Natural Gas and Efficient Technologies A Response to Global Warming

by
Meyer Steinberg
Brookhaven National Laboratory
Upton, NY 11973

February 1998

Abstract:

It has become recognized by the international scientific community that global warming due to fossil fuel energy buildup of greenhouse CO_2 in the atmosphere is a real environmental problem. Worldwide agreement has also been reached to reduce CO_2 emissions. A leading approach to reducing CO_2 emissions is to utilize hydrogen-rich fuels and improve the efficiency of conversion in the power generation, transportation and heating sectors of the economy. In this report, natural gas, having the highest hydrogen content of all the fossil fuels, can have an important impact in reducing CO_2 emissions. This paper explores natural gas and improved conversion systems for supplying energy to all three sectors of the economy. The improved technologies include combined cycle for power generation, the Carnol system for methanol production for the transportation sector and fuel cells for both power generation and transportation use. The reduction in CO_2 from current emissions range from 13% when natural gas is substituted for gasoline in the transportation sector to 45% when substituting methanol produced by the Carnol systems (hydrogen from thermal decomposition of methane reacting with CO_2 from coal-fired power plants) used in the transportation sector. CO_2 reductions exceeding 60% can be achieved by using natural gas in combined cycle for power generation and Carnol methanol in the transportation sector and would, thus, stabilize CO_2 concentration in the atmosphere predicted to avoid undue climate change effects. It is estimated that the total fossil fuel energy bill in the U.S. can be reduced by over 40% from the current fuel bill. This also allows a doubling in the unit cost for natural gas if the current energy bill is maintained. Estimates of the total net incremental replacement capital cost for completing the new improved equipment is not more than that which will have to be spent to replace the existing equipment conducting business as usual. The improved natural gas economy set forth here, resulting in stabilization of atmospheric CO_2 is predicated on (1) availability of long term supply of natural gas, the potential of which resides in its economical extraction from abundant methane hydrates deposits; (2) development of an efficient Carnol process for methanol production based on thermal decomposition of methanal gas and (3) development of an efficient direct liquid methanol fuel cell for automotive use.

NATURAL GAS AND EFFICIENT TECHNOLOGIES A RESPONSE TO GLOBAL WARMING

February 1998

1. INTRODUCTION

Global Warming (others like to call it Global Climate Change) as a result of increasing greenhouse gas buildup in the earth's atmosphere, particularly CO₂ gas from the combustion of fossil fuels (coal, oil and gas) has gained increasing attention of the nations of the world over the past decade. Numerous national and international conferences have been held on the subject, and a consensus among 2500 of the world's leading scientists has concluded that despite uncertainties, a discernable temperature effect can be attributed to man's emissions of CO₂ introduced into the atmosphere because of the need of the world's population to generate energy through the combustion of fossil fuels.⁽¹⁾ The general projections are that the CO₂ emissions will double in the atmosphere within the next century (from the 1995 level of 350 ppm to about 750 ppm CO₂) which could cause the earth's surface temperature to rise from 2.0° to 4.5°C. This would melt the antarctic polar icecap and increase the ocean level about an average of 50 cm (2 ft.) as well as cause other adverse environmental and health effects. The major CO₂ emitters are the industrially developed countries including the United States, Russia, Japan and European countries. Of particular concern are the large developing countries which mainly include China and India since they rely mainly on fossil fuels (and particularly coal) to bring their standards of living up to the level of the developed countries. There is a natural tendency to resist any CO₂ restrictions that the developed countries might be attempting to impose on the developing countries. The developed countries have their own internal problems of convincing their own industries to accept restrictions on their CO₂ emissions because they see this as a negative effect on their economy. However, some leading industries are beginning to recognize the problem and that searching for technological responses to the challenge of mitigating the effect should be cautiously pursued. Adapting to the effect of global warming (i.e., move to higher ground) is recognized as an alternative response to mitigation, and should be considered in terms of economically assessing the alternatives.

A useful equation which sums up the major factors for quantitatively determining CO₂ emissions from a given country is the modified Kaya Equation, modified by a removal term.⁽¹⁾

$$\text{Net C emissions as CO}_2 = P \times \frac{GDP}{P} \times \frac{E}{GDP} \times \frac{C}{E} - S$$

$$\begin{aligned} \text{Net Carbon Emissions as CO}_2 &= \text{Population (P) and per Capita Gross Domestic} && \left(\frac{GDP}{P}\right) \\ \text{to the atmosphere} &\quad \text{Product} && \\ &\times \text{Energy generated per Gross Domestic Product} && \left(\frac{E}{GDP}\right) \\ &\times \text{Carbon Emission per unit energy generated} && \left(\frac{C}{E}\right) \end{aligned}$$

-- Natural and induced removal of C as CO₂ from atmosphere (S)

The primary cause of greenhouse gas is the size of the population, P, which demands and consumes the energy. The products (GDP) generated by the public, which reflects the standard of living, is next in importance. The third term is related to the efficiency or the amount of energy consumed to produce the products. The last term deals with the quality of the fuel in terms of amount of carbon as CO₂ emitted per unit of energy derived from the fuel. When determining net CO₂ emission, a removal or sink term, S, must be subtracted from the emission equation which can be either natural removal (i.e., reabsorption in trees and plants) or technologically induced (i.e., CO₂ removal technologies from fossil fuel power plant stacks).

In terms of the application of CO₂ mitigation strategies, lower energy per unit of GDP and lower carbon emitted per unit of energy produced (C/E) are the more relevant factors, both of which opt for more efficient means of generating energy and producing goods.

This paper mainly addresses the E/GDP, C/E and S terms and attempts to quantify the effect of energy efficiency, fuel substitution as well as carbon removal and sequestration.

CO₂ Emissions from Various Energy Sources

The combustion of coal produces the highest emission of CO₂ per unit of energy released. Natural gas gives the least CO₂ emission, and oil is about half way between coal and oil. Table 1 shows the average emissions rates for each of the major natural fossil fuel sources.

Table 1
CO₂ Emissions from Combustion of Fossil Fuel (C/E term)

Fossil Fuel	CO ₂ Emission Lbs CO ₂ /MMBTU	Kg CO ₂ /GJ
Coal ^a	215	93
Oil ^b	160	69
Gas ^c	115	49

a Coal assumes HHV of 11,000 BTU/Lb and a carbon content of 76% by weight.

b Oil assumes a composition of CH_{1.8} and HHV of 6 MMBTU/bbl

c Gas assumes HHV of 1 MBTU/cu.ft.

HHV = higher heating value, MMBTU = 10⁶ BTU, MBTU = 10³ BTU

Converting Lbs CO₂/MMBTU to Kg CO₂/GJ, Multiply by 0.434

An assessment is made for various scenarios in substituting fuels and estimating the effect on CO₂ emissions. It should be pointed out that by removing carbon either as C or as CO₂ from fuels referred to as "decarbonization" either prior to or after combustion, the C/E term becomes modified. The term "Sequestration" refers to the long term disposal and storage of C or CO₂.

Current U.S. Energy Consumption and CO₂ Emission

The scenarios are applied to the recent energy consumption in the U.S. Table 2 shows fuel consumption, energy consumption by fuel and the CO₂ emissions by fuel type for the year 1995.⁽¹⁾ Table 2 also shows the world total. The U.S. consumes about 23% of the energy consumption in the world and generates and emits about 27% of the world's CO₂ emissions.

Table 2
Total Fossil Fuel Energy Consumption and CO₂ Emission for the U.S. in 1995⁽³⁾

Fuel Type	Quantity	Energy Consumption Q BTU	Principal Energy Service	CO ₂ Emission	
				GT(CO ₂)	%
Coal	0.9x10 ⁹ tons	20	electricity	2.15	35%
Oil	5.8x10 ⁹ bbls	35	Auto transport	2.80	45%
Gas	21.0 TCF	21	heating	1.21	20%
U.S. Total		76		6.16 (1.68 GT(C))	
World Total		330		22.7 (6.2 GT(C))	

TCF = Trillion (10¹²) cubic feet

GT = Giga (10⁹) tons

Q = Quads (10¹⁵) BTU

In the U.S., most of the coal is used for generation of electrical power, in large central power stations. Oil is mainly used for production of transportation fuel (gasoline and diesel) with some limited electrical power production and gas is mainly used for industrial and domestic heating. However, there is also lately a growing consumption of natural gas for electrical power production.

Substituting Natural Gas for Coal for Electrical Power Production

If all the current electrical power production in the U.S. is generated by natural gas in a combined cycle power plant, two benefits of CO₂ emission are achieved. First, the efficiency of electrical power production is increased from the current average coal-fired plant efficiency of 38% to 55% for a modern natural gas fired turbine combined cycle plant and secondly the CO₂ emission per unit of energy is reduced by 47% compared to the coal-fired plant. Applying this to the U.S. consumption, Table 3 gives the CO₂ emission for this scenario.

Table 3
CO₂ Emission When NG Substitutes For All Coal
In a Combined Cycle for Electrical Power Production

Current-coal-fired plant efficiency 38%
NG combined cycle efficiency 55%

Fuel Type	Natural Gas Consumption Quads	Energy Consumed Quads	Energy Service	CO ₂ Emission GT (CO ₂)
Gas substituted for coal	14	14	Electricity	0.79
Oil	--	35	Auto Transport	2.80
Gas	21	21	Heating	1.21
Total	35	70		4.80
Reduction from current CO ₂ emission				1.36
% CO ₂ reduction from 1995 level				22.1%

Thus, it is seen that there is a 22% reduction in overall CO₂ emission in the U.S. when natural gas is substituted for coal in combined cycle plant for all electrical power production. This scenario also assumes that natural gas usage remains approximately the same for supplying heat to the industrial and domestic sectors.

Substituting Natural Gas for Oil for Automotive Transportation

If natural gas is substituted for oil in the transportation sector at the same efficiency, the reduced CO₂ emission is calculated in Table 4.

Table 4
CO₂ Emission When Natural Gas Is Substituted for Oil in the Transportation Sector

Fuel Type	Natural Gas Consumed Quads	Energy Consumed Quads	Energy Service	CO ₂ emission GT (CO ₂)
Coal	--	20	Electricity	2.15
Gas substituted for oil	35	35	Auto Transport	2.01
Gas	21	21	Heating	1.21
Total	56	76		5.37
Reduction from current CO ₂ emission				0.79
% CO ₂ reduction from 1995 level				12.8%

Thus, it is seen that there is only a 12.8% reduction in CO₂ when natural gas is substituted for oil in the transportation sector at the same automotive efficiency. Natural gas heating remains the same for the industrial and domestic sectors.

Substituting Natural Gas for Coal and Oil for Electrical Power and Transportation Service

If natural gas is substituted for all the coal and oil consumption in the U.S., the sum of the emission reduction would be 34.9%, adding the results of Tables 3 and 4.

The Carnol System for Preserving the Coal Industry for Electrical Power Production and Reducing Oil Consumption by Methanol in the Transportation Sector

The Carnol System consists of generating hydrogen by the thermal decomposition of methane⁽¹⁾ and reacting the hydrogen produced with CO₂ recovered from coal-fired central power stations to produce methanol as a liquid transportation fuel.⁽²⁾ Figure 1 illustrates the Carnol System which has the following advantages:

1. The Carnol System preserves the coal industry for electrical power production.
2. The Carnol System produces a liquid fuel for the transportation sector which fits in well with the current liquid fuel infrastructure.
3. The Carnol System reduces consumption of the dwindling domestic supplies of fuel oil in the U.S.

In the Carnol System, the carbon from the coal is used twice, once for production of electricity and a second time for production of liquid fuel for fueling the transportation sector, in automobile vehicles. The reduction in CO₂ emissions results from two aspects. The elemental carbon produced from the thermal decomposition of the methane is not used as fuel. It is either sequestered or sold as a materials commodity. In this respect, thermal decomposition of methane (TDM) has an advantage over the conventional steam reforming of methane (SRM) for hydrogen production because in SRM the efficiency of hydrogen production includes the inefficiency separation and sequestering of the CO₂ produced. In the SRM process, CO₂ is produced, which must be sequestered either in underground aquifers or in the ocean and thus the efficiency of hydrogen production is reduced.⁽⁷⁾ In the TDM process only, carbon is produced as a solid which is much easier to sequester than CO₂ as a gas. Furthermore, the energy in the carbon sequestered is still available for possible future retrieval and use. The carbon can also be used as a materials commodity, for example, as a soil conditioner.

Table 5 gives the estimate of the CO₂ emission using the Carnol System based on the 1995 consumption of oil, gas and coal for energy generation in the various sectors.

Table 5
Carnol Methanol Substitution for Oil in the Conventional Auto Transportation Sector
Produced from Natural Gas and CO₂ from Coal-fired Power Plants

Fuel Type	Natural Gas Consumed Quads	Energy Consumed Quads	Energy Service	CO ₂ Emissions GT(CO ₂)
Coal ^a	--	20	Electricity	0.22
Methanol ^b substitutes for gasoline	41	24	Auto Transport	1.96
Gas	21	21	Heating	1.21
Total	62	65		3.39
Reduction from current CO ₂ emission				2.77
% CO ₂ Emission Reduction from 1995 level				45.0%
Elemental carbon sequestered				0.58 GT (C)

The following are explanatory notes for Table 5:

- a. The coal consumption remains at 0.9 GT which generates 20 quads of electricity and produces 2.15 GT of CO₂, 90% of which is recovered by absorption-stripping with an MEA solvent. The power plant then emits the remaining 10% or 0.22 GT CO₂ as shown in the table. The 1.93 GT (CO₂) then becomes available to the Carnol plant for producing methanol.
- b. The CO₂ from the power plant reacts with hydrogen from a methane decomposition reactor (MDR) which operates at 80% efficiency emitting 0.25GT (CO₂) and producing 35 quads of methanol liquid fuel for automotive vehicles equivalent to that of oil consumption. The methanol combusted in the automotive vehicles emits 1.71 GT CO₂ making up the 1.96 GT CO₂ shown in the table for methanol CO₂ emission. It should be noted that methanol is 30% more efficient than gasoline in IC internal combustion (IC) engines so that the CO₂ emission is reduced accordingly⁽²⁾ and only 70% of the 35 quad or 24 quad is needed in the transportation sector. The CO₂ recovered from the coal burning power plants matches the methanol production requirement at 24 quad. The natural gas requirement to produce 24 quad of methanol by the Carnol Process amounts to 41 Quad, which is about twice the current consumption of natural gas consumed for heating purposes. The sequestration of 0.58 GT (C) is half the tonnage of coal mined in the U.S.

Table 5 indicates that the Carnol System can reduce the CO₂ emission by 45% compared to current energy consumption and CO₂ emission. The natural gas requirement would have to increase to 62 quad which is 3 times the current consumption of natural gas for heating purposes. The reason the requirement for natural gas increases so rapidly is because in the Carnol methanol plant, only about 58% of the natural gas energy is utilized for producing hydrogen for methanol, the remainder of the energy is sequestered as unburned carbon. Table 5 shows that 0.58 GT is sequestered as elemental carbon. This can be considerably reduced by going to fuel cell vehicles as shown in the next scenario.

Carnol System with Methanol Fuel Cells for the Transportation Sector and Substituting Natural Gas with Combined Cycle Power for Coal Fired Central Station Power

In the not too distant future, fuel cells will be developed for automotive vehicles. This will improve the efficiency of automotive engines by at least 2.5 times compared to current gasoline driven internal combustion engines.⁽⁸⁾ Direct liquid methanol fuel cells are under development.⁽¹¹⁾ If we use coal or oil for central power stations, there will be too much CO₂ generated for liquid fuel methanol by the Carnol Process for the transportation sector using fuel cells. Therefore, it is much more energy balanced if we use natural gas for power because it generates the least amount of CO₂ per unit of energy. In this scenario, the natural gas in a combined cycle plant displaces coal for power production and displaces oil for methanol by the Carnol Process for transportation. The results are shown in Table 6.

Table 6
Natural Gas substituted for Coal Fired Power Production, Carnol Process for Methanol Production, Substituting for Oil in Fuel Cell Vehicles for the Transportation Sector

Fuel Type	Natural Gas Consumption Quads	Energy Consumption Quads	Energy Service	CO ₂ Emission GT (CO ₂)
Natural gas for coal ^a	14	14	Electricity	0.08
Methanol for oil	24	14	Auto Transport Fuel Cells	1.12
Gas	21	21	Heating	1.21
Total	59	49		2.41
Reduction from Current CO ₂ Emissions				3.75
% CO ₂ Emission Reduction from 1995 level				61%
Elemental carbon sequestered				0.34 GT (C)

- a) Natural gas for combined cycle power plant is 55% efficient and 90% of CO₂ emissions is recovered for Carnol plant.

There is a small deficiency (0.32 GT) CO₂ in the availability of CO₂ from the very efficient natural gas combined cycle plants to supply the Carnol methanol plant. This can be made up by allowing some (about 15%) of the natural gas plants to operate in a standard plant at 38% efficiency to generate the additional CO₂ to supply the Carnol plant for producing automotive methanol. It is also possible to utilize the CO₂ that may be associated with the natural gas from the wells to make up for the deficiency of CO₂ from the combined cycle natural gas fired power plants to supply the automotive Carnol methanol plant. Thus, by applying the all natural gas system for electrical power production, liquid fuels production for fuel cell driven automotive engines and for heating purposes in the industrial and domestic sectors, the overall CO₂ emissions reductions of over 60% can be achieved. This degree of CO₂ emission reduction could stabilize the CO₂ concentration in the atmosphere and prevent the doubling of the CO₂ in the atmosphere expected by the middle of the next century if business is conducted as usual. The 0.32 GT of carbon sequestered is about 3 times less than the

amount of coal mined in the U.S. currently. If a market can be found for this elemental carbon, such as a soil conditioner, the cost of methanol production can be significantly decreased.

The ultimate is to go to an all hydrogen economy producing hydrogen by thermal decomposition of methane for use in fuel cells for electrical power production, for transportation and for heating purposes. The CO₂ would be essentially reduced by 100%. Because of the higher efficiency the quantity of carbon for sequestration may be less than shown in Table 6. However, the production and handling of massive amounts of hydrogen probably will be a long time in coming, if ever.

Natural Gas Supply and Utilization

The all natural gas energy system of Table 6 requires a three-fold annual consumption in natural gas. Recent reports indicate that the current estimated reserve of conventional natural gas is of the same order of magnitude as the current estimated oil reserves which might last only another 80 years or so. However, unconventional resources, especially methane hydrates⁽⁹⁾ and coal bedded methane indicate an enormous resource which is estimated to be more than twice as large as all the fossil fuel resources currently estimated in the earth. If this is so, then we can begin to think of utilizing natural gas for reducing CO₂ emissions in all sectors of the economy. It appears that even today that deep mined coal in several parts of the world, especially in England, Germany, and the U.S., has become too expensive; and, as a result, many of these mines have been closed. Most economical coal used now comes from surface mined coal. Furthermore, the contaminants in coal sulfur, nitrogen and ash in addition to the high CO₂ emission mitigate against its use. Rail transportation of coal also becomes a problem compared to pipeline delivery of natural gas. When natural gas becomes available, even at a somewhat higher cost, it can displace coal and even oil for power production and transportation. Long term supply of economical natural gas is the main concern for utilization of natural gas.

Economics of Natural gas Displacing Coal and Oil

A cursory estimate of the economics of natural gas displacement in the U.S. can be obtained as follows: Table 7 indicates the unit price for each of the fossil fuels and the total energy bill for the U.S. over the last several decades.

Table 7
Unit Fossil Fuel Energy Cost and Total Fuel Cost for the U.S. - 1995 Basis

Fuel Type	Unit Energy Cost \$/MMBTU	Consumption Quads	Energy Service	Total Fuel Cost \$10 ⁹ (\$ Billion)
Coal	1.00	20	Electricity	20
Oil	3.00	35	Auto Transport	105
Gas	2.00	21	Heating	42
Total		76		167

If we now supply these same unit costs to the all natural gas scenario presented in Table 6 above, we can draw up Table 8.

Table 8

**Fuel Cost for All Natural Gas Scenario
Combined Cycle Power and Fuel Cell Automotive Power
Based on natural gas Cost = \$2.00/MMBTU**

Energy Demand Sector	Consumption Quads ^a	Natural Gas Fuel Cost \$10 ⁹ (\$Billion)
Electrical Power	14	28
Automotive Power	14	28
Industrial and Domestic Heating	21	42
Total	49	98

^{a)} from Table 6

Table 8 indicates that there is a \$69 Billion dollar decrease in the fossil fuel bill per year which is 41.3% lower than the current bill shown in Table 7 obtained by substituting an all natural gas economy for the current conventional coal and oil energy economy. It could also be pointed out that the cost of natural gas could go up to as high as \$3.50/MMBTU to break even with today's fossil fuel energy bill. This cost is almost double the current natural gas cost and would allow for increased production cost of natural gas from unconventional sources. A carbon tax would make the incentive to go to natural gas that much greater.

We can now attempt to estimate the incremental capital investment for replacement of the present power production structure with the new more efficient technology. Table 9 indicates this incremental capitalization. The concept is that the current capital investment will be replaced under current business as usual conditions. Therefore, what we are concerned with is what additional capital cost will have to be incurred because of the replacement with new technology equipment.

**Table 9
Capital Investment Required to Replace Present Power Structure**

Present Power Structure (and capacity)	Replacement Structure (and capacity)	Incremental Unit Capital Cost	Incremental Replacement Capital Cost \$10 ⁹ (\$ Billions)
Coal fired electrical ^{a)} power 400,000 MWe	Natural gas fired combined cycle electrical power	- \$1000/kw (savings) ^{a)}	- \$400
Oil refineries ^{b)} 35 Quads	Carnol methanol plants 14 Quads	\$10 ⁵ /T/D Methanol ^{b)}	+ \$200
Wells and pipelines ^{c)}	additional pipeline and new methane hydrate wells	\$10 ⁶ /mile ^{c)} 200,000 miles of gas lines	+ \$200
Automotive IC vehicles 100 x 10 ⁶	Fuel cell vehicles	0 ^{d)}	~ 0
Net total incremental replacement cost			~ 0

The following are explanatory notes for Table 9:

- a) For replacement of coal fired plants including scrubbers, etc., runs about \$2000/kw(€), with the more efficient natural gas combined cycle plants runs about \$1000/KW(€); thus, there is a \$1000/KW(€) capital cost savings and when applied to an installed capacity of 400,000 MW(€), the savings amounts to \$400 billion.
- b) For replacing oil refineries with Carnol Methanol plants which require removal and recovery of CO₂ from the natural gas plants, it is estimated that the current unit cost is \$100,000 per daily ton of methanol⁽¹⁰⁾ and the total incremental cost to supply 14 quads of methanol for fuel cell vehicles is \$220 Billion. Since no credit was taken for the replacement of oil refineries, over time, this incremental capital cost is probably high.
- c) New pipelines will have to be built to transport the natural gas and new methods of extracting natural gas eventually from deep sea wells containing methanol hydrates. Assuming \$1 million per mile for these new gas supply facilities and a rough estimate of 200,000 miles needed gives a capital cost of roughly \$200 billion. It is also assumed that the liquid methanol pipeline and tanker distribution will be about equal to the current liquid gasoline distribution for the transportation sector.
- d) In terms of replacing the current existing more than 100 million gasoline driven IC engine vehicles with fuel cell vehicles, it eventually should not cost much more than the present average cost of \$15,000 to \$20,000 per vehicle. And, so the incremental cost should be negligible and may even show a savings because of the more efficient fuel cell vehicle than the IC engine vehicle.

Thus, balancing the four power structures shown in Table 9, the incremental savings in the new technologies of the one electrical power sector just about balances the incremental cost in the other three sectors. Thus, the new total incremental capital replacement cost is a wash compared to the increasing capital cost requirement for continuing with the business as usual current power technology structures.

Summary and Conclusions

Table 10 summarizes the findings in this paper concerning natural gas fuel substitution and applying new efficient technologies. Natural gas substitution for oil in the transportation sector and coal in the power generation sector yields a 13% and 22% reduction in CO₂ respectively compared to current CO₂ emissions. Combining natural gas substitution in both sectors reduces CO₂ by 35%. Applying the new Carnol System producing methanol for conventional vehicles and obtaining the CO₂ from coal fired power plant stacks reduces the CO₂ emissions by 45%. By going to an all natural gas energy economy with combined cycle power generation and using the CO₂ from the natural gas power plant for producing methanol by the Carnol process and the methanol in efficient fuel cell automotive vehicles, can result in a 61% reduction CO₂. The latter result should stabilize the CO₂ emissions in the U.S. to well below the 1990 level. The all natural gas economy would require a three-fold increase in natural gas consumption compared to current consumption. For this all natural gas economy, the savings in the fuel bill for the U.S. can be as much as \$69 billion per year and the incremental capital investment required to replace the current technology with the new and improved efficiency technology would be negligible so that the cost of natural gas could almost double without adding to the burden of the current fuel economy. However, the all natural gas economy is predicated on the following assumptions and developments:

Table 10

**Summary of the Effect of Natural Gas Substitutions and Efficient Technologies
on CO₂ Emission Reduction in the U.S.**

Scenario	% CO ₂ Emissions Reduction from 1995 level
Natural gas substitutes for oil in the conventional transportation sector	13%
Natural gas (combined cycle) substitutes for coal in power generation	22%
Natural gas substitutes for oil and coal in the above transportation and coal power sectors	35%
Carnol System with coal power plants supplying CO ₂ for methanol replacing oil in IC motor vehicles	45%
Combined cycle natural gas substituting for coal in power generation and Carnol for Methanol production for fuel cell vehicles – all natural gas economy	61%

1. that there are vast reserves of natural gas that can be recovered from both conventional and non-conventional natural gas resources especially from methane hydrates and coal bedded methane at costs which are not more than about double current gas productions cost.
2. that an efficient Carnol process for methanol production based on thermal decomposition of methane can be achieved.
3. that an efficient direct methanol fuel cell vehicle can be developed.

The benefits in terms of mitigating global warming provides a strong incentive for working on and achieving the required development goals. The all natural gas economy with efficient technologies for CO₂ global warming mitigation avoids alternatives of (1) sequestering CO₂ in the ocean or underground, (2) switching to nuclear power, and (3) relying solely on solar and biomass energy.
