Abstract

Coaxial Helicity Injection (CHI) has been investigated on the National Spherical Torus Experiment (NSTX). Initial experiments produced 130kA of toroidal current without the use of the central solenoid. The corresponding injector current was 20kA. Discharges with pulse lengths up to 130ms have been produced.
I. Introduction

The Spherical Torus (ST) is a magnetic confinement concept that has the potential advantages of high beta, high bootstrap current fraction and increased stability. These favorable properties of the ST arise from its very small aspect ratio ($A \leq 1.5$). Experimental results from the Small Tight Aspect Ratio Tokamak (START) demonstrated some of the favorable high beta properties with good confinement [1,2]. This motivated the construction of two large STs, NSTX in the USA [3,4] and the Mega Ampere Spherical Torus (MAST) in the UK [5]. To minimize the aspect ratio, elimination of the central solenoid is a consideration for future ST designs. This requires the demonstration of plasma creation and sustainment by non-inductive current drive methods. Coaxial Helicity Injection (CHI) is a promising candidate for generating target plasma for non inductive current drive methods and for driving edge current (inside the last closed flux surface) during the sustained phase.

The first experiments on helicity injection current drive in a ST were conducted on the Current Drive Experiment-Upgrade (CDX-U) at the Princeton Plasma Physics Laboratory (PPPL) [6]. CHI was initially used for the generation of spheromak plasmas [7,8,9]. The possibility of using CHI in a ST was first proposed in the late 1980’s [10]. The idea gained support as a result of experiments conducted on the Proto-Helicity Injected Torus, and the Helicity Injected Torus-I (HIT-I) at the University of Washington [11]. These experiments used a thick conducting copper wall for equilibrium control of the CHI produced plasma configuration. These were followed by two other experiments, the Himeji Institute of Technology Spherical Torus (HIST) in Japan and the SPHEX
device (operated in a ST mode) in the UK [12,13]. These devices also employed passive wall stabilization for equilibrium control and confirmed that CHI could be used in the presence of an external toroidal. Later HIT was rebuilt as the HIT-II experiment, which extended CHI to a true ST device by employing 28 poloidal field coils for equilibrium control instead of from image currents induced on copper walls [14]. HIT-II produced substantial plasma currents (200 kA) using transformer action or using CHI [15]. An important goal for the NSTX program is to conduct proof-of-principle experiments to validate this concept on a device that has a volume about 30 times that of HIT.

The CHI method drives current initially on open field lines creating a current density profile that is hollow. Taylor relaxation [16] predicts a flattening of this current profile through a process of magnetic reconnection leading to current being driven throughout the volume, including closed field lines. Current penetration to the interior is eventually needed for usefully coupling CHI to other current drive methods and to provide CHI produced sustainment current during the long pulse non-inductive phase.

For an ST, the primary goal of a CHI system is to generate a suitable target plasma that can be ramped up in current to a high bootstrap current fraction regime using non inductive current drive methods and without the use of the Ohmic coil. On NSTX, this requires the CHI system to produce target plasmas with a temperature of about 200eV. This temperature is needed for coupling to High Harmonic Fast Wave (HHFW) current drive. A secondary goal is to extend the pulse duration of 1MA Ohmic discharges by producing target plasma for Ohmic discharges.
This paper is organized as follows. Section II describes the CHI components on NSTX. In section III we describe the experimental results obtained thus far; the final section is a brief summary of the results.

II. Experiment description

The nominal NSTX machine parameters are major/minor radius of 0.85/0.65m, elongation \( \leq 2.2 \), a plasma volume of 14m\(^3\) and a machine volume of 30m\(^3\) [3]. As on the HIT device, the stainless steel vacuum vessel of NSTX is fitted with toroidal ceramic breaks at the top and bottom so that the central column and the inner divertor plates (the inner vessel components) are insulated from the outer wall and the outer divertor plates. Four pairs of Poloidal Field (PF) coils placed symmetrically above and below the midplane outside the vacuum vessel are available for equilibrium control. The lower divertor region has an additional coil positioned below the inner divertor plate. This and the lowest PF coil allows one to set up the vacuum CHI injector flux in a manner that it connects the lower inner and outer divertor plates. The coils allow for the generation of up to 500mWb of injector flux. The corresponding maximum toroidal flux (TF) for a nominal 0.3T discharge is 1.5Wb.

CHI is implemented on NSTX by driving current along field lines that connect the inner and outer lower divertor plates. A 25kA, 1kV DC power supply is connected across the inner and outer vessel components, as shown in Figure 1, to drive the injector current. The standard operating condition for CHI in NSTX uses the inner vessel and inner
divertor plates as the cathode. The outer vessel is the anode. A dedicated gas injection system in the lower divertor region injects gas from four ports in the lower inner divertor plates toroidally separated from each other by 90 degrees. For the initial CHI experiments, a fixed volume plenum was filled to a known pressure and quickly emptied into the divertor region by opening a fast valve. To increase the speed of the gas delivery system, a total of four plenums and corresponding four fast valves are used, one for each of the four gas injection ports located in the cathode region. The initial fast puff transiently produces a high gas pressure in the lower divertor region. This facilitates gas breakdown when voltage is applied to the lower divertor plates. An 18 GHz, 10kW Electron Cyclotron Heating Pre Ionization system (ECH-PI) is used to produce a vertical EC resonance layer near the center stack (at a radius of 40cm). The EC resonance layer intersects the inboard injector flux footprints, facilitating gas breakdown at the lower fill pressures.

The operational procedure involves first energizing the TF coils and the CHI injector coils to produce the desired flux conditions in the injector region. A voltage is now applied to the inner and outer divertor plates and a pre-programmed amount of gas is injected from the inner lower divertor plate ports. ECH-PI is turned on for a pre-programmed time duration. These conditions cause the gas in the lower divertor region to ionize and result in current flowing along magnetic field lines connecting the lower divertor plates. The applied toroidal field causes the current in the plasma to develop a strong toroidal component, the beginning of the desired toroidal plasma current. If the injector current exceeds a threshold value, the resulting $\Delta B_{\text{tor}}^2$, $(J_{\text{pol}} \times B_{\text{tor}})$, stress across
the current layer exceeds the field line tension of the injector flux causing the helicity and plasma in the lower divertor region to move into the main torus chamber. Once extended into the vessel, currents need to be driven in the PF coils for equilibrium position control.

III. Experimental results

That this method works on a large ST is shown in Figure 2. First, Figure 2a shows a CHI discharge evolution as recorded by a fast framing camera [17]. These fish eye view images of the entire NSTX vessel show that at $t=16\text{ms}$, the discharge originates in the lower divertor region. As the injector current (shown in Figure 2b) increases, the fluxes connecting the lower divertor plates are extended into the confinement chamber (at $t = 18\text{ms}$). At even higher injector currents, the discharge nearly fills the entire chamber (at $t = 20\text{ms}$). In this discharge a peak toroidal current (Figure 2b) of 20kA is obtained for an injector current of about 7kA resulting in a current multiplication of about 3. The injector current is the current supplied by the 1kV CHI power supply that flows through the plasma load. The toroidal current is that measured by the NSTX plasma current measurement system.

Figure 3, shows the applied injector voltage, divertor coil current, injector current and CHI produced toroidal current, for a high current discharge. The divertor coil current is a measure of the poloidal flux (the injector flux) that connects the lower divertor plates (see Figure 1). For the case where the divertor coil currents are in the same direction and linearly proportional to each other the injector flux is nearly linearly proportional to the current being driven in the CHI divertor coil. The applied voltage determines the amount
of injector current that can be driven for this combination of injector flux and divertor gas pressure.

This discharge has two phases. For times less than 50ms (phase 1), the applied voltage and the divertor coil currents are constant. This results in an injector current of 20kA and a toroidal current of 50kA (a current multiplication factor of ~2). To increase the current multiplication factor, the divertor coil current is ramped down during phase 2 (t > 50ms). This results in reduced injector flux and consequently the injector impedance increases. To compensate, the injector voltage is increased as shown in Figure 3. The programmed voltage ramp maintains a constant injector current. Since the injector flux is decreasing with time, while the toroidal flux is constant, for reasons described in the next paragraph one expects the current multiplication factor to increase. Indeed, the toroidal current increased during the course of the discharge, resulting in a maximum of about 130kA at t = 100ms, a current multiplication factor of 6.5. The discharge for its entire duration was maintained in equilibrium using pre-programmed coil currents only.

Energy conservation and helicity balance require that the ratio $\lambda_{ST}$ of the obtained toroidal current to the toroidal flux of the discharge in the ST ($\lambda_{ST} = \mu_o I_{\text{toroidal}} / \Psi_{\text{toroidal}}$) be less than the ratio of the injector current to the poloidal flux ($\lambda_{\text{inj}} = \mu_o I_{\text{inj}} / \Psi_{\text{inj}}$) where $\Psi_{\text{inj}}$ is measured between the toroidal breaks between the inner and outer electrodes using the poloidal flux loop signals. Here the term ST refers to the device and not to the type of plasma present in the machine. During steady state current drive, the efficiency for current drive is given as, $\epsilon = \lambda_{ST} / \lambda_{\text{inj}}$ [16,18,11]. Here the efficiency is defined as injector flux utilization
efficiency. The maximum current multiplication is predicted to be the ratio of the ST flux over the injector flux. From the above, \( \left( \frac{I_{\text{toroidal}}}{I_{\text{inj}}} \right) = \left( \frac{\lambda_{\text{ST}}}{\lambda_{\text{inj}}} \right) \left( \frac{\Psi_{\text{toroidal}}}{\Psi_{\text{inj}}} \right) \), so current multiplication depends on the \( \lambda \) ratio, too. Uniform \( \lambda \) cannot be assumed. However, \( \lambda_{\text{ST}} \) is not expected to exceed \( \lambda_{\text{inj}} \). For the shot shown in Figure 3, Figure 4 shows the ratio of the toroidal flux, calculated assuming that the plasma fills the entire region between the electrodes, to injector poloidal flux multiplied by the injector current and compared to the measured toroidal current. This analysis shows that within uncertainties the amplification factor is nearly as large as possible (at \( t = 110\text{ms} \)). The measured current approaches 80\% of the theoretical maximum current showing that CHI is effective at driving toroidal current on large devices. The ratio is low during the early part of the discharge as only a small portion of the maximum possible toroidal flux (1.5Wb) links the injector flux. While the CHI has successfully driven toroidal current in NSTX, it is not yet known whether this current is flowing on closed field lines. Although a definite conclusion will probably have to await the implementation of diagnostics for the direct measurement of the spatial profile of the toroidal current, there is some indirect evidence for the reconnection process occurring during the CHI.

Figure 3 shows an increase in voltage fluctuations during phase 2 of the discharge. The fluctuations have a coherent mode at ~9kHz. Analysis of the Mirnov coil signals shows a similar global mode during phase 2. A toroidal Mirnov coil array on the center column shows the magnetic signature of the discharge to be toroidally symmetric with a coherent \( n=0 \) mode, similar to that seen in the HIST experiment [12]. There is no toroidal Mirnov array on the NSTX outer vessel to discern the toroidal mode number near the outer shell.
On the HIT experiments, an $n=1$ coherent mode activity, located on the outer shell probes only, is seen during high current discharges [11,14]; $n = 0$ activity is also seen by the outer Mirnov coils in some discharges. On NSTX, coherent fluctuations were also seen by a fast photodetector that sampled a chord passing through the center of the plasma. This mode activity seen by both magnetic and optical diagnostics is an encouraging result. On HIT experiments, an $n=1$ mode seen on the outer vessel Mirnov coils is deemed necessary for the generation of closed flux surfaces. An outer vessel Mirnov array is being installed on NSTX.

To examine the effect of injector impedance at lower pressure, a scan was conducted in which the injector current was measured as the vessel pressure was reduced from 16 to 4mTorr with the same flux and applied voltage. It was found that there is little change in injector current as the pressure is reduced. Experiments were also successful in generating discharges at a vessel pressure of 1mTorr. Since pressures of about 4mTorr are compatible with high recycling divertor operation, these results indicate that on NSTX, from a density standpoint, it should be possible to couple CHI discharges to Ohmic discharges. Compared to similar measurements on HIT-II, these results indicate a more favorable density scaling of the injector impedance that very likely result from the longer field line length on NSTX.

IV. Summary and Discussion

In summary, initial CHI experiments on NSTX have successfully generated 130kA of toroidal current using about 20kA of injector current. Stable discharges lasting for 0.13
seconds have been produced using pre-programmed coil currents and at vessel neutral
densities compatible with high recycling divertor operation. Experiments to date have
shown that CHI engineering systems can be successfully applied to a large ST for the
production of substantial toroidal currents as predicted by previous work on smaller
experiments. However, there is insufficient evidence at this time to confirm the
generation of closed flux surfaces in these discharges. Future experiments aimed at
studying closed flux generation will involve producing CHI discharges at higher toroidal
currents that will be diagnosed using multi point Thomson scattering temperature and
density profiles. The region of closed flux will be reconstructed using an equilibrium
fitting code adapted to allow current flow on open field lines and the private flux region.
