 3.6. The zero is taken when the water bath started heating. The temperature was recorded every 5 sec. The bed temperature at ambient hood conditions was collected for 15 minutes before heating was started (not shown). The setpoint on the water bath was set to the same value as for the actual elution (53.5°C). The bed temperature was observed to lag behind the water bath temperature by about 1°C during heating. The bed temperature reached 50°C within 28 minutes. The temperature never dropped below 50°C again, but took 80 minutes (from the start of heating) to stabilize at 53.6°C . At 1 hr 30 min elapsed time, the water bath setpoint was unintentionally reduced to 53.1°C , and the temperature dropped to 53.2°C , where it quickly restabilized (15 – 20 min).

Figure 3.6. Bed Temperature During Elution

Elution was started at about 2.3 hrs elapsed time (137 min). A slight ($0.1 - 0.2^{\circ}\text{C}$) drop in the bed temperature is observed starting 20 min after the elution was begun. Evidently the drop was insufficient to change the water bath temperature and trigger a correction. The elution was run for 4.5 hours. The data collection frequency was reduced to once every 10 min at about 3 hrs elapsed time. During the elution the bed temperature varied between a low of 52.9°C and a high of 53.4°C . The average feed rate was found to be 5.46 mL/hr , somewhat faster than for the actual elution test (4.75 mL/hr).

The temperature drop observed 20 min after elution was started is attributed to the introduction of cold eluant at the top of the bed. The 20 min lag is attributed to preheating of the eluant in the flow adapter. The adapter assembly is in direct, tight contact with the water jacket, so it and the eluant in it were heated with the column. The time required for the eluant to descend the full length of the adapter is estimated to be 15 - 20 min at the flow rate used. The fact that the drop was only 0.2°C is attributed to preheating of the eluant and the slow feed rate. The eluant was warmed as it traversed sections of tubing taped to the much larger water bath circulation tubing, as it descended the flow adapter, and in the small head (approx. 0.16 mL) of eluant above the resin bed.

In summary, the eluant temperature measured at the top of the resin bed remained between 52.9°C and 53.4°C , within 0.3°C of the water bath setpoint, during the 4.5 hour elution. The top of the bed is expected to be the lowest temperature location, and the faster feed rate used in this elution test is expected

to lead to a greater temperature drop than in the initial elution test. Therefore the assumption that the bed temperature was between 50°C and 55°C during the initial elution test appears justified. Note that preheating of the eluant is particularly important if the resin beds are loaded and eluted in the same direction, as in this test. The highest concentration of Tc will occur at the upstream end of the bed. If the bed is eluted in the same direction, the eluant must be at temperature when it first contacts the bed to ensure maximum elution of Tc.

The elution was faster than observed in a previous test when 0.5 M nitric acid (HNO₃) at ambient (room) temperature was used as an eluant (Blanchard, Kurath, and Bontha, 2000). This is evident in a plot of the data from the two elutions, shown in Figure 3.7. The concentrations of ⁹⁹Tc and ^{95m}TcO₄⁻ both peaked much higher and much more rapidly when DI water at 53.5°C was used. The comparison must be made with caution, however, since the Tc load on the column was almost certainly much lower for the elution reported here.

Figure 3.7. Comparison of Elution with 0.5 M Nitric Acid at Ambient Temperature To Elution with De-ionized Water at 53.5°C

More testing to determine optimum elution conditions to minimize the overall process cycle time may be desirable. Testing could include: 1) investigating the relationship between extent of column loading and rate of Tc elution; 2) investigating the relationship between the length of soak time prior to the start of the elution and the rate of subsequent Tc elution; 3) investigating the relationship between C/C_0 when the

elution is terminated and the amount of Tc that bleeds from the column with the next loading cycle;
4) investigating the relationship between temperature and rate of Tc elution.

The eluate samples were combined to produce a 145.9 mL composite, and a sample was submitted to the analytical laboratory for a number of analyses. The results are shown in Table 3.5. The BNFL specified minimum reportable quantity (MRQ) levels for the components determined by ICP were all met. Sodium is the dominant constituent at 105 µg/mL (5 mM). Other significant components may have leached from the glassware used to hold the samples (Si, B). The total organic carbon and total inorganic carbon were both less than 20 µg C/mL, meeting the MRQ. The MRQ levels for the anionic components determined by IC were all met. Nitrate was the dominant anion at 19 µg/mL (0.3 mM). Chlorine, nitrite, sulfate and hydroxide were also present. ⁹⁹Tc and ^{95m}Tc were the dominant radionuclides.

Table 3.5. Analysis of Eluant Composite and Minimum Reportable Quantities

3.5 Column Test: Reloading of Eluted Column

Following the elution, rinse and regeneration of the lead column, AN-107 simulant and feed were processed through the column to determine the amount of residual Tc on the resin that would bleed into the effluent with the next loading cycle. Simulant loading was started on December 9, 1999 at 10:30 AM. The column had been left in 1.0 M NaOH from the regeneration, so the first 3 BV of effluent were discarded. The simulant contained no $^{95m}\text{TcO}_4^-$ or ^{99}Tc tracers. However, ^{95m}Tc was detected in the effluent indicating that some of the residual $^{95m}\text{TcO}_4^-$ on the column was bleeding into the effluent. Once a $^{95m}\text{TcO}_4^-$ baseline was established (13.4 BV), the column was immediately flushed with 4.9 BV of 0.1 M NaOH. No effort was made to eliminate holdup. The 0.1 M NaOH was observed to elute the $^{95m}\text{TcO}_4^-$ slightly. The column was left overnight in the 0.1 M NaOH, and then loaded with actual AN-107 starting at 9:00 AM the next morning. Once a $^{95m}\text{TcO}_4^-$ baseline was established (29.8 BV), the column was immediately flushed with 4.6 BV of the regenerant, 1.0 M NaOH.

As for the other phases of testing, the $^{95m}\text{TcO}_4^- C/C_0$ for each sample was determined soon after collection and the ^{99}Tc concentrations in selected samples were determined later by ICP-MS. The $^{99}\text{Tc } C_0$ used for calculating C/C_0 values for the simulant was taken as C_0 of the actual feed. (This was found to be 45.0 $\mu\text{Ci/L}$, 21% lower than the previous value of 57.1 $\mu\text{Ci/L}$. Possible causes for this discrepancy are discussed below.) The data are plotted in Figure 3.8. The Y axis is linear and the C/C_0 values are given as percentages for ease of comparison with the breakthrough curves in Figure 3.1. The last elution, rinse and regeneration data are shown for comparison. The start of simulant loading is taken as 0 BV. Raw data may be found in the appendix. The 89% C/C_0 value corresponding to the expected maximum allowed effluent concentration needed to meet the average ^{99}Tc limit in the LAW glass (0.1 Ci/m^3) is indicated on the plot. This value is different from that in Figure 3.1 due to the difference in the measured C_0 value.

Both $^{95m}\text{TcO}_4^-$ and ^{99}Tc bleed from the column into the simulant at levels higher than observed in the last rinse sample and the regeneration sample. Both appear to dip and then rise very slightly, with $^{95m}\text{TcO}_4^-$ near 5% and ^{99}Tc near 2.5% after 13.4 BV. For comparison, the last rinse sample C/C_0 were 0.8% and 0.5%, for $^{95m}\text{TcO}_4^-$ and ^{99}Tc , respectively. After a 2 BV lag due to holdup, the 0.1 M NaOH begins to elute both $^{95m}\text{TcO}_4^-$ and ^{99}Tc .

The $^{95m}\text{TcO}_4^-$ continues to climb during another 2 BV lag as actual AN-107 is started loading, then drops to 5%. The contribution from the residual Tc on the column in this case is significant. The $^{95m}\text{TcO}_4^- C/C_0$ then rise in a fairly typical breakthrough curve, offset by the bleed from the residual $^{95m}\text{TcO}_4^-$ on the column. After another 2 BV lag, the C/C_0 begin to drop with the 1.0 M NaOH regeneration, but more slowly than expected.

In contrast to $^{95m}\text{TcO}_4^-$, the $^{99}\text{Tc } C/C_0$ rise sharply to 78% as the actual AN-107 is loaded. This breakthrough is attributed mostly to the non-pertechnetate present in the feed. The 22% ^{99}Tc that was removed is slightly better than the target of 20% for Envelope C. After the initial sharp rise, the $^{99}\text{Tc } C/C_0$ continue to rise slightly, as the pertechnetate ^{99}Tc breakthrough increases on top of the presumably constant non-pertechnetate ^{99}Tc breakthrough. The $^{99}\text{Tc } C/C_0$ then drop sharply with the 1.0 M NaOH regeneration as the feed is displaced.

Figure 3.8. Reloading of Eluted Column with Simulant and Actual Feed

An immediate high ^{99}Tc breakthrough (58%) was also observed during Phase IA testing by Hassan and McCabe (1997) for similar feed and the same resin, and was attributed to the presence of non-pertechnetate technetium. Comparison with the data from that report must be made with caution, however, as the feed was prepared differently and virgin SL-639 resin was used for that study.

If it is assumed that the resin retains none of the non-pertechnetate, the fraction of non-pertechnetate Tc in the AN-107 may be calculated using the data in Figure 3.7. The initial ^{99}Tc breakthrough is 78%. Subtracting the contribution from the column bleed (2.5%), the non-pertechnetate fraction is calculated to be about 75.5%, leaving 24.5% as TcO_4^- . This is close to the 29% estimated in Section 3.1, and certainly within the estimated error bars ($\pm 10\%$). It is also consistent with a previous estimate (Kurath et al., 1999).

Bleed from the residual Tc on a loaded and eluted column results in immediate breakthrough of 2.5% to 5%. For AN-107, this is dwarfed by the breakthrough of non-pertechnetate ^{99}Tc . For other waste feeds and/or envelopes, the column bleed may represent a much larger fraction of the initial breakthrough.

The plot suggests that a freshly eluted bed of SL-639 will remove sufficient ^{99}Tc from AN-107 feed, under the test conditions, to meet the average ^{99}Tc limit in the LAW glass without blending or additional alternate pretreatment. The C_0 determined for this set of loading cycle tests, $45.0\ \mu\text{Ci/L}$, is low relative to the value found for the first loading cycle test ($57.1\ \mu\text{Ci/L}$), although the same feed bottle was used. The first value found is consistent with three values found for this feed following Sr/TRU removal ($54.7\ \mu\text{Ci/L}$, $54.0\ \mu\text{Ci/L}$, and $60.4\ \mu\text{Ci/L}$, in sample DF-20, a duplicate of DF-20, and sample DF-21; Hallen, Bredt, Brooks and Jagoda, 2000).

The cause of the difference in the two C_0 's is unknown. If it is due to inadvertent dilution of the feed after the first set of tests, the expected average limit in Figure 3.8 would be reduced from 89% to 70%, the C/C_0 values would remain the same (i.e., jump to 78% immediately on loading), and it would be concluded that SL-639 will not be able to remove sufficient Tc to meet the expected average limit in AN-107 feed. If the low C_0 value is due to an error in only the feed sample analysis, the average limit in Figure 3.8 would be reduced to 70%, and the C/C_0 values would be reduced as well. The curve would jump to only 62% and would climb to 64% over the 30 BV run. In that case it would be concluded that the SL-639 will be able to remove sufficient Tc from AN-107 to meet the average limit, but most likely for a limited volume of feed per load cycle.

In either case it appears that the ratio of ^{99}Tc to sodium in AN-107 waste is low enough that SL-639 will provide sufficient Tc decontamination that the LAW limit can be met. If it is not possible to meet the limit specifically for AN-107 feed, it is expected that more than enough ^{99}Tc can be removed from other envelopes so that the limit can be met on average. It has been demonstrated, for example, that more than enough ^{99}Tc can be removed to meet the expected limit for AW-101, an Envelope A waste (Blanchard et al., 2000). However, other Envelope C wastes should be tested to confirm this, and to determine the removal requirements for the other envelopes. Although AN-107 is believed to have the largest fraction of inextractable Tc due to its high concentrations of organic complexants and complexant fragments, wastes from Tanks 241-SY-101 and 241-SY-103 contain over 4 times more Tc, and also have large fractions of inextractable Tc (50% or more; Blanchard et al., 1997).

4.0 CONCLUSIONS AND RECOMENDATIONS

Batch contacts of various Tank AN-107 (Envelope C) waste feeds with SL-639 showed reasonable removal of TcO_4^- (65% - 87%), as measured by a $^{95\text{m}}\text{TcO}_4^-$ tracer, but showed low total Tc removal (11% - 22%), as measured by ^{99}Tc .

An attempt to load ^{99}Tc from AN-107 waste onto a 4.7 mL bed of SL-639 that had been partially loaded with ^{99}Tc in a previous test of AW-101 waste resulted in elution of ^{99}Tc from the column. Even after passing through a second, eluted, 4.7 mL bed, the minimum concentration of ^{99}Tc in the effluent samples was greater than 54.7 $\mu\text{Ci/L}$ (3.21 mg/L). An overall DF of 0.96 was obtained using the two 4.7 mL beds in series, indicating that the concentration of ^{99}Tc in the effluent was slightly higher than in the feed. The ^{99}Tc concentration in the effluent was 59.3 $\mu\text{Ci/L}$ (3.47 mg/L). The poor performance is attributed to the presence of a large fraction of non-pertechnetate Tc in the AN-107 feed and the partially loaded column used for the tests.

Pertechnetate, as measured by a $^{95\text{m}}\text{TcO}_4^-$ tracer, was effectively removed by SL-639 during the small column test, in sharp contrast to results for total Tc. The maximum TcO_4^- DFs for the first and second columns were 9.9 and 74, as determined from the C/C_0 of the tracer in the first samples taken from the columns (after 10 BV). The relatively low values reflect the partially loaded lead bed used for the test. The overall TcO_4^- DF, determined from the C/C_0 of $^{95\text{m}}\text{TcO}_4^-$ for a sample of the effluent composite, was 22.5. Pertechnetate was not as effectively removed from this feed with this bed as it was from Tank 241-AW-101 (Envelope A) waste using virgin resin.

The feed displacement (0.1 M NaOH) volume of 7.5 BV was sufficient to flush feed from the columns, as indicated by the disappearance of the dark brown color of the feed and a 1.5 - 2 order of magnitude drop in the concentration of most feed components (Na, Al, P, etc.). However, the feed displacement appeared to elute Tc from the column slightly after the 5th BV. For this reason it is recommended that the feed displacement be terminated with the 5th BV. This feed displacement volume is larger than the assumed flow sheet volume, but the test system has a total system holdup in the pumps, valves and tubing equal to 3 bed volumes of resin. A smaller holdup volume would likely allow a reduction in the required amount of feed displacement. A subsequent rinse of only the first column further reduced most feed components, but also continued to elute Tc slightly.

Elution of the technetium-loaded columns with DI water at 53.5°C was much faster than a previous elution using 0.5 M nitric acid at room temperature. The concentration of ^{99}Tc peaked in the 2nd BV at $C/C_0 = 27$. The tail off was still quite slow, however, with more than 20 BV required to reach $C/C_0 = 0.10$. When the 53.5°C DI water was allowed to stand in contact with the loaded resin, the concentration of Tc in the eluate samples increased when the elution was restarted. The longer the contact, the higher the concentration on restart. The tail off from these spikes was still quite slow, however. After 46 BV, C/C_0 for ^{99}Tc was less than 0.05. When the column had cooled to room temperature, a 4 BV DI water rinse decreased the C/C_0 for ^{99}Tc in the eluate samples by another order of magnitude, to 0.005.

The SL-639 was regenerated with 6.4 BV of 1.0 M NaOH. The regeneration effluent was collected in one batch, in which the ^{99}Tc concentration was found to be 0.14 $\mu\text{Ci/L}$ (0.008 mg/L).

When AN-107 waste feed simulant containing no Tc was flushed through the eluted SL-639 bed, residual ^{99}Tc was found to bleed from the resin ($C/C_0 = 2.5\%$ relative to actual AN-107 feed). When actual AN-107 waste feed was then run through the column, there was immediate high breakthrough

($C/C_0 = 78\%$) of ^{99}Tc . The 22% initial removal slightly exceeds the target of 20% for this envelope. Removal drops below 20% by the 20th bed volume.

Special analysis of the feed, and the $^{99\text{m}}\text{TcO}_4^-$ tracer results from the batch contacts and column tests, are all consistent with the presence of $(29 \pm 10)\%$ pertechnetate ^{99}Tc in this feed, with the remainder present as a non-pertechnetate form that is not removed by the SL-639 resin.

The average maximum allowed concentration in Envelope C feed to meet the ILAW glass limit for ^{99}Tc (0.1 Ci/m^3) is expected to be 40 uCi/L (2.3 mg/L). Small column testing indicates that SL-639 will either barely provide, or not provide, sufficient ^{99}Tc decontamination to meet the limit in glass made from AN-107 waste. However, it was previously shown that an Envelope A waste (AW-101) can be ^{99}Tc decontaminated to a greater extent than needed to meet the ILAW limit. It is expected that sufficient ^{99}Tc can be removed from AW-101 and AN-107 wastes so that the average ^{99}Tc concentration in the ILAW glass produced from AW-101 and AN-107 wastes is less than or equal to the ILAW limit.

It is expected that this will be true in general – it will be possible to exceed the ^{99}Tc removal requirements for Envelope A and B wastes, so that the average ^{99}Tc concentrations in the ILAW glasses produced from Envelopes A, B, and C are less than or equal to the ILAW limit. The extent of ^{99}Tc removal possible in Envelope C waste will probably determine the required ^{99}Tc removal in Envelopes A and B. The concentration of ^{99}Tc in two other Envelope C wastes (241-SY-101 and 241-SY-103) is approximately four times higher than in AN-107, and the fraction of non-pertechnetate ^{99}Tc is expected to be nearly as high. Therefore it is recommended that flowsheet testing (including small column ^{99}Tc decontamination tests) of these and other Envelope C wastes be performed to determine the extent of ^{99}Tc removal possible in these wastes, and therefore the extent of ^{99}Tc removal required for Envelopes A and B.

Fouling of the resin bed was not observed.

APPENDIX A

Appendix A: Sample Identification

Sample ID	Description
N7-Tc-0	Initial feed sample
N7-Tc-L1 through L17	Loading samples from lead column
N7-Tc-P1 through P9	Loading samples from lag column
AN-107 Tc IX Effluent – 1	Effluent composite container
N7-Tc-PW1 through PW9	Feed displacement samples
N7-Tc-PR1 and PR2	DI water rinse samples
N7-Tc-E1-1 through E1-45	Lead column eluate samples
N7-Tc-ELU-COMP	Lead column eluate composite sample
N7-Tc-E1-R1 through R4	Lead column eluant rinse samples
N7-Tc-REG-01	Regeneration effluent composite container
N7-Tc-R01	Regeneration effluent composite sample
Tc-SL0	Actual feed sample, reloading test
Tc-SL2 through SL14	Simulant loading samples, reloading test
Tc-SW1 through SW4	Simulant displacement samples, reloading test
AN-Tc-L1 through L25	Actual feed loading samples, reloading test
AN-Tc-W1 through W4	Regeneration samples, reloading test

APPENDIX B

Appendix B: Data Sheets, Analytical Data, and Calculations

Batch Contacts: AN-107 Contacted with Superlig-639 (SL-639)

Performed 9/24/99 through 10/1/99, as per "BNFL AN-107/Tc Batch Contact Test Instructions", BNFL-TI-29953-050.

The AN-107 is an archive sample from Cs IX performed by Doug Hendrickson and Dean Kurath at 222-S in 1996.

Untreated samples, and samples treated by a permanganate precipitation were tested.

The treated samples are denoted with a "P."

The Kd's were determined for a Tc-95m pertechnetate tracer ONLY. Tc-99 Kd's were NOT determined.

The bed density was determined in a previous round of experiments,
published in BNW report BNFL - RPT - 009.

62																			

The effluent volumes on which the bed volumes are based were determined by determining the total mass and calculating the volume of waste pumped through the columns at the time of sampling. For column #1 this includes the mass of the waste in the effluent bottle + the samples taken from column #1 and #2 prior to the sample of interest (the mass of the effluent bottle was recorded during each sample event). For column #2 the effluent volume includes the mass of the waste in the effluent bottle + the samples taken from column #2 prior to the sample of interest (samples taken from column #1 did not go through column #2).

The system holdup is estimated to be 2 BV to the sample valve for the 1st column, and 3 BV to the sample valve for the 2nd column. The effluent was diverted into the waste jug for 10 minutes with the pump set at 50 mL/hr (controller set at 99) at the start of the loading cycle to flush out the holdup volume. The mass of effluent from this step was not determined, but from the pump speed and the duration, it must have been approx 8.3 mL = 1.8 BV. So given the estimates for the holdup, the BV scale should be about right for the 1st column samples, and 1 BV too high for the 2nd column samples.

ICPAES Data Report**

Six radioactive aqueous samples, Mn-23 through Mn-28 (ACL# 99-2255 through 99-2260), were analyzed by ICPAES after preparation by the Sample Receiving and Preparation Laboratory (SRPL). Samples were prepared by SRPL using PNL-ALO-128 acid digestion procedure. All samples were prepared using plastic labware. Approximately 5ml aliquots of sample solution were weighed, processed and diluted to a final volume of 20ml. All liquid samples were caustic, salt solutions prior to processing. Sample Mn-28 (ACL# 99-2260) was filtered after being diluted to 20 ml using 0.45 um membrane filter.

All results reported are in $\mu\text{g/g}$ including liquid samples as requested by client. All results have been corrected for preparation and analytical dilution. Volumes and weights are recorded on bench sheets (included with raw data, etc.). Analytes of interest include Al, Ba, Ca, Cd, Co, Cr, Cu, Fe, K, La, Mg, Mn, Mo, Na, Ni, Pb, Si, Ti, U, and Zn. No changes have been made relative to the preliminary report provided earlier to the client.

All quality control checks met tolerance requirements for analytes of interest except as noted below. Following is a list of quality control check measurement results relative to ICPAES analysis tolerance requirements under MCS-033.

Five fold serial dilution:

(Aqueous samples) All results were within tolerance limit of $\leq 10\%$ after correcting for dilution.

Duplicate RPD (Relative Percent Difference):

(Aqueous samples) All analytes of interest were recovered within tolerance limit of $\leq 20\%$ relative percent difference (RPD).

Post-Spiked Samples (Group A):

(Aqueous samples) All analytes of interest were recovered within tolerance of 75% to 125%.

Post-Spiked Samples (Group B):

(Aqueous samples) All analytes of interest were recovered within tolerance of 75% to 125%.

Blank Spike:

(Aqueous samples) All analytes of interest in the blank spike were recovered within tolerance limit of 80% to 120%.

8/13/99

**Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ...
ICPAES Data Report**

Matrix Spiked Sample:

(Aqueous samples)

All analytes of interest in the matrix-spike were recovered within tolerance limit of 75% to 125% except for Ba and Pb. Matrix-spike recovery for barium in sample Mn-22 (ACL# 99-2259) was only about 5%. Lead recovery in the same sample was about 41%. Low recovery for the two analytes may be caused by moderate to high concentration of sulfate in the sample. Post-spike and blank-spike recovery for all analytes of interest was recovered within tolerance limit of 75% to 125%.

Quality Control Check Standards:

Concentration of all analytes of interest was within tolerance limit of $\pm 10\%$ accuracy in the standards: QC_MCVA and QC_MCVB. Calibration Blank (ICP98.0) concentration was less than two times IDL.

High Calibration Standard Check:

Verification of the high-end calibration accuracy for all analytes of interest except lanthanum and uranium was within $\pm 5\%$ tolerance. The high-end calibration accuracy for lanthanum was somewhat low, about -6.9% and uranium was also low by about -5.7% . This will cause results for lanthanum and uranium concentration to appear lower than what is actually present in the samples. Lanthanum and uranium concentration measurements were all below EQL (and below MRQ).

Process Blank:

(Aqueous samples)

All analytes of interest were within tolerance limit of $\leq$ EQL or $< 5\%$ of sample concentration.

Laboratory Control Standard (LCS):

(Aqueous samples)

No LCS was prepared for PNL-ALO-128 acid digested samples.

Analytes other than those requested by the client are for information only. Please note bracketed values listed in the data report are within ten times instrument detection limit and have a potential uncertainty much greater than 15%. See attached ICPAES data results.

8/13/99

**Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ...
ICPAES Data Report**

Comments:

- 1) "Final Results" have been corrected for all laboratory dilution performed on the sample during processing and analysis unless specifically noted.
- 2) Detection limits (DL) shown are for acidified water. Detection limits for other matrices may be determined if requested.
- 3) Routine precision and bias is typically $\pm 15\%$ or better for samples in dilute, acidified water (e.g. 2% v/v HNO₃ or less) at analyte concentrations greater than ten times detection limit up to the upper calibration level. This also presumes that the total dissolved solids concentration in the sample is less than 5000 $\mu\text{g/mL}$ (0.5 per cent by weight).
- 4) Absolute precision, bias and detection limits may be determined on each sample if required by the client.
- 5) The maximum number of significant figures for all ICP measurements is 2.

Matrix spike recovery is calculated as follows:

Spike = 2.00 mL 0.1018 N NaOH was added to the 0.100-mL of sample for each matrix spike.

Spike Titrant vol. (sample @ .1mL + spike) - Sample Titrant vol. (average sample only equated to .1mL) * 0.2034 N (HCl titrant) = meq. OH

meq OH / 2.00 mL added = meq OH/mL found / 0.1018 N OH added * 100 = % recovered.

Prep record on 0.2034 M HCl is on following page.

Chem Rec_51a

Prep date: 4/18/99

Preparation of Standardized 0.2 M HCl

WP# K51300

Standardized 0.1021 M NaOH will be re-checked and then used to standardized the ~ 0.1 M HCl solution. The 0.1021 M NaOH was prepared in Chem Rec_37 (see Chem Rec_37 --prep.date 2-25-98 for original data) and re-verified against NIST SRM84 Potassium Acid Phthalate $\text{KHC}_8\text{H}_4\text{O}_4$ (KAP) = 204.23 g/mole -- Barcode # 52232 --- (see below verification check).

The re-standardized value of 0.1018 M NaOH was reassigned to this NaOH solution with a revised Expiration Date of Feb. 2000.

Prepared 1- liters of ~0.2 M HCl by diluting 100 mL of 1.029M HCl (Chemrec_10) to 0.5 L with DI. H₂O.

20 mL aliquots of 0.2 M HCl were were neutralized to the phenolphthalein endpoint using the re-standardized 0.1018 M NaOH. The volume of NaOH is accurate to +/- 0.02mL and the pipitting error is estimated to be < 1% @ 1s. Thus total error is < 3 % for the measurements

Discussion

Absolute values of the Tc+7 and total technetium are reported. Technetium speciation is also reported as a percentage of Tc+7 in the sample. In order to measure these values, sample sets were prepared in both non-oxidizing and oxidizing environments. In all analysis cases, a 0.1-mL aliquot was diluted to 0.5 mL (DI water or 8M HNO₃, depending on oxidizing or non-oxidizing conditions) and a 0.05-mL aliquot was processed and purified for Tc analysis. The Tc spike added to the reagent spike and matrix spike was the pertechnetate form.

Non-oxidizing conditions were provided by diluting sample aliquots in deionized water. Procedure PNL-ALO-432 was run with no added sodium dichromate (oxidizer). The only Tc that passes through the cation exchange column and is extracted as the tetraphenylarsonium pertechnetate is the Tc already in the +7 state. Under these conditions, the blank spike and matrix spike recovered well, the blank shows no evidence of contamination, and the precision measured by the sample duplicates is within the error of the method.

The ceric ammonium nitrate oxidation method, provided by Norm Schroeder from LANL, was used on one sample set. In this method, the sample aliquot was contacted with 8 M HNO₃ and 0.1M ceric ammonium nitrate in 0.15M HNO₃. The sample was heated. As the characteristic color of the ceric was lost, additional ceric was added and heating continued. The sample was reduced in volume to near dryness and 2-mL concentrated HNO₃ was added. The sample was again reduced to near dryness and another 2-mL concentrated HNO₃ was added. After a final volume reduction, 3-mL DI water was added and the sample was processed through the standard operating procedure PNL-ALO-432.

The potassium permanganate oxidation is similar to the ceric oxidation and was used on another sample set. A saturated solution of KMnO₄ was added to the sample aliquot and allowed to react. As the purple color was lost, additional KMnO₄ was added. The sample was allowed to sit over the weekend in contact with KMnO₄. The sample was then heated to low volume, 1 drop of H₂O₂ added to dissolve MnO₂ and the sample evaporated to near dryness. A 3-mL portion of DI water was added to each sample and the separation proceeded according to PNL-ALO-432.

In both oxidation cases, the blanks show no indication of cross-contamination. The reagent spikes and matrix spikes indicate no losses of Tc as a result of the vigorous oxidation processes. Precision was good, well below the threshold of 20% relative percent difference (RPD). The Tc concentration values of the 2 different oxidation techniques agree to within 6%.

Subject ICP/MS Analysis of Submitted Samples

(ACL #00-0626 through 00-0667) *ASR 5528*

Pursuant to your request, the 46 samples that you submitted for analysis were analyzed by ICPMS for ^{99}Tc . The results of this analysis are reported on the attached page.

An Amersham ^{99}Tc standard was used to generate the calibration curve and an independent Amersham ^{99}Tc standard was used as the continuing calibration verification (CCV) standard. The 1% high-purity nitric acid solution used to dilute the standards and samples was used as a reagent blank. The samples were diluted an extra 10x from the dilutions received. The results include your dilutions and are reported in ng analyte/ g (ppb) of original sample $\pm$ one standard deviation.

The ^{99}Tc values reported assume that the Ru present is exclusively fission-product Ru, and therefore does not have an isotope at m/z 99; i.e., everything observed at m/z 99 is due to ^{99}Tc . The fingerprint we're seeing for Ru is obviously not natural, and is consistent with that observed in previous tank waste analyses..

If you have any questions regarding this analysis, feel free to call me at 372-0700 or James Bramson at 372-0624.

Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ...
ICPAES Data Report

One radioactive aqueous sample, N7-Tc-Eff-Comp (ACL# 00-0380) was analyzed by ICPAES after the sample was dilute 10-fold using 2% nitric acid by the Sample Receiving and Preparation Laboratory (SRPL). Sodium was the only analyte requested. The sample was analyzed on two different days unintentionally. An analytical dilution of 5-fold and 25-fold was made due to the high concentration of sodium present in the sample. Results are calculated as shown below and reported as molarity of sodium (mols per liter). Preliminary results were sent by e-mail to the client earlier. The previously reported results were 4.97 M Na and 4.80 M Na, which is 0.01 M Na lower than results reported below. The difference is due to decimal value rounding.

Sodium concentration, as measured by ICP, was corrected for calibration drift by multiplying the ratio of a single element sodium standard ("true" value) to the concentration of the standard as measured by ICP.

Sodium molarity is calculated as follows:

$$[\text{Na}] = (\mu\text{g/ml})_{\text{ICP}} * \{(\mu\text{g/ml std})_{\text{TRUE}} / (\mu\text{g/ml std})_{\text{MEASURED}}\} * \\ 1.0\text{E-}03 \text{ (conversion factor to convert ug/ml to g/liter)} / \\ \text{gram formula wt of sodium (22.9898 g/L)} = \\ \text{mols Na}$$

First analysis (11-11-99):

$$[\text{Na}] = 119000 \mu\text{g/ml} * [(500 \mu\text{g/ml "True"}) / (520 \mu\text{g/ml "measured"})] * 1.0\text{E-}03 / \\ 22.9898 \text{ g/L} = 4.98 \text{ M Na}$$

Second analysis (11-17-99):

$$[\text{Na}] = 106000 \mu\text{g-Na/ml} * [(1000 \mu\text{g/ml "True"}) / (963 \mu\text{g/ml "measured"})] * 1.0\text{E-}03 / 22.9898 \\ \text{g/L} = 4.79 \text{ M Na}$$

$$\text{Average } [\text{Na}] = 4.88 \text{ M} \pm 0.09 \text{ M Na}$$

Measurement results reported have been corrected for preparation and analytical dilution. Weights and volumes used have been recorded on bench sheets and are included with this report.

Quality control check-standard results for sodium met tolerance requirements except as noted below. Following is a list of quality control measurement results relative to ICPAES analysis tolerance requirements under MCS-033.

1/13/00

Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ...
ICPAES Data Report

Five fold serial dilution:

(Aqueous sample)

All results for sodium in the diluted sample was within tolerance limit of $\leq 10\%$ after correcting for dilution.

Duplicate RPD (Relative Percent Difference):

(Aqueous sample)

All analytes of interest were recovered within tolerance limit of $\leq 20\%$ relative percent difference (RPD).

Post-Spiked Samples (Group A):

(Aqueous sample)

All analytes of interest were recovered within tolerance of 75% to 125%.

Post-Spiked Samples (Group B):

(Aqueous sample)

All analytes of interest were recovered within tolerance of 75% to 125%.

Blank Spike:

(Aqueous sample)

None.

Matrix Spiked Sample:

(Aqueous sample)

None.

Quality Control Check Standards (aqueous sample):

Concentration for all analytes of interest is within tolerance limit of $\pm 10\%$ accuracy except for a slightly high recovery for sodium in the standard QC_MCVA. One of five measurement results for sodium was 12%. The other four measurement results were within tolerance. Sodium was also measured using a single element standard that was measured about the same time as the sample and was within acceptable tolerance limits.

1/13/00

**Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ...
ICPAES Data Report**

High Calibration Standard Check (aqueous sample):

Verification of the high-end calibration concentration for all analytes of interest is within tolerance of $\pm 5\%$ accuracy.

Process Blank:

(Aqueous sample)

None.

Laboratory Control Standard (LCS):

(Aqueous sample)

None.

Please note bracketed values listed in the data report are within ten times instrument detection limit and have a potential uncertainty much greater than 15%.

Comments:

- 1) "Final Results" have been corrected for all laboratory dilution performed on the sample during processing and analysis unless specifically noted.
- 2) Detection limits (DL) shown are for acidified water. Detection limits for other matrices may be determined if requested.
- 3) Routine precision and bias is typically $\pm 15\%$ or better for samples in dilute, acidified water (e.g. 2% v/v HNO_3 or less) at analyte concentrations greater than ten times detection limit up to the upper calibration level. This also presumes that the total dissolved solids concentration in the sample is less than 5000 $\mu\text{g/mL}$ (0.5 per cent by weight).
- 4) Absolute precision, bias and detection limits may be determined on each sample if required by the client.
- 5) The maximum number of significant figures for all ICP measurements is 2.

Matrix spike recovery is calculated as follows:
Spike = 2.00 mL 0.1018 N NaOH was added to the 0.100-mL of sample for each matrix spike.
SpikeTitrant vol. (sample @ .1mL + spike) - SampleTitrant vol. (average sample only equated to .1mL) * 0.2034 N (HCl titrant) = meq. OH
meq OH / 2.00 mL added = meq OH/mL found / 0.1018 N OH added * 100 = % recovered.

Prep record on 0.2034 M HCl is on following page.

Chem Rec_51a

Prep date: 04/18/1999

Preparation of Standardized 0.2 M HClWP# K51300

Standardized 0.1021 M NaOH will be re-checked and then used to standardized the ~ 0.1 M HCl solution. The 0.1021 M NaOH was prepared in Chem Rec_37 (see Chem Rec_37 --prep.date 2-25-98 for original data) and re-verified against NIST SRM84j Potassium Acid Phthalate KHC₈H₄O₄ (KAP) = 204.23 g/mole -- Barcode # 52232 --- (see below verification check).

The re-standardized value of 0.1018 M NaOH was reassigned to this NaOH solution with a revised Expiration Date of Feb. 2000.

Prepared 1- liters of ~0.2 M HCl by diluting 100 mL of 1.029M HCl (Chemrec_10) to 0.5 L with DI. H₂O.

20 mL aliquots of 0.2 M HCl were neutralized to the phenolphthalein endpoint using the re-standardized 0.1018 M NaOH. The volume of NaOH is accurate to +/- 0.02mL and the pipetting error is estimated to be < 1% @ 1s. Thus total error is < 3 % for the measurements

NaOH Molarity verification

Verification Test #	Wt. of KAP	Vol. of 0.1021M NaOH to neutralize	NaOH Molarity = a * 1000 / b * 204.23	Molarity Error +/- @ 1 s
1	0.80894	38.95	0.1017	
2	0.80582	38.84	0.1016

Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ... ICPAES Data Report

Five radioactive liquid samples, N7-Tc-Elu-Comp to C1-Cs-E2-Composite (ACL# 00-0615 to 00-0619), were analyzed by ICPAES after each sample was diluted using dilute nitric acid by the Sample Receiving and Preparation Laboratory (SRPL). Final sample volume was 25ml (weighed). Concentration was adjusted for dilution using the weight of final solution divided by sample weight.

Eight radioactive liquid samples, N7-Tc-0 to N7-Tc-R01 (ACL# 00-0626 to 00-0664), were analyzed by ICPAES after samples were prepared by SRPL using PNL-ALO-128 acid digestion procedure. Approximately 3ml of sample (weighed) was digested and diluted to a final volume of approximately 10ml (weighed). Concentration was adjusted for dilution from processing using the weight of final solution divided by sample weight.

Measurement results reported have been corrected for preparation and analytical dilution. All results reported are in $\mu\text{g/ml}$ for liquid samples. Weights have been recorded on bench sheets and included with this report.

Liquid samples contained low to high concentrations of sodium ($<0.1\%$ to about 10%). All other analytes measured were typically much lower in concentration.

Quality control check-standard results met tolerance requirements except as noted below. Following is a list of quality control measurement results relative to ICPAES analysis tolerance requirements under MCS-033.

Five fold serial dilution:

(Aqueous samples) All results for analytes of interest were within tolerance limit of $\leq 10\%$ after correcting for dilution.

Duplicate RPD (Relative Percent Difference):

(Aqueous samples) All analytes of interest were recovered within tolerance limit of $\leq 20\%$ relative percent difference (RPD).

Post-Spiked Samples (Group A):

(Aqueous samples) All analytes of interest were recovered within tolerance of 75% to 125% .

Post-Spiked Samples (Group B):

(Aqueous samples) All analytes of interest were recovered within tolerance of 75% to 125% .

12/29/99

**Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ...
ICPAES Data Report**

Blank Spike:

(Aqueous samples) None required or prepared.

Matrix Spiked Sample:

(Aqueous samples) None required or prepared.

Quality Control Check Standards (aqueous samples):

Concentration of all analytes was within tolerance limit of $\pm 10\%$ accuracy in the standards: QC_MCVA, QC_MCVB, ICP98.0 and QC_SSTMCV except as follows. Tin and palladium was low by as much as 23% in QC_MCVB check standard measurements. Single element standards of tin at 2 $\mu\text{g/ml}$ and palladium 2 $\mu\text{g/ml}$ measured were well within the tolerance limit thus confirming calibration check for these two analytes.

High Calibration Standard Check (aqueous samples):

Verification of the high-end calibration concentration for all analytes is within tolerance of $\pm 5\%$ accuracy.

Process Blank:

(Aqueous samples) All analytes are within tolerance limit of $\leq \text{EQL}$ or $< 5\%$ of sample concentration.

Laboratory Control Standard (LCS):

(Aqueous samples) No LCS was prepared for PNL-ALO-128 acid digested samples.

Please note bracketed values listed in the data report are within ten times instrument detection limit and have a potential uncertainty much greater than 15%.

**Battelle PNNL/325 Bldg/RPG/Inorganic Analysis ...
ICPAES Data Report**

Comments:

- 1) "Final Results" have been corrected for all laboratory dilution performed on the sample during processing and analysis unless specifically noted.
- 2) Detection limits (DL) shown are for acidified water. Detection limits for other matrices may be determined if requested.
- 3) Routine precision and bias is typically $\pm 15\%$ or better for samples in dilute, acidified water (e.g. 2% v/v HNO_3 or less) at analyte concentrations greater than ten times detection limit up to the upper calibration level. This also presumes that the total dissolved solids concentration in the sample is less than 5000 $\mu\text{g/mL}$ (0.5 per cent by weight).
- 4) Absolute precision, bias and detection limits may be determined on each sample if required by the client.
- 5) The maximum number of significant figures for all ICP measurements is 2.

00-00626	N7-Tc-0	3,200	480	27,900	< 250	110,000	1,100	3,800	1,400
00-00626 MS	N7-Tc-0 MS Rec	112%	105%	122%	108%	OvrRng	111%	114%	111%

RPD = Relative Percent Difference (between sample and duplicate/replicate)

MS Rec = Matrix Spike Standard % recovery

(1) Fluoride is most likely formate or acetate due to slight peak shift and broadening

The samples were analyzed by ion chromatography (IC) for inorganic anions as specified in the governing ASR. The liquid samples were diluted at the IC workstation up to 4,000-fold to ensure that all anions were within the calibration range.

Q.C. Comments:

Duplicates: No actual sample duplicates were provided to the laboratory for analysis. However, the sample, A1-Cs-E2-Comp (00-0616), was split at the IC workstation and analyzed as two samples (replicate). For anions above the estimated quantitation level (i.e., the lowest calibration standard), the Relative Percent Difference (RPD) is will within the acceptance criteria of 20%.

Matrix Spike: Two matrix spikes were prepared from samples submitted. The recoveries for all anions were within the 75% to 125% recovery acceptance criteria for those anions measured within the calibration range.

Battelle PNNL/RPG/Inorganic Analysis --- IC Report

Blank Spike: No blank spikes were analyzed within the analytical runs.

System Blank/Processing Blanks: Twelve system blanks were process during the analysis of the samples. No anions were detected in the system blanks above the estimate quantitation level.

Quality Control Calibration Verification Check Standards: Seven mid-range verification standards were analyzed throughout the analysis runs. Except for only two oxalate values, the reported results for all anions of interest were recovered within the acceptance criteria of $\pm 10\%$ for the verification standard.

General Comments:

- The reported "Final Results" have been corrected for all dilution performed on the sample during processing or analysis.
- The low calibration standards are defined as the estimated quantitation limit (EQL) for the reported results and assume non-complex aqueous matrices. Actual detection limits or quantitation limits for specific sample matrices may be determined, if requested.
- Routine precision and bias are typically $\pm 15\%$ or better for non-complex aqueous samples that are free of interference and have similar concentrations as the measured anions.

ADDENDUM 1

The MS results reported in the original report are included in the table below.

Lab ID	Sample ID	F ⁻ µg/ml	Cl ⁻ µg/ml	NO ₂ ⁻ µg/ml	Br ⁻ µg/ml	NO ₃ ⁻ µg/ml	PO ₄ ³⁻ µg/ml	SO ₄ ²⁻ µg/ml	C ₂ O ₄ ²⁻ µg/ml
00-00615 MS	N7-Tc-Elu-Comp MS Rec	94%	OvrRng	101%	103%	103%	103%	103%	101%
00-00626 MS	N7-Tc-0 MS Rec	112%	105%	122%	108%	OvrRng	111%	114%	111%

The chloride for the 00-00615 spike and the nitrate for the 00-00626 spike were over range (OvrRng). The contribution of the sample for the chloride and nitrate were significantly higher than the contribution from the standard spike solution, and the sample was not diluted sufficiently enough to bring the sample plus spike contribution within the calibrations range. Using the over range chloride and nitrate results to calculate the spike recovery, the chloride spike recovery is 69% and the nitrate is 125%.

The QC protocol requires one matrix spike per analytical run for each sample "matrix type". Both samples 00-00615 and 00-00626 are aqueous solutions and as such constitute a single matrix type. The spike recovery is used to ascertain the "estimated" accuracy of the analytical measurement for the matrix type. Although the chloride and nitrate were over range one MS, the other MS (on a similar matrix) is used to ascertain the estimated accuracy.

Also, both samples from which the matrix spikes were generated were analyzed at more than one dilution. Sample 00-00615 produced chloride results of 13.0 µg/ml at 40-fold dilution and 14.9 µg/ml at 10-fold dilutions, and sample 00-00626 produced nitrate results of 113,600 µg/ml and 110,300 µg/ml at 40,000-fold and 10,000-fold dilutions, respectively. Based on this good agreement between serial dilutions, bias due to matrix effect is considered negligible.

RPD = Relative Percent Difference (between sample and duplicate/replicate)

n/a = Not applicable; either sample or duplicate result is <5 times MDL

See last page for
TIC.

The analysis of the subject samples submitted under ASR 5626 were performed by the hot persulfate wet oxidation method. The hot persulfate method uses acid decomposition for TIC and acidic potassium persulfate oxidation at 92-95°C for TOC, all on the same sample, with TC being the sum of the TIC and TOC. Per the ASR and since the samples were acidic, only TIC analyses were performed on these samples.

The table above shows the results, rounded to one to two significant figures. The result for A1-Cs-E2-Comp (i.e., 80 $\mu\text{g/ml}$) is only marginally above the method detection limit for the 0.3 ml sample size analyzed (i.e., 60 $\mu\text{g/ml}$) and should be considered qualitative. The raw data bench sheets and calculation work sheets showing all calculations are attached. All sample results are corrected for average percent recovery of system calibration standards and are also corrected for contribution from the blank

Q.C. Comments:

The TIC standard is calcium carbonate and TOC standard is α -Glucose (the certificates of purity are attached). The standard materials were used in solid form for system calibration standards as well as matrix spikes. TIC and TOC percent recovery are determined using the appropriate standard (i.e., calcium carbonate for TIC or glucose for TOC).

Battelle PNNL/RPG/Inorganic Analysis --- TOC/TIC Report

The QC for the methods involves calibration blanks, system calibration standards, sample duplicates, and one matrix spike per matrix type.

Calibration Standards: The QC system calibration standards were all within acceptance criteria, with the average recovery being 98.4% for TIC and 98.1% for TOC.

Calibration Blanks: The three calibration blanks run at the beginning and middle of the analysis run were acceptable, averaging 13.9 μgC TIC and 454.7 μgC TOC.

Duplicates: No actual sample duplicates were provided to the laboratory for analysis. However, each sample was analyzed in replicate and the relative percent differences (RPD) between replicates are within the acceptance criteria of 20% for all values measured above the EQL (i.e., 5 times the method detection limit).

Matrix Spike: The accuracy of the carbon measurements can be estimated by the recovery results from the matrix spike. A matrix spike was prepared from sample 00-0615 (N7-Tc-Elu-Comp) with the TOC spike recovery being 103.8%, well within the 75% to 125% recovery acceptance criteria.

General Comments:

- The reported "Final Results" have been corrected for all dilution performed on the sample during processing or analysis.
- Routine precision and bias are typically $\pm 15\%$ or better for non-complex samples that are free of interferences.
- The estimated quantitation limit (EQL) is defined as 5 times the MDL. Results less than 5 times the MDL have higher uncertainties, and RPDs are not calculated for any results less than 5 times the MDL.
- Some results may be reported as less than (" $<$ ") values. These less than values represent the sample MDL (method detection limit), which is the system MDL adjusted for the volume of sample used for the analysis. The system MDL is based on the attached pooled historical blank data. The evaluation and calculation of the system MDL is included in the data package.

Note added to TOC/TIC report for N7-Tc-Elu-Comp.

Although TIC is not reported, it is assumed to be <20 ug C/mL, as is the TOC. Normally TIC is determined by adding acid to the sample in a sealed vial and observing the quantity of CO₂ evolved. TOC is then subsequently determined by opening the vial, adding potassium persulfate and silver nitrate, resealing the vial, heating, and observing the quantity of CO₂ evolved. For the N7-Tc-Elu-Comp sample, it was incorrectly assumed that the sample was already acidic, so the persulfate and silver nitrate were added to the vial, it was sealed and heated, and the evolved CO₂ was measured. Any evolved CO₂ would have come from both TOC and TIC in this case, so the observation of <20 ug C/mL evolved indicates that there must have been <20 ug C/mL of either.

*Phill Thomas Farmer*Subject ICP/MS Analysis of Submitted Samples
(ACL #00-0615 through 00-0619)

Pursuant to your request, the 7 samples that you submitted for analysis were analyzed by ICPMS for ^{99}Tc . The results of this analysis are reported on the attached page.

An Amersham ^{99}Tc standard was used to generate the calibration curve and an independent Amersham ^{99}Tc standard was used as the continuing calibration verification (CCV) standard. The 1% high-purity nitric acid solution used to dilute the standards and samples was used as a reagent blank. The samples were diluted an extra 10x from the dilutions received. The results include your dilutions and are reported in ng analyte/ g (ppb) of original sample $\pm$ one standard deviation.

The ^{99}Tc values reported assume that the Ru present is exclusively fission-product Ru, and therefore does not have an isotope at m/z 99; i.e., everything observed at m/z 99 is due to ^{99}Tc . The fingerprint we're seeing for Ru is obviously not natural, and is consistent with that observed in previous tank waste analyses. Semiquantitative Ru concentrations, corrected for sample dilution, are provided for your information.

If you have any questions regarding this analysis, feel free to call me at 372-0700 or James Bramson at 372-0624.

Estimation of Tc-99 and Nitrate
In Untreated and Treated Archive AN-107 Samples

Assumptions:

- 1) Specific activity of Tc-99 = $1.71\text{E-}2$ Ci/g.
- 2) Tc-99 conc in archive samples same as found previously for this same material (Blanchard et al., 1997). This is reported as 55 uCi/L, or 3.2 mg/L.
- 3) Nitrate conc in archive samples same as found previously for this same material (Blanchard et al., 1997). This is reported as 2.2 M.

Nitrate to Tc-99 in untreated archive AN-107 sample:

$$\begin{aligned}\text{Tc-99 conc} &= 3.2 \text{ mg/L} = 3.2\text{E-}5 \text{ M} \\ [\text{Nitrate}]:[\text{Tc-99}] &= 2.2 \text{ M} / 3.2\text{E-}5 \text{ M} = 6.8\text{E+}4\end{aligned}$$

Tc-99 in treated archive sample:

Reported mass dilution (mass of final over mass of initial) due to treatment is 1.1247 (Hallen et al., 2000). Reported densities of untreated and treated samples are 1.26 g/mL and 1.23 g/mL, respectively.

$$\begin{aligned}\text{Vol. of untreated sample} &= (1.0000 \text{ kg}) / (1.26 \text{ kg/L}) = 0.7937 \text{ L} \\ \text{Vol. of treated sample} &= (1.1247 \text{ kg}) / (1.23 \text{ kg/L}) = 0.9144 \text{ L} \\ \text{Volume dilution} &= 0.9144 \text{ L} / 0.7937 \text{ L} = 1.152 \\ \text{Tc-99 conc in treated sample} &= (\text{Tc-99 conc in untreated}) / (\text{Vol dil}) \\ &= 55 \text{ uCi/L} / 1.152 = 48 \text{ uCi/L} = 2.8 \text{ mg/L} = 2.8\text{E-}5 \text{ M}\end{aligned}$$

Nitrate to Tc-99 in treated archive AN-107 sample:

Treatment included addition to make sample 0.075 M in $\text{Sr}(\text{NO}_3)_2$ (Hallen et al., 2000).

$$\begin{aligned}\text{Nitrate} &= \text{Initial conc (2.2 M), diluted by 1.152, plus } 2 * (0.075 \text{ M}), \text{ diluted by 0.95} \\ &= 2.05 \text{ M} \\ [\text{Nitrate}]:[\text{Tc-99}] &= 2.05 \text{ M} / 2.8\text{E-}5 \text{ M} = 7.32\text{E+}4\end{aligned}$$

Non-Pertechnetate Fraction in BNFL AN-107 from Batch Contact Results

Average pertechnetate extraction: $(87.0\% + 74.1\%) / 2 = 79.0\%$ of total pertech

Unextracted pertechnetate: $100\% - 79\% = 21\%$ of total pertech

Total pertechnetate = $x\%$

Total non-pertechnetate = $y\%$

Total Tc = $x\% + y\% = 100\%$

$x + y = 100\%$

Average total Tc extraction: $(22.3\% + 11.3\%) / 2 = 16.8\%$

Average total Tc unextracted: $100\% - 16.8\% = 83.2\%$

Assume none of the non-pertechnetate is extracted.

Then total Tc unextracted = total non-pertech + unextracted pertech
 = $y\% + 0.21x\% = 83.2\%$
 $y\% + 0.21(100 - y\%) = 83.2\%$
 $y\% = 78.7\%$

So total non-pertech = 78.7%.

Tc Limit in AN-107 (Env. C) Tc Removal Effluent

Assumptions:

- 1) Conc Na₂O in Env. C glass = 14 wt% (= 14 g Na₂O / 100 g glass), as per attached email message from Mike Johnson.
- 2) For max Tc-99 in glass, assume all Na comes from feed. If some Na added, multiply max Tc-99 value determined here by (Na conc after addition): (Na in Tc removal effluent).
- 3) Glass Density = 2.66 MT/m³ (=2.66 g/mL)
- 4) Max Tc-99 activity in glass = 0.1 Ci/m³ (=0.1 Ci / 1E6 mL = 1E-7 Ci/mL)
- 5) [Na] in Tc removal effluent = 4.8 M
- 6) Tc-99 specific activity = 1.71E-2 Ci/g = 1.71E-2 uCi/ug

Na Loading in Glass (g Na / mL glass):

$$(14 \text{ g Na}_2\text{O} / 100 \text{ g glass}) * (1 \text{ mole Na}_2\text{O} / 62 \text{ g Na}_2\text{O}) * (2 \text{ mole Na} / \text{mole Na}_2\text{O}) * (23 \text{ g Na} / \text{mole Na}) * (2.66 \text{ g glass} / \text{mL glass}) = 0.276 \text{ g Na} / \text{mL glass}$$

Max Tc:Na in Glass:

$$(1\text{E-}7 \text{ Ci Tc-99} / \text{mL glass}) / (0.276 \text{ g Na} / \text{mL glass}) = 3.62\text{E-}7 \text{ Ci Tc-99} / \text{g Na}$$

Na in Tc Removal Effluent (g Na / mL feed):

$$(4.8 \text{ mole Na} / \text{L feed}) * (23 \text{ g Na} / \text{mole Na}) = 110.4 \text{ g Na} / \text{L feed}$$

Max Tc in Tc Removal Effluent:

$$(3.62\text{E-}7 \text{ Ci Tc-99} / \text{g Na}) * (110.4 \text{ g Na} / \text{L feed}) = 40.0 \text{ uCi Tc-99} / \text{L feed} \\ = 2.34 \text{ mg Tc-99} / \text{L feed}$$

Example: Na added to make vit feed 150 g Na / L feed

$$\text{New maximum Tc:Na (before the additional Na is added, ie, in Tc removal effluent)} \\ = (150 / 110.4) * 2.34 \text{ mg Tc-99} / \text{L feed (before Na addition)} \\ = 3.18 \text{ mg Tc-99} / \text{L feed (before Na addition)}$$
