Introduction

The twin problems of global warming and diminishing finite fossil fuels resources have stimulated research into CO₂ fixation and utilization. Natural photosynthetic CO₂ fixation utilizes sunlight and chlorophyll as the energy source and photocatalyst to generate carbohydrates and oxygen from CO₂ and H₂O. Natural photosynthesis occurring over a few hundred million years has created a vast quantity of fossil fuels that currently fill our current energy needs. Unfortunately, current consumption rates are rapidly depleting our supply of fossil fuels. Even with the advent of fuel farms it is unlikely that natural photosynthesis will be able to balance the production and use of fuels. It is therefore necessary to explore alternative routes to fuel (and chemical) production and it is likely that artificial photosynthesis will play an increasingly important role in the future.

Because of the thermodynamic stability and chemical inertness of CO₂, both energy and catalysts are needed to transform CO₂ into fuels or useful chemicals. The large energy input needed to fix CO₂ requires the use of renewable energy if artificial CO₂ fixation is carried out on a large scale. The reduction potential to convert CO₂ to CO₂⁻ is -1.9 V vs. NHE, making this process highly unfavorable. In fact 0.1 to 0.6 V overpotentials are typically for the single-electron reduction of CO₂ at Pt or Hg working electrodes. This overvoltage partially results from the kinetic barrier arising from the geometric changes required for one-electron reduction of CO₂ (CO₂ is linear while CO₂⁻ is bent). Although CO₂ reduction by the proton-assisted multielectron steps shown Table 1 is often kinetically difficult, these steps are more favorable thermodynamically than the one-electron process.

Table 1. Reduction Potentials for CO₂ at pH = 7 with all other solutes at 1M.

Reaction	$E_{1/2}^a$, V	
$\text{CO}_2 + \text{e}^- \rightarrow \text{CO}_2^-$	-1.9	(1)
$\text{CO}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{HCO}_2\text{H}$	-0.61	(2)

^a Values are for water vs NHE. The $E_{1/2}'$ values in water vs NHE are close to the values in acetonitrile vs SCE because the ferricenium/ferrocene redox potential shifts by 0.25 V (vs SCE) on going from acetonitrile to water while the SCE potential in water is 0.24 V^[1, 2].

Since the two-electron reduction to formic acid or CO requires a lower potential, electrolysis using a multielectron transfer catalyst in aqueous or in low protic media can be carried out at considerably lower voltages. The simplest electrocatalytic system for CO₂ reduction is an electrochemical cell that contains: a working electrode, a reference electrode, a homogeneous electrocatalyst, the supporting electrolyte, CO₂ and an oxidizable species (often the solvent). The electrodes, such as those made of Mg, can be used as the oxidizable species. A heterogeneous catalyst attached to the electrode surface can be used in place of the homogeneous electrocatalyst.

The same considerations apply in the photochemical reduction of CO₂: the one-electron reduction to CO₂⁻ requires extremely strong reducing agents that are generally difficult to produce by photochemical methods utilizing visible light. The prototype photochemical system for CO₂ reduction contains a photosensitizer (or photocatalyst) to capture the photon energy, an electron relay catalyst (that might be the same species as the photosensitizer) to couple the photon energy to the chemical reduction, an oxidizable species to complete the redox cycle, and CO₂ as the substrate. Figure 1 shows a cartoon of the photochemical CO₂ reduction system. An effective photocatalyst must absorb a significant part of the solar spectrum, have a long-lived excited state, and promote the activation of small molecules. Both organic dyes and transition-metal complexes have been used as photocatalysts for CO₂ reduction.

1. Macrocyclic complexes of cobalt and nickel

1.1 Overview of CO₂ reduction systems mediated by cobalt and nickel macrocycles

Many 14-membered tetraazamacrocyclic complexes of cobalt and nickel serve as catalysts for electrochemical CO₂ reduction to produce CO and H₂ in water, acetonitrile/water, or organic solvents[3-6]. The structures of the macrocycles are shown in Figure 2. Among these, Ni(cyclam)²⁺ is a very effective and selective catalyst for the electrochemical reduction of CO₂ to CO[5, 6]. Ni(cyclam)⁺ adsorbed on the surface of the mercury electrode has been shown to be the active species. Ni(cyclam)²⁺ can have at least two isomers in solution (Figure 2) and studies on configurationally pure nickel complexes similar to Ni(cyclam)⁺ have been carried out to measure the activity of different isomers[7]. Structural differences are an important factor for both CO₂ binding and catalyst adsorption on mercury.

CoHMD²⁺ homogeneously catalyzes both electroreduction of CO₂ and water reduction in water, water/acetonitrile, or DMF solutions[3, 4]. The CO-to-H₂ ratio produced is typically less than 1 and strongly depends on the experimental conditions used (i.e., applied potential, amount of water, electrolysis time, etc). The chiral N-H centers of the HMD macrocycle give rise to two isomers, N-rac and N-meso as shown in Figure 2. The N-rac isomers of both Co^{II}HMD²⁺ and Co^IHMD⁺ predominate in MeCN (>90 %) and water at room temperature. The equilibrium between the N-rac and N-meso cobalt(II) isomers is very slowly established in acidic aqueous and organic media (< 2 × 10⁻⁷ s⁻¹); by contrast, equilibration of the cobalt(I) isomers is relatively rapid (> 2 × 10³ s⁻¹)[8, 9].

Photochemical CO₂ reduction to CO (and formate in some cases) has been reported in a catalytic system using Ru(bpy)₃²⁺ as the sensitizer, nickel or cobalt macrocycles as the electron relay catalyst, and ascorbate as a sacrificial reductive quencher[4, 10, 11]. These systems also produce H₂ via water reduction. While Ni(cyclam)²⁺ is an efficient and selective catalyst for electrochemical CO₂ reduction, even in H₂O, when used as a homogenous catalyst the quantum

yield and selectivity for CO formation is low. The yields of CO and H₂ are pH dependent and typically more H₂ than CO is produced.

Photoreduction of CO₂ with *p*-terphenyl (TP) as the photosensitizer and a tertiary amine as a sacrificial electron donor has been demonstrated^[12]. The same system with the addition of a cobalt macrocycle enhances the activity of the TP by suppressing degradative reactions of the TP and produces CO and formate efficiently with only small amounts of H₂.

Metal(I), metal(III) hydride, and metallocarboxylate complexes have all been postulated as intermediates in electro- and/or photo-chemical CO₂ reduction. These intermediates are discussed in the next sections.

1.2. Properties of the cobalt and nickel macrocycles

1.2.1 M(I) complexes

Reduction potentials of Ni^{II}(cyclam)²⁺, *RRSS*-Ni^{II}HTIM²⁺ and Co^{II}HMD²⁺ are -1.44, -1.43, -1.34 V (vs SCE in MeCN), respectively. The metal(I) complexes can be prepared by electrochemical, Na-Hg reduction, or pulse radiolysis. The spectra of all the M(I) species show a strong MLCT (metal-to-ligand charge transfer) band in the visible region (λ_{max} , ϵ): Ni^I(cyclam)⁺ at 384 nm, 4400 M⁻¹ cm⁻¹; *RRSS*-Ni^IHTIM⁺ at 388 nm, 4340 M⁻¹ cm⁻¹; and Co^IHMD⁺ at 678 nm, 18,000 M⁻¹ cm⁻¹ in MeCN. In the square-planar d⁸-Co^IHMD⁺, the electron-rich cobalt(I) center donates significant electron density to the imine moiety, causing the C=N stretching frequency (1571 cm⁻¹) to be much lower than for Co^{II}HMD²⁺ (1661 cm⁻¹). Interestingly, the square-planar d⁹-NiHMD⁺ complex donates less electron density: the C=N stretching frequency only shifts from 1655 to 1647 cm⁻¹ upon the reduction ($E_{1/2}$ = -1.22 V vs SCE in MeCN). EXAFS and x-ray structures reveal that the Co-N bond distances remain almost the same upon the reduction of the Co(II) macrocycles in both solid and solution^[13, 14].

Square-planar d⁸-Ni(cyclam)(ClO₄)₂ and *RRSS*-NiHTIM(ClO₄)₂ can be crystallized from water as low spin complexes. However, in solution the Ni(III) complexes can exist as high spin, octahedral complexes and/or as low spin, square-planar complexes depending on solvent^[15].

For example, $\text{Ni}^{\text{II}}(\text{cyclam})^{2+}$ and $\text{Ni}^{\text{II}}\text{HTIM}^{2+}$ are low spin in MeNO_2 , high spin in MeCN , and the high and low spin complexes are in equilibrium in water. EXAFS studies reveal that *RRSS*- $\text{Ni}^{\text{II}}\text{HTIM}^{2+}$ and *RRSS*- $\text{Ni}^{\text{I}}\text{HTIM}^+$ are 6-coordinate and 4-coordinate with avg. Ni-N distances of 2.08 Å and 2.05 Å, respectively, in MeCN [16]. The x-ray structures of square-planar *RSSR*- $\text{Ni}^{\text{II}}\text{HTIM}(\text{ClO}_4)_2$ (avg. Ni-N distance: 1.959 Å) and *RSSR*- $\text{Ni}^{\text{I}}\text{HTIM}(\text{ClO}_4)$ (avg. Ni-N distance: 2.068 Å) indicate that the bond lengths in the Ni(I) macrocycles increase 0.11 Å upon reduction[15]. This suggests that the $\text{Ni}^{\text{II/I}}$ self-exchange rates of both $\text{Ni}(\text{cyclam})$ and *RSSR*- NiHTIM complexes in MeCN will be slow due to the large structural changes upon electron transfer.

Some electron-transfer rates are summarized in Table 2. Owing to the large driving force for most of the reactions ($> 1.1 \text{ V}$), the rates constants are mostly $> 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ and are at or near the diffusion controlled limit. It would be helpful to have firm determinations of the self-exchange rates constants for the nickel systems.

Table 2. Comparison of electron transfer rates at 25 °C^a

Reaction	Complex	k, M ⁻¹ s ⁻¹	Ref.
ML ²⁺ + e ⁻ _{aq} → ML ⁺	Ni(cyclam) ²⁺	5.6 × 10 ¹⁰	[17]
	Ni(cyclam) ²⁺	4.1 × 10 ¹⁰	[18]
	RSSR-NiHTIM ²⁺	3.5 × 10 ¹⁰	[19]
	<i>N-rac</i> -CoHMD ²⁺	4.4 × 10 ¹⁰	[20]
	<i>N-meso</i> -CoHMD ²⁺	4.7 × 10 ¹⁰	[9]
ML ²⁺ + TP ^{•-} → ML ⁺ + TP	Ni(cyclam) ²⁺	4.3 × 10 ⁹	[21]
	<i>N-rac</i> -CoHMD ²⁺	1.1 × 10 ¹⁰	[22]

	Ni(cyclam) ²⁺	Never reported	

^a The reaction rates with e⁻_{aq} are measured in water. The electron-transfer rate from TP^{•-}, which has a potential estimated at about -2.5 V, is measured in MeCN. The electron-transfer rate from Ru(bpy)₃⁺, which has a potential of -1.33 V, is measured in H₂O.

1.2.2 M-H complexes

Although both cobalt(I) and nickel(I) macrocycles are stable in dry degassed MeCN, their lifetimes in water are limited because the M(I) complexes react with protons to form the corresponding metal hydrides, M(III)-H, as shown in Eq. 8.

The thermodynamics and kinetics of H^+ binding to cobalt(I) and nickel(I) macrocycles have been determined. The pK_a of $Ni(cyclam)(H)^{2+}$, $RRSS-NiHTIM(H)^{2+}$, and $N-rac-CoHMD(H)^{2+}$ are 1.8, 1.9, and 11.7, respectively[9, 18, 21]. As seen from Table 3, protonation rate constants for $N-rac-CoHMD^+$ depend on acid strength. The results are consistent with an associative reaction of the square-planar complex with an acid, HA. While the spectrum of $N-rac-CoHMD(H)^{2+}$ suggests the formation of a $[Co^{III}(H^-)]^{2+}$ species with an absorption band at 440 nm ($520 M^{-1} cm^{-1}$), $Ni(cyclam)(H)^{2+}$ shows no significant absorbance in the 300-700 nm region[9, 18].

1.2.3 M-CO₂ complexes

The reversible binding of CO₂ to M^IL⁺ has been studied using differential pulse polarography[24], cyclic voltammogram[25, 26], pulse radiolysis[9, 18], flash photolysis[18, 22], and conventional spectroscopic methods[26, 27]. The results are summarized in Table 4. The CO₂ binding constants of *N-meso*- and *N-rac*-Co^IHMD⁺ are quite different in both H₂O and MeCN.

The CO₂ binding constant for the *N-rac* isomer is about one-hundred times greater than for the *N-meso* isomer in both solvents. The difference is primarily due to steric interactions between the bound CO₂ and the macrocycle. While hydrogen bonding between the bound CO₂ and amine protons of the macrocycle stabilizes both adducts, the *N-meso* adduct is destabilized by steric repulsion between the macrocycle methyl groups and the CO₂. The equilibrium constants for the formation of CoHMD(CO₂)⁺ and Ni(cyclam)(CO₂)⁺ are $\approx 10^4$ and 4 times larger in water than in

MeCN, respectively. Water may stabilize the CoHMD(CO₂) complex by forming hydrogen bonds to the bound CO₂ as found in crystals of [Ru(bpy)₂(CO)(COO)]•3H₂O[28]. However, both CoHMD(CO₂)⁺ and Ni(cyclam)(CO₂)⁺ have shorter lifetimes in water than in MeCN due to subsequent reactions.

A redox potential threshold for CO₂ binding to the cobalt macrocycles seems to occur at ~ -1.2 V vs SCE[26]. The CO₂ binding constants for a series of Co(I) macrocycles show a strong correlation with the Co^{II/I} potential. This trend is consistent with charge transfer from the electron-rich cobalt center to the bound CO₂. The CO₂ binding rate constants seem also to correlate with the Co^{II/I} potential: $1.1 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for Co^IOMD⁺, $1.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for Co^IHMD⁺ and $3.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for Co^IDMD⁺.

^a Numbers in parentheses are calculated values. ^b Measured vs SCE ^c Measured vs ferricinium/ferrocene ^d The K_{CO_2} is assumed to be the same as K_9 in Eq. 9.

Although the *N-rac*-CoHMD(CO₂)⁺ adduct decomposes to *N-rac*-CoHMD²⁺ and CO in wet MeCN, it is stable in dry MeCN under a CO₂ atmosphere. The complex is thermochromic, being purple at room temperature and yellow at low temperature[29]. The 530-nm band diminishes in intensity and a 430-nm band increases in intensity as the temperature drops. Measurements over the range -40 to +40 °C give $K_s(298) = 0.11 \pm 0.13$, $\Delta G^\circ(298) \approx 1.3$ kcal mol⁻¹, $\Delta H^\circ = -7.0$ kcal mol⁻¹ and $\Delta S^\circ = -28$ cal K⁻¹ mol⁻¹ for Eq. 11 in MeCN.

A solid sample, obtained at -70 °C from a THF/MeCN mixture, shows $\nu_{\text{C=O}} = 1558$ cm⁻¹, $\nu_{\text{C=N}} = 1653$ cm⁻¹, and two $\nu_{\text{C=N}}$, 2337 cm⁻¹ (for coordinated MeCN) and 2272 cm⁻¹ (for free MeCN), consistent with the formation of [S-CoHMD(CO₂)]⁺ with S = MeCN. Increasing pressure also causes the color to change. A MeCN solution contains ~80% five-coordinate [CoHMD(CO₂)]⁺ and ~20% six-coordinate [CoHMD(CO₂)(MeCN)]⁺ under atmospheric pressure at 15° C. Increasing pressure shifts the equilibrium toward the six-coordinate species with an overall reaction volume $\Delta V^\circ = -17.7$ mL mol⁻¹[30]. Furthermore, the FTIR spectra measured over the range 25 to -75 °C in a CD₃CN/THF mixture indicate the existence of four CO₂ adducts: a five-coordinate, non-hydrogen-bonded form **A** ($\nu_{\text{C=O}} = 1710$ cm⁻¹, $\nu_{\text{NH}} = 3208$ cm⁻¹), a five-coordinate intramolecular hydrogen-bonded form **B** ($\nu_{\text{C=O}} = 1626$ cm⁻¹), a six-coordinate non-hydrogen bonded form **C** ($\nu_{\text{C=O}} = 1609$ cm⁻¹, $\nu_{\text{NH}} = 3224$ cm⁻¹), and a six-coordinate intramolecular hydrogen-bonded form **D** ($\nu_{\text{C=O}} = 1544$ cm⁻¹, $\nu_{\text{NH}} = 3145$ cm⁻¹). (See Figure 3.) The two five-coordinated (A and B) and two six-coordinated (C and D) species have similar UV-vis spectra, so only two species are observed by UV-vis spectroscopy.

The thermochromic behavior of the CO₂ adducts has been studied by an X-ray absorption spectroscopy[14]. The metal coordination number, geometry, and electronic properties can be studied using X-ray absorption near-edge spectroscopy while metal-ligand bond distances can be obtained through analysis of the extended X-ray absorption fine structure. XANES spectra for a series of the CoHMD complexes are shown in Figure 4. The X-ray absorption edge position of

the CoHMD complex is sensitive to the oxidation state of the cobalt. The edge energy of $\text{Co}^{\text{II}}\text{HMD}^{2+}$ decreases (1 eV) upon reduction and increases (2-eV) upon oxidation as can be seen in Figure 4a. The $1s \rightarrow 4p_z$ pre-edge peak, located ≈ 6 eV below the main edge, in the XANES spectrum for $\text{Co}^{\text{II}}\text{HMD}^{2+}$ is characteristic of a four-coordinate square-planar geometry. The XANES spectra of the CO_2 adducts at room temperature and 150 K are shown in Figure 4b. At room temperature the Co- CO_2 adduct is 90% five-coordinate $\text{CoHMD}(\text{CO}_2)^+$ and 10% six-coordinate S- $\text{CoHMD}(\text{CO}_2)^+$, whereas cooling the solution to 150 K results in 100% conversion to the six-coordinate species^[26]. The edge position of $\text{CoHMD}(\text{CO}_2)^+$ at room temperature is similar to that of $\text{Co}^{\text{II}}\text{HMD}^{2+}$, consistent with theoretical predictions^[31, 32] that the bound CO_2 receives significant electrons density (≈ 0.7 of an electron) mainly from the Co d_z^2 orbital. The XANES spectrum for S- $\text{CoHMD}(\text{CO}_2)^+$ at 150 K shows an increase of the $1s \rightarrow 3d$ peak (≈ 11 eV below the main edge) and almost complete loss of the $1s \rightarrow 4p_z$ transitions, indicative of six-coordinate distorted octahedral geometry. The six-coordinate S- $\text{CoHMD}(\text{CO}_2)^+$ species shows a 1.2 eV shift towards Co(III) and is interpreted as a $\text{Co}^{\text{III}}\text{-CO}_2^{2-}$ carboxylate complex. This assignment is consistent with the change of the CO_2 asymmetric stretch, $\nu_{\text{C=O}}$, from 1710 cm^{-1} for $\text{CoHMD}(\text{CO}_2)^+$ to 1544 cm^{-1} for S- $\text{CoHMD}(\text{CO}_2^{2-})^+$ discussed above. Although the cobalt(III) carboxylates have been postulated as intermediates in CO_2 reduction and water-gas shift reactions, the XANES results provide the first unambiguous evidence that active metal catalysts, such as $\text{Co}^{\text{I}}\text{HMD}^+$, can promote two-electron transfer to the bound CO_2 . The conversion of the $\text{M}^{\text{I}}\text{CO}_2$ species to a metallocarboxalate, $\text{M}^{\text{III}}(\text{CO}_2^{2-})$, is an important step in catalytic CO_2 reduction since it avoids the very high energy CO_2^- species.

1.3 Electrocatalytic systems

$\text{Ni}(\text{cyclam})^{2+}$ is a very effective and selective catalyst for the electrochemical reduction of CO_2 ^[5, 6]. The advantages of the catalyst are: high turnover frequencies (up to $10^3\text{ cycles h}^{-1}$); accessibility of the applied potential; high efficiency; good selectivity of CO formation at pH 4; and stability of the catalyst after a large number of turnovers ($> 10^4$). $\text{Ni}(\text{cyclam})^+$ adsorbs on the

surface of the mercury electrode and the adsorbed complex is the active catalyst. $\text{Ni}(\text{cyclam})^{2+}$ has configurational isomers in solution; the most stable two forms (*Trans III*, 85 % and *Trans I*, 14 % in water) are shown in Figure 2. It is possible to lock the cyclam ligand in one configuration (*Trans III*) by adding methyl groups to the six-membered ring as in HTIM. The catalytic activities of pure stereo-isomers, *RRSS*- and *RSSR*- NiHTIM^{2+} have been studied[7]. These isomers do not show any isomerization in solution. *RRSS*- NiHTIM^{2+} , which has no axial methyl groups, shows much higher catalytic activity than *RSSR*- NiHTIM^{2+} . *RRSS*- NiHTIM^{2+} has larger catalytic currents and more positive potentials for CO_2 reduction than $\text{Ni}(\text{cyclam})^{2+}$. The peak current density of the *RSSR*- NiHTIM^{2+} , which has axial methyl groups, is lower than that of $\text{Ni}(\text{cyclam})^{2+}$ [7]. Thus structural differences may play an important role in adsorption of the metal complex on a mercury electrode and in CO_2 binding by the absorbed complex.

CoHMD^{2+} homogeneously catalyzes electroreduction of CO_2 . However, it also catalyzes water reduction in water, water/acetonitrile, and DMF solutions[3, 4]. The CO -to- H_2 ratio strongly depends on the experimental conditions used (i.e., applied potential, amount of water, electrolysis time, etc) and is typically less than 1. Since the pK_a of $\text{CoHMD}(\text{H})^{2+}$ is 11.7, the hydride species also form in CO_2 -saturated water ($\text{pH} \sim 4$)[3, 4].

1.4. Photocatalytic systems involving CoHMD and $\text{Ni}(\text{cyclam})$ complexes

1.4.1 Systems with $\text{Ru}(\text{bpy})_3^{2+}/\text{Ni}(\text{cyclam})^{2+}$

CO_2 can be reduced using photogenerated reductants as shown in Figure 1. Photochemical CO_2 reduction has been reported in a catalytic system using $\text{Ru}(\text{bpy})_3^{2+}$ as the sensitizer, $\text{Ni}(\text{cyclam})^{2+}$ as the electron relay catalysts and ascorbate as a sacrificial reductive quencher (Table 5)[10, 11]. The quantum yield for CO production is $\sim 10^{-4}$ at $\text{pH} = 4$ with low selectivity for CO formation due to coproduction of H_2 . The yield of both CO and H_2 are pH dependent. Without $\text{Ni}(\text{cyclam})^{2+}$, a system containing $\text{Ru}(\text{bpy})_3^{2+}$ and TEOA produces HCOO^- with a quantum yield $\sim 5\%$, but no CO [33, 34]. In order to improve the CO yield, complexes that covalently link the sensitizer to the catalysts have been prepared. Complexes in which

$\text{Ru}(\text{bpy})_3^{2+}$ or $\text{Ru}(\text{phen})_3^{2+}$ are bound to $\text{Ni}(\text{cyclam})^{2+}$ have been studied[35-38]. However, these supramolecular photochemical systems have low yields of CO due to competing processes in the quenching of the photoexcited complexes[35, 38].

Bismacrocylic nickel complexes $[\text{Ni}_2(\text{bcyclam})]^{4+}$ and $[\text{Ni}_2(\text{bMe}_2\text{cyclam})]^{4+}$ have been prepared and tested as CO_2 reduction catalysts. The ligands bcyclam and bMe₂cyclam have two connected cyclam or dimethylcyclam units, respectively, as shown in Figure 2. While $[\text{Ni}_2(\text{bMe}_2\text{cyclam})]^{4+}$ shows good selectivity and a high yield for CO formation, $[\text{Ni}_2(\text{bcyclam})]^{4+}$ and the corresponding monomeric nickel complexes ($\text{Ni}(\text{cyclam})^{2+}$ and $\text{Ni}(\text{Me}_2\text{cyclam})^{2+}$) do not[39]. The authors attribute this to the configuration of the methyl groups which occupy the axial positions of the six-membered chelate rings. However, why axial methyl groups increase the catalytic activity is not clear, since axial methyl groups normally hinder CO_2 binding.

Table 5. Photochemical CO₂ reduction with metal macrocycles

Sensitizer	Catalyst or Relay	Donor	Product(s)	CO/H ₂	Φ^a mol einstein ⁻¹	Ref.
Ru(bpy) ₃ ²⁺		TEOA	HCOO ⁻		0.049 ^b	[33] [34]
Ru(bpy) ₃ ²⁺		TEOA	HCOO ⁻		0.096 ^c	[34]

Ru(bpy) ₃ ²⁺	Ni(cyclam) ²⁺	H ₂ A	CO, H ₂	0.16	0.001 (CO)	[10, 11]
Ru(bpy) ₃ ²⁺	Ni(cyclam) ²⁺	H ₂ A	CO, H ₂	0.12		[40]
Ru(bpy) ₃ ²⁺	Ni(cyclam) ²⁺	H ₂ A	CO, H ₂	0.4		[39]
Ru(bpy) ₃ ²⁺	Ni(cyclam) ²⁺	H ₂ A	CO, H ₂	0.02-0.07		[37]
Ru(bpy) ₃ ²⁺	Ni(Pr-cyclam) ²⁺	H ₂ A	CO, H ₂	0.10-0.65	~0.005 ^d (CO)	[37]
Ru(bpy) ₃ ²⁺	[Ni ₂ (bcyclam)] ⁴⁺	H ₂ A	CO, H ₂		~0.0006 ^d (CO)	[39]
Ru(bpy) ₃ ²⁺	[Ni ₂ (bMe ₂ cyclam)] ⁴⁺	H ₂ A	CO, H ₂	15	~0.008 ^d (CO)	[39]
<i>p</i> -Terphenyl	Co(cyclam) ³⁺	TEOA	CO, HCOO ⁻ , H ₂	6	0.075 (HCOO ⁻) 0.05 (CO)	[12, 41]
<i>p</i> -Terphenyl	CoHMD ²⁺	TEOA	CO, HCOO ⁻ , H ₂	1.4		[12]
Phenazine	Co(cyclam) ³⁺	TEOA	HCOO ⁻		0.035	[42]

^a Unless otherwise noted, the quantum yield of product formation is defined as the formation rate divided by the light intensity. ^b with 15 % water in DMF. ^c with 15 % water and excess bpy in DMF. ^d Assuming Φ for Ni(cyclam)²⁺ is 0.001.

1.4.2 System with *p*-terphenyl/CoL²⁺

Oligo(*p*-phenylene)s ranging from *p*-terphenyl (TP) to *p*-sexiphenyl sensitize the photoreduction of CO₂ to formic acid. The systems use triethylamine as a sacrificial electron donor in aprotic polar solvents such as DMF and MeCN[43, 44]. The photoreduction of CO₂ proceeds via electron transfer from the photogenerated anion radical of the *p*-phenylene directly to the CO₂ molecule. In the case of TP, the quantum yield of HCO₂⁻ formation is 3.6% at 313 nm. Unfortunately, a photo-Birch reduction of the TP producing dihydroterphenyl derivatives occurs in parallel with the photoreduction process and the photoactivity is quickly lost. The photodegradation is suppressed when metal macrocycles are added as electron mediators between the reduced terphenyl anion radical and the CO₂. Thus cobalt macrocycles mediate the photoreduction of CO₂ with TP and a tertiary amine (including the β-hydroxylated tertiary amine) as sacrificial electron donor in acetonitrile/methanol mixtures[12]. The system produces CO and formate efficiently with only small amounts of H₂. The combined quantum yield of CO and formate is 13% at 313 nm in the presence of triethanolamine and Co(cyclam)³⁺.

Mechanistic and kinetic studies of the TEA/TP/CoHMD²⁺/CO₂ system have been investigated[22] using flash photolysis techniques. In the absence of added CoHMD²⁺ and CO₂, the TP^{•-} spectrum was obtained in MeCN/MeOH within the resolution of the spectrometer, consistent with the reported rate constant for Eq 12 of $3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ in THF[44]; decay of TP^{•-} in MeCN/MeOH solution followed first-order kinetics with a rate constant of 400 s^{-1} .

The transient absorption spectrum of a sample with added Co^{II}HMD²⁺ indicates the formation of the reduced cobalt complex, Co^IHMD⁺ (Eq 13)[27, 29, 45]. The cobalt(I) complex is quite stable with a lifetime of > 1 s under the experimental conditions (Fig. 6a). The decay of the TP^{•-} absorption and the growth of the Co^IHMD⁺ absorption are shown in Figure 6b and 6c, respectively. The observed rate for the decay of TP^{•-} and growth of Co^IHMD⁺ are the same. The

magnitudes of the changes in absorbance at 470 and 685 nm establish that the stoichiometry of the formation of Co(I) from $TP^{\bullet-}$ is $1 : 1 \pm 0.2$. A plot of the observed first-order rate constant (k_{obsd}) for the decay of $TP^{\bullet-}$ is linear in $[Co^{II}HMD^{2+}]$ and gives a second-order rate constant close to diffusion controlled as expected due to of the reaction's large driving force (~ 1.1 V).

The dependence of the decay rate of $TP^{\bullet-}$ on $[CO_2]$, measured for solutions containing CO_2 with no cobalt macrocycle is not linear in CO_2 concentration. A rate constant of $< 10^6 \text{ M}^{-1} \text{ s}^{-1}$ is estimated for the $TP^{\bullet-}/CO_2$ reaction. This sluggish rate constant is consistent with the large reorganization of the $CO_2/CO_2^{\bullet-}$ couple and modest driving force for the reaction (0.5 V). Under photocatalytic conditions (continuous photolysis) the $TP^{\bullet-}$ reacts much faster with the cobalt complex than with CO_2 and $> 90 \%$ the photochemically generated reducing equivalents are captured by the cobalt macrocycle.

When CO_2 is introduced into the photosystem, the lifetime of the $Co^I HMD^+$ changes dramatically. The decay of $Co^I HMD^+$ monitored at 670 nm shown in Figure 7 has a rate constant of $6.5 \times 10^4 \text{ s}^{-1}$. The observed rate constant for $Co^I HMD^+$ decay is linearly dependent on CO_2 concentration. The CO_2 binding rate constant (forward reaction in Eq 15) is $1.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$.

The decay of the $Co^I HMD^+$ under a CO_2 atmosphere results in a finite absorbance at long times (Figure 7). In addition, the transient spectra measured at 50, 25, 0, and -25°C indicate a mixture of the five- and six-coordinate CO_2 adducts, $CoHMD(CO_2)^+$ and $S-CoHMD(CO_2)^+$. Since the CO_2 adducts have no significant absorption at 670 nm, the ratio of the total amount of cobalt- CO_2 complex, $[Co(CO_2)]_t$, to the unreacted complex, $[CoHMD^+]$, is given by the ratio of the change in the absorbance at 670 nm, $(A_\infty - A_0)$, to the final absorbance at 670 nm (Figure 4a). One can define an effective equilibrium constant

$$K_{\text{CO}_2} = \frac{[\text{Co}(\text{CO}_2)]_t}{[\text{Co}^{\text{I}}\text{HMD}^+][\text{CO}_2]} = \frac{A_\infty - A_0}{A_\infty[\text{CO}_2]} \quad (17)$$

where $[\text{Co}(\text{CO}_2)]_t = [\text{CoHMD}(\text{CO}_2)^+] + [\text{S-CoHMD}(\text{CO}_2)^+]$ and A_∞ and A_0 are the absorbances at 670 nm at long times and at $t = 0$, respectively. The above assumes that the $\text{Co}^{\text{I}}\text{HMD}^+$ is rapidly formed, both $\text{Co}^{\text{I}}\text{HMD}^+$ and the CO_2 adduct are stable on the transient absorption time scale, and only $\text{Co}^{\text{I}}\text{HMD}^+$ absorbs. When the CO_2 concentration is lowered, $(A_\infty - A_0)$ is reduced and A_∞ increases. K_{CO_2} is calculated from Eq 17 as $1.1 \times 10^4 \text{ M}^{-1}$ as shown in Table 4.

The equilibrium constant K_{CO_2} is also given by

$$K_{\text{CO}_2} = K_{15}(1 + K_{16}[\text{S}]) \quad (18)$$

where K_{15} and K_{16} are the equilibrium constants for Eq 15 and Eq 16, respectively. Equilibrium studies in MeCN indicates that K_{15} and $K_{16}[\text{S}]$ are $1.2 \times 10^4 \text{ M}^{-1}$ and 0.17, respectively, for $\text{Co}^{\text{I}}\text{HMD}^+$ at 25 °C[26, 27, 29], yielding a value of $1.4 \times 10^4 \text{ M}^{-1}$ for the K_{CO_2} . CO_2 binding rate constants determined by transient absorbance in MeCN/MeOH, by cyclic voltammogram in pure MeCN, and by pulse radiolysis in H_2O are all about $1.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. The CO_2 binding constant obtained by transient methods is in good agreement with the value obtained from equilibrium methods. These results also indicate that the CO formation proceeds via the initial formation of a five-coordinate $\text{Co}^{\text{I}}\text{HMD}(\text{CO}_2)^+$ complex that quickly forms an equilibrium mixture with the six-coordinate complex, $[\text{S-Co}^{\text{III}}\text{HMD}(\text{CO}_2^{2-})]^+$. The production of CO in the photolysis solution likely proceeds by the subsequent reactions of $[\text{S-Co}^{\text{III}}\text{HMD}(\text{CO}_2^{2-})]^+$ shown in Eqs 19 and 20.

The rate-determining step in the continuous photolysis system must be subsequent to the formation of the $\text{S-CoHMD}(\text{CO}_2)^+$ and is likely to be the C–O bond breakage in the bound

carboxylic acid in Eq 20. Recent developments in transient FTIR may allow the study of the reactions $\text{S-CoHMD}(\text{CO}_2)^+$ in the photocatalytic system.

Studies of catalytic systems with other cobalt macrocycles highlight some of the factors controlling the kinetics of the photoreduction of CO_2 . Photogenerated $\text{Co}^{\text{I}}\text{DMD}^+$ (lifetime 16 μs) is unstable while $\text{Co}^{\text{I}}\text{OMD}^+$ is very stable (lifetime 6 h) in MeCN solution. The CO_2 binding constants (K_{CO_2}) are 6 and $> 5 \times 10^4 \text{ M}^{-1}$ for $\text{Co}^{\text{I}}\text{OMD}^+$ and $\text{Co}^{\text{I}}\text{DMD}^+$, respectively, at room temperature. While the DMD complex with no axial methyl groups prefers the 6-coordinate CO_2 adduct, formation of the 6-coordinate $\text{S-CoOMD}(\text{CO}_2)^+$ is unfavorable due to the steric hindrance of the four axial methyl groups. The Co^{III} redox potentials, the CO_2 binding constants, and the lifetimes show a strong correlation: $\text{Co}^{\text{I}}\text{OMD}^+$ (-1.28 V, 6 M^{-1} , 16 μs), $\text{Co}^{\text{I}}\text{HMD}^+$ (-1.34 V, $1.2 \times 10^4 \text{ M}^{-1}$, $\sim 2 \text{ s}$) and $\text{Co}^{\text{I}}\text{DMD}^+$ (-1.51 V, $> 5 \times 10^4 \text{ M}^{-1}$, 6 h).

1.4.3 Systems with phenazine/ CoL^{2+}

Recently photoreduction of CO_2 to HCOO^- (together with small amounts of CO and H_2) has been achieved by UV-irradiation (313 nm) of a system involving phenazine as a photosensitizer, $\text{Co}(\text{cyclam})^{3+}$ as an electron mediator and TEA as an electron donor^[42]. The quantum yield for the formation of HCOO^- is 0.035. Electron transfer from the photogenerated radical anion ($\text{Phena}^{\bullet-}$) to $\text{Co}(\text{cyclam})^{3+}$ ($k = 4.3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) results in the formation of $\text{Co}(\text{cyclam})^{2+}$. Since the reduction potential of $\text{Co}(\text{cyclam})^{2+/+}$ is $\sim -1.9 \text{ V}$ vs SCE in MeCN, $\text{Phena}^{\bullet-}$ (-1.18 V vs SCE for a $\text{Phena}/\text{Phena}^{\bullet-}$ couple), unlike $\text{TP}^{\bullet-}$, is hardly capable of reducing $\text{Co}(\text{II})$ to $\text{Co}(\text{I})$. The authors suggest that: $\text{PhenaH}^{\bullet}$, produced by the protonation to $\text{Phen}^{\bullet-}$, may transfer a hydrogen atom to $\text{Co}(\text{cyclam})^{2+}$ to form $\text{Co}(\text{cyclam})(\text{H})^{2+}$ and insertion of CO_2 into the hydride produces HCOO^- via the Co^{III} -formate complex. Although the results appear to support the proposed mechanism, the hydrogen-atom transfer step and the CO_2 insertion step have not been investigated in detail.

2. *fac*- $\text{Re}(\alpha\text{-diimine})(\text{CO})_3\text{X}$, $\text{Re}(\alpha\text{-diimine})(\text{CO})_2\text{XX}'$ or similar complexes

2.1 Overview of CO₂ reduction systems mediated rhenium complexes

Complexes of the general formula, *fac*-Re(α -diimine)(CO)₃X and Re(α -diimine)(CO)₂X(X') (where α -diimine = bpy, phen, substituted bpy or phen, etc. and X, X' = halide, solvent, alkyl, benzyl, monodentate phosphine, CO, etc), have attracted interest since the mid-1970s^[46-48]. Many of these complexes show emission from their lowest long-lived MLCT state at room temperature in solution. Their catalytic properties for CO₂ reduction have also been investigated. Electrolysis of a solution containing *fac*-Re(bpy)(CO)₃Cl and 0.1 M Bu₄NPF₆ in freshly distilled CO₂-saturated MeCN at -1.5 V (vs SCE) produces both CO and CO₃²⁻ with current efficiencies of 98% and 110 %, respectively^[49]. Further, *fac*-Re(bpy)(CO)₃X (X = Cl, Br) has been used successfully as a photocatalyst for CO₂ reduction to CO with TEOA in DMF^[50-53]. When X = Cl, a quantum yield of 0.14 has been measured in the presence of excess Cl⁻. A formate-rhenium complex, *fac*-Re(bpy)(CO)₃(O₂CH), has been isolated in the absence of excess Cl⁻.

Among rhenium catalysts for the photochemical reduction of CO₂, *fac*-Re(bpy)(CO)₃{P(OEt)₃}⁺ is the best catalyst and irradiation of DMF solutions containing CO₂ and TEOA yields CO with a quantum yield of 0.38^[54]. However, the formate complex *fac*-Re(bpy)(CO)₃(O₂CH) is also produced upon irradiation of Re(bpy)(CO)₃(PR₃)⁺ (R = O-i-Pr, OEt, and Ph) in yields of 24, 73, and 55%, respectively, based on *fac*-Re(bpy)(CO)₃(PR₃)⁺. It is generally believed that the formate complex is produced by CO₂ insertion into a Re-H bond and leads to the production of free formate. However, neither electrochemical nor photochemical CO₂ reduction using *fac*-Re(bpy)(CO)₃X produces any significant amount of formate. Despite the great interest in CO₂ utilization, the mechanism of CO formation with *fac*-Re(bpy)(CO)₃X remains unclear. Below we discuss the possible involvement of intermediates such as Re-COO, Re-COOH, Re-CHO, Re-H, Re-CO, Re-O₂COH, Re-CH₂OH, etc.

2.2 Properties of Re(α -diimine)(CO)₃X and Re(α -diimine)(CO)₂XX'

2.2.1 Redox properties

The complexes can be both oxidized and reduced; reduction potentials for many of the complexes are shown in Table 6. Cyclic voltammograms of $\text{Re}(\alpha\text{-diimine})(\text{CO})_3\text{X}$ show that in most cases the first oxidation is chemically irreversible at scan rates of 0.1 - 0.2 V/s; however, at much faster sweep rates (> 100 V/s) a reversible wave is observed at 1.32 V (vs SCE) in MeCN for $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ [55]. The first oxidation is metal based and is followed by the rapid loss of carbon monoxide due to the weakening of the Re π -backbonding to CO. Oxidation of *fac*- $\text{Re}(\text{bpy})(\text{CO})_3\text{H}$ occurs more easily than that of *fac*- $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ indicating the increased electron density on the Re center.

The electrochemical behavior of $\text{Re}(\alpha\text{-diimine})(\text{CO})_3\text{X}$ in the negative potential region is usually shows three well-defined reduction waves. The first reduction wave is reversible and is assigned as a ligand-based reduction. The second wave is usually irreversible and assigned as a metal-based reduction followed by the rapid loss of X.

Spectroelectrochemical experiments using FTIR indicate that the reduced $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}^-$ shows a significant shift of the CO vibrational frequencies to lower energy. The electron, while primarily residing in the bpy ligand π^* orbital, increases the amount of charge on the Re center by reducing Re-bpy π -backbonding. This increases Re-CO π -backbonding and raises the electron density in the π^* orbital of the CO, and thus decreases the CO bond strength and vibrational frequencies. The IR absorption of the CO, ν_{CO} , shifts by about $\approx 30\text{ cm}^{-1}$ to lower energy.

The stability of the reduced complex depends on the ability of the X ligand to accommodate the increased electron density of the Re center. In the case of ligands that can not easily accept electron density into a low-energy orbital the increased electron density on the Re weakens the Re-X bond and can lead to loss of the X ligand. Complexes such as $\text{Re}(\text{dmb})(\text{CO})_3\text{Cl}$ tend to form the five-coordinate radical $[\text{Re}(\text{dmb})(\text{CO})_3]^{\bullet}$ species upon reduction even in MeCN[56]. This effect is stronger in the doubly reduced species that has an electron added directly to the Re center.

Table 6. Redox properties of $[\text{Re}(\text{bpy})(\text{CO})_3\text{X}]^{n+}$ and $[\text{Re}(\text{bpy})(\text{CO})_2\text{XX}']^{n+}$ vs SCE at room temperature

2.2.2. Excited-state photochemistry and photophysics

The photophysical properties of low-spin d^6 complexes, *fac*-Re(α -diimine)(CO)₃X, are summarized in Table 7. These complexes are often emissive in solution and generally have an intense MLCT absorptions ($\text{Re}^I d\pi \rightarrow \pi^*$ (α -diimine)) between 340 and 500 nm depending on the α -diimine, X ligands, and the solvent[48, 60]. Changes in solvent polarity lead to pronounced shifts of the absorption maxima (e.g. 370 nm in MeCN to 400 nm in benzene for Re(bpy)(CO)₃Cl) as shown in Table 7[47]). Modification of the α -diimine ligand also affects the MLCT absorption with the λ_{max} shifting to shorter wavelength in the order dmb > phen > bpy[47, 48]. The replacement of Cl⁻ by I⁻ changes the excited-state character from MLCT to XLCT (X = halide)[71]. The MLCT absorption of Re(bpy)(CO)₃X (X = H or CH₃) is red shifted compared to that of Re(bpy)(CO)₃Cl. An excellent review of the photophysics of these complexes by Stufken and Vlcek has recently been published[48].

For *fac*-Re(α -diimine)(CO)₃Cl the initial absorption at ≈ 400 nm populates a short-lived ¹MLCT state. This state rapidly decays to the long lived ³MLCT states. These states are actually three closely-spaced levels split by spin-orbit coupling. Since the splitting is small the states behave kinetically as a single level at temperatures above 77 K[48]. The ³MLCT excited state can be viewed as a charge-separated species $^*[\text{Re}^{II}(\alpha\text{-diimine}^-)(\text{CO})_3\text{Cl}]$. Transient UV-vis spectra show that the excited-state absorption corresponds to the α -diimine⁻ anion chromophore[60]. Transient IR spectroscopy of the excited state shows a significant shift (20 to 80 cm⁻¹) of the CO vibrational frequencies to higher energy. The shift is similar but smaller to that observed on oxidation of the Re(α -diimine)(CO)₃Cl complex[65]. The charge transfer in the excited state decreases the amount of charge on the Re center. This reduces the π -backbonding between the Re center and the CO ligands thereby increasing the CO bond strength and vibrational frequencies. Similar effects have also been observed in the time-resolved resonance Raman spectroscopy[48].

The complexes often undergo radiative decay from their lowest excited state both in fluid solutions at room temperature and in glassy media at 77 K[46, 48, 59, 66]. Emission lifetimes are typically 20 ns to 1 μ s at room temperature and are summarized in Table 7. The excited state can decay by two nonradiative pathways: by internal conversion to the ground state and by a thermally activated process through a higher energy excited state that rapidly decays to the ground state. The exact parameters for the two pathways depend on X, L, solvent, and temperature.

The 3 MLCT excited state is both a strong oxidant and a strong reductant and it can be quenched by either electron acceptors (oxidative) or donors (reductive quenching)[60, 66]. Table 9 indicates rate constants for oxidative and reductive quenching of MLCT excited state of a number of *fac*-Re(α -diimine)(CO) $_3$ X complexes.

Table 9. Oxidative and Reductive Quenching of MLCT excited state of $\text{Re}(\text{CO})_3\text{LX}$ by Q to Produce the Oxidized Re complex and Q^- in MeCN at room temperature.

The relationship between the absorption (E_{abs}), emission (E_{em}), reorganization (λ_r), the singlet-triplet splitting (E_{st}) energies[82] and the energy difference between the thermally relaxed excited and ground states (E_{0-0}) is shown in Figure 8[83].

$$E_{abs} = E_{em} + E_{st} + 2\lambda_r$$

The reorganization energy, λ_r , is generally broken into contributions from the solvent and/or low-frequency internal modes of the complex, λ_s , and from the internal high-frequency modes of the complex, λ_i , with the total reorganization energy given by $\lambda_r = \lambda_s + \lambda_i$. A spherical continuum model[84] can be used to estimate the solvent contribution to λ_s . Using this model[85] $\lambda_s = 0.18$ eV for $\text{Ru}(\text{bpy})_3^{2+/*}$ in H_2O and 0.33 and 0.22 eV for $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ in H_2O and CH_2Cl_2 , respectively. The larger value for the Re (vs the Ru) complex is due to its smaller size while the decrease in the value of λ_s on going from water to CH_2Cl_2 reflects the decrease in the polarity of the solvent.

An alternative method of estimating the reorganization energies involves spectral fitting of the emission[86, 87]. For a number of rhenium complexes the λ_s and λ_r values are given in Table 10. In general, similar λ_s values are estimated by either method with λ_s typically being about half of the total reorganization energy. As expected, the inner-shell reorganization energy for the Re carbonyl complexes is significant as indicated by the shifts in the ν_{CO} frequencies. The E_{0-0} and the E_{st} are estimated for a number of complexes in Table 10. One notes that E_{st} is approximately constant for the $\text{Ru}(\text{bpy})(\text{CO})_3\text{Cl}$ and $\text{Ru}(\text{phen})(\text{CO})_3\text{Cl}$ complexes if one excludes the two nonpolar solvents. The excited state energies, E_{0-0} are important since they can be used to estimate the redox potential of the excited state.

^a Calculated from the BES sphereical model. ^b $\lambda_i = 0.22$ eV[90].

The reduction potentials for either the oxidation ($E_{1/2}^{+/*}$) or the reduction ($E_{1/2}^{*/-}$) of the excited state can be calculated from the ground-state potential and the excited-state energy, E_{0-0} by

$$\begin{aligned}\Delta E_{1/2}^{*/-} &= E_{0-0} + \Delta E_{1/2}^{0/-} \\ \Delta E_{1/2}^{+/*} &= E_{0-0} - \Delta E_{1/2}^{0/+}\end{aligned}$$

The reduction potentials for the $\text{Re(phen)(CO)}_3\text{Cl}^{+/*}\text{Re(phen)(CO)}_3\text{Cl}$ and $^{*}\text{Re(phen)(CO)}_3\text{Cl}/\text{Re(phen)(CO)}_3\text{Cl}^{-}$ couples have been estimated[66] to be approximately -1.0 and $+1.0$ V (vs SCE in MeCN), respectively, using an excited-state energy of ≈ 2.3 eV. Using the estimates in Table 10 one obtains -1.2 and $+1.2$ V. The data in Tables 6 and 10 allow redox potentials for a number of other complexes to be calculated.

Visible light irradiation of a Re-alkyl complex, $[\text{Re}(\alpha\text{-diimine})(\text{CO})_3\text{R}]$ ($\text{R} = \text{CH}_3$, Et, iPr, or Bz; dmb = 4, 4'-dimethyl-2,2'-bipyridine) gives rise to a homolytic cleavage of the Re-R bond with formation of the radicals $[\text{Re(dmb)(CO)}_3]^{\bullet}$ and $\text{R}^{\bullet}$ [73]. The reaction proceeds with a quantum efficiency of 0.4 for $\text{R} = \text{CH}_3$ and 1 for $\text{R} = \text{Et}$, iPr, or Bz. The time-resolved UV-vis and IR absorption spectra reveal that for $\text{Re(dmb)(CO)}_3(\text{CH}_3)$ the initially formed excited state is a $^1\text{MLCT}$ state. The $^1\text{MLCT}$ state can either pass over a thermal barrier of 1560 cm^{-1} to the dissociative $^3\sigma\pi^{*}$ state (and decompose into radicals) or decay nonradiatively to the $^3\text{MLCT}$ state. In the case of $\text{R} = \text{Et}$, iPr, or Bz, the dissociative pathway to form the radical dominates. In all cases the radicals form in less than 10 ns.

2.2.3 Formate-rhenium complexes

Fac- $\text{Re(bpy)(CO)}_3\text{H}$ undergoes a thermally activated reaction with CO_2 in organic solvents to produce the stable formate adduct, *fac*- $\text{Re(bpy)(CO)}_3(\text{O}_2\text{CH})$ [93]. The rate of formation is first order in $[\text{CO}_2]$ and $[\text{Re}]$ with a rate constant of $2.0 \times 10^{-4}\text{ M}^{-1}\text{ s}^{-1}$ in THF and $2.7 \times 10^{-2}\text{ M}^{-1}\text{ s}^{-1}$ in MeCN. Kinetic studies using *fac*- $\text{Re(bpy)(CO)}_3\text{D}$ reveals an inverse $k_{\text{H}}/k_{\text{D}}$ isotope effect of ~ 0.5 for both solvents. The reaction occurs by associative hydride-transfer.

While the thermal reaction is very slow at room temperature irradiation by 436 nm light increases the rate by more than a factor of 10^[61]. While the CO₂ insertion into the Re-H bond reduces the CO₂, the authors do not report CO or formate production. Nor is formate a product in photochemical CO₂ reduction systems that utilize *fac*-Re(bpy)(CO)₃X^[51-53, 72], although the presence of Re(bpy)(CO)₃(O₂CH) was identified in such systems.

2.2.4 Re-CO₂ and Re-COOH complexes

Metallocarboxylates and metallocarboxylic acids are proposed as intermediates in photocatalytic reduction of CO₂ by *fac*-Re(α -diimine)(CO)₃X, but have not been directly observed in the photocatalytic systems. Re(dmb)(CO)₃(COOH), Re(bpy)(CO)₃(CH₂OH) and (CO)₃(dmb)Re-C(O)-O-Re(dmb)(CO)₃ have been prepared by different routes and characterized^[78, 79]. Reaction of Re(dmb)(CO)₄(Otf) with aqueous KOH in water produces *fac*-Re(dmb)(CO)₃(COOH) as a yellow precipitate. This complex has IR carboxylate absorptions, ν_{OCO} , at 1572 and 1194 cm⁻¹, which are at lower energy than those of the ruthenium analog, [Ru(bpy)₂(CO)(COOH)]⁺ (1618 and 1240 cm⁻¹). The ruthenium complex has been prepared by a similar reaction (Ru(bpy)₂(CO)₂²⁺ with KOH) and characterized by x-ray crystal structure^[94]. Reaction of Re(bpy)(CO)₄(Otf) with NaBH₄ in methanol leads to the formation of the red Re(bpy)(CO)₃(CH₂OH). Irradiation of Re(bpy)(CO)₃(CH₂OH) in dry MeOH yields a red solid, *fac*-Re(bpy)(CO)₃(OMe) in 97 % yield^[78]. The authors suggest a β -elimination converts Re-CH₂OH to Re-H, which upon photolysis reacts with MeOH to form Re-OMe.

The μ^2 - η^2 -CO₂-bridged complex, (CO)₃(dmb)Re-C(O)-O-Re(dmb)(CO)₃, is isolated (together with several unidentified species) on standing from an acetone solution of *fac*-Re(dmb)(CO)₃(COOH). Their IR data are summarized in Table 8. Neither *fac*-Re(dmb)(CO)₃(O₂CH) nor *fac*-Re(dmb)(CO)₃(H) has been observed as a products in the decomposition of *fac*-Re(dmb)(CO)₃(COOH)^[79]. However *fac*-Re(dmb)(CO)₃(COOH) with CO₂ in DMSO or DMF containing small amounts of water transforms to the bicarbonato complex, *fac*-Re(dmb)(CO)₃(OC(O)OH) together with a small amount of the formato complex,

fac-Re(dmb)(CO)₃(O₂CH)^[95]. The detail mechanisms involving these species need to be elucidated.

2.3. Electrochemical studies: One-electron and two-electron pathways

Extensive electrochemical studies on *fac*-Re(bpy)(CO)₃Cl in MeCN, THF or DMF indicate that reduction of *fac*-Re(bpy)(CO)₃Cl gives the radical anion, Re(bpy)(CO)₃Cl^{•-}, which reacts with CO₂ after loss of chloride. As shown in Figure 8, CO₂ reduction is proposed^[49, 56, 58] to occur by two independent routes, a 1e pathway via Re(bpy)(CO)₃[•] and a 2e pathway via Re(bpy)(CO)₃⁻. FTIR studies of Re(bpy)(CO)₃Cl^{•-} (ν_{co} 2012, 1903, 1882 cm⁻¹) indicate that it is in equilibrium with Re(bpy)(CO)₃(solvent)[•] (ν_{co} 2015, 1902 cm⁻¹) and [Re(bpy)(CO)₃]₂ (ν_{co} 1988, 1951, 1887, 1859 cm⁻¹) in THF and MeCN. Unfortunately, the equilibrium constants and the rate constant for Cl⁻ loss from Re(bpy)(CO)₃Cl^{•-} have not been determined. Reduction of Re(bpy)(CO)₃(MeCN)⁺ in THF leads to formation of three species: Re(bpy)(CO)₃(MeCN)[•], Re(bpy)(CO)₃(THF)⁺, and [Re(bpy)(CO)₃]₂. Re(bpy)(CO)₃(THF)[•] is not observed even in the reduction of Re(bpy)(CO)₃(Otf) in THF. Thus Re(bpy)(CO)₃(THF)[•] is unstable and rapidly dimerizes after loss of THF.

IR spectral changes during the further reduction of Re(bpy)(CO)₃Cl^{•-} indicate rapid loss of a Cl⁻ ligand with formation of [Re(bpy)(CO)₃]⁻. The further reduction of either [Re(bpy)(CO)₃(solvent)][•] or [Re(bpy)(CO)₃]₂ also yields [Re(bpy)(CO)₃]⁻. This illustrates the instability of non π -backbonding ligands coordinated to the formally Re⁰ center.

IR spectral changes of Re(bpy)(CO)₃Cl (with excess Cl⁻) or Re(bpy)(CO)₃(Otf) (without excess Cl⁻) in electrochemical reduction in THF under CO₂ atmosphere indicate the disappearance of Re(bpy)(CO)₃X (X = Cl or Otf) and the formation of [Re(bpy)(CO)₃(O₂CH)]^{•-} (ν_{COO} 1628 cm⁻¹), CO₃²⁻ (ν_{COO} 1643 cm⁻¹), CO and an unidentified species with ν_{COO} at 1680 cm⁻¹ (carboxylate?)^[56]. It is reported that the ν_{COO} band of Re(bpy)(CO)₃(O₂CH) and [Re(bpy)(CO)₃(O₂CH)]^{•-} are coincident (See Table 8). IR spectral changes of Re(bpy)(CO)₃Cl in MeCN with excess Cl⁻ under a CO₂ atmosphere have been reported to illustrate rapid

formation of free CO_3^{2-} (ν_{COO} 1643 cm^{-1}) and CO, together with an unassigned product having ν_{COO} at 1679 cm^{-1} . The unassigned product appears before formation of CO_3^{2-} . The IR spectrum in the ν_{CO} region shows only small amounts of $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]^{*-}$ and $[\text{Re}(\text{bpy})(\text{CO})_3(\text{MeCN})]^*$ compared to the parent $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ and free CO_3^{2-} , indicative of the catalytic nature of CO_3^{2-} production. Both $[\text{Re}(\text{bpy})(\text{CO})_3]^*$ (1e pathway) and $[\text{Re}(\text{bpy})(\text{CO})_3]^-$ (2e pathway) are alleged to react with CO_2 .

The authors suggest a modification of the original mechanism show in Figure 8. In this mechanism, shown in Figure 9, the actual catalytic species is $\text{Re}(\text{bpy})(\text{CO})_3\text{S}^*$ i.e., the one-electron reduced species that has had X replaced by a solvent molecule. This species is formed from the original $\text{Re}(\text{bpy})(\text{CO})_3\text{X}^{n+}$ upon one-electron reduction. It is asserted that the electron density on the Re center is of critical importance in the catalytic scheme. The Re center must be sufficiently electronically poor to allow coordination of Lewis bases such as phosphines or MeCN otherwise rapid dimerization will occur. The use of a slightly coordinating solvent or free Cl^- in solution helps to suppress this reaction. Alternatively, the Re center must be electronically rich enough to coordinate and reduce CO_2 .

The main products observed, CO and CO_3^{2-} , are produced by both pathways. The authors assert^[56] that production of the major side product $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ (ν_{COO} 1630 cm^{-1}) is suppressed when the two-electron pathway dominates as it does when using $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^+$ or $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ in MeCN. They assume that $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ is produced from either $[\text{Re}(\text{bpy})(\text{CO})_3(\text{CO}_2)]^*$ or $[\text{Re}(\text{bpy})(\text{CO})_3(\text{CO}_2)]^-$ by addition of e^- and H^+ or H^+ , respectively. However, such transformations to metal-formate complexes are not well characterized. Rhenium carboxylates ($[\text{Re}(\text{bpy})(\text{CO})_3(\text{COO})]$ and $[\text{Re}(\text{bpy})(\text{CO})_3(\text{COO})]^-$) are generally proposed^[96] as intermediates in the electrochemical reduction of CO_2 to CO (and CO_3^{2-}) but no direct spectroscopic evidence has been obtained except for the IR absorption, ν_{COO} , at 1680 cm^{-1} for an unidentified species. Reported IR spectra involving this unidentified species show a relatively intense ν_{COO} band compared to the of ν_{CO}

bands. Normally, the molar absorptivity of the ν_{CO} band for bound CO is typically 3-5 times larger than that for bound CO_2 [26, 97, 98]. The correct identification of this species is essential.

Table 11. Photocatalytic Reduction of CO₂ with Re(bpy)(CO)₃X in DMF with TEOA as an electron donor.

2.4. Photochemical CO₂ reduction with Re(α -diimine)(CO)₃X and Re(α -diimine)(CO)₂XX'

Re(α -diimine)(CO)₃X (X = halide, solvent, monodentate phosphine ligand, etc.) has been used as a photocatalyst for CO₂ reduction with TEOA in DMF[50-54, 67, 72] (Table 11). The ³MLCT excited states of these Re complexes are reductively quenched by TEOA (TEOA^{+•/0} potential $\approx$ 0.8 V) [47] to form [Re^I(bpy⁻)(CO)₃X][•]. Transient spectroscopy show the expected

bpy⁻ radical UV-vis absorption and ESR signals. When X = Br⁻, Cl⁻, or P(OEt)₃, the quenching rate constants are $6 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ [52], $8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ [60], and $1.1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ [67], respectively, in MeCN or DMF. Transient IR spectra of both the ³MLCT excited state and the radical anion for Re(bpy)(CO)₃Cl [76], Re(4,4'-bpy)₂(CO)₃Cl [75], Re(4,4'-bpy)₂(CO)₃(MeCN)⁺ [74], Re(bpy)(CO)₂{P(OEt)₃}₂⁺ [64], Re(bpy)(CO)₃(MeCN)⁺ [80], [74], Re(dmb)(CO)₃(MeCN)⁺ [74], and Re(dmb)(CO)₃(CH₃) [73] have been measured. Transient IR shows the expected shifts of ν_{CO} for both the excited state to higher (20-80 cm⁻¹) and the reduced species to lower energy (-15 to -40 cm⁻¹) [69, 74-76] (see Table 8). Interestingly a small amount of doubly reduced [Re(dmb)(CO)₃]⁻ has been observed in the flash photolysis of Re(dmb)(CO)₃(MeCN)⁺ in MeCN with TEA [74].

The subsequent reactions of the radical species depend on the nature of α-diimine, X, solvent, and electron donor as also found in the electrochemical studies. The mechanism for photochemical CO₂ reduction must account for reactions of the electron donor (e.g., TEOA or TEA) and its reaction products. TEOA or TEA can coordinate to metal complexes and change their redox properties [21]. The following reactions can all become important under different conditions.

Both electrochemical and photochemical reduction of $\text{Re}(\text{bpy})(\text{CO})_3\text{X}$ ($\text{X} = \text{halide}$), yield $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]^{\bullet-}$ [49]. It has been suggested that $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]^{\bullet-}$ reacts directly with CO_2 ; however, electrochemical results[49, 56] indicate that CO_2 attachment only takes place after loss of Cl^- . The labilization of Cl^- produces either a five-coordinate $[\text{Re}(\text{bpy})(\text{CO})_3]^{\bullet}$ or the six-coordinate $[\text{Re}(\text{bpy})(\text{CO})_3\text{S}]^{\bullet}$. The five-coordinate species can dimerize but under photolysis conditions their low concentration makes this reaction slow. The intermediates may react with CO_2 or pick up a second electron and a proton to give $\text{Re}(\text{bpy})(\text{CO})_3\text{H}$. The formation of $\text{Re}(\text{bpy})(\text{CO})_3\text{H}$ and $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ have been reported for $\text{Re}(\text{bpy})(\text{CO})_3\text{X}$ ($\text{X} = \text{Cl}$ and Br) systems[33, 49, 50, 52, 53, 61]. While formato complexes generally produce formate, metal carboxylates (or metal CO_2 adducts) generally lead to CO production[96]. Hawecker et al[51] concluded that the $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ is a side-product and an unlikely intermediate in the photochemical CO production, since: $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ is less active as a CO_2 photoreduction catalysts than $\text{Re}(\text{bpy})(\text{CO})_3(\text{Cl})$; the system with $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ produces only a small amount of H_2 without any CO ; and $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ production is suppressed in the presence of excess Cl^- whereas in the absence of excess Cl^- ion $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ accumulates. Also $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ is formed as a side-product in the electrochemical reduction[56].

$\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}^+$ produces CO with the highest quantum yield of up to 0.38[54]. The quantum yield and turnover number using $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}^+$ depend on the intensity and wavelength of the exciting light; however, for $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ neither quantum yield nor turnover number are intensity and wavelength dependent. Since the lifetime of $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^{\bullet}$ (514 s) is much longer than that of $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]^{\bullet}$ (6 s) under Ar in DMF, an inner filter effect by $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^{\bullet}$ may explain the wavelength and intensity dependence [54].

Electrochemical studies indicate that $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^{\bullet}$ is very stable and does not lose $\text{P}(\text{OEt})_3$ or react with CO_2 in THF[56]. Only on further reduction does the complex lose $\text{P}(\text{OEt})_3$ to form the five-coordinate anion $[\text{Re}(\text{bpy})(\text{CO})_3]^-$ which can react with CO_2 . The

first and second reduction potentials of $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}^+$ are reported to be -1.25 and $\approx$ -1.9 V vs SCE in MeCN[56, 62], assuming the Fc/Fc^+ and Ag/AgNO_3 potentials are 0.38 V and 0.33 V vs SCE, respectively. The E_{0-0} of the $^3\text{MLCT}$ state of the $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}^+$ is $\approx$ 2.8 eV (Table 10) thus the excited-state reduction potential is $\approx$ 1.5 V ($E_{1/2}^{+/0} = -1.25$ V vs SCE) thus the quenching of the $^*\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}^+$ by TEOA ($E_{1/2}^{+/0} = 0.6$ V vs SCE[99]) has a $\Delta E^0 \approx 0.9 = (1.5 - 0.6)$ V.

The $\text{TEOA}^{\bullet+}$ radical, $(\text{HOCH}_2\text{CH}_2)_3\text{N}^{\bullet+}$, can react with another TEOA to form the carbon radical $(\text{HOCH}_2\text{CH}_2)_2\text{NC}^*\text{HCH}_2\text{OH}$ as shown in Eq 32a.

While $(\text{HOCH}_2\text{CH}_2)_2\text{NC}^*\text{HCH}_2\text{OH}$ is known to be a strong reducing agent its potential is not known. The reduction potentials of $\text{TEA}^{\bullet+}$ and $\text{TEOA}^{\bullet+}$ are 0.96[100] and 0.6 V[99] vs SCE in MeCN, respectively. Thus TEOA, with its electronegative oxygens, is a better reducing agent than TEA. The reduction potential of $\text{Et}_2\text{N}^+=\text{CHCH}_3$ (of Eq. 32d) has been measured to be -1.12 V vs SCE in MeCN, [101] so the potential of $(\text{HOCH}_2\text{CH}_2)_2\text{N}^+=\text{CHCH}_2\text{OH}$ (of Eq. 32b) will be more negative than -1.12 V. Thus while $(\text{HOCH}_2\text{CH}_2)_2\text{N}^+=\text{CHCH}_2\text{OH}$ may reduce $\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}$ ($E_{1/2} = -1.35$ V) and $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^+$ ($E_{1/2} = -1.25$ V), it is not expected to reduce $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]^*$ ($E_{1/2} \sim -1.7$ V) or $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^*$ ($E_{1/2} \sim -1.9$ V). The above suggests that while the doubly reduced $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^-$ is formed in the electrochemical system the formation is not possible in the photochemical system. Since the $[\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}]^*$ does not lose $\text{P}(\text{OEt})_3$ [54], it is hard to understand how the singly reduced Re complex can acquire a CO_2 ligand.

Koike et al. assume that the monoreduced $[\text{Re}(\text{bpy})(\text{CO})_3(\text{PR}_3)]^*$ reacts with CO_2 or dimerizes in the photochemical system they studied[67]. From the decay of $[\text{Re}(\text{bpy})(\text{CO})_3(\text{PR}_3)]^*$ observed during continuous photolysis under CO_2 , the CO_2 binding rates

constants have been estimated: $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}$: $8.8 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [54]; $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{OEt})_3\}$: $5.6 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [67]; $\text{Re}(\text{bpy})(\text{CO})_3\{\text{P}(\text{O}-i\text{-Pr})_3\}$: $9.4 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [67]; $\text{Re}(\text{dmb})(\text{CO})_3\{\text{P}(\text{OEt})_3\}$: $18.6 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ [67]. These CO_2 binding rate constants are very slow compared to those of other metal complexes that act as photocatalysts: (CoHMD^+ : $1.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ [22], $\text{Ni}(\text{cyclam})^+$: $3.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ [18], $\text{Pd}(\text{etpC})(\text{DMF})^+$: $53 \text{ M}^{-1} \text{ s}^{-1}$ [102]) The authors did not detect formation of either the Re dimer or the CO_2 complex. Since they did not measure the dependence of the CO_2 binding rate on Re or CO_2 concentration, the actual pathway in the photochemical system is probably more complicated. Thus of fundamental importance in understanding photochemical CO_2 fixation is the elucidation of the mechanism that allows the singly reduced Re complex to bind CO_2 . One interesting possibility is that the reduced Re complex is photolabile and that the absorption of a second photon assists the loss of the sixth ligand. Detailed studies of the $\text{Re}(\text{bpy})(\text{CO})_3\text{X}$ ($\text{X} = \text{Cl}$ and Br) photochemical systems that report formation of $\text{Re}(\text{bpy})(\text{CO})_3\text{H}$, $\text{Re}(\text{bpy})(\text{CO})_3(\text{O}_2\text{CH})$ and $\text{Re}(\text{Mebpy})(\text{CO})_3\text{Br}$ in addition to the dimer [33, 49, 50, 52, 53, 61, 103] are needed.

3. Conclusions

Nonbiological artificial photosynthetic systems offer the possibility of producing fuels and chemicals from CO_2 and sunlight in fewer steps and with higher efficiencies than in natural systems. It may also be possible to design such systems to operate under conditions and in environments where plant growth is not optimal or practical. Light capture, electron transfer, and catalysis must be coupled efficiently. However, the approaches described in this chapter have several problems. All the systems require a sacrificial reagent. The stability of the systems is limited, the catalytic activities are too low, and the overall costs are too high for commercialization. Dark reactions including the bond formation and cleavage steps are relatively slow. It is very important to investigate the factors controlling reaction rates and efficiencies through kinetic and mechanistic studies. At this stage, many questions remain. Hopefully, the insight obtained from a fundamental understanding of the reactions occurring in

the above systems will provide the knowledge for the design of practical systems. One fundamental and formidable challenge is the replacement of the "sacrificial" electron donors by species that will lead to useful (or benign) chemicals in their own right.

Acknowledgement. We thank Drs. Norman Sutin and David Thompson (BNL) and Prof. Osamu Ishitani (Saitama University, Japan) for their helpful comments, and Prof. Shoichi Kita (Hirosaki University, Japan) for providing his unpublished data obtained during his stay at BNL. Brookhaven National Laboratory is funded under contract DE-AC02-98CH10886 with the U.S. Department of Energy and supported by its Division of Chemical Sciences, Office of Basic Energy Sciences.

Appendix A Abbreviations

Abbreviation	Chemical Name
bcyclam	6,6'-bis(1,4,8,11-tetraazacyclotetradecane
bMe ₂ cyclam	6,6'-bis(5,7-dimethyl-1,4,8,11-tetraazacyclotetradecane)
4,4'-bpy	4,4'-bipyridine
bpy	2,2'-bipyridine
bpz	2,2'-bipyrazine
Brphen	5-bromo-1,10-phenanthroline
Cl ₂ bpy	4,4'-dichloro-2,2'-bipyridine
Clphen	5-chloro-1,10-phenanthroline
(CO ₂ Et) ₂ bpy	4,4'-bis(ethoxycarbonyl)-2,2'-bipyridine
cyclam	1,4,8,11-tetraazacyclotetradecane
DCE	1,2-dichloroethane
dmb	4,4'-dimethyl-2,2'-bipyridine
DMD	5,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene
DMF	N,N-dimethylformamide
DMSO	dimethylsulfoxide
dpp	2,3-di(2-pyridyl)pyrazine
dpq	2,3-di(2-pyridyl)quinoxaline
EtCN	propionitrile
EtOH	ethanol
etpC	bis[(dicyclohexylphosphino)ethyl]phenylphosphine
4Etpy	4-ethylpyridine
H ₂ A	ascorbic acid
HMD	5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene
3HOpy	3-hydroxypyridine
HTIM	2,3,9,10-tetramethyl-1,4,8,11-tetraazacyclotetradecane
(isn) ₂ bpy	4,4'-isonitrile-2,2'-bipyridine
Me ₂ cyclam	5,7-dimethyl-1,4,8,11-tetraazacyclotetradecane
Mebpy	5-methyl-2,2'-bipyridine
MeCN	acetonitrile
Meimz	N-methylimidazole
MeOH	methanol
Mephen	5-methyl-1,10-phenanthroline
2Mepy	2-methylpyridine
3Mepy	3-methylpyridine
4Mepy	4 methylpyridine

MeTHF	2-methyltetrahydrofuran
MV ²⁺	methylviologen
(NEt ₂) ₂ bpy	4,4'-di(N,N-diethylamino)-2,2'-bipyridine
(NH ₂) ₂ bpy	4,4'-diamino-2,2'-bipyridine
(OCH ₃) ₂ bpy	4,4'-dimethoxy-2,2'-bipyridine
OMD	3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene
Otf	trifluoromethanesulfonate
Ph ₂ bpy	4,4'-diphenyl-2,2'-bipyridine
Ph ₂ phen	4,7-diphenyl-1,10-phenanthroline
phen	1,10-phenanthroline
Phena	phenazine
4Phpy	4-phenylpyridine
PrCN	butyronitrile
Pr-cyclam	6-((N- <i>p</i> -methoxybenzyl)pyridin-4-yl)methyl-1,4,8,11-tetraazacyclotetradecane or 6-((N-benzyl)pyridin-4-yl)methyl-1,4,8,11-tetraazacyclotetradecane
py	pyridine
TEA	triethylamine
TEOA	triethanolamine
THF	tetrahydrofuran
TP	<i>p</i> -terphenyl

Techniques

$E_{1/2}$	half-cell potential
E_{pa}	peak potential of the anodic scan
E_{pc}	peak potential of the cathodic scan
EXAFS	extended X-ray absorption fine structure
FTIR	Fourier-Transform Infrared
NHE	normal hydrogen electrode
SCE	saturated calomel electrode
SSCE	Sodium-saturated calomel electrode
XANES	X-ray absorption near-edge spectroscopy

- [82] For the complexes considered here we expect that the nuclear configuration of the singlet and triplet MLCT states to be similar. Thus the Stokes shift between the two states is small.
- [83] The singlet-triplet and ground-excited state energy difference and the absorption and emission energies are treated as unsigned quantities and taken as positive.

- [85] The spherical cavity model requires parameters for the solvent and the cavity to calculate the reorganization energy. The dimensions of the molecule have been obtained from models created in MacSparten. The cavity radius was calculated as $r = \left(\sqrt[3]{d_1 d_2 d_3} \right) / 2$ where d_i are the three principle diameters of the molecule (including van der Waals end radius for each atom) and are 7.8, 11.26 and 11.26 respectively, with $r = 5.0$ Å. The Re atom is placed off center by 1.3 Å and the electron transfer distance is 3.5 Å. The optical (square of the refractive index) and static dielectric constants of the solvent have been used.
