Abstract

We report molecular dynamics simulations of liquid alkanes, squalane and tetracosane, confined between moving walls to which butane chains are tethered, effectively screening the details of the wall. As in an experiment, heat is removed by thermostating the tethered molecules. Results obtained at high strain rates, typical of practical applications, suggest little or no difference between the bulk rheology and confined flow, and the occurrence of a high degree of slip at the wall-fluid interface at the conditions studied. At relatively low velocities and high densities, tetracosane shows the formation of fully-extended chains at certain wall spacings.

Keywords: molecular simulation, rheology, molecular dynamics, alkanes

1 Introduction

Recent advances in experimental and computer simulation techniques for studying lubrication at the atomic scale have led to an increased understanding of fluids in ultra-thin films.

Surface force apparatus (SFA) experiments have clearly shown that the static and dynamic properties of fluids in molecularly thin films can be noticeably different from those of bulk fluids [1, 2]. In general, bulk behavior persists until film thicknesses of order ten molecular diameters. Differences in the dynamic response from the bulk behavior are quite dramatic [1]. The effective viscosities of thin films rise orders of magnitude above the bulk values with a corresponding increase in the molecular relaxation times [3]. However, it should be recognized that dynamical experiments with extensions of the surface force apparatus are conducted at strain rates ($10 - 10^5 \text{ s}^{-1}$), orders of magnitude below the strain rates which are found in the lubrication of disk drives, of micromachines, and of camshaft lifters in automobile engines (*ca.* 10^8 s^{-1}) and which

are only accessible computationally [4]. Table 1 compares the temperatures and strain rates for SFA experiments, prior bead-spring molecular dynamics (MD) simulations, and this study to those that exist in practical applications. The MD simulations of chains [5, 6, 7, 8] with the fully-flexible bead-spring model are performed at temperatures which are apparently very low. However, because of an apparent time-temperature scaling, the effective regime of the bead-spring system is similar to the experimental regime [4]. This scaling could explain the reasonable success of the bead-spring simulations in qualitatively reproducing many aspects of the experiments.

Some of the difficulties with realistic (as compared to bead-spring) simulations of confined fluid rheology involve realistic treatment of the specific wall-fluid interactions and of the thermostating of the simulation. We have addressed these challenges with a novel simulation approach which we believe may also be amenable to experiment. We have studied the dynamic response of liquid alkanes confined between walls that have short alkane chains (C_4H_{10}) tethered to them, which effectively screen the details of the wall. Shear flow is induced in the film by moving the walls, and heat is removed by thermostating the first two atoms of the tethered chains. Our goal is to study the confined flow of alkanes of intermediate size range, comparable to many lubricants, and here we present some results obtained for tetracosane ($C_{30}H_{62}$), which is a linear molecule, and squalane ($C_{30}H_{62}$), a branched molecule with six symmetrically placed methyl side groups along a 24 carbon backbone. Detailed results from our simulations [9] will appear in a subsequent publication [10].

In Section 2 we present the molecular model and the simulation method, while Section 3 compares the rheological properties of the confined films to those of the bulk fluid, and presents some insights into the conformations of these molecules.

2 Molecular Model and Simulation Method

We perform two types of simulations: (i) nonequilibrium molecular dynamics (NEMD) simulations in a confined geometry, and (ii) NEMD simulations for the bulk fluid. The bulk fluid simulations are performed at the same conditions as those that exist in the confined geometry, i.e. at the same temperature and strain rate. The density used for the bulk simulations is the average density in the central region of the confined geometry. Limited simulations also compare the confined and bulk results under constant pressure conditions.

2.1 Potentials

The model used for the alkanes is the united atom model previously used by Siepmann *et al.* [11, 12] and also by Mondello and Grest [13]. We have also used this model to successfully predict the Newtonian viscosities of various bulk fluid alkanes, including squalane [14]. The methyl and methylene groups are treated as spherical interaction sites with the interaction centers located at the centers of the carbon atoms. The interaction between atoms on different molecules and atoms separated by more than three bonds in the same molecule is described by the well-known Lennard-Jones (LJ) potential, with a cutoff distance of $2.5\sigma_{CH_2}$. The intramolecular interactions include a stretching term, a bending term and a torsional term. The bond stretching is described by a harmonic potential [15], with an equilibrium bond length of $1.54\text{\AA}$ and a force constant $A/k_B = 452,900K/\text{\AA}^2$. The bond angle bending is also described by a harmonic potential while the torsional potential is that by Jorgensen *et al.* [16]. To prevent umbrella inversion of the sp_3 bond configuration at tertiary carbon branch points, we use a harmonic potential similar to the bending term, introduced by Mondello and Grest [13]. The LJ size and energy parameters, and the intramolecular interaction parameters can be found in [13].

For the atom-wall interactions, we use the potential proposed by Padilla and Toxvaerd [17], modified to model a structureless wall,

$$U^W(y) = \frac{2\pi\rho_s\epsilon_w}{3} \left(\frac{2\sigma_w^{12}}{15y^9} - \frac{\sigma_w^6}{y^3} \right) + 10\epsilon_w \exp \left[-21.0 \left(\frac{y}{a_1} - y_0 \right) \right] \quad (1)$$

The parameters that characterize $U^W(y)$ are collected in Table 2. The size parameter $\sigma_w = 0.5(\sigma_s + \sigma)$, where $\sigma_s = 2.22 \text{ \AA}$ determines the size of the “atoms” in the solid surface. The energy parameter is ϵ_w , and a_1 is the lattice parameter. The exponential term in y ensures the impenetrability of the wall. The interaction of every atom in the simulation with the wall is considered.

The first atom of each tethered chain is attached at a distance $w_1 = 0.673\sigma_{CH_2}$ from the wall by a harmonic potential with the same force constant as for the bond stretching term. We use a spacing of $2a_1$ for the tethering sites on a square grid parallel to the walls. We choose to use a wall without structure because the tethered alkane chains effectively screen details of the wall.

2.2 Simulation method

For both the confined and bulk simulations, we use rRESPA multi-timestep dynamics [18, 19]. For the bulk NEMD simulations, the motion of the particles can be described by the SLLOD algorithm [20]. The SLLOD equations of motion (incorporating a Nosé thermostat) for a system under planar Couette are given by

$$\begin{aligned} \dot{\mathbf{r}}_{ia} &= \frac{\mathbf{p}_{ia}}{m_{ia}} + \gamma y_{ia} \hat{x} \\ \dot{\mathbf{p}}_{ia} &= \mathbf{F}_{ia} - \gamma p_{y,ia} \hat{x} - \zeta \mathbf{p}_{ia} \\ \dot{\zeta} &= \frac{p_\zeta}{Q} \\ \dot{p}_\zeta &= F_\zeta \end{aligned} \quad (2)$$

where $\mathbf{r}_{ia}$ and $\mathbf{p}_{ia}$ are the vector coordinates and peculiar momentum of atom a in molecule i , y_{ia} and $p_{y,ia}$ are its y components, $\mathbf{F}_{ia}$, the force and m_{ia} , the mass. The strain rate of the imposed shear field is denoted by γ , $\hat{x}$ is a unit vector in the x direction, ζ , p_ζ , and Q are the variables related to the Nosé thermostat, $F_\zeta = \sum_{i,a} \frac{p_{ia}^2}{m_{ia}} -$

$3Nk_B T$, $Q = 3Nk_B T \tau^2$, τ is the Nosé thermostat time constant, and N is the total number of atoms in the system.

For the confined simulations, the above equations apply, but without the γ terms for all atoms, and without thermostating terms for all but the two atoms of each tethered molecule that are closest to the wall. The motion of the walls is simulated by moving the points of attachment of the tethered chains. The top and bottom walls move at velocities $(v_{wall}, 0, 0)$ and $(-v_{wall}, 0, 0)$, respectively.

3 Results

We present some results for the confined alkanes; magnitudes are presented in reduced units (length is reduced with σ_{CH_2} , energy with ϵ_{CH_2} and the mass with m_{CH_2}) unless otherwise stated. The distance between the walls is $w = 9.25$ and the number density $N/V = 2.15$, where V is defined as the dimensionless volume obtained by subtracting a volume $2l^2 w_1$ (l is the box-length along the wall) from the total volume between the walls, and N is the total number of atoms in the simulation. The simulations at this wall spacing use 64 molecules of the alkane. We thermostat the first two atoms of the tethered C_4 molecules to 300 K. Fig. 1 shows the velocity profile and the shear stress $\langle P_{yx} \rangle$ profile for the fluid in the confinement. Since the wall velocity is $v_{wall} = 0.5$, Fig. 1 indicates considerable slip at the interface between the tethered chains and the confined fluid. Previous studies have reported observing a similar slip [6, 8]. The shear stress $\langle P_{yx} \rangle$, which is calculated by the method of planes [21], is constant across the width, and agrees very well with the value computed as the average friction force between the fluid and the tethered chains per unit area of the walls, and also with the average heat dissipated by the thermostat per unit of time. We calculate the strain rate, $\gamma = \partial v_x(y)/\partial y$, by fitting the velocity profile to a straight line.

The data in Fig. 2 show the viscosities obtained for confined squalane and compares

them with the bulk fluid values. Note the fluid undergoes shear thinning. The bulk viscosities are calculated at the same strain rates and temperatures as for the confined simulations (the temperature for the confined fluid was determined to be constant to within 2% across the gap). Remarkably, over the range of strain rates examined, the confined viscosity is identical to the bulk viscosity; the slight discrepancy seen at the lower strain rates has been determined to be due to differences between the calculated confined and bulk pressures; note the data point denoted by the solid triangle in Fig. 2, which is at the same pressure as the corresponding confined result. Stevens *et al.* [4] in their simulations of hexadecane report a similar observation, though the agreement between the bulk and confined viscosities is of a more qualitative nature. It must be pointed out that the results at various strain rates are all at different fluid temperatures (at the higher strain rates, there is significant viscous dissipation, which is negligible in SFA experiments). However, just as one would control the temperature in an experiment, in each case only the first two atoms of the tethered C_4 molecules are thermostatted at 300 K.

Including the effect of the change in temperature with $\dot{\gamma}$, the rate of shear thinning of the confined fluid follows an empirical power law, $\eta \propto \dot{\gamma}^{-0.68}$, which is similar to results from experiments on shorter linear alkanes. The reported exponents are in the range -0.45 to -0.7 [3, 22], albeit at lower strain rates, with onset of nonlinear response occurring between 10 – 100 s⁻¹. We have performed additional simulations at high strain rates with a thermostat also for the confined fluid to remove heat generated by viscous dissipation and maintain a fluid temperature of 300 K. A power-law fit to these ‘constant temperature’ data indicates a marginal effect on the exponent ($\eta \propto \dot{\gamma}^{-0.60}$). Fig. 2 also shows the viscosity of confined squalane for a smaller wall spacing (= 6.7) and at the same number density as for the wider spacing. The monomer density profiles indicate 3 and 5 layers respectively. For the two wall spacings, however, the strain rate

dependent viscosities appear to coincide.

The results in Fig. 2 suggest that at high strain rates the rheological behavior of the confined fluid (regardless of wall spacing) is the same as that of the bulk fluid at the same temperature and strain rate. Concerning the structure of the molecules, our results indicate that the molecules are coiled up with the longest semi-axis being about 1.2 nm. Reiter *et al.* [23] in their SFA experiments with squalane speculate that the molecules have a rather globular shape with a diameter of about 1.0 nm. These results suggest that confined flow SFA experiments may yield a useful, perhaps even quantitative, model of practical lubrication applications because the SFA experiments impose a similar structure on the fluid yielding similar power law rheological behavior as in lubrication but at experimentally accessible strain rates. However, proper interpretation of the SFA experiments will require careful accounting for the slip at the wall.

Results for tetracosane also indicate that for the range of strain rates in our simulations, there is little or no difference between the bulk and confined viscosities. However, tetracosane shows a remarkably interesting behavior at high densities and at relatively low strain rates (when viscous dissipation is negligible). In spite of the absence of a crystalline solid surface, when the wall spacing is close to an integral multiple of the molecular diameter, the lack of side branches in tetracosane allows for the formation of very well-defined layers with the majority of the molecules being in a fully extended state. Fig. 3 shows the normalized density profile from a simulation of tetracosane at $v_{wall} = 0.05$; the distance between the walls is $w = 9.25$ and the number density $N/V \approx 2.15$ (the densities are normalized by the average density in the center). Note the five peaks of equal height. It is suggested that this tight packing of fully-extended chains is what gives rise to the high frictional forces that are observed in SFA experiments.

A future publication [10] will present further details of our simulations results. These

results do not suggest either a crystallization or a glass transition of the confined alkanes. We compare the density profiles and chain conformations of squalane and tetracosane under similar conditions. We also examine how the molecular structure affects the interfacial slip behavior of these alkanes. In particular tetracosane shows a higher degree of slip than squalane, which is related to the conformational structure of the molecules. We present results which indicate that the shear thinning power-law exponent increases modestly with increasing density.

Acknowledgments

The authors gratefully acknowledge Gary Grest for suggesting the use of tethered chains; and Maurizio Mondello, Paz Padilla, and Shengting Cui for helpful discussions.
