Studies of Annual and Seasonal Variations in Four Species of Reptiles and Amphibians at
Los Alamos National Laboratory

by

Esther I. Nelson, Tim Haarmann, David C. Keller, and Teralene Foxx

ABSTRACT

Baseline studies of reptiles and amphibians of the Pajarito wetlands at Los Alamos National Laboratory have been conducted by the Ecology group since 1990. With the gathered data from 1990–1997 (excluding 1992), we plan to determine if patterns can be found in the annual and seasonal population changes of four species of reptiles and amphibians over the past seven years. The four species studied are the Woodhouse toad, the western chorus frog, the many-lined skink, and the plateau striped whiptail lizard. Statistical analysis results show that significant changes occurred on a seasonal basis for the western chorus frog and the many-lined skink. Results indicate a significant difference in the annual population of the Woodhouse toad.

INTRODUCTION

Research has demonstrated the importance of reptiles and amphibians in natural ecosystems. Reptiles and amphibians are indicators of general environmental health while aquatic amphibians and snakes are good indicators of the health of aquatic systems. These animals are especially sensitive to pollution and loss of aquatic habitat (Hall 1980). Amphibians and reptiles are also important in food chains, and they make up large proportions of vertebrates in certain ecosystems (Bury and Raphael 1983). Because of recent concern for non-game wildlife, biologists and land managers find themselves faced with studies and management needs for a group of animals they know little about (Jones 1986). Long-term studies can provide insight into relationships between environmental variation and variation in population dynamics (Dunham 1994).

DISTRIBUTION OF THIS DOCUMENT IS UNLIMITED

Seasonal and annual population variations fluctuate from year to year as well as month to month. In lizards for example, growth rates have been shown to differ among years, the variation often being attributed to differences in rainfall or food availability between years (Ballinger and Congdon 1980; Dunham 1978). The variation among years is a proximate response to variation in rainfall and temperature (Smith 1995). Influences by humankind such as development and disturbance of areas, also pose to be detrimental as well. With these factors in mind, we wish to examine if any significant changes within populations have occurred seasonally or annually.

Pitfall trapping has been employed widely for surveys of amphibian and reptile diversity and abundance in different habitat types. Also, pitfall trapping is useful for investigating seasonal activity patterns. Traps can be operated continuously so that variation in activity due to weather can be detected (Bury and Corn 1987).

Monitoring of reptiles and amphibians have been conducted via pitfall trapping at Los Alamos National Laboratory (LANL) by the Ecology group (ESH-20) since 1990 to determine seasonal and annual trends among reptiles and amphibians of the Pajarito wetlands. Seasonal and annual differences were analyzed in populations of the four most common species caught. The results will show if any significant changes within these four species have occurred over the past seven years.

Monitoring generally requires sampling over several years so that species and community health can be accurately estimated. This is especially needed in sampling amphibians and reptiles because populations fluctuate greatly from year to year with environmental changes. Multiyear data collection allows biologists to determine which population trends are due to naturally fluctuating environmental conditions and which ones are due to other causes (Jones 1986). Studies such as this will allow ESH-20 to provide pertinent information for LANL management decisions as they pertain to reptiles and amphibians.

The four most common species of reptiles and amphibians were used to study seasonal and annual fluctuations. Two species of reptiles, plateau striped whiptail lizard

(*Cnemidophorus velox*) and many-lined skink (*Eumeces multivirgatus*), and two species of amphibians, Woodhouse toad (*Bufo woodhousii*) and western chorus frog (*Pseudacris triseriata*) will be analyzed to determine if there are any significant fluctuations in populations.

MATERIALS AND METHODS

Study area

The traps are located within LANL's Technical Area 36, known as the Pajarito wetlands. The wetlands are located 804 m (2655 ft) west of White Rock on Pajarito Road (Figure 1). The study site is 127 m (419 ft) wide by 356 m (1175 ft) long.

This area is classified as both a riparian association (Degenhart et al. 1996) and a dry upland. The major vegetation in the upland area is Apache plume (*Fallugia paradoxa*), rabbitbrush (*Chrysothamnus nauseosus*), big sage (*Artemisia tridentata*), and blue grama (*Bouteloua gracilis*). Vegetation in the wetland area are rush (*Juncus* spp.), willows (*Salix* spp.), and broad-leaved cattail (*Typha latifolia*). Pitfall traps are located by both upland and riparian vegetation types.

Pitfall traps

Approximately 16 pitfall trap arrays are located within the study site. The study site is divided into two areas—denoted as north and south—by an ephemeral stream. Seven ponds are located adjacent to the north side of the stream.

Drift fences (aluminum flashing) with pitfall traps (large buckets) are commonly used to inventory and monitor populations of amphibians and reptiles (Heyer et al. 1994). Aluminum flashing is placed in the ground and used to intercept and direct animals into pitfall traps. Lids are elevated above the traps to provide overhead protection by attaching uniformly shaped wooden blocks underneath the corners. The entire trap system, including the aluminum flashing and buckets, are referred to as a pitfall trap array. This method was used for trapping reptiles and amphibians at LANL. Nine pitfall trap arrays were placed in the wetland area in 1990, and

trapping was continued on a seasonal basis until 1991. All data collected for 1992 was invalidated because of predation within the pitfall traps. In 1993, seven pitfall trap arrays were added to the study site at the wetland area. The total number of pitfall traps (1-gallon buckets) in the arrays was 72. The 72 1-gallon buckets were placed side by side with the drift fence intersecting the very edge of the buckets. In 1997, all pitfall traps were replaced with 5-gallon buckets to reduce the potential for escape by larger animals. The total number of traps was also reduced from 72 to 40. Although the number has changed, the actual traps are in the same location and encompass the previously occupied space.

Traps were opened for the season in late April and run through late September. They were checked daily Monday through Friday and closed on the weekends. Trapping days for all years are similar. Field technicians responsible for checking the traps changed on a yearly basis. Because data collected from 1992 are incomplete, we excluded them from our analysis.

Animal processing

Once animals were captured, they were brought back to the laboratory to be measured. The mass of the animal was measured in grams with a Mettler electronic scale. Then the distance from the tip of the rostrum to the vent (snout-vent length) was measured in millimeters with Mitytoyo electronic calipers. Total tail length was measured from the vent to the tip of the tail. If the tail had been damaged or showed regeneration, then the regenerated portion of the tail was measured from the anterior portion of where the tail was broken off to the most posterior portion of the tail. The data were recorded with date, trap number, and comments.

Analysis

Data for 1990 and 1991 have been adjusted to equal 16 traps for all seasons. The total number of captures (1990 and 1991) were divided by nine to get an average number of captures per trap. The resulting number was multiplied by 16 to estimate the number of animals that would have been caught if 16 traps were first present when trapping began.

Annual and seasonal fluctuations in the number of captures were analyzed for each species using a Kruskal-Wallis non-parametric test. Populations of reptiles and amphibians were compared on a year to year basis during 1990–1997 (excluding 1992). Populations of reptiles and amphibians were also compared on a month to month basis during 1990–1997 (excluding 1992).

RESULTS

Table 1 lists all of the reptiles and amphibians captured at the Pajarito wetlands since 1990 (excluding 1992). The four reptiles and amphibians of interest caught on an annual basis at the Pajarito wetlands since 1990 (excluding 1992) have been recorded and are included in Table 2. The four reptiles and amphibians of interest caught on a seasonal basis (excluding 1992) are included in Table 3. Table 4 shows the results of the Kruskal-Wallis test conducted for the species of interest by year and month.

TABLE 4. Results of Kruskal-Wallis Non-Parametric Test for Annual and Seasonal Variation.

Species	p-value for ANNUAL	p-value for SEASONAL
Woodhouse toad	0.05*	0.64
Western chorus frog	0.10	0.04*
Plateau striped whiptail	0.16	0.27
Many-lined skink	0.74	<0.01*

*Significant at $P = 0.05$

Woodhouse Toad

Figure 2 shows graphs indicating seasonal and annual fluctuations of the Woodhouse toad. The seasonal variation shows a low number of toads captured (9) for the month of June, while the highest captured is 16.8 for the month of August. The graph displaying annual variation indicates a low number of captures (1-2 toads caught) for 1994–1996, and a high number of captures (27) for 1997.

As indicated in Table 4 the P-value for annual variation is 0.05. Where the P-value for a seasonal variation is 0.64.

Figure 2. Annual and seasonal variations of the Woodhouse toad.

Western Chorus Frog

In Figure 3 the graph representing annual variation of the western chorus frog shows a low number of captures being 8.6 for June and the high number of captures of 78.4 for September. The graph indicating annual variation shows a low number of captures of 4 in 1995, while in 1995 a high number of frogs (55) were caught. Shown in Table 4 are the P-values for annual and seasonal variation. Annual variation is 0.10. Seasonal variation is 0.04.

Figure 3. Annual and seasonal variations of the western chorus frog.

Plateau Striped Whiptail

Figure 4 shows graphs indicating annual and seasonal variations of the plateau striped whiptail. The smallest amount of lizards caught was 62.6 individuals in May, while the highest number of lizards caught was 138.8 in June. Shown in Table 4 are the P-values for seasonal and annual variation. The P-value for annual variation is 0.16, the P-value for seasonal variation is 0.27.

Figure 4. Annual and seasonal variations of the plateau striped whiptail lizard.

Many-Lined Skink

Figure 5 shows graphs indicating annual and seasonal variations of the many-lined skink. The smallest number of skinks captured on a seasonal basis is 17.9 for May. The greatest number of skinks captured is 138 for August. The lowest number of skinks that were caught on an annual basis was 22 in 1995. The greatest number captured being 81.8 was in 1990. As shown in Table 4, the P-value for seasonal variation is <0.01 . For annual variation the P-value is 0.74.

Figure 5. Annual and seasonal variation of the many-lined skink.

DISCUSSION

Annual variation of the Woodhouse toad is quite significant in 1997 as compared to other years (1990–1996). More juveniles were caught in 1997 than any other year. The majority of all juveniles caught in 1997 were in the months of August and September. Reasons for this may be attributed to increased precipitation in the late summer months. Gehlbach (1965) suggested that populations in northwestern New Mexico have a biannual breeding regime, corresponding to spring and summer peaks in precipitation. Currently, there are no data to support his suggestion (Degenhardt et al. 1996).

The western chorus frog showed a significant difference in May and September as compared to other months. This may be due to the fact that chorus frogs are much more active during the day in early spring and late fall. Also, the monsoon season in New Mexico occurs in mid-summer, which may cause the frogs to gather in ponds and breed, thus producing large quantities of young frogs in the fall months.

The many-lined skink has shown a significant difference in terms of seasonal variation for the month of August as compared to other months. Large quantities of juvenile skinks were

caught in all of August for all years sampled. This is probably due to emergence of hatchlings and increased activity for foraging purposes, prior to aestivation during the winter months.

Reptiles and amphibians have been trapped at the Pajarito wetlands using pitfall traps since 1990, excluding 1992. Animals were trapped, but data could not be used. The project was initiated to monitor these species as they are affected greatly by environmental changes. Through the years we have modified our sampling design and implemented new techniques to help us better understand the population dynamics of these animals. Monitoring generally requires sampling over several years so that species and community health can be more accurately evaluated. This is especially needed in sampling amphibians and reptiles because populations fluctuate greatly from year to year with environmental changes, with respect to precipitation. Data collected over several years allows biologists to determine if population trends are due to naturally fluctuating environmental conditions or to other causes (Jones 1986).
