LINAC98 Proceedings

LINAC98 Home

to LINAC98 HOME

Papers are organized according to session number. For example, session number **MO4037** represents: **MO** (Monday) **4** (sessions 1,2=invited; session 4=poster) **037** (order of presentation).

These papers are available in PDF format only. To view a paper, click on either the session number or the paper title. Papers should be viewed using Adobe Acrobat Reader 3.0 or 3.01, which can be downloaded from the Adobe site. Acrobat Reader 3.01 is available for the following platforms: Windows (32 bit), Windows (16 bit), Macintosh, IBM-AIX, SGI-IRIX, Sun Solaris, SunOS, HP-UX, Linux, Digital Unix, OS/2 Warp (Adobe Acrobat Reader 3.0 only).

Questions about these papers should be directed to: cee@aps.anl.gov

XIX International Linear Accelerator Conference

Fairmont Hotel, Chicago, Illinois, USA
August 23 - 28, 1998

Organized by Argonne National Laboratory in association with Fermi National Accelerator Laboratory

LOW-β SC LINACS: PAST, PRESENT AND FUTURE*

Lowell M. Bollinger
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

This paper is a general review of superconducting low-β technology and applications from its beginning in 1969 into the near-term future. The emphasis is on studies of accelerating resonators and on SC linacs that boost the energy of heavy-ion beams from tandem electrostatic accelerators used for nuclear-physics research. Other topics are positive-ion SC injectors to replace tandems and the need for accelerating structures with β outside of the present proven range, $0.008 < \beta < 0.2$.

1 EARLY HISTORY

The development and construction of the superconducting (SC) electron linac at Stanford stimulated others to investigate SC technology needed to accelerate low-β ions [1]. This effort started (1969) at Karlsruhe, Germany. Much of this work was devoted to Nb helix resonators and related technology. Accelerating fields of 2 to 3 MV/m were achieved for $\beta = 0.04$, suggesting that it was feasible to build a useful SC low-β linac. However, it was difficult to control the RF phase of a helix because of its mechanical instability.

In 1970, a small group at Cal Tech also started studies of the helix, but later found that other geometries provided greater accelerating fields and mechanical stability. These new units included the "split ring", two curved RF arms driving two drift tubes with opposite phases. Unlike the helix, for the split ring the RF and the field-formation elements are independent, thus allowing the RF arms to be mechanically stiff. All of the low-β structures at Cal Tech used lead plated on copper as the SC.

In 1971, a group at Argonne joined the study of SC low-β technology and, from the beginning, the goal was to build a SC linac to boost the energy of heavy ions from a tandem electrostatic accelerator. Again, this work started with the single-cell helix, and two such Nb structures ($\beta = 0.06$) with independent phase control accelerated an ion beam (proton) for the first time. This and other achievements led to a proposal to build a small SC low-β linac.

A fourth effort (1973) on a low-β structure was at Stanford, where a small group studied a Nb cavity with $\beta = 0.04$ and $f = 430$ MHz. For these parameters, the accelerating gap was very narrow (~ 1 cm), which required the accelerating field to be exceptional large for this unit to be competitive with other structures, which had active gaps ranging from ~ 5 to 15 cm.

*Work supported by the U.S. Department of Energy, Nuclear Physics Division, under Contract W-31-109-ENG-38.

2 FIRST SC ION LINAC

The demands on SC low-β studies at Argonne changed greatly in 1974 when the Atomic Energy Commission agreed to support construction of a small SC linac, i.e., we had to consider all aspects of the system: RF phase control, beam optics, cryogenics, etc. - not just the accelerating structures. Our initial plan was to use 5-cell helix resonators for a 13-MV linac to boost the energy of heavy ions from our 8.5-MV tandem. Fortunately, before our funding arrived in late 1975 we were able to replace the helix with the Cal Tech split ring, but with several changes: (1) Nb as the SC, (2) a smaller frequency (97 MHz) so as to increase the active length, and (3) an outer housing made of Nb explosively bonded to copper. Figure 1 compares our design to other structures that were available at the time.

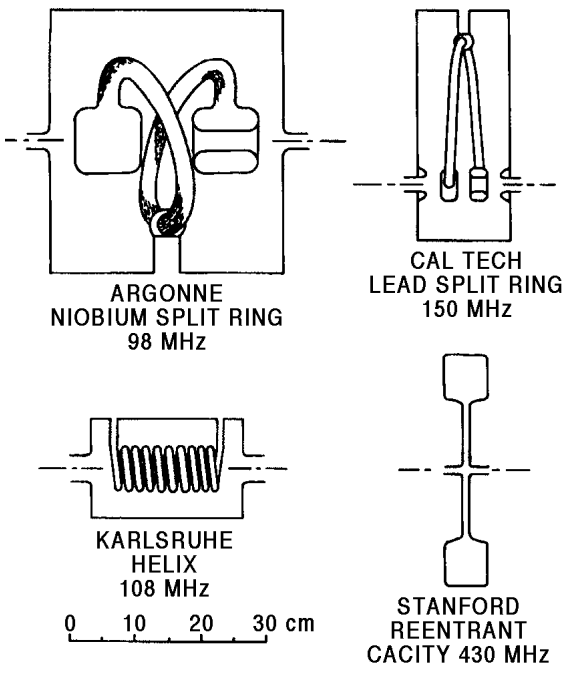

Figure 1: Heavy-ion accelerating structures in 1977.

The layout of the tandem-booster linac system [2] is shown in Fig. 2. Note the beam bunching system [3], 2 bunchers and a chopper, which converts ~ 65% of the DC beam of the tandem into narrow beam pulses (~ 200 ps). Initially the pulse rate of the beam was 97/2 = 48.5 MHz but, at the user's request, it was soon reduced to 97/8 = 12.125 MHz. Two classes of resonators are used in the booster: $\beta = 0.065$ and $\beta = 0.105$. The split rings are closely mounted in groups of 2 separated by SC beam-

focusing solenoids, the first accelerator of any kind in which SC was used for both acceleration and beam optics.

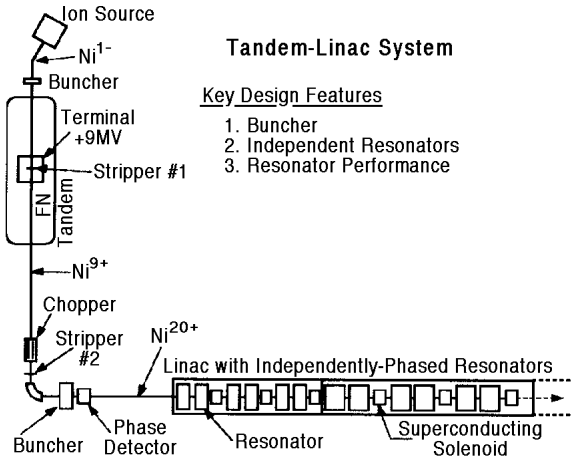

Figure 2: Main components of a tandem-linac system.

The phase control of each resonator is controlled by a VCX (voltage control reactance) but, in spite of the sturdy arms of our split rings, our initial VCR's provided only marginal control. After several major upgrades, the control problem was removed by a VCX that has a stored energy of 30 kW.

As soon as a small part of the booster was operable it was tested (June, 1978) and soon used for research (September, 1978). This step-by-step approach was continued for the next 3 years until the booster was completed. The goals of the project were more than met: an accelerating voltage of ~ 22 MV, excellent beam quality, short beam pulses, adequate acceptance of the tandem beam, easy change of beam energy, and future expandability.

In late 1983 funding was obtained to extend the booster linac and to add an adequate experimental area. The goal was to be able to accelerate ions with $A \leq 130$ to energies above the Coulomb barrier (~ 5.5 MeV/A). Since the original linac was operating well, we used the same technology for the addition. After completion in 1985, the entire linac provides ~ 38 MV; and the enlarged tandem-linac system [1,4] was named ATLAS.

3 EXISTING SC LOW-β LINACS

During the twenty-year period following the initial success of the tandem-linac system at Argonne, other laboratories undertook similar projects [5-15], listed in Table 1. Their primary goals were the same as discussed in Sec. 2, but often with significant differences in technology, as indicated in Table 1 and in [1,16]. For lack of space, only a few of these tandem-linac systems are mentioned below. Accelerating structures are treated in Sec. 4.

Table 1. Heavy-Ion Tandem-Linac Accelerators

Location	Accelerating Structure	f (Mhz)	β
Argonne--(In USE)	Split Ring (Nb)	97	.065 → .105
Stony Brook--(In USE)	SR + 1/4 Wave (Pb)	150	.06 → .10
Florida State--(In USE)	Split Ring (Nb)	97	.105
Saclay--(Terminated)	Helix (Nb)	135	.08
U. Washington--(In USE)	1/4 Wave (Pb)	150	.10 → .20
JAERI (Japan)--(In USE)	1/4 Wave (Nb)	130	.10
Kansas State--(In USE)	Split Ring (Nb)	97	.105
Legnaro (Italy)--(In USE)	1/4 Wave (Pb, Nb, Nb/Cu)	80, 160	.055 → .11 → .15
Sao Paulo--(?)	Split Ring (Nb)	97	.105
Bombay--(?)	1/4 Wave (Pb)	?	?
Delhi--(Under Construction)	1/4 Wave (Nb)	97	.08
Canberra--(In USE)	Split Ring (Pb)	150	.10

The second SC linac was built at Stony Brook [5] with split-ring Pb/Cu resonators provided by Cal Tech. The other parts of the linac were handled by a small group of faculty members and students at Stony Brook. I was especially impressed that students, after training, did work such as welding large pipes.

The linac at U. of Washington [8] was the first to use the quarter-wave resonator (QWR), a new class of structure developed at Stony Brook [17]. Two types of units are used: $\beta = 0.10$ and $\beta = 0.20$, both with Pb/Cu as the SC. These relatively large values of β indicate that the goal was to accelerate rather light ions, including protons, as needed by the research program.

The linac at JAERI (Japan) [9] was the first to use Nb for QWR. The oval-shaped outer shell of these units are explosively-bonded Nb to Cu. These units provide an average accelerating field > 5 MV/m, much greater than other SC low-β linacs in routine use.

The most ambitious of all SC low-β projects [11-13] is at Legnaro (Italy). It's injector is a 15-MV tandem, and the linac is designed to provide 48 MV, both substantially larger than any other tandem-linac system. The initial plan was to use QWR units with Pb/Cu as the SC, and some such units were installed, tested, and used. These initial structures are now being replaced by several kinds of RFQ units in which the SC is bulk Nb metal in some and Nb sputtered on Cu in others [11,12,13,18].

An interesting aspect of the teams that have designed and built the SC low-β linacs is that very few persons who played major roles had much experience in accelerator technology before entering the SC low-β game; indeed, I can think of only one American who did have earlier experience. On the other hand, most of the leading figures were physicists who had a thorough understanding of their goals.

4 ACCELERATING RESONATORS

The SC low-β resonators available in 1977 are shown in Fig. 1. Since then, many other structures have been studied, starting with the quarter-wave resonator (QWR) developed [17] at Stony Brook in 1983. The laboratories involved in these investigations are listed in Table 2, which includes (a) work before 1983, (b) other designs

that have been fully tested, and (c) work now in progress. Most of these units were designed for use in planned or existing linacs.

Table 2. Development of Accelerating Structures

Split Ring		**1974-1982**

Figure 3 shows some of the resonators initiated in the 1980's; all but the half-wave unit are now in use. The units in Fig. 4 are more recent products for which an important objective is to reduce fabrication costs. Design changes and improvements in welding appear to have reduced costs by a factor of ~ 1.5.

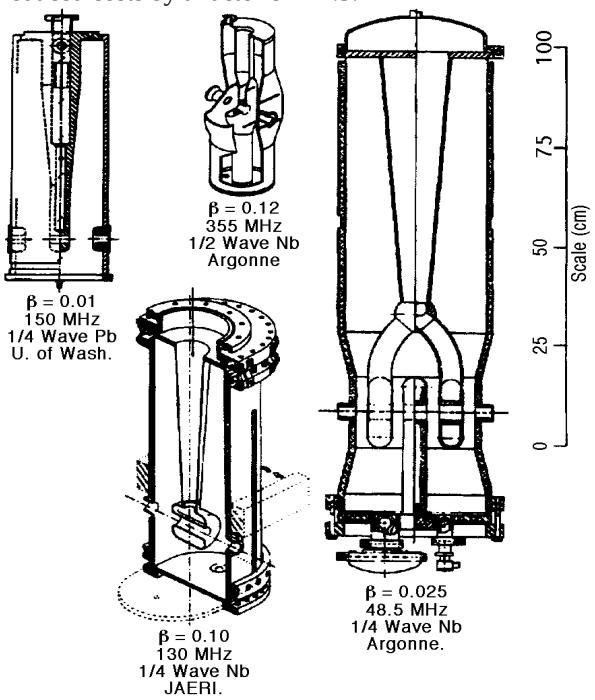

Figure 3: SC resonators from the 1980's.

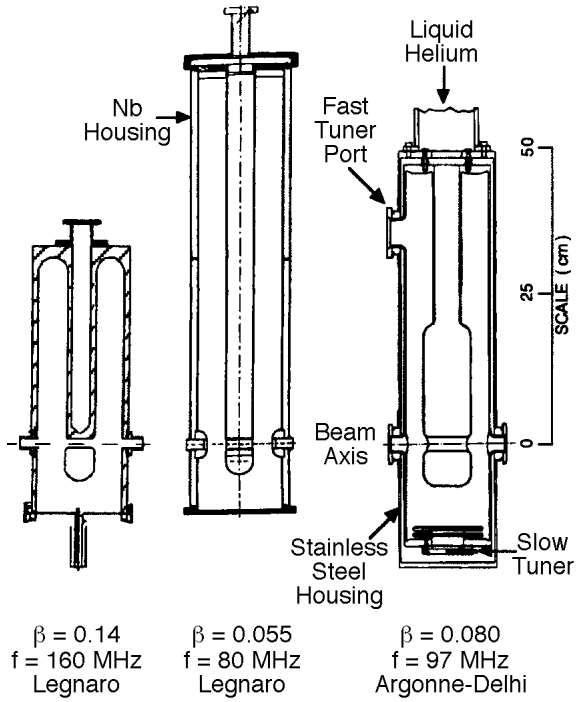

Figure 4: New resonators.

The long-term efforts at Legnaro and Canberra to use sputtered Nb on Cu as the SC surface are now being tested on the linac at Legnaro and the results are very encouraging [18,19]. It seems unlikely that sputter Nb will be superior to bulk metal, but it may reduce costs.

In SC low-β resonator design, many factors need to be considered: the SC material, RF frequency, optimum β, number of accelerating gaps, mechanical stability, the number of different resonator types needed, the ratio of accelerating field to maximum surface field, fabrication difficulties, and costs. Many of these factors interact with each other, making it impossible to determine a unique solution. For example, for resonators in routine use, the split ring in ATLAS has the greatest accelerating voltage because of its large size generated by its three gaps, low frequency, and high β. However, the higher-frequency 2-gap QWR in the JAERI linac has a greater accelerating field, is more stable mechanically, and is effective over a wider range of β. Which one is better?

5 POSITIVE ION INJECTOR

The linacs discussed above were energy boosters for tandems, an injector which requires a negative-ion source. By 1983 we at Argonne recognized that our tandem needed to be replaced because it could not produce useful beams for the upper half of the periodic table. After considering several possibilities, including a much larger tandem, we decided to build a positive-ion injector (PII) consisting of an ECR ion source on a voltage platform followed by a very-low-β SC linac [20,21].

Since ECR sources were well developed by the mid-1980's and the bunching concept used at our tandem could

be used at PII, the main challenge was the linac, which had to accelerate ions from $\beta = 0.008$ up to $\beta = 0.05$ without destroying the excellent quality of beams from the ECR. The front end of the linac seemed especially difficult because of the very low velocity and the rapid change in velocity of the beam.

One of the four interdigital resonators [22] used to span the required β range is shown in Fig. 3. The housing is Nb explosively bonded to Cu, and this housing is compressed around the beam line so as to form an oval-like shape. As in the booster linacs, SC solenoids are located after one or two resonators so as to minimize the beam size within resonators. The PII linac is easily tuned and, in practice, the whole ATLAS linac (including PII) is now usually tuned to the same recorded velocity profile for many ion species, and consequently tuning is exceptionally easy and rapid [23].

A different positive ion injector [24] is planned for the SC linac at Legnaro. The ion source is an ECR, of course, and its output is injected into an array of three Nb SC RFQ's followed by a QWR section. These RFQ 80 MHz units are designed to cover the β range 0.009 to 0.05. A full-scale stainless-steel model of an RFQ has been studied and a Nb unit is under construction. Based on the experience for other SC low-β resonators, phase control for a large SC RFQ may be difficult. In the early 1990's a SC low-β RFQ was built and tested at Stony Brook [25], but phase control was not attempted.

6 OPERATIONAL EXPERIENCE AT ATLAS

ATLAS is the largest and most intensively used SC low-β linac now in operation. The overall layout of the system is shown in Fig. 5. The primary injector is PII, where a second, more powerful ECR ion source has been added recently. The tandem is still used for very light ions and for radioactive species.

The first experiment with a small part of ATLAS was 20 years ago, Sept. 1978. Since then the system has been used steadily as the linac grew, and in recent years its beam has been used for research and occasionally development for more than 5,000 hr. annually [23]. Overall, since 1978 ATLAS has provided ~ 70,000 hr. of useful beam time.

Because of its positive ion injector, ATLAS provides beams for all parts of the periodic table. This wide range is used regularly; for example, 28 different isotopes ranging from hydrogen to uranium were used in FY1997. Altogether, there were 63 separate runs ranging from 8 hr. to 8 days.

7 NEEDS FOR NEW ACCELERATING STRUCTURES

Several future applications of SC linacs come to mind: (1) small linacs for purposes other than nuclear physics, (2) accelerating structures for intermediate-β ions, and (3) radioactive ion accelerators (RIB).

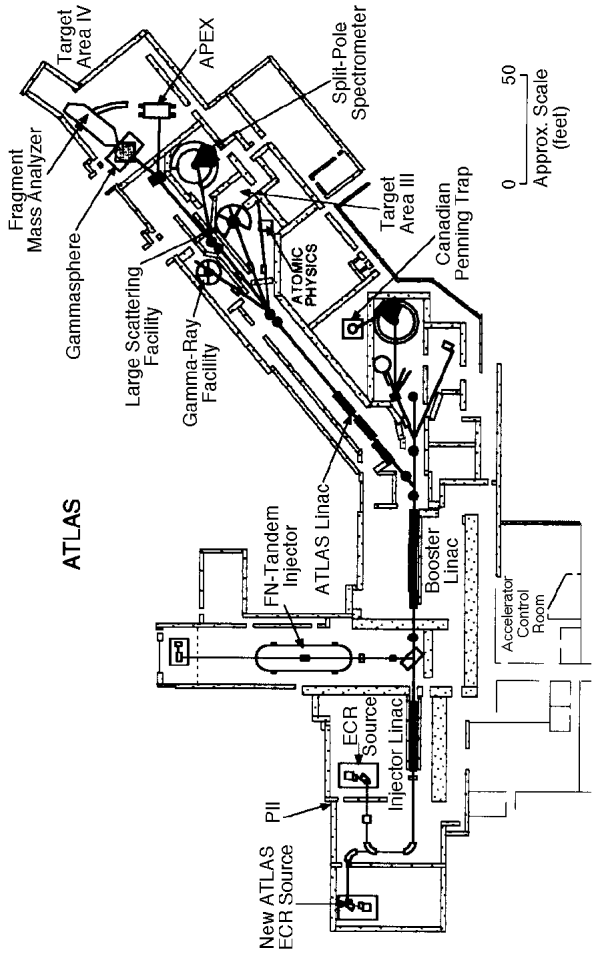

Figure 5: ATLAS in 1998.

Small linacs might be useful in materials science and industry. For example, most ion implantation is done with small electrostatic accelerators which provide limited depths of implantation and range of ion species. These limitations could be removed by a small SC low-β linac. However, it is not obvious that this approach is optimum, especially since CW operation may not be needed.

SC accelerating structures for intermediate-β ions may be attractive for a number of accelerators now being considered, of which I will mention two. One class is the high-current high-energy machines that have been studied at Los Alamos. They have tested 700 MHz SC cavities with $\beta \approx 0.48$, 0.64, and 0.82, and have concluded that for them, room-temperature structures are better for $\beta = 0.48$, and SC is optimum for the other two [25].

Another active proposal is a radioactive ion beam accelerator (RIB) at Argonne. The driver of this system is to be a 200-MV linac that can accelerate both protons and much heavier ions. CW operation is highly desirable, which makes SC technology very attractive. In an

Argonne-CEBAF collaboration [27], a SC 1/2-wave resonator with f = 350 MHz and $\beta = 0.4$ is being built for possible use in the RIB driver. An important feature of the 1/2-wave design (see Fig. 3) is that its ratio of accelerating field to surface field is substantially greater than for all other low-β resonators and, consequently, in an earlier test [28] on a $\beta = 0.10$ unit, the maximum accelerating field was 18 MV/m, ~ 50% greater than other low-β units as shown in Table 3 of [20]. However, additional experience is needed before the optimum structure can be chosen.

The third need for resonators is in the range below $\beta = 0.008$, the present limit set for SC by the first resonator in PII at Argonne. The requirements for the Argonne RIB are extreme: to accelerate a CW beam of radioactive ions with q/A = 1/120 through the range from $\beta = 0.001$ to $\beta = 0.008$ without seriously deteriorating the beam quality. The system planned [29] has two steps: a CW room-temperature 12.125 MHz RFQ on a 300 kV platform for the β range 0.001 to 0.0025, followed by a second RFQ on an independent voltage platform for the β range 0.0025 to 0.008. The first RFQ is undergoing tests now [29] and seems likely to be an excellent solution, and the second RFQ should be less demanding than the first because of the greater velocity of the beam. Note that the very low RF frequency is an essential design feature because of its low RF-power requirements. It appears, then, that if a very low RF frequency is acceptable and if the 12.125 MHz RFQ's function as well as expected, then SC structures are not competitive below $\beta \approx 0.008$.

As has been hinted by the topics mentioned in this section, there are still many questions to be answered about SC low-β linacs. Unlike most of the past, these questions are concerned with the two fringes of the low-β spectrum, and answers are needed for small but important parts of future accelerator systems. The subject is still interesting - but, for me, not as exciting as it was in the 1970's.

STATUS OF THE TESLA DESIGN

D. Trines for the TESLA Collaboration [*]
Deutsches Elektronen-Synchrotron DESY, 22603 Hamburg, Germany

Abstract

The status of the layout of the linear collider project, TESLA, which employs superconducting accelerating structures, will be presented. Latest results from the R&D program on 1.3 GHz superconducting cavities, the accelerating gradients and quality factors which were achieved will be shown as well as the performance of the TESLA Test Facility linear accelerator.

1 INTRODUCTION

Since the first proposal for a superconducting linear $e^+ e^-$ collider by M. Tigner [1] in 1965, accelerator builders [2,3,4] have been fascinated by the potential of superconductivity for high energy linear $e^+ e^-$ colliders. The low resistive losses in the walls of superconducting cavities yield a high conversion efficiency from mains to beam power. As energy can be stored very efficiently in the cavities, a large number of bunches can be accelerated spaced far apart in a long RF pulse. This allows for a fast bunch to bunch orbit feedback which guarantees that bunches from the opposing beams hit head on at the IP despite ground motion effects.

The shunt impedance per unit length for superconducting cavities depends on RF frequency ω as

$$r_s \sim \frac{\omega}{A\omega^2 + R_{res}} \qquad (1)$$

favouring RF frequencies in the range of 0.5 to 3 GHz. A is a function of temperature and material and R_{res} is the residual surface resistance. Because low frequencies are preferred for s.c. cavities, this make them ideally suited to accelerate low emittance beams, as the emittance dilution by wakefields is small ($W_\perp \sim \omega^3$). In addition tolerances on the fabrication and alignment of cavities are very relaxed.

The luminosity of a linear collider is given by [5,6]

$$L \approx const. \frac{\sqrt{\delta_B}}{E_{CM}} \cdot \frac{\eta}{\sqrt{\varepsilon_{yN}}} \cdot P_{AC} \cdot H_D \qquad (2)$$

where δ_B is the relative energy loss caused by beamstrahlung, E_{CM} is the centre of mass energy of the $e^+ e^-$ collision, η is the conversion efficiency from mains power P_{AC} to beam power, ε_{yN} is the normalised vertical emittance at the IP and H_D is the disruption factor. Thus, the figure of merit [7] for the luminosity performance of a linear collider is given by $\eta/\sqrt{\varepsilon_{yN}}$. Therefore the combination of high conversion efficiency and small emittance dilution makes a superconducting linear collider the ideal choice with respect to the achievable luminosity.

2 A SHORT HISTORY OF TESLA

The major challenges to be mastered so that a superconducting linear collider becomes feasible were to increase the accelerating gradients from about 5 MV/m to 25 MV/m and to reduce the cost per length from existing systems by about a factor of four to obtain ~ 2000 $/MV. Encouraged by results from R&D work at CEBAF, CERN, Cornell, DESY, KEK, Saclay and Wuppertal [12,13,14], several institutions - the nucleus of the TESLA Collaboration formally established in 1994 - decided in 1991 to set up the necessary infrastructure at DESY [8] to process and test 40 industrially produced 9 cell 1.3 GHz solid Niobium cavities. The aim was to achieve gradients of 15 MV/m at a Q value of $3 \cdot 10^9$ in a first step and finally reach 25 MV/m at a Q value of $5 \cdot 10^9$ suitable for the linear collider. The infrastructure of the TESLA Test Facility TTF consists of cleanrooms, chemical treatment installations, a 1400° C purification furnace, a high pressure water rinsing system, a cryogenic plant to operate vertical and horizontal cavity test stands at 1.8 K and a 1.3 GHz RF source. A detailed description of the infrastructure, which was completed by the end of 1995, will be given in [9].

In addition the collaboration decided to build a 500 MeV linac as an integrated system test to demonstrate that a linear collider based on s.c. cavities can be constructed and operated with confidence.

Considerable attention has been given to the subject of cost reduction [10,11]. For example:

- The number of cells per accelerating structure was increased to 9 compared to the customary 4-5. This

reduces the number of RF input and HOM couplers, tuning systems and cryostat penetrations, it also simplifies the RF distribution system and increases the filling factor.

- Costly cryostat ends and warm to cold transitions were avoided by combining eight 9 cell cavities and optical elements, which were all chosen to be superconducting, into one long, simple cryostat. Also the complete helium distribution system has been incorporated into the cryostat using the cold low pressure gas return tube as support structure for cavities and optical elements.

From the work starting in 1990 [13] a concept for a 500 GeV cm energy superconducting linear collider emerged, operating at 1.3 GHz with a gradient of 25 MV/m at $Q=5\cdot10^{9}$ and a luminosity of some $5\cdot10^{33}$ cm^{-2} sec^{-1}. A conceptual design report (CDR) was published in May 1997 [15] giving a complete description of the machine including all subsystems. The report includes a joint study with ECFA on the particle physics and the detector layout.

Since 1990 interest has grown [16,17] in linac driven X-ray FEL radiation, based on the Self-Amplified Spontaneous Emission (SASE) principle [18,19]. As the requirements on the emittance of the beam for a short wave length FEL are very demanding, again a superconducting low RF frequency linac lends itself as the best choice for such an application. The CDR includes the layout of an X-ray FEL facility integrated into the linear collider as well as various scientific applications of the FEL radiation. A detailed report on the status of the X-ray facility will be given at this conference [20].

3 R&D RESULTS AND ACTIVITIES

Up to now 25 9-cell Niobium cavities have been tested at the TTF. The majority of the cavities exceeded the initial TTF design goal of 15 MV/m at $Q=3\cdot10^{9}$. Fig. 1 shows the measurements in the vertical test stand [26] of all cavities excluding only those with a well identified fabrication error. On average a gradient of 22 MV/m at $Q=10^{10}$ is obtained. In the most recent measurement in the horizontal test [25] a gradient of 33 MV/m at $Q=4\cdot10^{9}$ has been achieved.

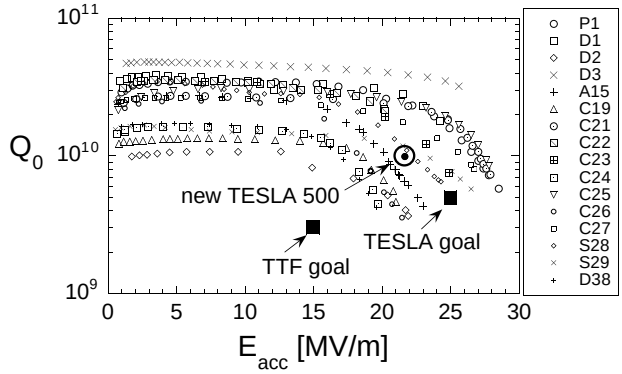

Figure 1: Quality factor Q versus acc. gradient for all 9-cell cavities without fabrication error (vertical test).

The performance limitations seen in six cavities were due to an improper welding procedure and could be eliminated in the subsequent cavity production. The remaining cavities not performing to expectations showed inclusions of Tantalum grains in the Niobium. Such defects will be avoided by scanning all Nb sheets for impurities with an eddy-current method. For a detailed information on cavity treatment procedures and results see [9,21].

All components for beam acceleration through the first cryomodule were installed in May 97. As the 14 MeV injector was already in operation at design values [22], stable beam acceleration in the first module could be established within a few days. Although the module contained 5 out of 8 cavities with fabrication errors, acceleration gradients of 16.7 MeV/m were obtained in a RF pulse of 100 μsec. For more details see [21,27].

The measurement of cryogenic properties of the module such as cryogenic loads, behaviour of cavity positions during thermal cycles and vibrations stayed well within the expected limits [23]. Detailed reports on the low level RF control, achieving a very impressive stability of phase and amplitude of the accelerating fields, will be given at this conference [24].

Several alternatives to the welding of dumb-bells for the production of 9-cell Niobium cavities - like hydroforming [28,32], spinning [29], or plasma spraying of copper on thin walled Nb cavities [30] - are being pursued within the collaboration. If successful, these methods may eventually lead to a further cost reduction in the cavity fabrication.

A very important new development was initiated by the proposal of a cavity "superstructure" [31]. In this scheme the spacing between adjacent cavities is reduced from 1.5 to 0.5 RF wavelengths and a group of 4 or more of these closely spaced cavities is supplied with RF power by only one input coupler. In this way the filling factor - the ratio of active to total length - increases from 66 % to 76 % or more, thus reducing the required gradient for 500 GeV cm operation from 25 to 21.7 MV/m for fixed linac length. The cost reductions due to the smaller number of RF input couplers and cryostat penetrations, and the simplification of the RF distribution system are obvious.

4 TESLA PARAMETERS

In the Conceptual Design Report the machine parameters were chosen such that luminosity and beamstrahlung energy loss were comparable to other linear collider designs [33]. The potential of the superconducting linac to accelerate a very small emittance beam with small emittance dilution was not exploited intentionally, keeping requirements on the alignment and stability of the linac and final focus components quite relaxed. Since the completion of the CDR, however, this strength of the TESLA concept has been investigated to some extent [34] leading to a new parameter set [35] suited for high luminosity operation at 500 GeV cm energy (see Table 1). The bene-

fits of the new "superstructure" concept have been incorporated into the design.

Table 1: Updated parameters at E_{cm}=500GeV in comparison with the original reference parameters.

	TESLA (ref.)	TESLA (new)
site length [km]	32.6	32.6
active length [km]	20	23
acc. Gradient [MV/m]	25	21.7
quality factor Q_0 [10^{10}]	0.5	1
t_{pulse} [μs]	800	950
# bunches n_b/pulse	1130	2820
bunch spacing Δt_b [ns]	708	337
rep. rate f_{rep} [Hz]	5	5
N_e/bunch [10^{10}]	3.6	2
ε_x / ε_y (@ IP) [10^{-6}m]	14 / 0.25	10 / 0.03
beta at IP $\beta_{x/y}^*$ [mm]	25 / 0.7	15 / 0.4
spot size σ_x^*/σ_y^* [nm]	845 / 19	553 / 5
bunch length σ_z [mm]	0.7	0.4
beamstrahlung δ_B [%]	2.5	2.8
Disruption D_y	17	33
P_{AC} (2 linacs) [MW]	95	95
efficiency $\eta_{AC\to b}$ [%]	17	23
luminosity [10^{34} $cm^{-2}s^{-1}$]	0.68	3

The reduction of the required gradient (25→21.7 MV/m) leads to an increase of the quality factor from $5\cdot10^9$ to 10^{10}. Both effects lower the required power for the cryogenics. This power savings has been invested in the beam power. The resulting lower loaded Q-value corresponds to a shorter filling time of the cavities, which in turn results in an increased conversion efficiency from mains to beam power (17→23 %).

Although the vertical emittance has gone down by almost an order of magnitude as compared to the CDR, tracking simulations [36] show that the emittance only grows by 23 % and 17 % due to single bunch and multi bunch effects respectively. However, most of the growth due to multibunch effects is not an incoherent spot size dilution but a systematic variation of the beam center along the bunch train at the IP. In combination with the larger disruption parameter - as compared to the CDR - these offsets may drive the opposing beams apart and critically reduce the luminosity. Fortunately, being mostly systematic, the offsets can be strongly reduced by the fast bunch to bunch orbit feedback. Further investigations of this topic will be needed, however.

As is to be expected the smaller spot sizes of the colliding beams put stronger requirements on the accuracy of the fast orbit feedback at the IP [37]. To keep the luminosity loss below 7 % the relative offset of the opposing beams at the IP has to be kept below 0.1 σ_y [38]. This requires a bpm resolution at the final focussing quadrupoles of 2 μm, which should be feasible.

As, for a given beam energy and beam power, the disruption parameter D_y is proportional to the product of luminosity and bunch length [35], the increase of D_y at a higher luminosity can be compensated by shortening the bunchlength. This handle has been applied only moderately up to now in the new design due to problems in the damping rings.

The TESLA damping rings are quite unconventional machines. At a beam energy of only 3.2 GeV they have a circumference of 17 km, of which 95 % are straight sections, located inside the TESLA tunnel (see Figure 2). Only two short return bends on either side with extra tunnels are needed ("dogbone"), thus saving substantially on civil engineering costs. However, the large circumference C and the low energy lead to an unfavourable enhancement factor of the incoherent space charge tune shift:

$$\Delta Q \sim \frac{C}{E^2}\cdot\frac{N_e}{\sigma_z\sqrt{\varepsilon_x\varepsilon_y}} \qquad (3)$$

Already for the CDR parameters the vertical tune shift amounted to -0.18. Further reductions of bunchlength and emittances therefore would lead to uncomfortably large tune shifts. The proposed cure for this problem [39] is to increase the beam size in the long straight sections by coupling the longitudinal or horizontal emittance to the vertical plane. First calculations [40] show that the space charge tune shift can be very effectively reduced in this way without trading in problems due to intra-beam scattering.

5 LAYOUT OF THE COLLIDER FACILITY

There has been consensus within the collaboration that the linear collider facility must be built at an existing high energy physics laboratory to make use of the existing infrastructure and staff. In the CDR two possible sites have been envisaged, one being DESY, the other Fermilab. Both sites allow for a future option to collide 500 GeV e^-/e^+ with high energy protons circulating in HERA or the Tevatron.

This option fixes the possible direction of the linear collider. At DESY the tunnel is foreseen with the main linac axis being tangential to the West straight section of HERA, extending about 32 km into the state of Schleswig-Holstein. The countryside is flat at about 10 m above sea level with maximum height variations of some 10 m. The tunnel axis is foreseen at 8 m below sea level, giving more than sufficient soil coverage for radiation protection. The soil, consisting mainly of sand, allows for easy tunneling by the hydroshield method, which was also used at HERA. The tunnel follows the earth's curvature

over most of its length, except for a section of about 5 km length to direct the tunnel axis tangentially to HERA.

A view into the planned tunnel (diameter 5.2 m) is shown in Fig. 2 at a section which contains the straight sections of the "dogbone" damping ring (upper left side) and several beam lines (right below the cyromodule) to the FEL facility. At the top of the tunnel there is a monorail for the transportation of equipment and personnel.

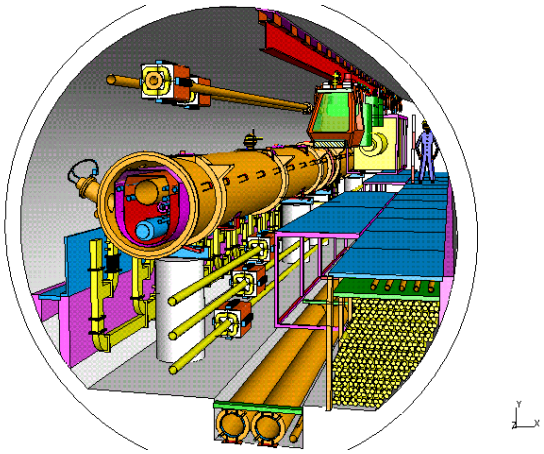

Figure 2: View into the TESLA Tunnel.

Klystrons and their pulse transformers are installed horizontally below the floor in the middle of the tunnel above the cooling water tubes. There is a total of about 625 10 MW klystrons including about 2.5 % spare. Each klystron feeds 32 9-cell cavities corresponding to a length of about 48 m. With a lifetime of 40,000 hours about 10 klystrons will have to be replaced in a one day interruption once per month.

The experience of the SLC [41] on the failure rate of modulators does not permit an installation into the tunnel, inaccessible during machine operation. Therefore in the present layout the modulators are housed in service halls above ground connected to the pulse transformers in the tunnel by long cables (Fig. 2, lower right). However, the design of modulators reliable enough to be installed into the tunnel is being investigated.

Service halls, spaced along the collider at a distance of about 5 km are needed for the cryogenic plants [42] in any case. The length of superconducting linac that can be cooled by a cryoplant is about 2.5 km. This distance is mainly determined by the pressure drop in the large return tube (300 mm diameter) for low pressure Helium gas at about 2 K. The pressure in tube determines the vapour pressure of the superfluid helium surrounding the cavities and thus the operating temperature of the cavities.

Each service hall houses two cryoplants each supplying a 2.5 km section of the linac. In case of a failure of one plant, the other one can supply two sectors operating the collider at a reduced repetition rate. The big cryogenic boxes are planned to be installed in the 14 m diameter shaft connecting the service hall with the tunnel (see Fig. 3).

Due to the large spacing between consecutive bunches, there is no crossing angle required at the IP and consequently no angle between the tunnel axis of the two linacs. The beams are deflected by electrostatic separators, having passed the interaction region and the large aperture, superconducting quadrupole doublet. A tunnel length of about 1.2 km between the IP and the ends of either superconducting linac is needed for the beam delivery system [15] containing beam collimation systems, beam diagnostics and orbit correction elements, and the final focus system, demagnifying the beam size and correcting chromatic effects. These tunnel sections also house the beam dumps and the positron source.

As the amount of positrons needed for a beam pulse exceeds the potential of conventional positron sources, the electron beam having passed the interaction region is used to produce the required number of positrons. In this scheme, proposed in the original VLEPP design [43], the spent electron beam is collimated and passed through a wiggler producing large quantities of γ-rays, which convert in a thin rotating target into $e^+ e^-$ pairs. The fraction of positrons which can be captured by the source optics, accelerated to 3 GeV and stored in the dogbone damping ring yields a sufficient number of particles for the operation of the linear collider. With the new design parameters the fraction of the spent electron beam usable for positron production actually increases from 86 % to 93 % due to the smaller beam emittance, thus substantially reducing the power load on the collimators [44]. Although a detailed technical layout of the positron source is still missing, first investigations indicate that the whole system can well be accommodated into the tunnel.

6 ENERGY UPGRADE POTENTIAL

With the new "superstructure" concept the gradient needed for 800 GeV cm energy is 34 MV/m. From the results on cavity R&D (section 3) the optimism, that average gradients well above 30 MV/m at Q values of $5 10^9$ can be reached within the near future, is well justified. The theoretical maximum gradient for our structures limited by the critical magnetic field is at about 55 MV/m.

All subsystems of the collider have been laid out for 800 GeV operation. The number of klystrons and modulators will be doubled. With the present layout of the cryogenics the repetition rate of the collider will have to be reduced from 5 to 3 Hz to maintain the level of available cooling capacity. By further reducing the normalised vertical emittance by a factor 3 to 10^{-8} m , a luminosity of $5 \cdot 10^{34}$ cm^{-2} sec^{-1} can be obtained [35], the beamstrahlung energy loss staying below 5 %. The mains power requirement will go up to 130 MW. An upgrade of the cryogenic cooling capacity will allow luminosities close to 10^{35} cm^{-2} sec^{-1} to be reached by running the collider at a repetition rate of 5 Hz.

7 OUTLOOK

On the basis of the existing knowhow, orders to industry are being issued to evaluate the requirements of large scale industrial cavity production. Together with a detailed layout of all subsystems of the collider the information from the industrial studies will allow for a proposal containing technical design of the facility, and a reliable schedule and cost evaluation, to be submitted in two to three years from now. To obtain public acceptance the states, the communities, and the residents involved have been informed about the planning. An administrative procedure to eventually ensure the necessary legal conditions for the construction of the facility - if approved - is underway.

8 ACKNOWLEDGMENTS

I would like to express my respect to the many people in and outside the collaboration who have been working on the cavity R&D over the years. This work has been certainly cumbersome at times but finally lead to the beautiful cavity results, which we have today. Many people have contributed to the present status of the TESLA design, whom I cannot give proper credit to. But I would like to give special credit to the late G. Horlitz for designing the complete cryogenics system of TESLA.

RESEARCH AND DEVELOPMENT FOR AN X-BAND LINEAR COLLIDER*

C. Adolphsen
Stanford Linear Accelerator Center, Stanford University, Stanford CA 94309 USA

Abstract

At SLAC and KEK research is advancing toward a design for an electron-positron linear collider based on X-Band (11.4 GHz) rf accelerator technology. The nominal acceleration gradient in its main linacs will be about four times that in the Stanford Linear Collider (SLC). The design targets a 1.0 TeV center-of-mass energy but envisions initial operation at 0.5 TeV and allows for expansion to 1.5 TeV. A 10^{34} cm^{-2} s^{-1} luminosity level will be achieved by colliding multiple bunches per pulse with bunch emittances about two orders of magnitude smaller than those in the SLC. The key components needed to realize such a collider are under development at SLAC and KEK. In this paper we review recent progress in the development of the linac rf system and discuss future R&D.

1 INTRODUCTION

For the next generation electron-positron linear collider, one wants to generate at least one TeV center-of-mass collisions to complement the physics reach of the Large Hadron Collider (LHC) that is being constructed at CERN. At SLAC and KEK research has been focused on a collider design that uses X-Band (11.4 GHz) rf technology to achieve this goal [1,2]. The design has evolved largely from the experience gained from operation of the Stanford Linear Collider (SLC) where S-Band (2.9 GHz) rf technology is used to accelerate beams to about 50 GeV. Increasing the rf frequency allows for higher gradients (72 MeV/m versus 17 MeV/m in the SLC) which keeps the machine cost from becoming prohibitive at the higher energies.

To be efficient, multiple bunches (95) will be accelerated on each rf pulse (120 Hz repetition rate). There will be about 10^{10} particles per bunch and the bunch spacing will be 2.8 ns. These 0.6 A beams will reduce (load) the gradient in the 1.8 m long X-Band accelerator structures by 16%. Including energy overhead, the effective gradient in the structures will be 55 MeV/m. The structures will fill 86% of the lineal distance along the main linacs so 10.4 km long beam lines will be required to accelerate the electron and positron beams from their 10 GeV injection energies to 500 GeV. However, the collider will be operated initially with a 500 GeV center-of-mass energy where only the first half of each of the opposing linacs will contain rf components, and the beams will 'drift' through the remaining halves.

The main components of the linac rf system are the modulators that power the klystrons, the 75 MW klystrons that generate the rf, the distribution system that transports the rf to the accelerator structures, and the structures themselves. In the following sections, we review the designs, recent R&D and future development plans for these components.

2 MODULATORS

The modulators that are used in the SLC are conventional line-type with pulse-forming networks (PFN). These networks are composed of discrete inductors and capacitors that are slowly charged and then rapidly discharged (via a thyratron) through a step-up transformer to generate the high voltage pulse needed to drive an SLC klystron. A similar approach is being pursued at SLAC to produce the 490 kV, 260 A, 1.5 μs long pulses required for the X-Band klystrons that are being developed [3]. The current design has a single modulator powering two klystrons through a 14:1 transformer. A prototype version has been built using high-energy-density glass-type capacitors, and tested with a single S-Band klystron at a lower voltage (290 kV) to produce the same impedance as two X-Band klystrons. In this configuration, 89% of the stored energy is transferred from the modulator to the klystron, and 82% of the transferred energy is within the 1.5 μs long pulse flattop, between the pulse rise (350 ns) and fall (450 ns) periods. The charging power supply used in the test was not particularly efficient; however, if the goal of 90% is achieved, the overall energy transfer efficiency from AC to usable klystron beam power would be 66%.

To improve efficiency, KEK is working with a Blumlein modulator configuration [2]. Here a step-up transformer of half the turns-ratio as the conventional configuration sits between two PFNs of the appropriate impedance to double the primary voltage. In principle, this should yield a faster rise time due to the lower leakage inductance of the transformer [4]. However, tests thus far with klystron loads have yielded values comparable to the SLAC results. Both groups will continue to upgrade their test setups to improve

* Work Supported by DOE Contract DE-AC03-76F00515.

efficiency, reduce costs, and handle the full klystron pulse requirements.

One drawback of these modulator designs is their use of thyratrons which in general have relatively short lifetimes (10-20 khour) and require periodic tuning. As an alternative, a solid-state induction-type modulator is being developed at SLAC and LLNL that has the potential of better reliability and higher efficiency [5]. The basic idea is to sum many low voltage sources inductively to yield the desired klystron voltage. This has been realized by having each source drive a transformer made from a 4.5 inch ID, by 11.5 inch OD, by 2 inch thick Metglass core. The cores are stacked so the secondary windings, which sum the output voltages, can be threaded through their IDs. Each source is essentially a capacitor that is slowly charged and then partially (20%) discharged through a solid-state switch to generate the pulse.

Recent improvements in Isolated Gate Bipolar Transistor (IGBT) switches, which are used in electric trains for example, have made this induction scheme conceivable. They have relatively fast rise and fall times (< 100 ns between 10% and 90%) with turn-off occurring after a fixed delay of about 100 ns from the end of the gate pulse. Tests so far have been done with resistive loads: a single source has directly (no core) switched 1.5 kA at 2 kV, and an 18 kV pulse has been generated inductively through a six-core stack with single-turn primaries and a four-turn secondary.

Although the switching times are fast in these cases, the rise and fall times in actual operation will be somewhat longer due to the combination of the modulator leakage inductance and the klystron capacitance. Simulations have shown that a 1:1 turns-ratio is needed to produce fast enough rise and fall times (≈ 200 ns) to yield an overall efficiency of 75%. Part of this efficiency would come from including circuitry in each source that would recover much of the stored energy remaining in stray inductances and capacitances after the IGBTs shut off.

For the 1:1 turns-ratio design, one hundred 5 kV, 2 kA sources are summed to drive 8 klystrons. IGBTs capable of switching such power are expected to be available soon. Failure of any single source should be benign; the core will saturate and be nearly transparent to the pulse. Some overhead in voltage capability will be included to offset such a loss. Also, the sources will be independently timed to better shape the pulse, for example, to offset the natural droop. One potential problem in driving many klystrons is that an arc in one will be fed by the stored energy in the others (the circuit itself can be shut off in time to not be a problem). Adding inductors in the power feeds that fan out to the klystrons should reduce the discharge power to a manageable level. In the next year a more realistic prototype will be built to better evaluate this induction modulator scheme.

3 KLYSTRONS

During the past decade at SLAC and KEK, research has been directed at developing X-Band (11.4 GHz) klystrons in the 50 to 130 MW range [1,2,6,7,8]. Until the last few years these klystrons have used large solenoid magnets to focus the beam in its path from the gun through the bunching and output sections to the collector. However, the power used by these magnets, around 20 kW, is comparable to the average rf output power so it has a big impact on efficiency. This has prompted the development of a focusing scheme that uses permanent magnets so there is no associated power loss.

Before discussing this scheme however, we review results from the latest and perhaps last generation of solenoid-focused X-Band klystrons that SLAC and KEK will develop. They operate with a perveance (I [Amps] / $V^{3/2}$ [Volts]) of 1.2×10^{-6} and contain four-cell traveling wave output cavities. At SLAC, the XL4 klystrons are the culmination of its 50 MW klystron development program. Six of these tubes have been built, and they are used as X-Band rf sources for component testing and beam acceleration in the Next Linear Collider Test Accelerator (NLCTA). They reliably generate 1.5 μs long, 50 MW pulses with a 41% beam-to-rf efficiency. In a brief test, one klystron produced 75 MW, 1.2 μs long pulses at 48% efficiency. At KEK, the XB72K #9 tube, which was developed with BINP, has recently produced 72 MW with a 31% efficiency although the pulse length was limited to 200 ns by the modulator. KEK, in collaboration with Toshiba, has also recently completed assembly of a tube that is expected to produce 126 MW, 1.5 μs long pulses at 48% efficiency. It uses longer cavity cells with a lower Q_{ext} to be able to operate at higher currents for the same cavity surface fields. Testing of this tube has just started.

At SLAC, permanent magnet tubes are now being developed. In these designs, about 40 magnet rings with alternating polarities are interleaved with iron pole pieces to generate a periodic (i.e., sine-like) axial field along the ≈ 0.5 meter region between the gun anode and beam collector. The resulting focusing strength is proportional to the RMS of this axial field. About 2 kG can be achieved practically, which is smaller than the ≈ 5 kG field in the solenoid-focused tubes. This has led to a lower perveance (0.8×10^{-6}) design where the space charge defocusing is smaller. To handle the increased voltage drop along the output cavity, it was lengthened to five cells. The lower perveance has the advantage of increasing efficiency through improved bunching, but it makes the modulator harder to build due to the higher voltage hold-off (490 kV). The efficiency goal for these Periodic

Permanent Magnet (PPM) klystrons is at least 60% when generating 75 MW, 1.5 μs long pulses at 120 Hz.

Thus far, SLAC has built a 50 MW PPM klystron using samarium cobalt magnets. This tube has produced 2 μs long pulses with a 55% efficiency at the design power. A 75 MW PPM tube has also been built but has had operational problems that are thought to arise in part from using magnets that do not fully meet specifications. A switch to NbFeB magnets was made for machining and cost reasons, but they proved harder to manufacture within the desired magnetic tolerances. The present program is to improve the operation of this tube and concurrently to build a new version that is more suited for mass production. It should be completed by the end of 1999. At KEK, a 75 MW PPM tube that was designed and built by BINP was tested with limited success. Work there has recently focused on more accurate klystron modeling using the MAGIC code. These studies have resulted in a better understanding of existing tubes and will be used as the basis for designing the first PPM tube at KEK.

4 RF DISTRIBUTION

The function of the rf distribution system is to transport the klystron output power to the accelerator structures. This task is made more difficult by the fact that the klystrons optimally generate a lower power and longer pulse than that needed for the structures. In past linac designs and in the NLCTA, the solution was to use pulse compression, namely the SLED II system which is a delay line version of the SLAC Linac Energy Doubler (SLED) [1]. It consists of a 3 dB hybrid divider that routes the klystron output power equally to two delay lines made of circular waveguide. These lines are shorted at the far end and have irises at the near end that partially reflect the rf. During operation in the NLCTA, for example, the two 40 m long lines are resonantly filled during the first $5/6^{th}$ of the 1.5 μs long klystron pulse, and then effectively discharged through the remaining hybrid port by a 180º reversal of the klystron phase during the last $1/6^{th}$ of the pulse. This yields a shorter ($1/6^{th}$ as long), higher power pulse that is used to power two NLCTA accelerator structures. Although it works well, it is not particularly efficient; about 30% of the power goes to the structures during the filling of the delay lines, so the power gain is about four.

Although there are more efficient pulse compression methods, the scheme now being pursued sums the power from four pairs of klystrons, 'slices' it into four equal time intervals, and then distributes it up-beam to four sets of accelerator structures that are appropriately spaced so that the beam-to-rf arrival time is the same in each case. Hence no power is wasted although there are still resistive wall losses.

In the original version of this Delay Line Distribution System (DLDS), which was proposed by KEK, the power is summed with 3 dB hybrid combiners and distributed up-beam through individual circular waveguides to each set of structures [2,9]. The power routing is accomplished by varying the relative rf phases of the four sources. In the circular waveguides, the power is transported in the low-loss TE_{01} mode as is done in the SLED II delay lines. To reduce the length of waveguide, a multimode version of this system has been proposed at SLAC in which the power is distributed through a single circular waveguide, but in four different modes [10]. In this case the power from the four klystron pairs is sent to a 'launcher' that generates the modes based on the relative rf phases of the four inputs. During operation, the phases are varied to excite the four modes sequentially in equal time intervals. The circular waveguide modes are TE_{01}, TE_{12H}, TE_{12V} and TE_{21} where the H and V subscripts refer to horizontal and vertical polarizations. Three of modes travel up-beam and are extracted at appropriate locations to arrive 100 ns (the structure filling time) before the beam. Each 'extractor' couples out only one mode and passes the remaining modes. The fourth mode (TE_{21}) is extracted at the launcher. KEK is considering a similar scheme but with the power distributed in two circular waveguides where two modes (TE_{01}, TE_{12H}) are launched and extracted in each waveguide.

For the rf transport between the klystrons and launcher, and between the extractors and the structures, the TE_{01} circular waveguide mode is used. The extracted power in each case feeds three contiguous accelerator structures. To power a contiguous array of structure triplets, nine DLDSs (a nonet) are interleaved to form a 225 m long sector. The sector length is set by the 1.5 μs klystron pulse length and the relative beam-to-rf group velocity (about 2c). Twenty-two sectors are required to produce a 500 GeV beam.

An important requirement of this distribution system is its power handling capability. With eight 75 MW klystrons, 600 MW of rf power will be launched, extracted and 'taped-off' in thirds to feed 200 MW to each structure. Based on operational experience, the goal is to keep the surface fields in all transport components below about 40 MeV/m [11]. Recently, two planar-style 3 dB hybrids and several rectangular (TE_{10}) to circular (TE_{01}) mode converters were successfully tested to 420 MW with 150 ns long pulses. To test components at their design power level and beyond, the NLCTA is being upgraded to produce 800 MW, 240 ns long pulses.

Concepts for the launcher, extractors and bends are in hand and development programs have begun at SLAC and KEK. In addition to reducing the surface fields, the designs aim for a power reduction of < 1% in each component due to mismatches and resistive

wall losses. Overall, a klystron-to-structure transfer efficiency of about 85% is expected where only a small portion of the power loss occurs in the long circular waveguides. This assumes no mode conversion in these sections. A joint experiment is under way to verify that such conversion losses are small, especially from rotation of the polarized modes.

5 ACCELERATOR STRUCTURES

SLAC and KEK have enjoyed an active collaboration in X-Band accelerator structure development for more than five years. This has led to a common structure design that uses an electrical scheme developed at SLAC and assembly techniques pioneered at KEK. The electrical design addresses both the requirement of efficient beam acceleration and the need to suppress the long-range transverse wakefield generated when a beam travels off-axis through the structure. Unless the wakefield is reduced by about two orders of magnitude, the coupling of the bunches in a multibunch train will resonantly amplify any betatron motion of the train by a significant amount. This difficult goal has been met by using a combination of two methods.

The first to be developed was mode detuning whereby the frequencies of the lowest (and strongest) band of dipole modes are systematically varied along the 206 cell structure to produce a Gaussian distribution in the product of the mode density and the mode coupling strength to the beam [12]. With this detuning, the modes excited by an off-axis bunch add deconstructively, yielding an approximately Gaussian falloff in the net wakefield generated after each bunch. A sigma of 2.5% was chosen for the 206-mode frequency distribution to produce more than a hundred-fold wakefield suppression by 1.4 ns, the nominal bunch spacing in the early linear collider designs.

This detuning works well to suppress the wakefield for about the first 30 ns, after which its amplitude increases due to a partial recoherence of the mode excitations. This has led to the introduction of weak mode damping to offset this rise [13]. The damping is achieved through the addition of four single-moded waveguides (manifolds) that run parallel to the structure and couple to the cells through slots. For each dipole mode, the power flow to the manifolds occurs in that region of the structure where the cell-to-cell phase variation of the mode matches that of the manifold mode. When terminated into matched loads, the manifolds reduce the mode Q's from about 6000 to 1000, enough to keep the wakefield from significantly increasing again.

To date, three of these Damped Detuned Structures (DDS) have been constructed. The cells for the most recent version were manufactured at LLNL using diamond-point turning. The mating surfaces of the cells were machined flat to < 0.5 μm and smooth to < 50 nm. The cells were then assembled in Japan using a two-step diffusion bonding technique. In the first step, the cells were stacked on an inclined V-block and pressed by 600 kg of force for 48 hours in a 180 °C environment. This procedure partially bonded the surfaces which prevented cell-to-cell slippage when the stack was placed upright to be fully bonded. For this step, the stack was placed under 24 kg of force at 890 °C for 4 hours.

The straightness of the resulting structure varied with scale, increasing from a few μm cell-to-cell to a few hundred μm over its 1.8 m length. However, the long wavelength (> 0.5 m) offsets were reduced by counter bowing the soft copper structure. A straightness of +/- 20 μm was achieved, yielding an overall alignment that meets the requirements of the linear collider design. In this design, the long wavelength alignment of the structures will be set and maintained by the support system. The structures will be attached to girders in sets of three with a single rf feed per girder that is 'tapped-off' to each structure. Each girder will have remote adjustment capability and will be positioned to best center the beam in the three structures based on the information obtained from processing the dipole mode signals from the structure manifolds. Thus, only the internal alignment of the structures along the girders will have to be established with precision (about +/- 20 μm) and be kept stable. Studies of long-term stability have been done with mock structures on a prototype girder. They show that the desired level of alignment is maintainable in an operating-like environment.

In the most recent DDS prototype, the rf match through the output ports of the manifolds was improved and the dipole frequency profile was changed slightly to increase the wakefield suppression. To gauge the effect of these changes, the long-range wakefield of the structure was measured in the Accelerator Structure Setup (ASSET) facility in the SLAC Linac [14]. Here a positron beam was used to induce a wakefield in the structure and an electron beam was used to 'witness' it. The measurements show larger than expected values for the wakefield, particularly at short times (< 20 ns). This increase is thought to be the result of systematic errors in the cell dimensions. Errors of roughly the size required to explain these data were observed in a sample of cells measured for QC purposes prior to assembling the structure.

Centering tests were also done in ASSET in which the dipole signals were used as a guide to position the positron beam. Measurements of the resulting short-range wakefield (< 300 ps) indicated that the beam had been centered to < 20 μm in the structure which is roughly the requirement during linear collider operation. However, monopole-like components of the

transverse wakefield were also observed and need to be understood.

The next structure that will be built will have rounded shaped cavities instead of the cylindrical shape used so far. This increases the shunt impedance of the structure by 12% which yields a 6% increase in the rf-to-beam efficiency. This rounded-DDS or RDDS will have an average iris radius equal to 18% of the X-Band wavelength. This value was derived from a joint SLAC and KEK study to optimize the linac performance. The main design difficulty thus far has been in damping the modes in the few cells at the downstream end of the structure that cannot be coupled to the manifolds due to space limitations. Several solutions are being considered including adding individual absorbers in these cells. Otherwise, the electrical design is nearly complete; SLAC and KEK will jointly build and test an RDDS by the end of 1999.

The suppression of the long-range wakefield is not the only difficult structure performance requirement. The structures must also operate reliably at a high gradient, about 70 MeV/m. Three structures have been rf conditioned to this level, the most recent one up to 85 MeV/m after 440 hours of operation [15]. It is a 1.3 m long, diamond-turned structure built at KEK to study detuning. During its conditioning, the rf power was slowly increased until a breakdown occurred in which > 5 MW of power was reflected back toward the source. The rf was then shut off for 2-4 minutes to allow the structure to pump down, and then it was slowly ramped up again. This procedure was continually repeated under computer control during most of the conditioning period.

At the highest gradient, the dark current emitted from the downstream end of the structure was about 5 mA and the mean time between breakdowns was less than a minute. Reducing the power to yield a 70 MeV/m gradient reduced the dark current to about 0.5 mA and increased the periods between breakdowns to several hours. Even at the highest gradient, however, the loading due to the dark current should not have been significant.

Another dark current related concern is the excitation of transverse fields. To the extent that such fields are the result of excitations of the lowest band of dipole modes, an estimate of their size was made by measuring the dipole signals from a manifold of a DDS during rf conditioning to 70 MeV/m. No significant signals were observed (except during breakdown) which puts a limit on the transverse field amplitude that is within the tolerance required in the linear collider design. The latest DDS prototype will be conditioned in the near future as part of a more systematic program to understand high gradient limits in the structures.

6 SUMMARY

The four major components of an rf system for an X-Band linear collider - the modulators, klystrons, rf distribution system and accelerator structures - are being actively developed at SLAC and KEK. Once their designs are more mature, an integrated rf system with eight klystrons will be built that will serve as a model element of a full-scale linac.

SCALING LAWS FOR NORMAL CONDUCTING e^+ e^- LINEAR COLLIDERS

J.-P. Delahaye, G. Guignard, I. Wilson/CERN, T. Raubenheimer /SLAC.

Abstract

Design studies of a future TeV e^+e^- Linear Collider (TLC) are presently being made by five major laboratories within the framework of a world-wide collaboration. A figure of merit is defined which enables an objective comparison of these different designs. This figure of merit is shown to depend only on a small number of parameters. General scaling laws for the main beam parameters and linac parameters are derived and prove to be very effective when used as guidelines to optimize the linear collider design. By adopting appropriate parameters for beam stability, the figure of merit becomes nearly independent of accelerating gradient and RF frequency of the accelerating structures. In spite of the strong dependence of the wakefields with frequency, the single bunch emittance preservation during acceleration along the linac is also shown to be independent of the RF frequency when using equivalent trajectory correction schemes. In this situation, beam acceleration using high-frequency structures becomes very favourable because it enables high accelerating fields to be obtained, which reduces the overall length and consequently the total cost of the linac.

1 INTRODUCTION

A lot of progress has been made in the last ten years on design and development studies towards high-luminosity TeV-range Linear Colliders (TLC). Various options for efficient beam acceleration have been explored and periodically compared within the framework of a world-wide collaboration [1]. Two basic technologies have been developed for beam acceleration: TESLA proposes to use 1.3 GHz super-conducting (SC) structures whereas SBLC, JLCc, JLCx, NLC,VLEPP and CLIC have chosen normal-conducting travelling-wave (NCTW) structures operating at the very different frequencies of 3, 5.6, 11.4, 14 and 30 GHz, respectively. General scaling laws have been derived [2] for multi-bunch TLCs which use NCTW structures, taking into account the basic physics processes which have been used to optimise the different designs. For completeness, the graphs also include data points for both TESLA and VLEPP in spite of their respective SC and single bunch operation. The motivation for the scaling study is two-fold. First, by comparing the parameters adopted by the various design studies which cover a decade in operating frequency, the study provides an insight into the way the different optimisations have been achieved. Secondly, it provides a logical strategy based on objective, physics-based arguments for designing or re-optimising any new or presently-proposed linear collider.

2 LUMINOSITY - FIGURE OF MERIT

The luminosity of an e^+/e^- linear collider is given by:

$$L = \frac{k_b N_b^2 f_{rep}}{4\pi\bar{\sigma}_x^*\bar{\sigma}_y^*} = \frac{N_b P_b}{4\pi e U_f \bar{\sigma}_x^*\bar{\sigma}_y^*} = \frac{H_D N_b \eta_{RF}^{AC}\eta_b^{RF} P_{AC}}{4\pi e U_f \sigma_x^*\sigma_y^*} \quad (1)$$

where P_{AC}, η^{AC}_{RF} and η^{RF}_{b} are the AC power, the AC-to-RF and RF-to-beam efficiencies, U_f, P_b, and N_b are the beam energy, beam power and number of particles per bunch, $\bar{\sigma}_x^*$ and $\bar{\sigma}_y^*$ are the r.m.s. beam sizes at the Interaction Point (I.P.) after being pinched by the beam-beam interaction, and H_D is the corresponding luminosity enhancement factor. Each particle is decelerated by the beam-beam interaction losing on average an energy δ_B and emitting n_γ γ-rays. At c.m. energies < 2 TeV the parameters are chosen such that δ_B does not exceed a few %, this is the so-called low beamstrahlung (LB) regime. At higher energies, to get adequate luminosity, the parameters are chosen in the high beamstrahlung (HB) regime [3]. In the HB regime, where $n_\gamma = 3.5\delta_B$, choosing $n_\gamma \approx 2$ ensures a reasonable compromise between the fraction of total luminosity contributed by particles with energies within 1-2 % of the maximum, and the number of $e^\pm$ pairs which appear as background in the detector. In both regimes therefore δ_B is an essential design parameter. The assumption of flat beams ($\sigma_x >> \sigma_y$) to enhance the luminosity and to decrease δ_B leads to the following expressions in the LB and HB regimes:

$$\delta_B \propto \frac{U_f}{\sigma_z}\frac{N_b^2}{\bar{\sigma}_x^{*2}} \quad \text{and} \quad \delta_B \cong \frac{n_\gamma}{3.5} \propto \frac{\sigma_z^{1/3}}{U_f^{1/3}}\frac{N_b^{2/3}}{\bar{\sigma}_x^{*2/3}} \quad (2)$$

Using (1), (2), and assuming in the LB regime a vertical beta function at the I.P. equal to the bunch length to minimise the "hourglass" effect, the luminosity scales as:

$$L \propto \frac{\delta_B^{1/2} H_{Dy}\eta_{RF}^{AC}\eta_b^{RF} P_{AC}}{U_f \varepsilon_{ny}^{*1/2}} \text{ and } L \propto \frac{\delta_B^{3/2} H_{Dy}\eta_{RF}^{AC}\eta_b^{RF} P_{AC}}{U_f^{1/2}\beta_y^{*1/2}\sigma_z^{1/2}\varepsilon_{ny}^{*1/2}} \quad (3)$$

In both cases, the luminosity only depends on a small number of parameters. For objective comparisons, a figure of merit M, is defined as L normalised to P_{AC}, δ_B, and U_f. Neglecting the variations of H_D (small for a flat beam) and of η^{AC}_{RF} (similar in all designs), M becomes:

$$M = L\frac{U_f}{\delta_B^{1/2}P_{AC}} \propto \frac{\eta_b^{RF}}{\varepsilon_{ny}^{*1/2}} \text{ and } M = L\frac{U_f^{1/2}}{\delta_B^{3/2}P_{AC}} \propto \frac{\eta_b^{RF}}{\sigma_z^{1/2}\varepsilon_{ny}^{*1/2}} \quad (4)$$

The TLC design optimisation consists of selecting beam parameters, and choosing a technology that is able to accelerate, at a reasonable cost, a high power beam with an optimum AC-power to beam-power conversion efficiency (Sections 3 and 4) while preserving a very small vertical normalised beam emittance (Section 5).

3 RF POWER TO BEAM EFFICIENCY

The RF-to-beam conversion efficiency is directly related to the choice of the RF frequency and the beam parameters. In order to obtain a high RF-to-beam transfer efficiency, all TLC designs (except VLEPP) have chosen to operate with a large number of bunches. In the extreme case of an infinite number of bunches, the formulation of the RF to beam efficiency becomes extremely simple [2] with a dependency on only two parameters: the field attenuation constant of the structures, τ, and the normalised beam current, J:

$$\eta_b^{RF} = \frac{2\tau g(\tau) J}{\left[1+\frac{J}{2}\left(1-\frac{e^{-2\tau}}{g(\tau)}\right)\right]^2} \qquad (5)$$

where $$J = \frac{R' q_b}{G_a \Delta_b} = \frac{R' I_b}{G_a} \qquad (6)$$

and R', I_b, q_b, Δ_b, G_u, G_a are respectively the shunt impedance per meter, the beam current, the charge per bunch, the interval between bunches, the unloaded and loaded accelerating gradient. For a given J, there is a value τ_{opt} which maximises the RF to beam efficiency:

$$\tau_{opt} = \frac{G_u \Delta_b}{R' q_b} = \frac{1}{J(1-\delta)} \qquad (7)$$

Using accelerating structures with an optimum field attenuation, τ_{opt}, following equation (7), and for the more usual range of beam parameters, $0.5 \le J \le 2$, where the beam loading parameter δ is limited to 50% (Fig. 1), the scaling of η^{RF}_b and τ_{opt} is approximated by:

$$\eta_b^{RF} \propto (J)^{1/2} = \left(\frac{R' q_b}{G_a \Delta_b}\right)^{1/2} \quad \text{and} \quad \tau_{opt} \propto J^{-9/10} \qquad (8)$$

Here, $\propto$ is the approximate proportionality implied by the straight line fit in Fig. 1 over the range of parameters considered. The figure of merit then becomes:

$$M \propto \frac{\eta_b^{RF}}{\varepsilon_{ny}^{*1/2}} \propto \left(\frac{J}{\varepsilon_{ny}^{*}}\right)^{1/2} = \left(\frac{R' q_b}{\varepsilon_{ny}^{*} G_a \Delta_b}\right)^{1/2} \qquad (9)$$

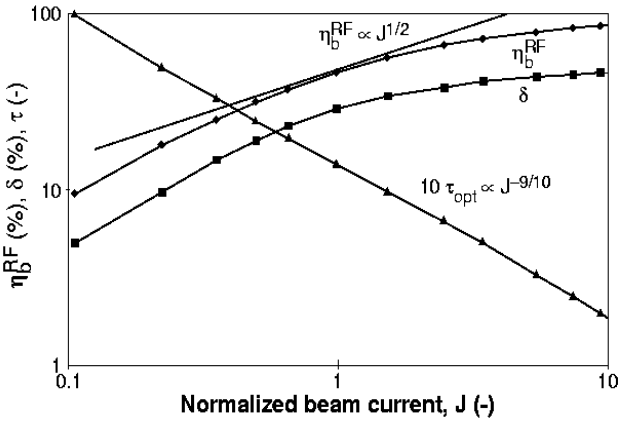

Figure 1: Optimum RF to beam efficiency, η^{RF}_b, field attenuation, τ, and beam loading parameter, δ.

4 THE NORMALIZED BEAM CURRENT

To optimise the design of a linear collider, the beam and linac parameters are therefore chosen to maximise the J parameter while preserving the initial vertical normalised beam emittance. All four parameters in the expression for J, (eq. 6) are directly related to the RF frequency, ω, of the accelerating structures. This is why the different TLC designs are mostly frequency driven.

- The well known scaling with frequency of R', when taking into account the iris to wave-length ratio, a/λ, is well verified in the TLC designs (Fig.2):

$$R' = r'Q \propto \omega^{1/2} (a/\lambda)^{-1} \qquad (10)$$

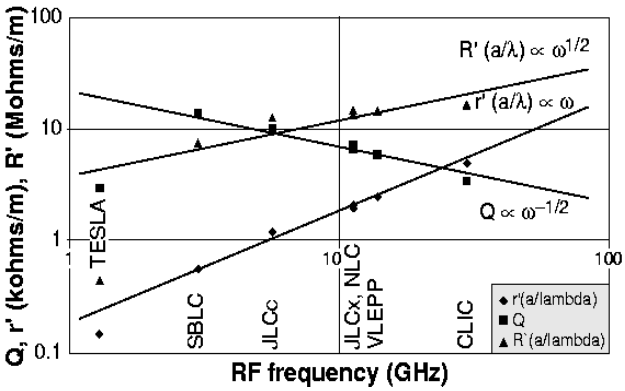

Figure 2: Accelerating structure parameters.

- The minimum distance between bunches is limited by the transverse wakefield level that can be obtained at the second and subsequent bunches by damping and/or detuning. For a given type of structure the number of RF periods needed for the same relative wakefield reduction is constant. This is reflected in Fig. 3 which shows that in spite of the different structure designs, the distance between bunches adopted in the various TLC designs scales with the RF wavelength:

$$\Delta_b \propto \omega^{-1} \qquad (11)$$

The J parameter then becomes:

$$J = \frac{R' q_b}{G_a \Delta_b} \propto \omega^{3/2} (a/\lambda)^{-1} G_a^{-1} N_b \qquad (12)$$

The charge per bunch is therefore made as high as possible to maximise J. Its maximum value is limited by beam stability considerations as developed in section 5.

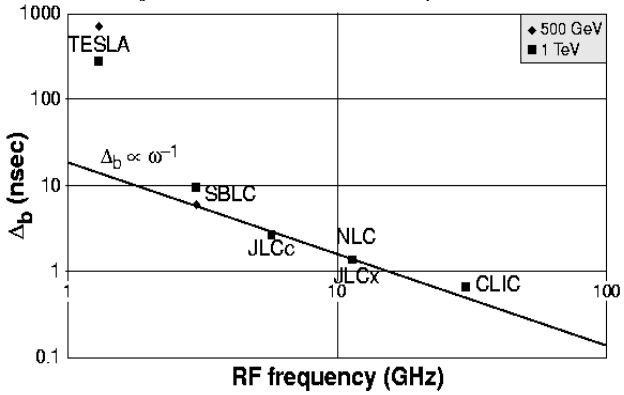

Figure 3: Time interval between bunches.

5 BEAM EMITTANCE PRESERVATION

Very small vertical normalised beam emittances of a few 10^{-8} rad-m are expected from state-of-the-art damping rings presently under development. During acceleration along the several-kilometer-long linacs however, the beams suffer a transverse blow-up $\Delta\varepsilon_n$, which is especially important in the vertical plane because of the particularly small initial emittance. One of the primary causes of emittance blow-up comes from the transverse wake-fields induced by the misalignment of the accelerating structures and by the beam trajectory deviations.

5.1 BNS damping

The single-bunch beam stability is greatly improved by so-called BNS damping [4] using a correlated energy spread which is introduced along the bunch such that:

$$\Delta p / p = \delta_{BNS} \propto N_b \langle W_T \rangle \frac{\langle \beta \rangle \langle L_{CELL} \rangle}{U} \qquad (13)$$

where $<\beta>$ is the mean betatron amplitude of the focusing optics along the linac, and W_T is the short range transverse wakefield averaged over the bunch with an r.m.s. length, σ_z, and scaling as:

$$\langle W_T \rangle \propto W_T' \sigma_z \propto \omega^4 (a/\lambda)^{-7/2} \sigma_z \qquad (14)$$

Under BNS damping conditions when taking into account equation (14), the vertical blow-up induced by the transverse wake-fields [5] shows a strong dependence (to the eighth power) on the frequency:

$$\left(\Delta\varepsilon_{ny}\right)_{RF} \propto N_b^2 \sigma_z^2 (a/\lambda)^{-7} \omega^8 G_a^{-1} \langle \beta_0 \rangle L_s \left\langle \Delta y_{RF}^2 \right\rangle \qquad (15)$$

but the other parameters in equation (15) also scale strongly with the frequency as shown hereafter.

5.2 Bunch length

The bunch length, σ_z, is made as small as possible in order to decrease the average transverse wakefield in the bunch according to equation (14). However, the minimum acceptable bunch length is determined by the need to compensate, towards the end of the linac, the energy spread associated with the longitudinal wake-fields, by positioning the bunch off the crest of the accelerating RF wave. Thus:

$$\frac{N_b W_L}{G_a} \propto \sigma_z \omega \sin(\Phi_{RF}) \Rightarrow \sigma_z \propto N_b G_a^{-1} (a/\lambda)^{-2} \omega \qquad (16)$$

where W_L is the short range longitudinal wakefield and Φ_{RF} is the off-crest RF phase which is limited to small values for the sake of beam acceleration efficiency.

5.3 Ratio of iris radius to RF wavelength

As shown in Fig. 4 for the different TLC designs, the ratio of iris radius to RF wavelength, a/λ, increases with increasing frequency in order to minimise the effect of the transverse wakefields (equation 14):

$$a/\lambda \propto \omega^{1/5} \qquad (17)$$

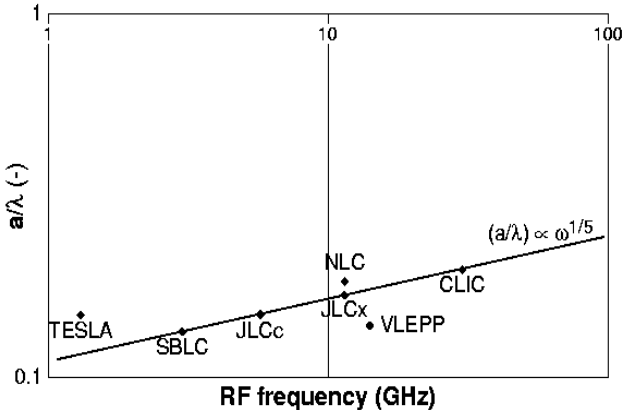

Figure 4: Iris to wavelength ratio.

5.4 Focusing optics of the linacs

In order to limit the BNS momentum spread needed for beam stability (eq. 13), the focusing strength along the linac is usually increased with the operating frequency as shown in Fig. 5. This is possible at higher frequencies because of the reduction in size of the linac components. Assuming the inner diameter, *D*, of the quadrupoles is scaled inversely with frequency in the same way as the inner radius of the iris, a, of the RF structures, then for the same magnetic field on the poles, *B*, the same phase advance per cell, β_0, and the same quadrupole filling factor, *F*, the FODO cell length, L_{cell}, scales as follows:

$$L_{cell} \propto \frac{D}{F L_{cell} B} \Rightarrow \langle \beta_o \rangle \propto L_{ocell} \propto (a/\lambda)^{1/2} \omega^{-1/2}$$

5.5 Pre-Alignment tolerances of the RF structures

Since the size of the accelerating structures becomes smaller with increasing frequency, the accuracy with which they can be made and pre-aligned is expected to approximately scale with the inverse of the frequency. As seen in Fig. 6, the variation of the pre-alignment tolerances of the RF structures in all TLC designs is well approximated by the following scaling law with frequency, which indeed is very close to expectation:

$$\langle \Delta y_{RF} \rangle \propto \omega^{-3/4} \qquad (19)$$

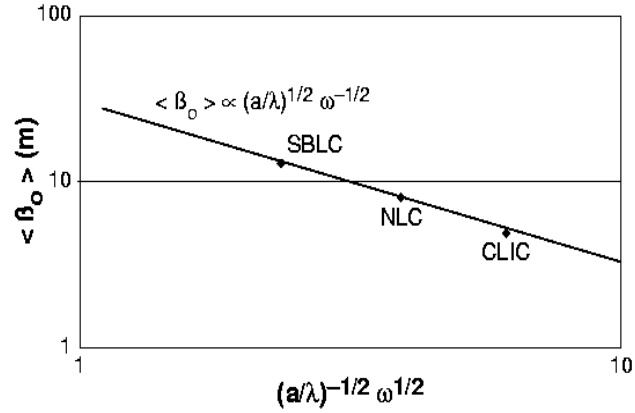

Figure 5: Focusing optics at injection into the linac.

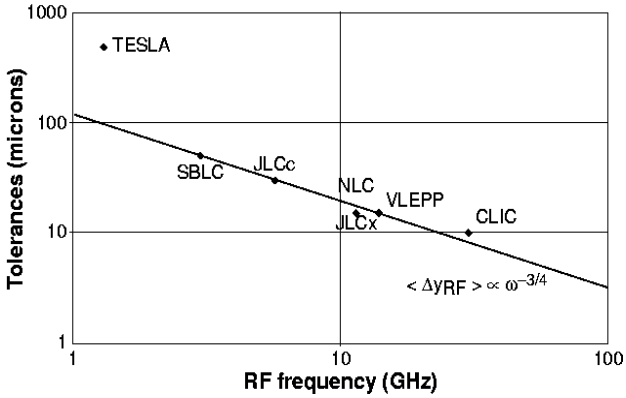

Figure 6: Pre-alignment tolerances of RF structures.

5.6 Accelerating section length

The length of the accelerating section, L_s, is adjusted to obtain an optimum field attenuation parameter, τ_{opt}, to maximise the RF-to-beam efficiency (equation 7)

$$L_S = \frac{2Qv_g\tau_{opt}}{\omega} = \frac{2Qv_g}{\omega J(1-\delta)} \qquad (20)$$

Neglecting the variation of the beam loading parameter δ, for small δ values, and introducing the scaling for J (eq. 6) as well as of the quality factor Q and the group velocity v_g, the optimum length of the accelerating sections, in the extreme case of an infinite number of bunches, becomes:

$$L_S \propto \omega^{-3}(a/\lambda)^4 G_a N_b^{-1} \qquad (21)$$

5.7 Charge per bunch

Finally, it is possible to derive the scaling of the maximum charge per bunch. This is the charge which produces a tolerable and frequency-independent beam blow-up during acceleration. It is deduced by substituting the relations for the scaling of all the different parameters (eq. 16, 17, 18, 19 and 21) in eq. 15.

$$\left(\Delta\varepsilon_{ny}\right)_{RF} \cong Const. \Rightarrow$$

$$N_b \propto \omega^{-5/3}(a/\lambda)^{13/6} G_a^{2/3} \propto \omega^{-6/5} G_a^{2/3} \qquad (22)$$

After substitution of eq. 22 for N_b in eq. 13, 16, and 21, σ_z, L_s, and δ_{BNS} become:

$$\sigma_z \propto \omega^{-2/3}(a/\lambda)^{1/6} G_a^{-1/3} \propto \omega^{-2/3} G_a^{-1/3} \qquad (23)$$

$$L_S = \frac{2Qv_g\tau_{opt}}{\omega} \propto \omega^{-4/3}(a/\lambda)^{11/6} G_a^{1/3} \propto \omega^{-1} G_a^{1/3} \qquad (24)$$

$$\delta_{BNS} \propto \omega^{2/3}(a/\lambda)^{-1/6} G_a^{1/3} \propto \omega^{2/3} G_a^{1/3} \qquad (25)$$

As shown in Figs 7, 8, 9 and 10, the charge per bunch, the bunch length, the length of the accelerating structure and the theoretical momentum spread for BNS damping adopted in the TLC designs compare favourably with the above scaling laws.

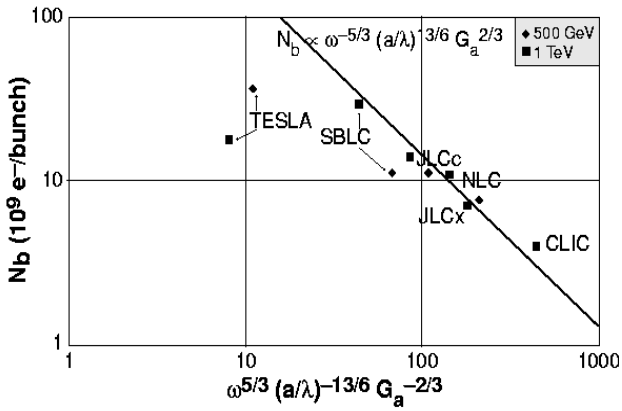

Figure 7: Charge per bunch.

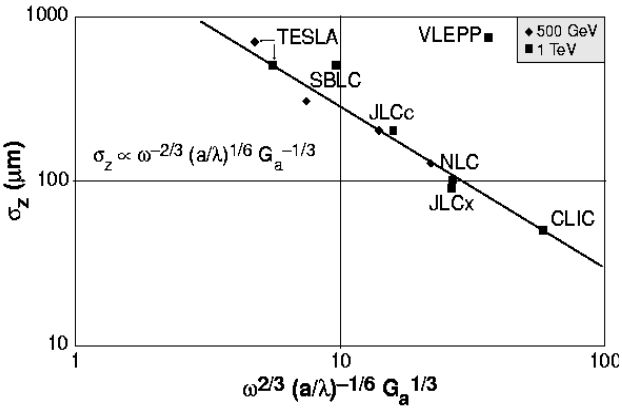

Figure 8: Bunch length.

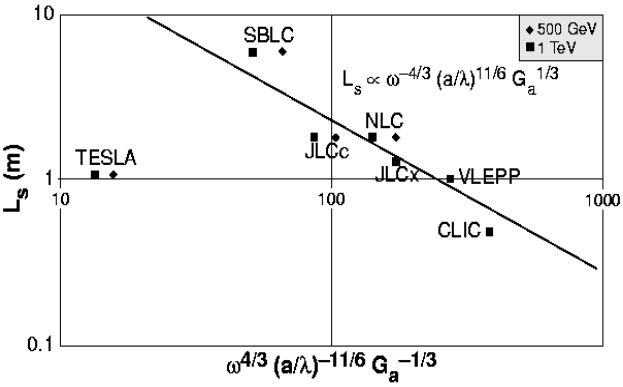

Figure 9: Length of the accelerating structures.

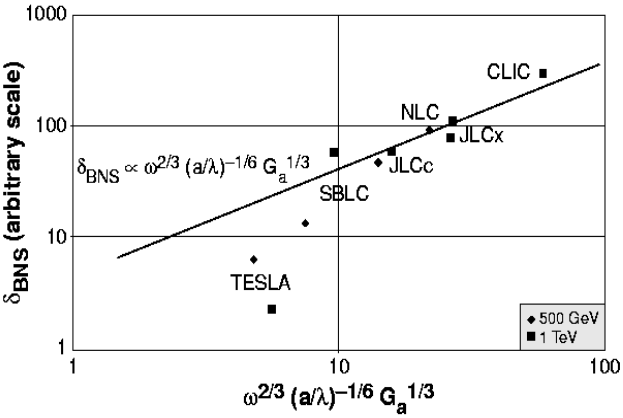

Figure 10: Momentum spread for BNS damping.

The strong dependence on frequency of the vertical blow-up induced by transverse wakefields is therefore cancelled by an appropriate choice of the other parameters and reduced to an acceptable level in all the TLC designs, independently of the RF frequency:

$$\varepsilon_{ny}^{*} \propto \varepsilon_{ny} = \varepsilon_{nyo} + \Delta\varepsilon_{ny} \quad \text{with} \quad \Delta\varepsilon_{ny} \cong Const. \qquad (26)$$

There is also a contribution [5] to $\Delta\varepsilon$ coming from the beam position monitor (BPM) misalignments. The same condition (26) on the emittance growth produces for Δy_{BPM} the generally expected dependence with ω^{-1} (Section 5.5),

$$\langle \Delta y_{BPM} \rangle \propto \omega^{-1/4} G_a^{1/6} \langle \Delta y_{RF} \rangle \propto \omega^{-1} G_a^{1/6} \qquad (27)$$

Finally, by introducing the frequency laws obtained up to this point, the normalised beam current and the RF-to-beam efficiency become roughly independent of the RF frequency and accelerating gradient,

$$\eta_b^{RF} \propto J^{1/2} \propto \omega^{-1/12} (a/\lambda)^{7/12} G_a^{-1/6} \propto \omega^{1/30} G_a^{-1/6} \qquad (28)$$

6 SENSITIVITY TO GROUND MOTION

The slow ground motion, modelled by the standard ATL law [6], causes all linac components to move with time. If uncorrected, the resulting trajectory variation will lead to emittance dilution [7]. The dominant effect comes from the quadrupoles with a contribution

$$\Delta\varepsilon_{nQUAD} \propto ATN_{cell}^3 \delta_{BNS}^2 \qquad (29)$$

where N_{cell} is the number of focusing cells in the linac, which is proportional to L_{cell} and G_a. Thus, using the above scaling laws, the time interval required between corrections to limit the emittance growth is

$$T_{QUAD} \propto \frac{G_a^{7/3} \varepsilon_{ny}}{A\omega^{5/2}} \left(\frac{\Delta\varepsilon_{ny}}{\varepsilon_{ny}} \right)_{ATL} \qquad (30)$$

The equivalent time interval related to cavity drift shows a similar dependence $\propto G_a^{1/3} \omega^{-5/3}$. Finally, the high frequency vibration of the focusing magnets induces a pulse-to-pulse trajectory variation which cannot be corrected with beam-based feedbacks. In local beam-size units, this induced beam jitter is [5]:

$$\frac{\langle \Delta y^2 \rangle}{\sigma_y^2} \approx \langle y_{QUAD}^2 \rangle \frac{4U_0 N_{CELL}}{\varepsilon_{ny} L_{oCELL}} \left(\frac{U_f}{U_o} \right)^{(1-\alpha)} \tan\left(\frac{\Psi}{2} \right) \qquad (31)$$

where y_{QUAD} is the focusing magnet movement. As a consequence, the vibration tolerance scales as:

$$\langle y_{QUAD}^2 \rangle \propto \frac{\langle \Delta y^2 \rangle}{\sigma_y^2} \frac{G_a}{\omega^{2/3}} \varepsilon_{ny} \qquad (32)$$

7 CONCLUSION

The figure of merit *M*, defined in Section 2, has been used to optimise the design of a future TeV e^+e^- Linear Collider. ***M is only dependent on two parameters: the AC-to-beam power transfer efficiency and the vertical beam emittance at the IP.*** Scaling laws have been derived for both the linac and beam parameters for an infinite number of bunches, stable beam operation and minimum energy spread at the linac end. Under these conditions, the main beam parameters are fully determined. Using them, and choosing an optimum field attenuation for the RF structures in order to obtain an optimum RF-to-beam efficiency, it is found that:

- ***The RF-to-beam efficiency is a weak function of the frequency and accelerating gradient*** (Eq.28)
- In spite of the large increase of the wake-field amplitude with frequency, ***the wakefield effect and the corresponding beam emittance blow-up are independent of the RF frequency*** (Eq. 26), ***for equivalent beam trajectory correction techniques.***
- ***In the low-beamstrahlung regime,*** generally adopted for intermediate-energy TLC designs (0.5 to 2 TeV), ***the luminosity slightly increases with RF frequency and slightly decreases with accelerating gradient***

$$L \propto \frac{\delta_B^{1/2} \eta_{RF}^{AC}}{U_f} \frac{\omega^{1/30} G_a^{-1/6}}{\varepsilon_{nyo}^{1/3} \left[1 + \Delta\varepsilon_{ny}/\varepsilon_{nyo} \right]^{1/2}} P_{AC}$$

- ***In the high-beamstrahlung regime,*** usually adopted for high-energy TLC designs (3 to 5 TeV), ***the luminosity increases with RF frequency but is independent of accelerating gradient***

$$L \propto \frac{\delta_B^{3/2}}{U_f^{1/2}} \frac{\eta_{RF}^{AC}}{\beta_y^{*1/2}} \frac{\omega^{1/3}}{\varepsilon_{nyo}^{1/2} \left[1 + \Delta\varepsilon_{ny}/\varepsilon_{nyo} \right]^{1/2}} P_{AC}$$

Finally, the use of high frequencies in accelerating structures for main linacs of future TeV e^+e^- Linear Colliders is particularly appropriate, since they allow operation with high accelerating gradients, which minimise the overall length and therefore the cost of the linacs. Provided that the beam and linac parameters are chosen to fulfil beam stability criteria and optimum RF-to-beam transfer efficiency, high frequency designs benefiting from high accelerating gradients result, when compared to lower frequency designs with lower gradient and similar beam quality, with the same or better RF efficiency and figure of merit.

AN INDUCTION LINAC FOR THE SECOND PHASE OF DARHT

H. L. Rutkowski
Lawrence Berkeley National Laboratory
One Cyclotron Road, Berkeley, CA 94720, USA

Abstract

The Dual Axis Radiographic Hydrodynamics Test facility (DARHT) is under construction at Los Alamos National Laboratory. The facility will contain two electron accelerators arranged perpendicular to each other. The second accelerator is a long pulse induction linac using Metglas core technology and will provide a beam pulse at 20MeV with flat top current of 4KA. The focal spot should be less than 1.2mm in diameter. Generation of beam breakup (BBU) and corkscrew motion at the focal spot must be minimal. Very flat beam energy, excellent alignment of transport magnets, and low values for TM mode impedances in the accelerator cavities are needed. The accelerator will consist of a diode injector using a dispenser cathode, providing 3.2MeV energy together with a linac with 88 acceleration cells. Marx generators will provide pulsed power for both injector and linac. The pulse will be transported to a kicker (designed by Lawrence Livermore National Laboratory) which selects four 60ns pulses for transport to the final focus and the conversion target. The status of the design of the accelerator system will be presented along with results from prototype tests. Effect of operational requirements on the design of the accelerator will also be discussed.

1 INTRODUCTION

The accelerator for the second axis of the DARHT facility is a long pulse induction linear accelerator that provides an electron beam that will be used to produce a series of fast high energy X-ray pulses. The fast electron beam pulses, nominally 60 ns in duration, will be chopped out of a 2 μs single pulse and will be transported to a set of X-ray conversion targets. The X-rays will be used to image dense metal objects driven by high explosives. Initially four short pulses are required from the machine though the system could be upgraded to use the remaining part of the long pulse to provide additional views or more time resolution. Lawrence Livermore National Laboratory has the responsibility for the system from the point where the beam exits the accelerator up to the final focus on the X-ray conversion target or targets. The subject of this paper is the injector, accelerator and pulsed power systems that are being designed and built by Lawrence Berkeley National Laboratory.

* This work was supported by the U.S. Department of Energy under Contract No. DE-ACO3-76SF00098.

The injector is a dispenser cathode diode driven by a long pulse Marx generator at 3.2 MV peak flat voltage. The injector beam pulse enters a first cell block of 8 large bore induction cells that accelerate it to 4.6 MeV energy. The rest of the accelerator consists of 10 cell blocks of 8 cells each that accelerate the beam to the full 20 MeV energy. The exit current is 4kA maximum for 2μs. Between each cell block, an intercell provides a pumping point and a station for inserting diagnostics. The entire system is 175 ft. long, from the injector to accelerator exit. The induction cells use Metglas as the ferromagnetic material. The first cell block has a 14" diameter beam pipe while the bulk of the cells have a 10" beam pipe. This is to reduce generation of BBU in the front end. The system is presently in the design stage with prototyping work supporting the design. The injector design is fairly detailed and two options exist for the design of the accelerator cells. A concept of the accelerator sitting inside the building is shown in Fig. 1. The downstream transport and chopper are also shown. The pulsed power units are in an adjacent hall not shown.

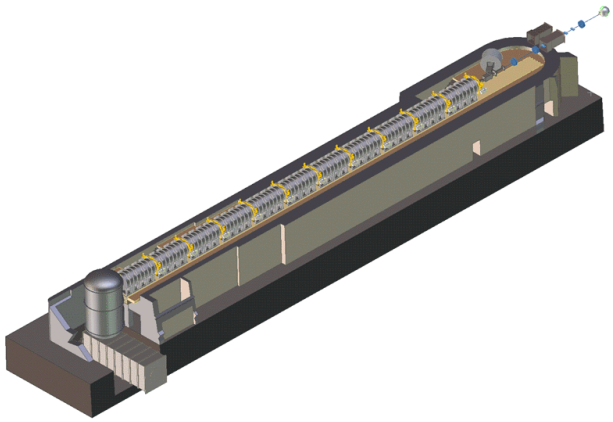

Fig. 1 Accelerator in Second Axis Building

2 INJECTOR

The injector is shown in Fig. 2 together with its first block of 8 cells. The first block of 8 cells is included here because the physics design of these cells is intimately connected with the injector design.

The injector itself is a simple diode designed for rapid acceleration of the electrons emitted by the cathode to 3.2 MeV in order to minimize emittance growth at the start. The emittance required at the final focus at the X-ray converter target is 1500 π mm-mrad normalized. This emittance limit is derived from the 1.2mm focal spot desired at the converter. This spot size is in turn required by the spatial resolution desired in the radiographs. The

required maximum flat current is 4 kA for 2.1 μs. However, the current must also be adjustable to allow for operation of the accelerator down to 1 kA to accommodate various commissioning and operational modes. There are a few options for achieving this such as changing cathodes and reducing voltage. The power supply for the diode is a Marx generator being designed by Pulse Sciences Inc. The Marx must provide matched voltage pulses of up to 3.5 MV to the combination diode and ballast resistor load with a flatness of ± 0.5%. The dielectric for the high voltage system is oil and it is being designed to survive a variety of failure modes. The maximum rep rate is 5 shots per minute. The insulator column itself is made of glued Mycalex sections with resistive grading and MOV's for damage protection. The injector is still being designed with fabrication to begin in October 1998.

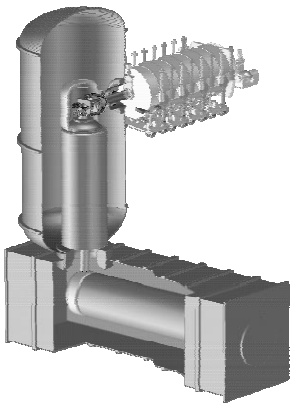

Fig. 2 Injector and First Cell Block

A more detailed drawing of the diode itself is shown in Fig. 3. The cathode is a type M dispenser cathode (8" diameter) which can deliver up to 20 A/cm^2 in a space charge limited mode. The operating temperature will be 1050°C with a uniformity of ±1% across the face. The cathode shroud is partially water cooled near the source and will be made of optically polished molybdenum, stainless steel, or coated stainless steel. Small scale tests on breakdown in vacuum are being carried out on these materials and molybdenum appears to be the best choice so far. However, full size shrouds using all three materials will be tested in the injector. The peak enhanced field stress on the cathode shroud is 162 kV/cm. The shroud material must not only be good to this level of enhanced stress but it must also survive in case of breakdown. Comparison with other machines and the test results so far indicate that the configuration can be made to work at this stress. The plate on which the cathode mounts is attached to a hexapod mounting system that is moved for alignment by six pressure activators. A bucking solenoid can be seen inside this mount in Fig. 3. This solenoid serves to cancel the field at the cathode caused by the focusing solenoids located inside the anode surface. The anode itself is stainless steel and the diode gap is 30cm. As can be seen in Fig. 2, the main current feed from the Marx makes a right angle bend. The vertical part of the feed is 1.5m behind the cathode face. This current feed geometry results in a dipole error field of 3-5 gauss in the diode gap. A quadrupole error field also exists. Correcting coils for these fields are being designed. The sextupole field which could increase emittance was shown to be negligible in calculation as were all higher order fields. A gate valve isolates the diode from the accelerator.

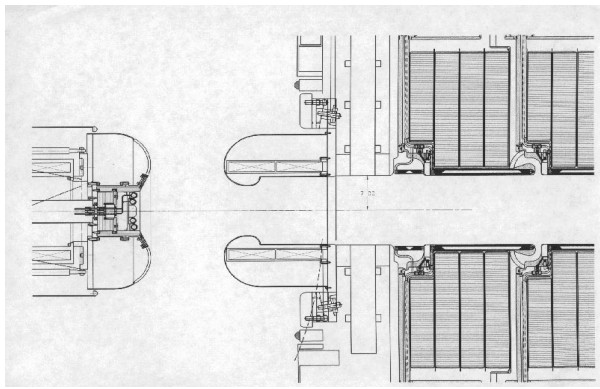

Fig. 3 Diode and First Cells

The rise time of the injector is required to be less than 400 ns and the design point is 200 ns. The fall time is planned to be 100 ns with use of a laser triggered crowbar. The off energy particles produced in the rise and fall must be dumped in a non-destructive way. Conical scapers will be placed in the first 8 cells to remove these electrons. The design of the accelerator cells will be discussed below in the next section.

The insulator column in the injector is designed with a combination of Mycalex insulator rings and high purity aluminum oxide rings. The rings will be glued (Hyso 9359.3) with metal grading rings. The overall height is almost 13 ft. with grading rings and joints. The Mycalex rings were obtained from LANL where they were spares for the column of a decommissioned Van de Graaff accelerator. These rings are 47.5" outside diameter with 3" wall thickness. They offer very large cost savings over building a ceramic brazed column of the same size or a column made of new Mycalex. Mycalex which is a mica-glass mixture seems to be mechanically tougher than ceramic and to have very good breakdown resistance. The clear space inside the insulator column is 38" diameter after the grading resistors (liquid), metal oxide varistors (MOV's) for damage protection, and shock guard rings are in place. Shock guard rings are incorporated to shield the insulator material from any shock waves generated by a breakdown in the oil dielectric. Mycalex is expected to be more survivable than alumina with respect to such shocks.

The original dielectric choice of high pressure SF_6 was discarded for oil because of the fear of insulator catastrophic failure after the column aged and was subject

to damage from electrical breakdown. The injector pulse generator is an 88 stage PFN Marx. It can be used to drive different beam currents by varying the resistance of the liquid grading and ballast resistors. The entire high voltage system is being designed to 3.5 MV for safety factor. A laser triggered spark gap is included in the design to reduce unwanted beam in the pulse tail and to aid in shorting the pulse for lower pulse energy applications. The pulse can be shortened in six steps by shorting out PFN stages in the Marx. The design will accommodate diode impedances from 714Ω to open circuit (875Ω nom). A high voltage dome is located at the end of the Marx and contains a hydraulically driven motor generator that provides 15KW power to the cathode dome, power supplies, and diagnostic/controls units to bring information out to the cathode dome. Voltage flatness will be ± 0.5%. The injector Marx and all the accelerator pulsers are required to hold charge for up to one minute to accommodate firing site needs with no more than one failure in 20 attempts. This is an experimental diagnostic requirement. In the experimental shot firing mode the accelerator system cannot fail more than one shot in 600 where failure is defined as detonating the explosive without obtaining beam.

In addition to the design activity there are several testing activities underway. Materials for the cathode shroud are being tested at small scale for field emission threshold, breakdown, and breakdown dependence on vacuum. So far, optically polished Mo has shown the best results with a field emission threshold of 300 kV/cm (200 kV total voltage). Breakdown thresholds above 400 kV/cm have been shown for both Mo and uncoated stainless steel. The breakdown threshold doesn't seem to depend significantly on vacuum between 10^{-8} and 10^{-5} Torr. A scaled version of the injector gun is being set up on the Relativistic Two-beam accelerator (RTA) at LBNL. The RTA machine operates at 1MV total gun voltage, 1.2 kA maximum current, and 0.3 μs pulse length. This test with a 3.5" diameter dispenser cathode will test the beam optics and breakdown at full field stress, current density and in a space charge dominated regime. This scaled gun will be used to test diagnostics and to benchmark the EGUN, IVORY SLICE, and GYMNOS codes that are being used for design to ensure that correct emittances are being calculated. A cathode test stand and a Long Pulse Development Facility are being assembled at LANL to allow testing of full size cathodes and to perform beam tests of accelerator cells respectively. Once the parts for the full injector are ready, the entire system will be assembled and tested as a unit at an industrial location near LBNL prior to being sent to LANL for final commissioning.

Use of a dispenser cathode in the diode dictates an excellent vacuum system and clean servicing environment. The system design calls for three 16" cyro pumps. The design baseline pressure in the tank in 2×10^{-8} t. There is sufficient pumping to reach this pressure in less than 1 hour after roughing.

3 ACCELERATOR

The accelerator must take the 3.2 MeV injector beam up to 20 MeV while not growing the emittance by more than 1000 π mm-mrad normalized. The other major requirement is that the beam at exit cannot have transverse motion of its centroid greater than ± 10% of the beam radius due to all sources. This means both corkscrew and BBU motion. Corkscrew motion of the beam centroid arises because of the misalignment of solenoids in the transport line and energy variations during the beam pulse. BBU arises if transverse magnetic (TM) modes are excited in the accelerating cavities. Since these modes have axial E fields that change direction across the beam axis they can extract beam energy and put it into mode energy. The transverse B field of the mode creates a transverse kick in the beam. In order to reduce corkscrew motion the pulsers for the cells must generate voltage pulses that are flat to ± 0.5%. After the solenoids have been aligned mechanically as well as possible the corrector coils in each cell can be used together with a "Tuning-V" algorithm [1] developed by LLNL to reduce corkscrew motion to a minimum. The voltage for each cell is nominally 193 kV for the small bore cells and 168 kV for each of the first 8 cells. The first block of 8 cells (injector cells) is designed with a 14" beam pipe while the rest of the machine (generic cells) is designed with a 10" beam pipe. This was done because use of a larger bore at low energy reduces the transverse mode impedance in an area particularly susceptible to BBU growth. In a pillbox cavity design the transverse mode impedance scales as [2] w/b^2 where w is the gap and b is the beam pipe radius. Another way to reduce BBU generation besides increasing the pipe size is to increase the solenoid field. However, one cannot arbitrarily increase the transport solenoid field at low energy because it causes emittance growth. The original cell design for the entire accelerator is shown in Fig. 4a
The original 10" cell was designed with a conical section Mycalex insulator. Originally the insulator was to be Rexolite because of the favorable experience LANL has had with this material. However tests at LBNL indicated that it does not survive breakdown from microsecond scale pulses well even though it works very well in the regime below 100ns. Therefore Mycalex was chosen because of its mechanical toughness, good breakdown behavior, and good vacuum properties. A Rexolite insulator will however be tested in the prototype cell. A disadvantage of Mycalex is its high dielectric constant (6.9) which increases the transverse mode impedance of the cavity compared to a Rexolite insulated version. Calculations with AMOS for a cavity without Metglas gave values of 450 Ω/m for the dominant mode. Measurements have been done on a full scale cavity without Metglas and with a cast epoxy insulator of the same dielectric constant as Mycalex. The result for a damped cavity was 330 Ω/m for the dominant mode (TM110). This measurement technique which uses loops to drive modes selectively and probes inserted into the

cavity on axis to displace field gives a measurement of Z/Q through interpretation of the frequency shift of a mode due to the probe [3]. This measurement becomes more unreliable as the mode is increasingly damped. Since one wants to damp these modes as much as possible other methods must be used to get definitive results with strong damping. This original cell design is a shielded gap with peak field stress of 100 kV/cm on the negative electrode and 40 kV/cm on the insulator surface.

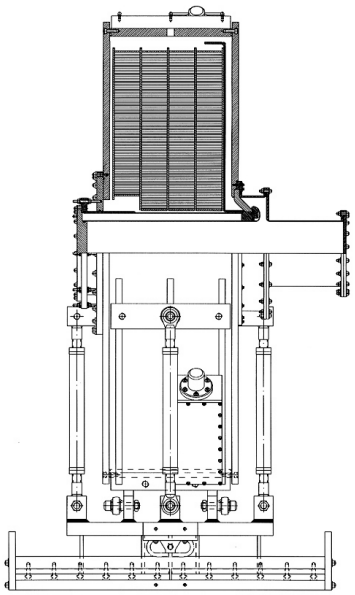

Fig. 4a Original Cell

The process of designing the special cells for the first block led to the design shown in Fig.4b. This design used a different insulator shape and created a space for diagnostics which were desired in the first cells because of the importance of beam motion at the beginning of the machine. Another reason for the change was to create a mode frequency shift between the two types of cells. This configuration will probably be used for the smaller bore cells as well because of the opportunity to place diagnostics anywhere and because of some mechanical design advantages. AMOS calculations give transverse mode impedances of 185 Ω/m at 170 MHz and 170 Ω/m at 450 MHz for this design with a Mycalex insulator and a 14" beam pipe. Applying the same configuration to the smaller bore cells gives 300 Ω/m at 200MHz and 310 Ω/m at 540 MHz. The mode frequencies are shifted between the first block and the rest of the machine which reduces BBU.

Corkscrew motion is combatted by generating flat voltage pulses in the pulsers which are E type Marx PFN's. The transport solenoid fields must also be well aligned to reduce corkscrew. LANL [4] experience in using the Stretched Wire Alignment Technique (SWAT) leads to the expectation of aligning the magnetic center of each solenoid to ± 0.1 mm and the tilt to ± 0.3 mrad. A precise calculation of the final corkscrew motion requires a final machine tune.

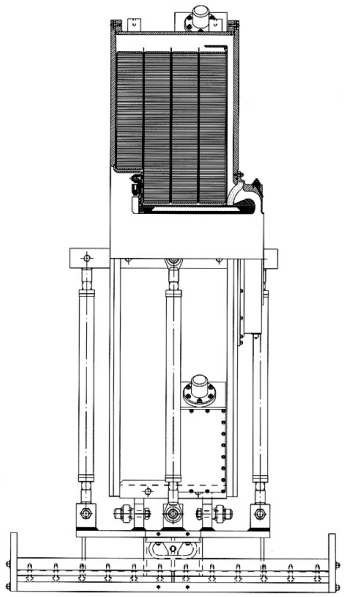

Fig. 4b Injector Cell

The transport solenoids in the generic cells are 12 layer fine wire solenoids 16" long impregnated with epoxy. The 8 injector cell solenoids are only 6 layers thick. The total power for running these solenoids plus the 5" long coils in the eleven intercells is 1.5 MW steady state if each solenoid is at maximum field (0.22T generic, 0.11T injector). The solenoids reside in cavities within the beam pipe and are DC, water cooled units. They float electrically from the machine. PC board type corrector coils are also placed between the solenoid and the pipe wall. An initial tune has been calculated for these solenoids and the beam envelope at exit is 1 cm diameter. Based on the use of the two pipe sizes in the machine, a BBU amplification relative to a straight pipe has been calculated. The values are 12.2 at 170 MHz, and 11.0 at 535 MHz. These numbers are based on a resonant seed at the exit of the injector at the relevant frequency. The amplification is the ratio between the displacement with cavity impedances present to displacement in the presence of continuous beam pipe with no cavities.

The intercells shown in Fig. 1 serve as pumping points with a turbo pump and a cryo pump at each intercell. Design vacuum in the accelerator is 10^{-6} t. The intercells also provide a place for intercepting diagnostics for beam profile and emittance measurement, B-dot loops for beam motion, and beam position monitors.

An important part of the pulsed power design is the Metglas core material. Allied Signal 2605 SC is the baseline design material because of its high ΔB of 2.8T with relatively low drive current. The magnetization current is relatively linear and the short pulse losses relatively low. 2605 SA1 has been tested at LBNL in the unannealed state and is just marginally acceptable. The

drive current is very non-linear and the ΔB is about 2.4T. Another candidate is Hitachi Finemet material if it can be obtained at an acceptable cost. The pulser used to drive both types of cells is an E-network Marx PFN. The pulser will feed to the cores at four points to eliminate production of quadrapole fields near the beam. The voltage pulse must be flat to ±.5%. The cell units will be mounted on rails. Removal of a cell requires removal of an intercell to create space for movement. The cells themselves will be capable of individual alignment using a differential screw system developed at the LBNL Advanced Light Source. Each cell weighs about 5 Tonnes. The differential screw system allows accurate movement of such massive structures to 0.001 inches manually. The cells will be vacuum sealed to each other with an inflatable bladder technique.

In addition to RF cavity tests mentioned above, two prototype cells are being constructed. The first uses the original cell design and will be used to measure damped transverse mode impedances and pulsed power tests of breakdown and core compensation. It has SA1 cores. This time Metglas will be in the cell and termination conditions at the outer radius will be realistic. The test cavity had a simple short at the outside. After the coupled loop-probe measurements are performed for comparison with the previous cavity measurements, breakdown tests with Rexolite, Mycalex, and cast epoxy will be performed and the core compensation will be optimized. Finally two wire [5] impedance measurements of the actual damped cell-cavity structure will be performed. The second prototype is a large bore unit that will have SC cores. It will be tested for pulsed power properties and then sent to LANL for beam spill tests. In 1999, 8 small bore cells will be put on the Long Pulse Development Facility at LANL to study beam effects in a full cell block before design of the generic cells is frozen for the large production phase.

ACKNOWLEDGEMENT

The author wishes to thank all the members of the LBNL-DARHT project team for their contributions especially D. Anderson, R. Briggs, E. Burgess, Y-J Chen, S. Eylon, W. Fawley, J. Fockler, E. Henestroza, T. Houck, T. Jackson, C. Peters, L. Reginato, M. Vella, and S. Yu.

HIGH-POWER PROTON LINAC FOR APT; STATUS OF DESIGN AND DEVELOPMENT

G. P. Lawrence
Los Alamos National Laboratory, Los Alamos, NM, 87545, USA

1 INTRODUCTION AND OVERVIEW

In one of two options being considered for a new source of tritium, the US Department of Energy (DOE) is planning an Accelerator Production of Tritium (APT) plant [1] that would be built at its Savannah River Site in South Carolina. The facility will employ a high power linear accelerator to produce neutrons by spallation reactions of protons in tungsten and lead contained in a target/blanket (T/B) assembly. The fast neutrons produced in the target are moderated in the light water that cools the blanket elements, and then captured by ^{3}He gas to produce tritium. The tritium is separated from the ^{3}He by permeation through a palladium membrane, with cryogenic distillation used for isotopic purification.

The APT design is based on a 1700-MeV proton linac operated at 100 mA CW. However, changing tritium requirements may reduce the energy to 1030 MeV, so the plant has been designed in a modular configuration to provide construction flexibility. Figure 1 shows the architecture of the modular plant. Heavy shading and lines indicate the 1030-MeV configuration; light shading and dashed lines show the portions added in a 1700-MeV system.

The project Conceptual Design Report [2] was issued in April, 1997, and formal design of the plant technical and conventional systems has now begun. A program of engineering development and demonstration (ED&D) has been underway since 1995 to support the plant design and subsequent construction.

2 ACCELERATOR DESIGN

The APT linac is designed as a two-stage machine [3], using both normal-conducting (NC) and superconducting (SC) accelerating-cavity technologies. Except for the first accelerating structure, a 350-MHz RFQ, the entire linac operates at a frequency of 700 MHz, with rf power supplied by 1-MW CW klystrons. After acceleration, a high-energy beam transport system (HEBT) consisting of magnetic focusing and bending elements conveys the beam to the T/B assembly. The architecture of the transport system depends on the machine energy, as indicated in Fig. 1. At the end of the HEBT, a raster beam expander transforms the beam into a rectangular, uniform large-area distribution, providing an acceptable power density in the target.

The linac design is driven strongly by the large amount of rf power required to accelerate the 100-mA CW beam. Efficient conversion is needed at each stage in the power train (from the ac grid to the beam) to minimize capital and operating costs. Other important design factors and considerations are the need to keep beam losses at a very low level, avoiding generation of beam halo, tight control of the high-power beam (in terms of the coupled beam/cavity/rf-drive interaction), current-independent operation and tuning, and high operational availability. Parameter selection and cost/performance modeling to achieve these objectives have been discussed previously [4]; key parameters are listed in Table 1.

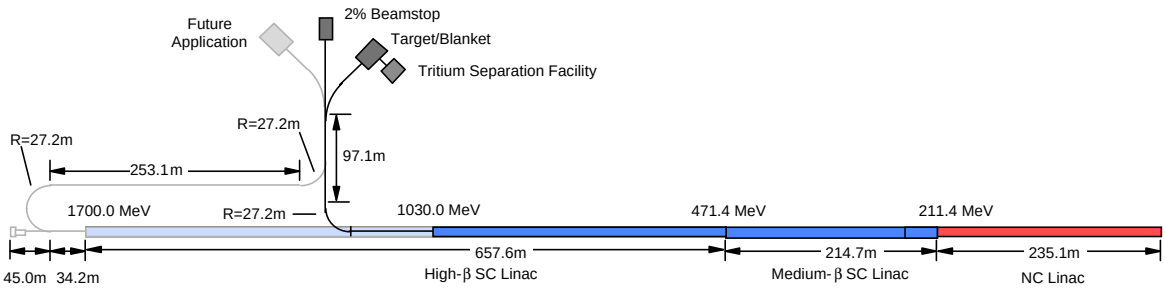

Fig.1 Modular design architecture for APT Plant.

2.1 Normal-Conducting Low-Energy Linac

The low-energy NC linac accelerates a 100-mA proton beam to 211.4 MeV in copper water-cooled structures. A 75-keV injector using a microwave-driven ion source produces a continuous 110-mA proton beam. From this input, a 350-MHz, 8-m-long RFQ (radio-frequency quadrupole) produces a CW 100-mA beam at 6.7 MeV. This RFQ is built in four resonantly-coupled segments, with rf drive provided by three 1.2-MW CW klystrons through 12 windows; it provides a current independent match into the next accelerating section.

Parameter	Normal-Conducting Linac			Superconducting Linac		
	RFQ	**CCDTL**	**CCL**	**β = 0.64-1**	**β = 0.64-2**	**β = 0.82**
Output energy (MeV)	6.7	96.6	211.4	242.0	471.4	1700 (1030)

* Normalized rms values, 700 MHz. Quantities in parentheses are for a 1030-MeV output energy.

The RFQ is followed by π/2-mode coupled-cavity accelerating structures, each optimized for maximum rf-to-beam efficiency over a specific velocity range [5]. The first set of structures, which accelerates the beam to 96.6 MeV, is a 700-MHz CCDTL (coupled-cavity drift-tube linac) made up of 2-gap and 3-gap DTL cavities that are embedded in a FODO singlet focusing lattice. The latter begins with an 8-βλ period and transitions to a 9-βλ period at 10 MeV to provide additional space for quadrupoles and beam diagnostics. The quadrupoles are external to the cavity structures, separating the focusing and accelerating functions, and providing easy beam energy and is free from phase-space transitions after the RFQ. Beam dynamics analyses and simulations show these factors to be important in terms of minimizing core emittance growth [6] and the generation of beam halo [7]. As seen in Table 1, both transverse and longitudinal emittance growth are negligible. To obtain a current-independent match between the NC linac and the SC linac (which has weaker focusing), the quadrupole strength is reduced gradually as the transition energy is approached.

The CCDTL and CCL are sectioned into rf super-modules, which are each powered by 4 to 7 klystrons. Each klystron distributes power to the accelerating struct-

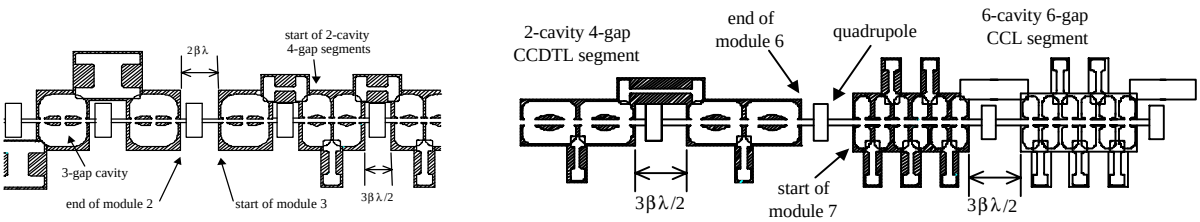

Fig. 2. CCDTL and CCL accelerating structure segments

alignment. Acceleration proceeds to 211.4 MeV in a 700-MHz side-coupled CCL that continues the 9-βλ focusing period. Fig. 2 displays representative segments of the CCDTL and CCL.

The NC linac has a short focusing period that elongates with beta, and the average accelerating gradient is ramped up gradually from 0.77 to 1.2 MV/m. The result is a linac that has strong focusing at low beam ure through four coaxial ceramic windows that are tested to 1-MW power levels [8]. The maximum rf power input to the cavities that is required from any of the klystrons is 0.84 MW, which allows for 10% control margin as well as rf transmission line losses. There are six supermodules in the CCDTL, with 28-57 segments per module. The CCL is divided into five supermodules, with 21-54 segments per module.

2.2 Superconducting High-Energy Linac

The SC high-energy linac consists of cryomodules containing two, three, or four 5-cell 700-MHz niobium SC accelerating cavities. Focusing is provided by NC quadrupoles in a doublet lattice located in the warm regions between cryomodules; these regions also contain the beam diagnostics. There are two kinds of SC cavity shapes, each type designed for efficient acceleration in a different velocity range. The cavity shape in the medium-beta section (211.4 MeV to 471.4 MeV) is optimized for $\beta = 0.64$, and in the high-beta section (471.4 MeV to 1700 MeV) for $\beta = 0.82$. The shapes are similar to the well-established elliptical designs for electron machines, but are compressed longitudinally in proportion to beta. Because the cavities are short and are driven independently, each section of the SC linac has a broad velocity bandwidth, which allows the gradient profile and output energy to be adjusted over a wide range. Because of the high beam current, the major design issue is not attainment of high cavity gradients, but high power rf coupler capability. Performance specifications of 140 kW and 210 kW have been chosen for the medium-β and high-β couplers respectively, values that are at the advancing edge of the demonstrated technology base. Each cavity is supplied by two antenna-type coaxial couplers mounted on opposite sides of the beam tube. Dual coaxial (warm) windows are planned, located so that they do not see the beam directly.

Figure 3 depicts the cryomodule, rf, and focusing-lattice architecture for the different sections of the SC linac. The high-β section contains 77 (35) of the four-cavity cryomodules shown in the right-hand sketch. Two 1-MW 700-MHz klystrons are used to power pairs of adjacent cavities. The nominal energy gain per cavity is 4.0 MeV. The medium-β SC linac is divided into two sections, both containing $\beta = 0.64$ cryomodules. The first section, starting at 211.4 MeV consists of six 2-cavity cromodules, and the second, starting at 242.0 MeV, consists of thirty 3-cavity cryomodules. Nominal energy gain per cavity is 2.6 MeV. The first section provides a transition between the short focusing period of the NC linac and the longer focusing period of the SC linac, and allows a current independent match to be obtained with minimal emittance growth.

The left-hand sketch in Fig. 3 shows the 3-cavity $\beta = 0.64$ cryomodules; the 2-cavity unit is not shown, but looks structurally like one-half of the high-β unit. Both are powered by a single 1-MW klystron. Earlier doublet-lattice medium-β linac designs with 2-cavity cryomodules attempted a configuration in which a klystron powered cavities in adjacent cryomodules. In beam simulations that included machine errors, it was found that this architecture gave rise to significant emittance growth because of the large cavity-to-cavity phase/energy errors that were introduced.

Table 1 lists key parameters of the SC linac. The selection of cavity gradients and numbers of cells per cavity were restricted by the need to keep peak surface fields below a safe level and by the power-coupler specifications. The rf power distribution is governed by the need to fully utilize the 840-kW power available from each 1-MW klystron. The design specification for the average cavity Q_0 is taken as 5×10^9. A 2.15 K operating temperature for the niobium cavities has been selected to minimize the static and rf heat loads to the LHe refrigerator and cryo-distribution system. Total cryoplant loads are estimated at 14.5 kW at 2.15K and 22.4 kW at 45K, for a 1700-MeV linac. These loads will be handled by three identical LHe refrigerators that are about 50% larger than those in service at CEBAF.

2.3 Beam Dynamics

The key beam dynamics [9] goal is to achieve very low losses (< 0.1 nA/m at 1700 MeV) in order to assure unrestricted hands on maintenance for the linac. This is provided by strong focusing at low energies and avoidance of phase-space mismatches, coupled with apertures that are much larger than the rms beam size, with the largest aper-tures at high energies where the activation threat is greatest. In the NC linac, the aperture increases in steps to 64 mm, while in the SC linac it jumps to 130 mm at 211.4 MeV, and then to 160 mm at 471.4 MeV. Figure 4 shows 100,000-particle beam simulations for both an error-free machine design, and for one with a set of randomly chosen imperfections, with magnitudes about a factor of two worse than typical errors expected in operation. The simulations compare the linac aperture dimension with both the rms beam size and the radius of the outermost particle in the distribution (the halo). At full energy, the aperture ratio (ratio of aperture to rms-beam-size) is close to 80, providing a very large clearance for the beam halo. At low energies,

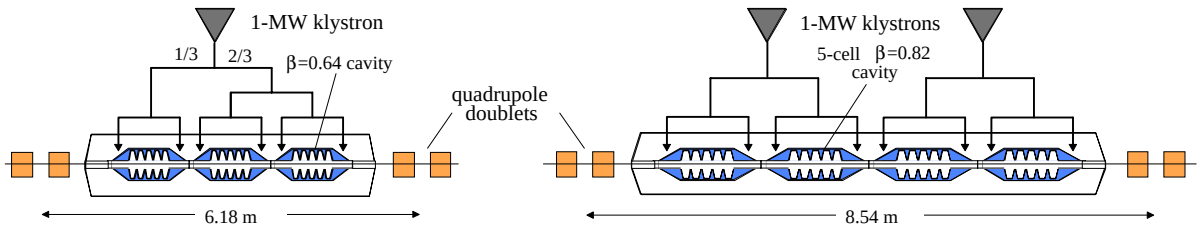

Fig. 3. Medium-β and high-β cryomodule and rf architecture in superconducting linac.

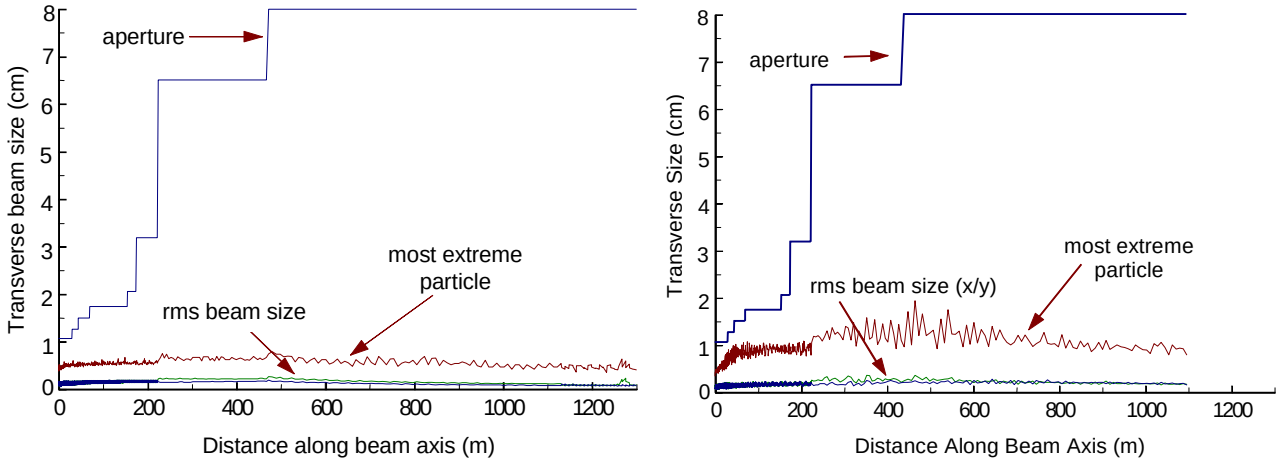

Fig. 4. Beam simulations for APT linac design showing rms beam size and radius of outermost particle, compared with aperture. Left: No machine errors. Right: Standard set of machine errors.

the clearance is less generous, and some small losses may occur.

2.4 Availability

Because the SC linac operates with short independently-driven accelerating cavities, the linac output energy may be adjusted over a wide range, providing considerable operational flexibility. Simulations confirm that, because of this feature, the SC linac is insensitive to a broad range of construction or operating errors and also can continue to function in a variety of off-normal conditions, such as having single klystrons, cavity pairs, and quadrupole pairs out of service. In order to meet the high annual availability goal for the accelerator (> 85%), redundancy schemes are used to provide excess rf drive in both the NC and SC linacs, but are implemented differently in each. The NC linac is divided into supermodules consisting of 100-150 coupled accelerating cells, with each unit supplied by n klystrons (typically 4 to 7), where only n-1 units are need-ed for operation. When an rf station fails, it is isolated by a waveguide switch and the accelerating structure drive iris is shorted. Power from the remaining klystrons is increased to compensate for the lost unit, and the supermodule continues to provide the full energy gain needed in that section. In the SC linac, redundancy is achieved by providing a modest level of reserve power in each rf station, above that needed to deliver the nominal output beam power, allowing increased energy gain in adjacent cryomodules to compensate for failed units. The power reserve is 5% in the high-β section and 9% in the medium-β section.

3 HIGH ENERGY BEAM TRANSPORT

A High Energy Beam Transport (HEBT) system [9] delivers the beam from the end of the linac to the (T/B). The HEBT focusing lattice continues the doublet-quadrupole optics in the high-β linac to a magnet switchyard. Here the beam is directed either to a tuning beamstop that can take up to 2% of the full-energy beam power, or into the beam line serving the T/B assembly. This beam line terminates in a raster beam expander, which converts the small-diameter Gaussian-like beam distribution into a large-area rectangular (19 cm wide x 190 cm high) uniform distribution at the target. The beam expander consists of two sets of four sweep magnets driven with triangular waveforms by IGBT modulators at frequencies close to 500 Hz. One set is for the horizontal-plane sweep, and the other for the vertical plane. Because the sweep frequencies are slightly different, the raster system paints the T/B uniformly once per 30 ms. A multiply-redundant modulator fault detector system protects the T/B from excess beam power density due to degradation or interruption of the sweep pattern. In the modular plant configuration, the T/B is located near the end of the 1030-MeV linac, following a 10-period drift and a 90-degree bend. If the linac is built to 1700 MeV, the beam returns to this target line through a transport system consisting of a 180-degree bend, a straight beam channel parallel to the linac, and a reverse 90-degree bend. Beam dynamics studies have shown that the insertion of these bends, which are first-order achromats, have essentially no effect on beam loss and on the beam performance on the target. They do, however, introduce some additional operational complexity.

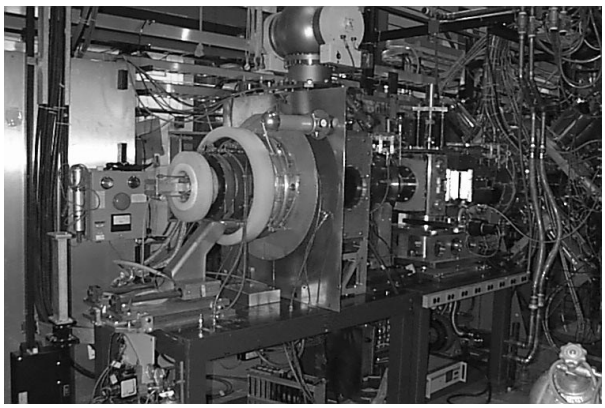
4 ENGINEERING DEVELOPMENT AND DEMONSTRATION (ED&D)

The APT accelerator design is supported by a broad ED&D program that will demonstrate and prototype key components and systems. The program (Fig. 5) consists of 1) a Low-Energy Demonstration Accelerator (LEDA) that will prototype the APT linac front end up to 20 MeV, 2) development of high-β and medium-β SC-cavity and cryomodule prototypes, and several smaller programs. LEDA [10] will consist ultimately of a proton injector, a

6.7-MeV 350-MHz RFQ, and a 20-MeV CCDTL section. Its purpose is to confirm beam performance parameters, demonstrate integrated operation at full CW power, assess overall availability, and identify component failure modes. The major stages involve 1) construction and testing of a 75-keV, 110-mA proton injector; 2) addition of a 350-MHz RFQ to accelerate a 100-mA CW proton beam to 6.7 MeV; and 3) addition of a 700-MHz CCDTL to accelerate the beam to 20 MeV.

The LEDA injector has been built and successfully tested at APT performance specifications (110 mA H^+, <0.2 mm-mrad emittance). Construction and assembly of the RFQ is well advanced; the eight sections have been fabricated, and initial rf tuning of the whole structure is complete. The injector was recently successfully operated with a 1.25-MeV 267-MHz CW RFQ available from another program. Beam output current and transmission (100 mA, 85%) were as predicted, a strong validation of the codes used to design the APT RFQ.

A prototype of the highest-energy CCDTL segments (near 97 MeV) will be built and tested at full rf power to demonstrate RF coupling, manufacturability, and thermal performance of the section of the NC linac that is the most difficult to cool.



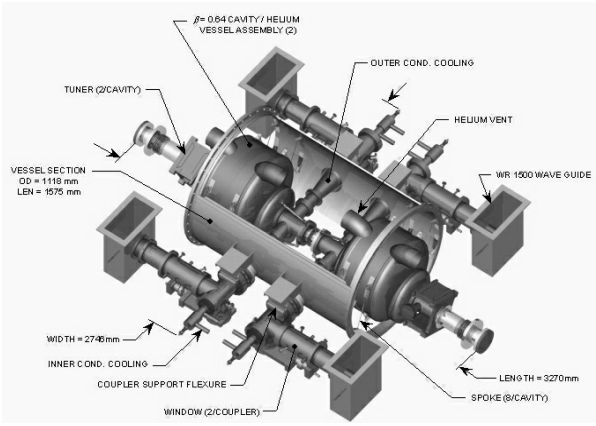


Fig. 5. ED&D program elements. Top: LEDA injector. Bottom: β = 0.64 2-cavity cryomodule.

The SCRF ED&D program [11] has as its basis the β = 1 cryomodules operating successfully in several electron accelerators. For the APT SC linac, it is necessary to develop cryomodule prototypes containing the lower-β cavity shapes needed for a proton accelerator. Development of these prototypes will confirm design parameters, component integration, and constructibility, and will support transfer of the technology to industry for manufacture of plant cyromodules. The elements of the SCRF program include: 1) fabrication and high-field testing of single-cell cavities; 2) evaluation of radiation damage to a prototype cavity; 3) fabrication and testing of high-power rf couplers; 4) fabrication and testing of multicell SC cavities; and 5) assembly and tests of complete prototype cryomodules. The first and second of these activities have already been successfully accomplished.

Other elements of the ED&D program include: 1) development of a prototype 1-MW 700-MHz High-Order-Mode Inductive-Output tube, which would offer improved efficiency and reliability (lower operating voltage) compared with a klystron, 2) construction and testing of a full scale raster beam expander prototype, 3) development and testing of high-power rf components (windows, waveguide valve, etc.), and 4) development of prototype diagnostics for measuring beam profiles at medium and high energies.

HEAVY ION FUSION EXPERIMENTS AT LBNL AND LLNL*

Larry Ahle (presented for the groups at LBNL and LLNL)
Lawrence Livermore National Laboratory, Livermore, CA 94551 USA

Abstract

The long-range goal of the US Heavy Ion Fusion (HIF) program is to develop heavy ion accelerators capable of igniting inertial fusion targets to generate fusion energy for electrical power production. Accelerators for heavy ion fusion consist of several subsystems: ion sources, injectors, matching sections, combiners, induction acceleration sections with electric and magnetic focusing, beam compression and bending sections, and a final-focus system to focus the beams onto the target. We are currently assembling or performing experiments to address the physics of all these subsystems. This paper will discuss some of these experiments.

1 HEAVY ION FUSION DRIVER

In a heavy ion inertial power plant, particle beams are focused onto a target causing ignition. These targets consist of a hohlraum with a Beryllium (or other low Z ablator material) capsule inside. The capsule surrounds a frozen spherical shell of D-T, which is heated and compressed by X-rays created from the stopping of the ions in the holhraum. The accelerator will need to provide approximately 5-MJ of energy on a time scale of ~ 10-ns for ignition [1] and at a rate of ~5-Hz for a cost effective power plant [2]. Further, the range of the ion beams should be roughly 0.1-g/cm^2 which implies a total kinetic energy per beam particle of a few GeV.

The target specifications above are now based on sophisticated simulation validation and are generally demanding lower emittance beams than believed necessary a few years ago. There also appears to be a trade off between beam current and ion kinetic energy. Higher beam current implies a higher technical risk but the resulting lower energy may produce a cheaper power plant.

Current conceptual designs for a heavy ion fusion driver start with ~100 beam 2-MeV injector and ESQ matching section providing a initial pulse of 20-μs with approximately 1-A of current for each beam with radius of several centimeters. This is followed by an accelerator section. Whether the initial part of the accelerator is electrostatically focused, followed by beam merging, or magnetically focused is still being studied, but the end of the accelerator will be magnetic. The acceleration is accomplished through magnetic induction cores at the rate of 1-MV/m through most of the machine. The pulses on these induction cores are tilted to longitudinally compress the pulse from an initial length of ~30-m to ~10-m, which corresponds to a pulser duration of about 100-ns at the end of the accelerator. Following this is the drift compression, final focus, and target chamber section. The drift compression will do the final longitudinal compression to ~1-m in length. The final focus section will focus the beam to the target in the chamber reducing the radius of the beam to a few millimeters.

2 SOURCE AND INJECTOR

In developing sources and injectors for a driver, high current density is desired because it allows smaller and/or fewer beams and thus a cheaper injector. The current density is limited by voltage breakdown in the injector and transport limitations in the accelerator section and not by the emission limit of the source itself. Currently the design goal of an injector for a driver is many beam channels in one single vacuum chamber with a current density of 8-mA/cm^2 Cs equivalent.

2.1 Source Development

There are many possible types of ion sources for HIF, generally producing singly charged ions but higher charge states are also of interest in some driver designs. Surface ionization sources provide alkali metal ions, while a gas source is suitable for generating Hg, Xe, Ar and Ne ions, and a metal vapor vacuum arc source (MEVVA) would be more appropriate for ions such as Gd and Bi. Most HIF induction linac designs have used surface ionization sources because their performance already approaches the HIF requirements.

LBNL has been working with two types of surface ionization sources, contact ionizer and aluminosilicate. In a contact ionizer, alkali atoms are continuously fed to a heated surface, which ionizes the atoms. This type of source routinely produces low emittance and highly uniform beams. It also has the potential for a long lifetime source, but since alkali metal vapor deposits can deteriorate the high voltage property of accelerator components, it is important to minimize the cesium flow. In a recent experiment [3], the Cs^+ beam current from a 2-cm diameter contact ionizer was measured to be > 15-mA/cm^2 at 1145°C. In addition, the rate of the cesium neutral current evaporation was measured to be 1.7x10^{14}/cm^2/s or equivalently 0.14 mg/cm^2/hr. To test these sources in a real application, a Cs^+ contact ionizer will be installed in the scaled final focus experiment

described in section 4.2. This source will provide a factor of four increase in the current density and a more uniform beam.

For aluminosilicate sources, a layer of aluminosilicate doped with an alkali metal, is melted on a tungsten surface. This tungsten surface is then heated during operation. The neutral current for these sources should be lower than for the contact ionizer [4], but its lifetime for a driver before ion depletion is about one month [5]. Current densities of ≈15-mA/cm^2 of potassium, 7.9-mA/cm^2 Cs equivalent, have been achieved with a 2-cm aluminosilicate source [3]. For these sources to achieve uniform emission and high current density, a smooth layer must be melted on a large spherical area, which has proven to be a significant technical challenge. Recently, a different method to produce the aluminosilicate sources, in which a mixture of aluminosilicate and tungsten powder is sintered to form an emitter has been adopted [6].

2.2 2 MeV Injector

Based on ESQ beam transport considerations, a 2-MeV driver-scale injector should provide beams with a line charge density of approximately 0.25x10^{-6} C/m. A prototype injector, as shown in figure 1, was built for the Elise/ILSE project. It consists of a 17-cm diameter potassium aluminosilicate source as part of a 750-kV extraction diode which is in series with a 1250 kV ESQ accelerator. Both diode and ESQ are powered by a Marx Generator using a resistive divider. The column is completely enclosed in a steel tank (at 80 PSI compressed gas atmosphere) for compatibility with using SF_6.

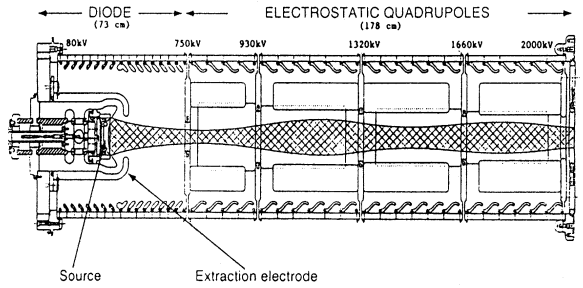

Figure 1: Schematic diagram of the 2-MeV injector.

Earlier tests have demonstrated beam current of up to 0.8 A of potassium ions (space-charge-limited) with a ε_{4rms} projectional emittance < 1.0 π-mm-mrad [7]. However, it was also discovered that the beam current density profile at the end of the injector has a hollow shape instead of the calculated uniform shape. In order to find out what causes the beam non-uniformity, a movable Faraday cup array was recently constructed to measure the beam profile at locations (along beam axis) inside the ESQ accelerator. Some preliminary data indicates the problem may occur at the extraction diode. At present, a new contact ionizer source of the same dimension is being prepared to replace the aluminosilicate source in order to determine if the phenomenon is related to non-uniform ion emission.

3 THE ACCELERATOR

3.1 Beam Merging

Transverse beam combining at the transition from electrostatic to magnetic quadrupole transport could lower the cost of a multiple beam induction linac driver. The cost of induction core material and HV breakdown dictate a small aperture in electrostatic quadrupoles, while magnetic quadrupole transport -- very effective at higher kinetic energy, favors larger apertures (and fewer beams). The challenge for beam merging is to limit resulting emittance growth (minimized by closely packing the merged beams in phase space [8]).

The 4-to-1 beam combining experiment [9] is designed to establish the ability to merge beams with considerable space charge, and measure the phase space evolution of the merged beams. The four initial Cs^+ beams are generated in 160 kV diodes and initially converge at a 6^o angle relative to the combiner center line. Four arrays of electrostatic quadrupoles (Q1-Q4) followed by the combined function dipole-quadrupole element ("wire cage", QD5) focus each beam and straighten its trajectory to be parallel to the downstream transport line. After the wire cage, the merged beam is transported and diagnosed at several locations along the merged beam transport line (Q6-Q67).

We reported earlier [10] measuring 88% transmission through the combiner. These data indicated that the beam edge to beam edge separation was <4 mm at the merge point, with the 1 mm tungsten rods (of the wire cage) in between. The measured phase space between Q7 and Q8 (one lattice period downstream of the cage) was in agreement with the 2D PIC simulations. The initial beams (4.5-mA) had a factor 1.65 more current than originally thought compatible with the transport of merged beams in the (previously existing) downstream transport lattice. As a consequence of the higher current there was not enough clearance between the merged beam and electrodes in the matching quadrupoles (Q6-Q11) to enable further transport without significant beam loss.

Recently, each initial beam current has been lowered to 2.7-mA by altering the Pierce electrodes. This has improved beam matching through the combined function element and the 10.4-mA merged beam through the first downstream lattice period has several millimeters more clearance to the quadrupole electrodes. Beam loss in the transport lattice following the merge should also be negligible, allowing a more quantitative interpretation of the merged beam distribution function.

Figure 2 shows the phase space measured in the vertical plane between Q7 and Q8. Though the beam distribution function has not equilibrated at this point, the rms emittance, $\varepsilon_n \approx 0.2$ π-mm-mR, has decreased by a factor

~0.5 compared to the previous measurements with the higher beam current reported in [10]. Transport measurements through Q67 are currently underway. These results will establish some limits on emittance growth through for this approach to beam merging.

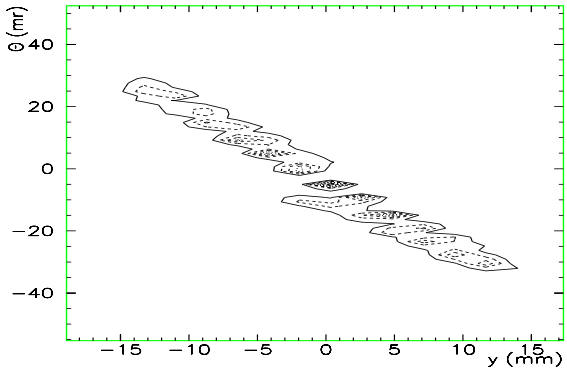

Figure 2: Contour plots from two-slit emittance scan of the merged beams between Q7 and Q8.

3.2 The Recirculator

Most designs of a driver are linear machines, but using a circular machine may provide significant cost savings. Such a machine, a circular ion induction accelerator for space charge dominated beams, or recirculator, have never been built before. Thus, a group at LLNL has been developing a small recirculator in order to validate the recirculator concept for an IFE power plant driver.

In designing this machine, all of the important dimensionless beam parameters, such as perveance, were kept the same as a full scale driver machine. Each half lattice period (HLP) of the recirculator consists of a permanent magnetic quadrupole for focusing, an electrostatic dipole for bending the beam, and an induction core, or modulator, for acceleration and longitudinal compression. The dipole plates are designed to provide a 9 degree bend to the beam while the modulators are designed to provide 500-eV of acceleration.

In the fall of 1997, the machine was extended from a 45 degree bend to a 90 degree bend section. Figure 3 shows the current layout of the machine. Initially, a 4-μs beam pulse is injected by a source diode with an energy of 80-keV through an aperture of diameter 1-cm which provides an initial beam current of 2-mA. Upon injection the beam enters an electrostatic matching section which is followed by a short magnetic transport section before the 90 degree bend section. Following the bend section is the End Tank which houses several diagnostics. As part of the upgrade, magnetic induction cores were added to 5 of the 10 HLP's as shown.

The first attempts at beam transport through the 90 degree section were done with no acceleration and DC voltages (+/- 6.575-kV) on the bending dipole plates. Full current transport was achieved with less than 1% loss as measured by Faraday Cups. The RMS normalized emittance for the 90% of full beam current was also measured at the source injector, 0.021 π-mm-mR, and after 90 degrees, 0.045π-mm-mR in x and 0.068 π-mm-mR in y. The growth seen is within the design specifications.

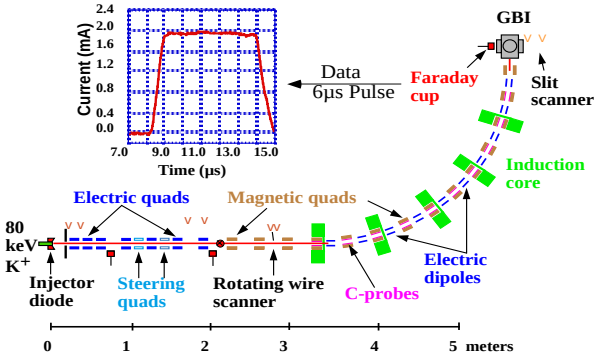

Figure 3: Current Recirculator Layout.

A network of C-probes (capacitively coupled beam position monitors) before and throughout the bend section has been enabled to measure the transverse beam position as a function of time. All four signals from each C-probe are amplified, digitized, and analyzed through the computer control system to obtain the charge centroid. Bench tests of the system using a conducting rod to simulate the beam have yielded a resolution of 70 μm. Figure 4 shows the x position measured by the C-probes for various dipole voltages.

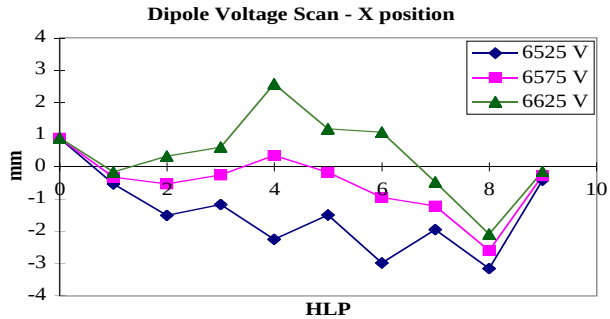

Figure 4: Time averaged X positions as measured by C-probes for various dipole voltages.

LLNL has developed a new device to measure the emittance, the Gated Beam Imager (GBI). The GBI is based on the pepperpot design in which the beam is incident on a hole with 100 μm diameter holes creating many beamlets. Each beamlet is allowed to drift to a micro channel plate(MCP) which is coated with a thin layer of stainless steel, ~150 nm, to stop the ions and produce secondary electrons. After passing through the MCP, the electrons are proximity focused on to a phosphor screen, and the light generated is focused and captured on a CCD camera. Recently, after the analysis of the GBI images was changed to more closely mimic the more traditional slit scan, the GBI was fully reconciled with the slit scanner.

Currently the initial implementation of the electronics necessary for acceleration and ramped dipole voltages, is underway. The first attempts at acceleration should occur shortly. For more information about the recirculator, please refer to the paper in these proceedings [11].

3.3 Induction Core Material

Currently one of the major cost items for a driver is the price of magnetic material for the induction cores. Recently, a survey of various commercially available material was done [12]. Two type of materials were tested, amorphous alloys and nanocrystalline alloys. The amorphous alloys cost less, have slightly higher flux swing (about a factor of 1.2), but have a significantly higher energy loss (about a factor of 5) than the nanocrystalline material. The important figure of merit for selection of material is the final cost of electricity. Obviously the nanocrystalline material will mean a lower operating cost, but a higher capital cost. System studies to determine which of these two materials produces a lower cost of electricity are underway.

4 FINAL FOCUS

There are several proposed schemes, depending on the intensities of the beams, for achieving the final spot size necessary to hit the target. At low intensities, vacuum ballistic focusing would suffice, but at high intensities a scheme involving charge neutralization or establishing a focusing current in a plasma must be invoked. Currently experiments are being performed investigating the ballistic focus scheme and one of the more exotic schemes, plasma channel transport [13].

4.1 Plasma Channel Transport

Plasma channel experiments, for heavy ion transport, are being conducted at LBNL to measure their time and space resolved plasma density evolution. These channel experiments are scaled versions that provide understanding of the channel's behavior under different regimes or parameter space, such as pressure, gas type, and discharge energy deposition, which directly relate to the transport efficiency. A working reactor ion transport design relies on proper selection of these parameters.

The plasma channel in these experiment are produced by a double voltage discharge technique initiated by the creation of a preferential discharge path produced by a KrF excimer laser. Plasma density space profiles have been obtained at several times during the first quarter cycle of channel current (peak current 29 kA). The measured pinch occurring (7 Torr N_2, 200 mTorr Benzene, 15 kV discharge) at t=2.2 microseconds is in agreement with previous experiments.

These measurements were made using a Michelson-type optical interferometer (1064 nm) with a time resolution of approximately 20 ns, determined by the probe laser pulse width. The on-axis plasma density time evolution (n_e = 1.3 x 10^{17} cm^{-3} at pinch time) provides input to the determination of a plasma conductivity model to be implemented in computer simulations.

Future experiments include the use of spectroscopy of the plasma's emitted radiation to measure the Zeeman and Stark broadening, as well as the Faraday rotation technique. These experiments will permit the mapping of the channel's magnetic field distribution and time evolution as well as the determination of its electron temperature.

4.2 Scaled Focusing Experiment

Vacuum ballistic focusing is one method to achieve the heavy ion beam spot size necessary for an inertial confinement fusion target. Proper scaling of particle energy, mass, beam current, beam emittance, and magnetic field replicates the dynamics of a full driver beam in a small laboratory beam. Thus, a one-tenth scale experiment, based on the HIBALL II design, is currently being assembled at LBNL. This scaled experiment uses a K^+ ion source to send a 120 keV beam through an aperture and electrostatic matching section. Approximately 80 μA of beam is then sent through a set of six magnetic quadrupoles that comprise the final focus. By expanding the beam and then focusing to a very small spot, the effects of aberrations and space charge on this method of final focus can be studied. Figure 5 shows the beam envelope for the final focus section.

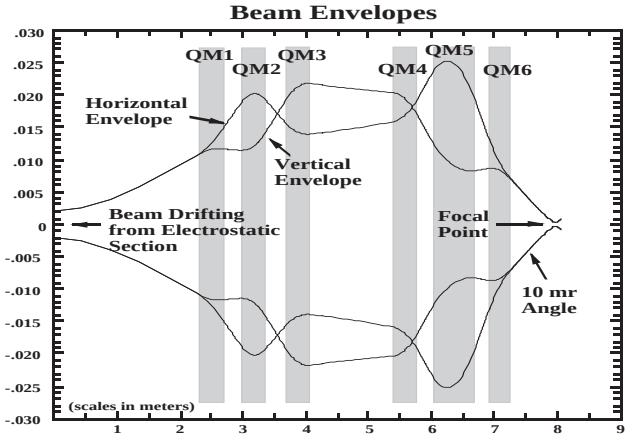

Figure 5: Plot of beam envelopes for magnetic focusing section.

Two-slit scanners measure beam properties after the electrostatic matching section, as well as after the third and sixth magnetic quadrupoles. Measurements of the beam have already been made through the first three magnets with encouraging results, and the second set of three magnets has just been installed, aligned, and pulsed. The beam spot size measurement will be made with a single slit probe that will translate along the beam axis as well as in the transverse directions so as to determine the precise nature of the beam waist.

Subsequently, a separate target injection experiment (section 4.3) may be coupled to the final focus in order to demonstrate the ability to hit a simulated heavy ion fusion target "on the fly". This will require a set of steering electrodes that have been designed to provide a real time correction to the beam to account for the shot-to-shot variation in target position. The emerging beam from the magnetic section will also be suitable for studying electron neutralization of space charge, and its effect on the focus.

4.3 Fusion Target Injecting and Tracking

An experiment is being conducted at LBNL to investigate and demonstrate the engineering feasibility of accurately injecting and tracking IFE targets into a vacuum chamber [14]. As indicated in figure 6, a gas gun is used to inject non-cryogenic, aluminum and delrin (plastic) target-sized projectiles. These projectiles are optically tracked at three locations using photodiodes to accurately provide real-time transverse and longitudinal target position prediction. This real-time information would then be used to trigger the ion beam and control small beam steering magnets to direct the beam on target.

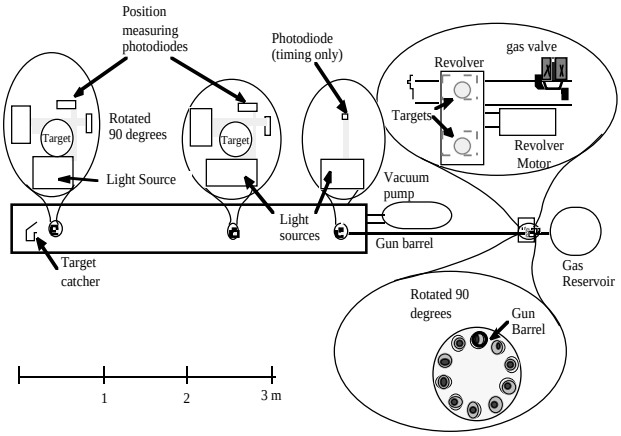

Figure 6: Schematic of Target Injector.

The position prediction is achieved by sending voltage data from one photodiode detector near the gun barrel and another 1 m downstream to a real-time target position prediction circuit. This circuit electronically latches the voltage as the center of the target passes the second detector, and compares this voltage with that when the target is not present. The voltage ratio and the time of passage between these detectors are used to predict the transverse position at which the target passes a third detector located 3 m from the gun barrel. The prediction is in the form of an output voltage that is proportional to the target's transverse position at detector 3; it is available microseconds after the target passes detector 2.

Although the standard deviation in projectile position in each transverse direction is about 2 mm, a standard deviation of 0.1 mm between predicted and measured positions in both transverse directions is achieved. Using an up-down counter, the arrival time of the target has been predicted such that the standard deviation in predicted target position along the direction of motion is 0.37 mm. These prediction capabilities are adequate for a heavy ion driver.

5 OUTLOOK

The road to a heavy ion IFE power plant is still a long one. Before a machine that achieves fusion with heavy ion beams can be realized, a scaled facility to test many, if not all of the accelerator issues in an integrated way must be built. We plan on being in a position to propose such a facility in a few years. To be in that position, the groups at LBNL and LLNL will continue conducting small experiments to explore issues in HIF.

6 ACKNOWLEDGMENTS

I would like to acknowledge the efforts of Joe Kwan, Peter Seidl, David Ponce, Ron Petzoldt, and Steve Maclaren of LBNL and Art Molvik of LLNL for providing the necessary input for this document.

LINEAR ACCELERATORS FOR EXOTIC ION BEAMS

Pierre Bricault
TRIUMF
4004 Wesbrook Mall, Vancouver, BC, V6T 2A3, Canada

Abstract

One of the new frontiers in nuclear science is the use of exotic ion beams. In the past, nuclear reaction studies were restricted to the use of stable projectiles or a few long-lived isotopes. The possibility of producing intense exotic ion beams opens a wide variety of research opportunities in nuclear astrophysics, nuclear physics, material sciences, etc. This field has grown considerably in the past ten years owing to progress in the production techniques of isotopic separation on-line and in particular in the field of heavy-ion accelerators. One of the breakthroughs is the possibility to accelerate very low energy heavy-ions using a low frequency RFQ at the front end of a linear accelerator.

This paper will review exotic ion beam facilities, based on the ISOL method, using or proposing a linear accelerator as a post-accelerator.

1 INTRODUCTION

The opportunities offered by beams of exotic nuclei for research in the areas of nuclear physics, nucleosynthesis and nuclear astrophysics, and for critical tests of fundamental symmetries, are very exciting. The worldwide activity in the installation of different types of facilities for exotic nuclei reflects the strong scientific interest in the corresponding physics.

The choice of the post accelerator depends on the physics program, which defines the energy and mass range, duty factor and pulse characteristics of the desired ions. This paper reviews only exotic ion beam facilities using LINAC's as post-accelerators. One LINAC has already being built for exotic beam applications, this is the prototype of the JHF E-arena at INS-Tanashi, now, KEK-Tanashi. Two more LINAC's are under construction: one at ISOLDE-CERN and the other at ISAC-TRIUMF. Proposals for second generation exotic ion beams facilities based on the ISOL method which have selected a LINAC as post-accelerator are: JHF E-arena, Argonne National Laboratory, Oak Ridge National Laboratory, Munich and ISAC2 at TRIUMF. A proposed upgrade of the accelerator of the BRNBF in Beijing will also be mentioned.

2 EXISTING RIB LINAC FACILITIES

2.1 E-arena Prototype at Tanashi

A prototype radioactive ion beam facility has been built at KEK-Tanashi. The main components are: target/ion source, mass separator, RFQ and IH linear accelerators. The exotic species are produced using the ion beams extracted from the INS SF cyclotron. The exotic ions are then accelerated to energy ≤ 1 MeV/u through a split-coaxial RFQ (SCRFQ) and an interdigital-H type (IH) linacs. The project is regarded as a prototype of the more ambitious RIB facility for the E-arena in the proposed Japanese Hadron Facility (JHF). The main accomplishments were:

1) Test off- and on-line of target/ion-source systems, ECR, plasma and surface ion sources;
2) Off- and on-line beam tests of the ISOL system as well as the construction of the beam-transport system;
3) Construction and operation of a 25.5 MHz split-coaxial 4-rod RFQ;
4) Construction and operation of a 51 MHz IH linac composed of 4 tanks;
5) Construction and operation of the stripping and matching section between the RFQ and the IH LINACs.
6) Pilot experiments with exotic beams.

2.1.1 Split-Coaxial RFQ LINAC

The split-coaxial RFQ is designed to accelerate ions with charge-to-mass ratio (q/A) ≥ 1/30 from 2 to 172 keV/u. The split coaxial resonant cavity was invented by R. W. Müller[1] and development and investigation took place in several institutes: GSI[2], Frankfurt[3], and Argonne[4].

Various kinds of electrode structure have been proposed: modulated vanes, circular rods, drift tubes with fingers. At INS they selected modulated vanes. In order to achieve easy assembly of the vanes and a stable mechanical structure, a multi-electrode cavity is employed. Two opposite electrodes are fixed and electrically grounded at one end of the cavity. The other opposite electrodes are fixed and grounded at the other end of the cavity. That is, the electrodes are supported at only one point.

The module length, 0.7 m, was determined so that the drop of the vanes due to gravity may not exceed 35μm, with the cavity diameter not exceeding 1m. By introducing spacer rods, it was possible to align the vanes with accuracy better than ± 40 μm before installation into the unit-cavity tank.

The cavity, comprising 12 module cavities, is 0.9 m in diameter and 8.6 m long. The measured resonant resistance is 25.55 ± 0.44 kΩ. The measured unloaded Q-value is 5800. The nominal vane voltage is 109 kV for q/A ≥ 1/30 ions. This corresponds to an input power of 240 kW. The maximum duty factor is 30%.

2.1.2 Medium Energy Beam Transport (MEBT)

The MEBT system between the SC-RFQ and the IH LINAC comprises a charge stripper (Carbon foil of 10 $\mu g/cm^2$), a rebuncher and two quadrupole doublets. Since a frequency of 25.5 MHz is required for the rebuncher, a double-coaxial resonator with 6 gaps was developed to maintain the size of the cavity small and the power low.

2.1.3 Interdigital-H type LINAC

The Interdigital-H LINAC is composed of four tanks. It accelerates ions with charge-to-mass ratio ≥ 1/10 from 172 to 1053 keV/ nucleon. In order to obtain high shunt impedance, the accelerating mode is π-π, and no transverse focusing element is installed into the drift tubes. The operating frequency is twice the RFQ frequency. Each gap length between drift tubes is equal to one half of the first cell length. Both end structures of the cavity, *i.e.*, the magnetic flux inducer and the gaps between end-wall and ridges are determined experimentally so that the longitudinal field distribution becomes flat over the cavity. The synchronous phase is –25° to assure a stable longitudinal motion.

The tuning of the cavities is achieved using three kinds of tuners: a capacitive tuner (C-tuner), an inductive end-tuner (End L-tuner) and an inductive piston tuner (L-tuner). The C-tuner is a manually movable disk facing a ridge; The L-tuner is moved automatically to compensate for the frequency shift.

The first acceleration of an exotic ion beam has been carried out successfully on Mach 14th, 1997 at the INS prototype E-arena.

2.2 ISAC-TRIUMF

2.2.1 RFQ

A cw radio-frequency quadrupole provides the initial acceleration of the ion beam delivered by the ISOL. The total length of the vane-shaped rods is 7.60 m. Given that the radioactive ion beam intensity will be small, space charge can be neglected. A truncated Yamada-style recipe was used for the vane profiles. Due to a requirement from the experimenters for 86 ns time structure, beam bunching is achieved in an external, quasi-sawtooth pre-buncher. The shaper and gentle buncher portions of the RFQ are omitted, leading to substantial shortening. The pre-buncher is located in the LEBT section ~ 5 meters from the RFQ. A 4-rod split-ring RFQ structure has been chosen because of its relatively high specific shunt impedance, its mechanical stability, and the absence of voltage asymmetries in the end region[6]. It is a variation of the 4-rod RFQ built by Schempp[5]. The thermal and dynamic stability have been measured and are well within tolerance[7]. The final RFQ will be composed of 19 modules, but in order to test the beam dynamics and the injection of a bunched beam into the RFQ a 7-ring-RFQ section has being built installed in the 8 m long tank and tested first.

A $^{14}N^+$ beam test with the ISAC split-ring 4-rod RFQ has been successfully completed in June 1998. 7 of the 19 rings were installed for a final beam energy of 54 keV/u. The RFQ was operated in continuous wave (cw) mode. Operation at the nominal peak voltage of 74 kV was achieved in July 1998. This allowed the acceleration of $^{14}N_2$ (q/A = 1/28). The beam transmission was 80% at the nominal voltage in perfect agreement with PARMTEQ calculations. The energy spread of both bunched and unbunched ^{14}N and $^{14}N_2$ beams was measured and showed good agreement with PARMTEQ calculations.

2.2.2 Stripper and matching section

The charge-state selector is composed of a symmetric QQDDQQ section. A four-quadrupole system and a 35 MHz $\lambda/4$ rebuncher provide transverse and longitudinal match into the DTL. Provision is also made for installation of a rebuncher between the RFQ and the stripping foil to produce an upright ellipse for the longitudinal emittance at the stripping foil.

Several options for the 35 MHz $\lambda/4$ rebuncher were investigated. It is likely that a spiral $\lambda/4$ will be used.

2.2.3 Drift-Tube Linac

The drift tube linac is required to accelerate, in cw mode, ions with a charge to mass ratio ≥ 1/7 from 0.15 MeV/u to a final energy variable between 0.15 and 1.5 MeV/u. An IH structure[8] is chosen because of its very high shunt impedance. A *separated function* DTL concept has been adopted[9]. Five independently phased IH tanks operating at $\Phi_S = 0^o$ provide the main acceleration. Longitudinal focusing is provided by independently phased three-gap split-ring resonator structures positioned before the second, third and fourth IH tanks. When operating at full voltage the beam dynamics resembles that of a so-called 'Combined 0° Synchronous Particle Structure'[8]. To reduce the final energy, the last IH tanks may be turned off while voltage and phase of the last powered tank are varied. The split-ring resonators are all designed for β = 0.023 and are effective over the whole DTL velocity range. They also permit the beam to be kept well bunched over the entire energy range.

The first ISAC-IH-DTL tank has been built and is waiting for copper plating. Cooling channels are machined in bulk copper material to assure efficient cooling.

2.3 REX-ISOLDE

REX-ISOLDE is a first generation RIB project aimed at exploring the possibility of an efficient post acceleration of exotic ions based on LINAC after charge breeding with a trap-EBIS system.

The LINAC complex is composed of a 4-rod RFQ, an IH-structure and three seven-gap spiral resonators. To match the phase spread of the ion beam out of the RFQ to the longitudinal phase acceptance of the IH-structure a

three-gap split ring resonator is used. The maximum duty cycle is 10% with a maximum repetition rate of 50 Hz.

To reduce the cost of the LINAC a charge-to-mass ratio of 1/4.5 was chosen. Highly charged ions can be produced using an Electron Cyclotron Resonance Ion Source (ECRIS) or an Electron Beam Ion Source (EBIS). For a RIB facility it is essential to get high efficiency charge state breeding from 1+ to n+ ions and in a short time compared to the half-life of the nucleus considered.

2.3.1 REX-ISOLDE charge breeding scheme

In the REX-ISOLDE scheme a Penning trap is used for accumulation, cooling, and bunching[10]. The Penning trap is however limited in the number of particles which can be trapped. The maximum ion density for the REX-Penning trap is estimated for A = 140 at 10^6 ions/mm^3, which correspond to some 10^8 ions per accumulation cycle.

The Penning trap is located on a high voltage platform an the same potential as the singly charged ion source at the ISOLDE target. The transfer line consists of two electrostatic benders and two electrostatic quadrupole doublets. The confinement time required to reach a charge-to-mass ratio larger than 1/4.5 is less than 20 ms. The EBIS magnet has a magnetic field of 2 T with an homogeneity of about 2.5‰ along the confinement length of 0.8 m. The ions ejected from the EBIS are mass analyzed with a magnetic achromat composed of two 90° dipoles.

2.3.2 The 4-rod RFQ

The ions are accelerated from 5 to 300 keV/u by a 4-rod RFQ. This RFQ is similar to the one used for the High-Current -Injector at Heidelberg[11] and the GSI HLI-RFQ[5]. The results from these two RFQ show that about a quarter of the power is dissipated on the ground plate of the resonator. The new REX-RFQ will have additional cooling of the ground-plate, which must have a better electrical contact to the stems along the entire structure. Furthermore, for the cooling of the electrodes a new stem design has been made at Hiedelberg. The main characteristic of the new design is that channels for cooling water are now completely inside the stem.

Regarding the particle dynamics, they add to the present design a so-called “matching out section” at the high-energy end of the RFQ. The focusing strength is reduced stepwise at the last cells of the accelerator. This leads to decreased beam divergence at the exit of the RFQ and thus reduces the required field gradients of the following matching section between the RFQ and the IH LINAC.

2.3.3 REX-MEBT

The beam dynamics concept of the 0° synchronous phase of the IH structure requires a small longitudinal phase spread and a converging beam in both transverse directions at the entrance of the IH-LINAC. Thus, the matching section includes a rebuncher and two quadrupole triplets. The three-gap split-ring rebuncher operates at the RFQ’s frequency with a gap-voltage of 50 kV.

2.3.4 REX-IH LINAC

The IH-structure is a short version of the GSI HLI-IH-structure[12]. The energy gain required is about 0.9 MeV/u, which corresponds to 5 MV absolute voltage. The IH-structure uses the “Combined Zero Degree Structure” beam dynamics concept developed by Ratzinger[8]. A new approach of the REX-IH resonator is the possibility to vary the final energy between 1.1 and 1.2 MeV/u by adjusting the gap voltage distribution via two capacitive plungers and by adjusting the RF-power level in the resonator[13].

2.3.5 REX-7-Gap Resonators

The final energy of 2.2. MeV/u at the target is achieved by three 7-gap spiral resonators. These type of resonators were developed and built first at the Max Plank Institute in Heidelberg for the High-Current-Injector[14]. The resonators have a single resonance structure, which consists of a copper half shell and three arms attached to both ends of the shell. The resonators are optimized for synchronous particle velocities of 5.4%, 6.0% and 6.6%. The total resonator voltage is about 2 MV for a power consumption of 90 kW. The output of the IH structure is matched with a triplet lens to the first 7-gap resonator. Between the first and second 7-gap resonator there is a doublet for transverse focusing.

3 PROJECTS AND PLANNED UPGRADES

3.1 Japanese Hadron Facility E-arena

The E-arena is a second-generation exotic ion beam facility based on ISOL and post-accelerator scheme. It aims at new regions in nuclear physics and related fields of science by supplying high-quality intense RIB of energies from nearly zero to 6.5 MeV/u for ion mass up to 240.

The RIB facility will utilize 10 μA from the 3-GeV proton booster synchrotron for the production of unstable nuclei. A wide variety of intense exotic ion beams can be produced via spallation, multi-fragmentation and/or fission process of target nuclei. After selection the exotic ion beam can be accelerated through a heavy ion linac, consisting of a split-coaxial RFQ (SCRFQ), and two IH type linacs, IH1 and IH2. The maximum output energy at each stage being 0.17, 1.05 and 6.5 MeV/u, respectively, with a duty cycle of 30% for q/A equal to 1/30.

The proposed E-arena is a natural extension of the RIB facility at the Institute for Nuclear Study (INS) of Tokyo. The new merits of the E-arena are:

1) Primary accelerator: 3-GeV protons are known to produce exotic nuclei with large probability, while reaction residues produced with low-energy beams available from the K=68 cyclotron, are limited to nuclei close to the stability line.

2) The secondary beam energy: this would be increased, by adding a new IH linac, from 1 to 6.5 MeV/u. Nuclear reactions become therefore possible over the whole region of target nuclides.

3.2 ANL Exotic-Ion-Beams Facility

Argonne National Laboratory proposes a two-accelerator ISOL-type facility to provide intense exotic ion beams at energies required for nuclear structure research and for reactions of astrophysics interest[15]. The heart of the exotic-ion-beam accelerator is the present ATLAS superconducting LINAC[16] which can accelerate ions from protons through Uranium to an energy range from 6 to 15 MeV/u. The ATLAS accelerator complex can presently accelerate ions of $q/A \geq 1/6.6$. The new front end has to accelerate ions of low charge-to-mass ratio $\geq 1/132$ to the energy necessary for efficient stripping to higher charge state, while maintaining excellent beam quality to match the actual ATLAS beam characteristics.

The new front end accelerator can be divided into three distinct sections. A short RFQ1 operating at low frequency will be installed on a high voltage platform. After gas stripping the ions of $q/A \geq 1/70$ will be accelerated by a combination of a second RFQ and a 48 MHz superconducting LINAC. After a second stripper, which will increase the q/A to over 1/6.6, a 72 MHz superconducting LINAC module which match the velocity profile to the present ATLAS LINAC will be installed.

Work started on the room temperature cw RFQ at low frequency. Ions with $q/A \geq 1/132$ call for a 12 MHz frequency range. The selected Split-Coaxial RFQ-structure is a modified version of the MAXILAX built at GSI[1].

The status of the RFQ development is the following; a 2 m prototype section has been constructed and operated cw at the design voltage (100 kV). They are currently preparing a prebuncher and LEBT section for beam tests scheduled for end of August 1998[17].

3.3 ORNL Facility

ORNL operates the Hollifield Radioactive Ion Beam Facility based on the ORIC cyclotron and on the 25 MV tandem accelerator as a post-accelerator. A second-generation ISOL facility based on the utilization of the driver of the Spallation Neutron Source (SNS) is proposed [18]. A decision on the construction of the SNS is expected by late 1998. The scheme for the post-accelerator is not yet finalized; but a low frequency RFQ would be utilized to accelerate low charge-to-mass ratio exotic ions $\geq 1/140$ to an energy suitable for stripping. The second stage would used superconducting quarter-wave resonators similar to the ones developed at Argonne[16].

Three take-off points are foreseen at 1, 6 and 15 MeV/u, which will cover most of the nuclear physics studies.

3.4 ISAC2 at TRIUMF

The aim of ISAC-II is a final energy of 6.5 MeV/u for a mass range up to A = 150[21]. The energy increase can be achieved by adding cavities at the end of the present LINAC. However, the mass limitation comes from the stripping at 0.15 MeV/u. The optimum stripping energy for mass 150 is 400 keV/u. To take these ions from 0.15 to 0.4 MeV/u requires a new LINAC, very similar to the ISAC1 DTL. To reach 6.5 MeV/u from 0.4 MeV/u with $A/q = 7$ requires a total voltage gain of 42.7 MV. Independently phased superconducting cavities similar to the ones developed at ANL for ATLAS[16] or LNL for ALPI [22] will be used. The maximum energy of particles with $q/A > 1/3$ will be around 15 MeV/u.

A charge state breeder based on an ECRIS will be placed upstream of the 35 MHz RFQ to increase the charge to mass ratio to 1/30 or greater.

The plan is to build and install superconducting modules downstream of DTL1 as they become available. This would allow higher energy-experiments (~ 5 MeV/u) to start before the end of 2003.

3.5 LINAC for the Munich Fission Fragment Accelerator

A Linear accelerator is proposed for the new Munich high flux reactor, FRMII. This LINAC is based on a charge state breeding of singly charged ions coming from the ISOL system. The required charge-to-mass ratio from the CSB is $q/A>0,16$. The LINAC will operate with a duty cycle of 10% and the final energy will be between 3.7 and 5.9 MeV/u. The LINAC complex will be composed of an RFQ, three IH structures similar to the Lead LINAC at CERN and two 7-gap IH-resonators for the variation of the final energy[20].

3.6 Beijing LINAC

The Beijing Radioactive Nuclear Beam Facility (BRNBF) proposal consists of three accelerators, a compact cyclotron which would deliver 70 MeV proton for the production of radioactive nuclei, an existing Tandem (13 MV) and a superconducting LINAC which will boost the final energy. The superconducting LINAC will use Niobium-sputtered Copper quarter-wave-resonators, currently developed at Peking University[19].

4 DISCUSSION AND CONCLUDING REMARKS

With the new exotic ion beam facilities based on the ISOL method it will be possible to have access to new extreme neutron-to-proton ratios to identify new phenomena and improve our understanding of nuclei, their origin and their properties.

These opportunities are possible because of the development of efficient accelerating structures for very low velocity heavy-ions. All sorts of linear accelerating structures are used or proposed. Both room temperature

and superconducting Drift-Tube LINACs are envisaged, see Table 1.

The injection scheme can vary from very low to very high charge-to-mass ratio using Charge State Breeders (CSB). We can highlight four major schemes:

1) High-charge state breeding as used by REX-ISOLDE for experiments with neutron rich isotopes of Na, Mg, K and Ca. The charge-to-mass ratio required is 1/4,5.
2) Medium-charge state breeding as proposed for ISAC2 and E-arena for nuclear physics up to the Coulomb barrier (6.5 MeV/u). The charge-to-mass ratio required are 1/7 and 1/10, respectively. Such a charge-to-mass ratio remove the need for the medium energy stripper.
3) Low-charge state breeding as proposed for ISAC2 for nuclear physics with masses lower then 150 up to the Coulomb barrier (6.5 MeV/u). The charge-to-mass ratio required is 1/30. In that case a medium energy stripper is required.
4) Low-charge-state LINAC injector as proposed by ANL and ORNL for nuclear physics with masses up to 140. Low frequency RFQ and two strippers are used to reach Coulomb barrier energies.

From the available information on the intensity out of the CSB for a given charge state we can say that the fourth option will give a larger final exotic ion beam intensity on target. However, this may also be the most costly option.

Table 1: Summary of the LINAC for Exotic Beams

	q/A	Type	Type	Mass range	E range MeV/u
KEK-Tanashi	.≥ 1/30	SCRFQ (RT)	IH (RT)	6 ≤ A ≤ 30	0.172 to 1.05

μ^+-μ^- COLLIDER: μ^+-μ^- GENERATION, CAPTURE AND COOLING

David Neuffer
Fermilab, P. O. Box 500, Batavia IL 60510

Abstract

A μ^+-μ^- collider requires a high-intensity proton source for π-production, a high-acceptance π-μ decay channel, a μ-cooling system, a rapid acceleration system, and a high-luminosity collider ring for the collision of short, intense μ^+-μ^- bunches. Critical problems exist in developing and compressing high-energy proton bunches for producing π's, in capturing π's and their decay μ's, and in cooling μ's into a compressed phase-space at which high luminosity collisions are possible. These problems and some possible solutions are discussed; the current μ^+-μ^- collider research program is described

1 INTRODUCTION

Considerable interest has developed in the possibility of a high-energy high-luminosity μ^+-μ^- collider [1,2,3,4], and a multi-laboratory collaboration has been formed to study this concept [4]. Initially the concept of a 4 TeV collider with a luminosity of $L = 10^{35}cm^{-2}s^{-1}$ was developed [1]. Recently the research has concentrated on developing a design concept for a lower-energy first μ^+-μ^- collider at ~100GeV, and in developing the new technologies needed for that and any μ^+-μ^- collider [5].

Particle physics has identified some clear physics goals for μ^+-μ^- collider technology. Recent LEP and SLC results imply that the Higgs mass is in the 100-170 GeV range. A small energy spread μ^+-μ^- Collider at that energy would be uniquely capable of precise Higgs studies [6]. Also, ν-oscillations have been recently reported. These could be checked by ν-beams that are produced through μ^+-μ^- collider methods of intense π production, μ collection and cooling, with the ν-beams produced by μ-decay in a storage ring [7,8].

The first μ^+-μ^- collider would be a low-energy machine (possibly at 50×50 to 70×70 GeV), designed both to test the basic concepts as well as to provide significant physics at the Higgs mass, and may be at somewhat lower intensity. This machine would be particularly valuable if it could deliver high luminosity at very small energy spreads, matched to the expected Higgs width of $\delta E \sim 1.5$ KeV. Later, higher-energy machines could probe energy frontiers beyond that accessible to existing technology.

Table 1 shows parameters of possible μ^+-μ^- colliders, including a ~100GeV Higgs factory, a 400 GeV and a 4 TeV machine, and Fig. 1 shows a layout view of a 100-GeVcollider facility. The collider requires a high-intensity proton source for π-production, a high-intensity π-production target with a high-acceptance π-μ decay channel, a μ-cooling system to cool the beams to collider requirements, a rapid acceleration system, and a high-luminosity collider ring for the collision of short, intense μ^+-μ^- bunches.

In Table 1, nearly identical proton source parameters are shown for each collider case. This is based on an assumption that a single new high-intensity source is developed and is used to drive different colliders. Also in developing parameters for different energy colliders, we have assumed that the cooling system can cool in 6-D normalized phase space to a fixed emittance, which can then be distributed betweeen transverse and longitudinal for differing collider requirements. (Lower-energy colliders require smaller longitudinal phase-space, and a Higgs Collider should have very small energy spread.) Greater variations in p-source and cooling scenarios are possible.

The critical property of muons in a collider is that the muons decay, with a lifetime of $\tau_\mu = 2.2\ (E_\mu/m_\mu)\ \mu s$. This is sufficient for multiturn acceleration and storage, but only a few hundred turns can be allotted to the μ^+-μ^- collection, cooling, and acceleration, which means that obtaining high luminosity requires frequent production of high-intensity μ-bunches and compressing and cooling the bunches to high densities.

Table 1: Parameter lists for μ^+-μ^- Colliders

Parameter	Higgs Factory (Small-LargeδE)	Top Source	4TeV
Collision Energy ($2E_\mu$)	100	400	4000 GeV
Energy per beam (E_μ)	50	200	2000 GeV
Luminosity ($L=f_0 n_s n_b N_\mu^2/4\pi\sigma^2$)	10^{31}-10^{32}	10^{33}	$10^{35}\,cm^{-2}s^{-1}$
Source Parameters (4 MW p-beam)			
Proton energy(E_p)	16	16	30 GeV
Protons/pulse(N_p)	$4\times2.5\times10^{13}$	$4\times2.5\times10^{13}$	$4\times3\times10^{13}$
Pulse rate(f_0)	15	15	15Hz
μ acceptance(μ/p)	0.2	0.2	.2
μ-survival (N_μ/N_{source})	0.4	0.4	.4
Collider Parameters			
Collider mean radius(R)	50	150	1200m
μ /bunch (N_{μ_c})	4×10^{12}	2×10^{12}	2.5×10^{12}
Number of bunches(n_B)	1	2	2
Storage turns($2n_o$)	1000	1500	1800
Norm. emittance(ε_N)	0.028-.01	10^{-2}	5×10^{-3}cm-rad
μ-beam emittance ($\varepsilon_t=\varepsilon_N/\gamma$)	$(5.6\text{-}2)\times10^{-5}$	5.3×10^{-6}	2.5×10^{-7} cm-rad
Interaction focus β_o	13-4	1	0.3 cm
IR Beam size $\sigma=(\varepsilon\beta_o)^{1/2}$	270-90	23	2.1 μm
δE/E at collisions	0.003-0.12	0.12	0.12%

In this paper we discuss the key technologies which are needed to develop these high intensity μ^+-μ^- beams, identify the critical difficulties, and describe the current

and planned research program on these topics. We also discuss the remaining unsolved problems and challenges.

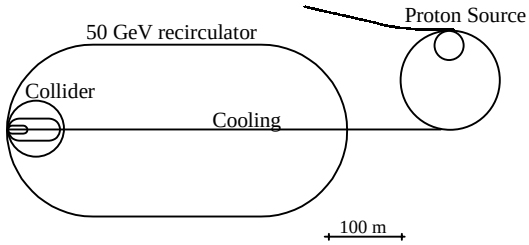

Figure 1. Overview of a 100 GeV μ^+-μ^- Collider facility showing p-source, μ-Cooling, recirculating-linac acceleration (RLA) and collider.

2 PROTON SOURCE

The collider requires an intense source of protons for $\pi \Rightarrow \mu$ production. Present studies indicate that a proton beam at energies of 16-30 GeV at a beam power of ~4 MW is optimal. This is an intensity comparable to that proposed for a KAON factory [9] or a spallation neutron source [10], but with the significant difference that the beam is extracted in short bunches to set up rf rotation (i. e., bunches of 2.5×10^{13}p of ~1 ns). Strategies to reach this intensity are being developed [5], and considerable variation is possible, as long as the high beam power in a bunch structure suitable for development of intense μ-bunches is obtained.

Table 2 shows parameters of a possible proton driver, which consists of a 1 GeV linac, a 3 GeV prebooster and a 16 GeV booster. The parameters are from a Fermilab-based plan for a multipurpose proton source upgrade (K-ν factory/μ-collider/Tevatron, etc.), which would replace the existing Fermilab booster [11]. A new booster tunnel would be required, and the linac would be either extended from its current location or moved.

The 1 GeV Linac is based on the Fermilab 400MeV linac, which consists of a 18 kV magnetron ion source which feeds a 0.75 MV Cockroft-Walton column, followed by a 100 MeV 201 MHz linac, and a 300 MeV 805 MHz side coupled linac. The upgrade requires a magnetron source which can provide 100 mA of beam in 250μs pulses (~1.2×10^{14} H^- ions). The additional 600 MeV structure is an extension of the 805 MHz linac, using 11½ additional modules (131.3m).

The H^- ions are multiturn injected through a foil stripper into the 3 GeV prebooster (500 turns), where they are captured in 6.64 MHz buckets and accelerated as 4 bunches of 2.5×10^{13} protons to 3 GeV in 33ms. The four bunches are then transferred into matched buckets in the 16 GeV booster for acceleration to full energy. At full energy, the bunches are compressed to minimal lengths (σ_z ~ 0.3m) and extracted to the π-production target. The 16 GeV ring circumference is matched to that of the existing Fermilab booster for compatibility with existing Fermilab accelerators.

A key limitation is transverse space charge and the design goal is to keep the space-charge tune-shift $\delta\nu = r_pN/(4\varepsilon_n\beta\gamma^2B)$ less than ~0.25-0.4 throughout the cycle, where r_p is the classical proton radius, N the number of protons, B the bunching factor(average/peak current), and ε_n is the normalized rms emittance. This is minimized by higher injection energies, and large emittances, and larger B. ε_n is increased to ~ 33 mm-mrad (rms) by painting the beam across the foil in multiturn injection. B is conservatively set at 0.25 at injection into the prebooster, which is initially filled with 4 bunches (large B). The beam bunches as it accelerates, and is transferred to the larger ring at 3 GeV, at $\delta\nu \cong 0.25$ (small B but larger γ), with minimal bunch lengths at the extraction bunch rotation.

The beam transports of both rings consist of rapid-cycling separated-function magnets. The peak dipole field is set at 1.3 T in both lattices, and the transition energy ($\gamma_t m_p c^2$) is set above extraction so that the beams are always below transition, which avoids instabilities due to "negative mass" and at transition crossing, and maintains a stable natural chromaticity. The high-γ_t is obtained by use of a "flexible-momentum-compaction" lattice, which gives a tuneable γ_t [12]. The large emittances imply large apertures (13cm for the 3 GeV ring and 10cm for the 16 GeV ring). To minimize eddy currents from rapid-cycling, a high-impedance beam pipe using Inconel or ceramic with conducting wires/strips is needed.

Griffin has developed an acceleration scenario with rf system designs for each ring [13]. The rf cavities are 1m long units with ceramic accelerating gaps and metal-alloy tape-wound cores, with outboard inductive tuners containing NiZn ferrite rings with bias current windings for tuning from 6.6 to 7.4 MHz during the acceleration. Power amplifiers for cavity excitation and transient beam loading compensation are coupled directly to the accelerating gaps. 10 such cavities can generate up to 200 kV in the prebooster, and 40 cavites can produce 1.5 MV in the booster. Bunches injected with ~100ns full-width in the prebooster are compressed to ~20ns after booster acceleration, and rotated to ~6ns (σ_{rms}• 1ns and $\delta E = \pm 200$ MeV) at booster extraction. An inductive insert to cancel space charge is helpful in the final compression. Simulations of this acceleration and bunching have been performed [14].

Some critical experiments testing elements of the proton source design have been performed. A set of inductive ferrite modules was placed in the LANL Proton Storage Ring. Longitudinal space charge effects were reduced without generating instability, and the results supported the use of inductive inserts to cancel space charge [15]. At the BNL AGS experiments in bunching the beam near transition were performed, at parameters similar to the post-acceleration bunching of the proton source. The rms bunch length of the 3 MHz, 8 GeV

bunches was reduced from 6.7 to 2.1 ns [16]. The results support the proposition that initially long proton bunches can be accelerated and compressed to ns lengths, as is required for the μ^+-μ^- collider.

3 π-PRODUCTION AND μ-COLLECTION

The purpose of the production target and subsequent transport is to produce the maximum number of muons which can be subsequently accepted and cooled into collider bunches. From recent studies, maximal capture is obtained by immersing the production target in a high-field solenoid, with sufficient aperture such that most π's are trapped (a 20T solenoid with 7.5cm radius is proposed). This is followed by a solenoid transport which accepts most of the low energy μ's (100-600 MeV/c) produced by π-decay. (see Fig. 2) An rf system within that decay transport reduces the energy spread by "rf rotation", in which the faster particles decelerate while slower ones accelerate. This transforms the short-bunch beam on target producing a large momentum spread in μ's to a longer μ-bunch with reduced δp/p.

Table 2: Parameters of 16 GeV Proton Source

Parameter	Linac	PreBooster	Booster
Final kinetic energy (E_p)	1	3	16 GeV
Pulse rate(f_0)	15	15	15Hz
Protons/pulse($n_B \times N_p$)	$40000 \times 3\ 10^9$	$4 \times 2.5\ 10^{13}$	$4 \times 2.5\ 10^{13}$
Length/circumference	+134	158	474 m
Emittance (95%, 6×rms)	6	200	240πmm-mrad
Dipole packing factor (1.3 T peak field)		0.39	0.575
Aperture		13	10 cm
Tunes(ν_x,ν_y)		3.9,2.4	9.4,4.9
Transition γ (γ_T)		7	25
rf Parameters			
rf frequency(f_{RF})	201→805	6.6-7.4	7.4-7.5MHz
rf harmonic	-	4	12
rf voltage /turn		0.2	1.2 MV
rf length		10	40 m

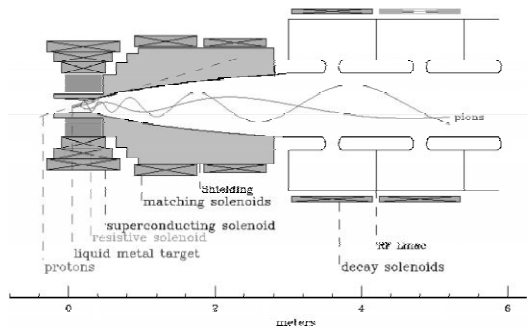

Figure 2. Capture solenoid and match to transport for π→μ decay + rf rotation (from ref. 5).

Extensive simulations on π-production as a function of proton energy, target material and geometry within a capture geometry have been performed, using Monte Carlo codes such as MARS [17] (and DPMJET [18] and ARC [19])and these codes have been verified by comparison with experiments, particularly the recent pion production experiment 910 at BNL [20]. They show that the target should be ~2-3 interaction lengths of a high-density, relatively high-Z material. Optimal proton energy was in the 10-30 GeV range. A target radius of ~1cm appears optimal, maximizing secondary production while minimizing absorption. Tilting the target by 100-150mrad was found to minimize absorption of low-energy π's, which follow helical trajectories through the magnetic region. π-yield is maximal for longitudinal momenta of the same order as the rms transverse momentum (~200 MeV/c). The magnetic field (20T, r=7.5cm) is designed to capture these momenta in helical orbits [21].

About 400 kW of energy is deposited in the target and handling that is a serious problem. Cooling with a thermal bath would lead to large π-absorption and thermal radiation is insufficient. Moving solid metal and flowing liquid jet targets are under consideration. Conducting liquid jets may be distorted by the magnetic fields; however, nonconducting jets are considered. A moving cable or "band-saw" target is possible.

Following the target, the magnetic field is adiabatically decreased and the beam size is increased, following Br^2 = constant to B=5-1.25T (r=15-30cm). The magnetically confined transport continues through a sufficient length for π-decay. This transport also contains a multiharmonic ~30-150MHz rf system embedded in a short-period solenoid transport. In studies rf rotation section solutions with lengths of 40-80m containing a total of 200-500 MV of rf cavities. In simulations ~0.35 μ's (of one sign)/proton are captured from 16-30 GeV protons within an acceptance window of a bunch length of ~6m and δE ~±100 MeV. This is roughly half the number of initially produced π's [1,22,23]. Energy selection in the μ-decay can be used to select a relatively high polarization in the μ-beams [24].

Significant problems exists in designing the rf + focusing system, since it requires combining large low-frequency, relatively high-gradient cavities with relatively high-field superconducting solenoids. Several design iterations have been considered; a recent one (see Fig. 2) uses low-field 1.25T magnets completely outside the cavities; a previous one uses 5T magnets placed in the cavity irises.

An experiment is proposed at the AGS on targetry related issues, which will test some of these systems [25]. It would include tests of liquid jet and other targets, placed within magnets, and then with beam, measuring π-production. An rf cavity with solenoid would be added to test rf rotation components.

4 μ-COOLING

After rf rotation the beam still has both a large momentum spread (δp/p ≅ 10%) and transverse phase space ($\varepsilon_T \cong 0.015$ m-rad). The μ^+-μ^- collider concept relies on ionization cooling to compress the beam phase-space volume to obtain high luminosity. In ionization cooling [2,3], the beam loses transverse and longitudinal

momentum while passing through a material medium, and regains only longitudinal momentum in acceleration cavities. Cooling by large factors requires successive stages of energy loss and reacceleration (20 to 50 stages) [1]. Since ionization cooling does not directly cool the beam longitudinally, these stages must include wedge absorbers at non-zero dispersion to exchange longitudinal and (cooled) transverse phase-space.

The differential equation for rms transverse cooling is:

$$\frac{d\varepsilon_T}{ds} = -\frac{1}{\beta^2 E}\frac{dE}{ds}\varepsilon_T + \frac{\beta_\perp E_s^2}{2\beta^3 m_\mu c^2 L_R E}$$

where the first term is the frictional cooling effect and the second is the multiple scattering heating term. Minimal heating requires that $\beta_\perp$, the betatron focusing amplitude at the absorber, be small, and that L_R, the absorber radiation length, be large (light elements; i.e. Li or Be or H). The energy loss mechanism also causes energy-loss straggling, which naturally sets rms $\delta p/p$ at the ~4% level, even with longitudinal cooling.

The beam dynamics problems in μ-cooling include the beam-material interactions intrinsic to the cooling process, the single-particle beam transport problems associated with obtaining strong foci at the absorbers, the chromatic effects of ~4% $\delta p/p$, dispersion and transverse matching at wedge absorbers, as well as longitudinal motion control with rf reacceleration, and the multiparticle constraints imposed by space-charge and wake-fields in the short intense bunches, where the beam intensifies as it is cooled.

Lattices for cooling have been developed and a favored design includes sequences of solenoid cells with rf cavities and LiH or H absorbers at low-β of the lattice [26]. Another desirable focusing situation is obtained by confining the cooling beam within a high-current Li rod which both focuses and cools the beam [27]. The transport must include arc segments with wedges for cooling longitudinally; obtaining large $\delta p/p$ acceptance configurations with cooling and transport stability is nontrivial.

An outline design scenario for μ-cooling has been developed, and critical sections of the cooling section have been simulated [28,29]. Figure 3 displays transverse phase space before and after a cooling section which cools transverse phase space by $10^4\times$. However an integrated design including the full complexity of the beam transports, reacceleration and bunching, and including nonlinear beam dynamics coupled with the ionization interactions, has not yet been fully developed. Initial cooling experiments verifying cooling efficiency must also be developed. Because effective μ-cooling has not yet been demonstrated and because of its importance in establishing the feasibility of a μ^+-μ^- collider, an extensive R&D program has been established.

Simulation efforts have been intensified, by developing the codes ICOOL [30] and DPGeant [31] and extending their capabilities to include a complete description of μ-material interactions and beam optics. These tools will be used to develop and optimize complete cooling systems.

An experimental collaboration called MUCOOL has been formed in order to establish and demonstrate the technologies needed for effective μ-cooling [32]. In MUCOOL, a muon beam line will be built which would include equipment for precision measurement of muon trajectories entering and leaving a cooling system test channel. Beam cooling sections will be inserted into the test channel, and measurement of muon beams entering and leaving the channel will determine the degree of cooling effectiveness. The cooling sections consist of arrays of absorbers within focusing systems with reacceleration rf. As an initial example a cooling system which includes H_2 cooling elements within strong (15T) solenoids and 800MHz rf cavities has been designed. Detailed designs of rf systems, solenoids and detector components have been developed, and construction of a prototype rf cavity with Be windows has begun [33]. MUCOOL will also include development of Li lenses for cooling, with construction and testing of a 1m long, 1cm radius, 10 T lens.

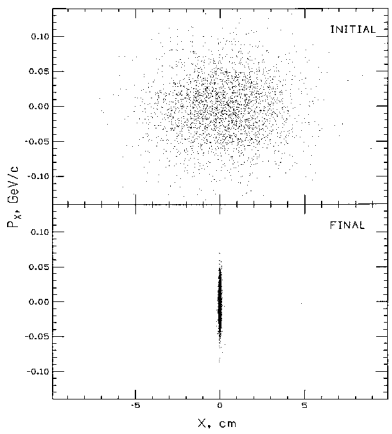

Figure 3. Transverse phase space (p_x-x) before and after a Li lens cooling channel which reduces ε_T from 0.01 to 0.00009 m-rad.

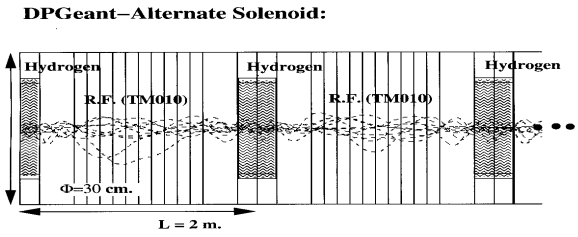

Figure 4. Schematic view of 2 cells of an alternate solenoid cooling system, with H_2 absorbers and 1.3m multicell Cu copper cavities with Be windows. Simulation tracks through the transport are shown.

5 μ-ACCELERATION AND COLLISIONS

Acceleration must be completed before μ-decay. This constraint can be written as the equation:

$$eV_{rf}' >> \frac{m_\mu c^2}{L_\mu} \cong 0.16 \text{ MeV/m},$$

where eV_{rf}' is the acceleration rate, and L_μ is the μ decay length (660m). Relatively fast acceleration is required, and two alternatives have been developed: recirculating linacs (RLAs) or very rapid-cycling synchrotrons (RCS). In both cases significant challenges exist in obtaining acceleration without phase-space dilution. Simulations show that longitudinal matching is relatively straightforward [34], and transverse matching is possible. However precise matching in rapid-cycling systems may be difficult, and beam decay within the transport and acceleration must be tolerated.

After acceleration to full energy, the μ^+-μ^- beams are inserted into a storage ring for multiturn collisions at full energy until μ-decay. The number of storage turns before decay is ~300B, where B is the mean ring bending field in T, or ~2000 turns at B=6.7 T. High luminosity requires that the beams be focussed to small spots and short bunches at the interaction points (IPs). It also implies high beam densities and that could allow multiparticle instabilities. The small focus at the IP with the geometric and chromatic acceptance requirements is a significant design challenge [35].

6 CURRENT R&D PROGRAM

Following initial studies presented at Snowmass, the high-energy physics advisory panel recommended expanded research including simulations and experiments to determine the feasibility of μ^+-μ^- colliders [36]. In response the μ^+-μ^- collaboration is expanding its efforts, including experiments on targetry/production at BNL and cooling at Fermilab. (discussed above) Much research and innovation is needed toward obtaining complete and optimal solutions to the difficult problems in developing a practical μ^+-μ^- collider.

We acknowledge the assistance of the many contributors to the μ^+-μ^- collider studies, based at BNL, Fermilab, LBL, and other universities and laboratories, including R. Palmer, S. Geer, A. Tollestrup, A. Sessler, J. Gallardo, D. Cline, K. MacDonald, R. Noble and many others.

BEPC INJECTOR UPGRADE

-For-
Electron Linac Division
Pei, Guoxi
Institute of High Energy Physics, Academia Sinica, Beijing 100039,China

Abstract

BEPC is a 2.2×2 GeV electron- positron collider with luminosity of $2\times10^{30}cm^{-2}s^{-1}$. Its injector is a 1.3GeV electron Linac. As a part of BEPC upgrades for higher luminosity, the Linac energy will be increased to 1.55 GeV of J/• physics energy region, and further to 1.75 GeV or higher. The main measures we took are: 1) to use 4 sets of high power RF sources, including newly designed 65MW klystrons and 150 MW modulators; 2) to rebuild local control system for more stable operation. After a few years effort with collaborating companies, main upgrades and relevant improvements (15 dB high power directional coupler, high power vacuum valve, RF pulse widening to increase the multiplication factor of SLED etc.) are completed. Now the machine can be operated stably at 1.55GeV.

Keywords: BEPC injector, high power RF source, Linac control system

1 INTRODUCTION

Full energy injection is necessary for any high luminosity storage rings, such as PEP-II• KEKB etc., because it can avoid beam loss during ramping or omit ramping process to shorten the injection time. For BES, the most important physics is J/• of 1.55GeV. So, to increase BEPC injector energy from 1.3GeV to 1.55GeV for J/• and further to 1.75GeV for other physics is significant.

BEPC injector [1], built in 1987, was a 1.3GeV• 200-meter electron Linac. HK-1 klystrons (35MW) were the RF power sources. The standard acceleration unit consists of four 3-meter constant gradient accelerator tubes, driven by one klystron with SLED. The energy gain can be expressed as W (MeV) = 20 M $\sqrt{P}$, where M is the multiplication factor of SLED, and P the klystron output power. It is clear that higher energy can be obtained by both increasing the klystron output power and enhancing multiplication factor. There are 12 such acceleration units downstream of BEPC positron production system. If we replace three of them with 65MW klystrons (operating at 45MW at the first stage), we can hope to get 200MeV energy gain. For the rest RF power supplies, we are going to make some modifications. Widening the pulse width from 3.2•s to 3.7•s by adjusting the modulator PFN, we can increase the multiplication factor of SLED from 1.4 to 1.5. Using higher ratio of 1:14 pulse transformer, we can arise the pulse voltage a little bit from 260KV to 270KV, so that the average output power of the klystrons can be increased from 19MW to 22MW. By all measures mentioned above, it is hopeful to increase the positron energy to 1.75GeV as shown in Table 1.

Table 1: Energy Upgrade

	Before upgrade	After Upgrade
RF Power Source	11×19MW	8×22MW 3×45MW
RF pulse width	3.2μS	3.7μS
EMF of SLED	1.4	1.5
Injector Energy	1.3GeV	1.75GeV

Besides energy upgrade, another important upgrade is to rebuild the local control system. The old one was manually operated, complex and inconvenient, especially in our case, both electrons and positrons use the same beam line. When we made mode change, say from e^- to e^+, a lot parameters should be changed. Computer can do it very easily.

In what follows, the author will present the technique issues underneath the energy upgrade and the local control system rebuild.

2 TECHNIQUE UPGRADE

2.1 65MW klystron

Table 2: 65MW Specifications and Test Results

Parameters	Design	1st Tube	2nd Tube	3rd Tube
Frequency (MHz)	2856	2856	2856	2856
Cathode	Dispenser	Dispenser	Dispenser	Dispenser
Heater Volt.(V)	22	20.5	23	21.6
Heater Curr.(A)	36	38	41	38
Pulse Volt.(KV)	350	330±5	342	350
Pulse Curr. (A)	415	406	401	444.1

Pout •MW•	65	50.4	58.5*,66**	63*,76**
RF Width (•s)	3.5	3.0	3.3~3.35	2.5~3.0
Efficiency (%)	45	37.6	42.6*,48**	
Gain (dB)	51		~50	
Lifetime (Hrs)	•15000	3500	8000	Alive

*Measured by thermocoupler

**Measured by peak power meter

The new high power klystron[2] was designed in 1992, the prototype was SLAC 5045 tube. After many trials, we got the first tube in 1995, manufactured by 4404 company in Wuhan. The output power on the test stand was about 50MW, not bad for the first tube. In succession, we totally got three 65MW klystrons from the company. Their test

results and operation records at the gallery are listed in Table 2. From this table we can see, the output power is acceptable both on the test stand and at the gallery, but the lifetime is too short. Now we are trying to open the two failure tubes and analyse the problems with company people.

2.2 150MW modulator

Referring to high power modulator techniques of world class labs, such as SLAC, KEK, DESY, etc., and our own 80MW modulator experience, we designed the 150MW modulators [3] for 65MW klystrons. The specifications and pulse voltage output waveform are listed separately in Table 3 and Figure 1. We have made four 150MW modulators, two of them are now working at klystron gallery for a few years, very stable and low noise.

Table 3: Parameters of New and Old Modulators

	Old	New
Output Power	80MW	150MV
Output High Voltage	260KV	350KV
Repetition Rate	12.5Hz	25Hz
Anode Voltage of Thyratron	42KV	44KV
Anode Current of Thyratron	3240A	6500A
Pulse Transformer	1:12	1:15
Pulse Width	3.0•s	3.5•s
Rise Time	0.7•s	0.9•s
PFN Impedance	6.2•	3.3•
PFN Total Capacitance	0.34•f	0.9•f
Charging Current	3.7A	2.53A
Charging Time	5.5ms	2.6ms
Charging Inductance	10H	30H

2.3 Local control system

Linac control system[4] reconstruction includes following parts as illustrated in Fig.2.

a. *RF power source*

A new local control system based on the PLC was installed and the communication between the control room and modulators was accomplished. PLC was used to replace the original relay control logic circuits of the modulators. The control PC inspects the PLCs through the RS-232 port. The DC voltage, charging current, external failure signal and filament current are sent to the control room. DC voltage can be remotely controlled.

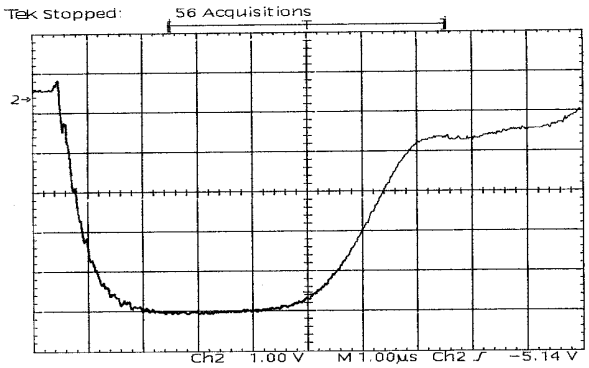

Figure 1: 150MW Modulator Output Waveforme

b. *Magnet power supplies*

There are 88 sets of DC power supplies used for quadrupoles, steering coils and focusing solenoids. Now the adjustment can simply be done by the PCs. Good data are saved on the hard disk for further analysis and reference.

c. *Vacuum*

A PC is used for inspecting the status of the Linac vacuum. All parameters can be shown on the screen with proper colours. When there is any trouble, a sound and red colour warning will appear.

d. Mode change and RF phase

As mentioned above, in our Linac e^- and e^+ beams use the same beam line. When changing modes, we need switch the stepping motor to arise or put down the target, and adjust the capture section RF phase and all the optical parameters downstream. In order to get the highest energy, the RF phases of the klystrons are controlled. All these are now accomplished by a PC.

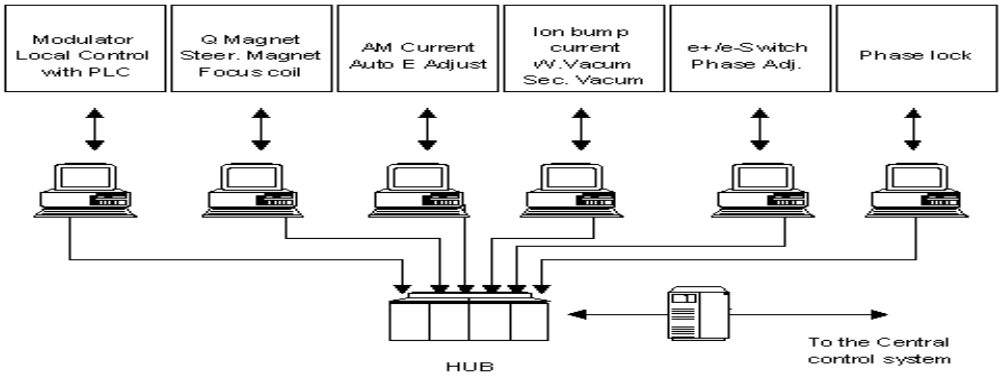

Figure 2: Linac Control System

2.4 High power vacuum valve[5]

Between klystron window and the downstream RF structure, there is an valve for vacuum separation. The one used for HK-1 klystron is SLAC old design, which is Indium sealed and only can bear 35MW power. For 65MW klystron, we must use new one. The new design is a two part U type waveguide. These two parts can be set apart a little bit to let seal plate with fluorine O ring insert into the gap to separate vacuum.

2.5 15dB high power coupler

In our system, the first klystron is driven by an RF amplifier. The following tubes are driven with part of the power from No.1 tube by directional coupler. In order to ensure enough driving power for 65MW klystrons, 15dB directional coupler was designed and used to replace the original 20dB one.

3 CONCLUSION

Except the lifetime of 65MW klystron need to be further studied, all other upgrades have reached the design targets. They are working smoothly on the machine, especially the modulators and local control system. Because only two 65MW klystrons were installed (including one SLAC 5045 tube) at the gallery, not four as planned ,the linac can only work at 1.55GeV.

DEMONSTRATION OF TWO-BEAM ACCELERATION IN CTF II

R. Bossart, H.H. Braun, G. Carron, M. Chanudet, F. Chautard, J.P. Delahaye, J.C. Godot, S. Hutchins, I. Kamber, C. Martinez, G. Suberlucq, P. Tenenbaum*, L. Thorndahl, M. Valentini, I. Wilson, W. Wuensch, CERN, 1211 Geneva 23, Switzerland

Abstract

The second phase of the Compact LInear Collider (CLIC) Test Facility (CTF II) at CERN has demonstrated the feasibility of two-beam acceleration at 30 GHz using a high-charge drive beam, running parallel to the main beam, as the RF power source. To date accelerating gradients of 59 MV/m at 30 GHz have been achieved. In CTF II, the two beams are generated by 3 GHz RF photo-injectors and are accelerated in 3 GHz linacs, before injection into the 30 GHz modules. The drive beam linac has to accelerate a 16 ns long train of 48 bunches, each with a nominal charge of 13.4 nC. To cope with the very substantial beam-loading special accelerating structures are used (running slightly off the bunch repetition frequency). A magnetic chicane compresses the bunches to less than 5 ps fwhm, this is needed for efficient 30 GHz power generation. The 30 GHz modules are fully-engineered representative sections of CLIC, they include a 30 GHz decelerator for the drive beam, a 30 GHz accelerator for the main beam, high resolution BPM's and a wire-based active alignment system. The performance achieved so far, as well as the operational experience with the first accelerator of this type, are reported.

1 INTRODUCTION

After successfully completing the first phase of CTF in 1995 [1], the construction of CTF II was launched in 1996 with the following goals:

1. To demonstrate the feasibility of the CLIC two-beam accelerator scheme [2] and its associated 30 GHz technology.
2. To build and test prototypes of the 30 GHz modules
3. To study the dynamics of a high-charge, multibunch drive beam.
4. To test the active alignment system in a realistic accelerator environment.
5. To test CLIC beam monitoring equipment.

The layout of CTF II with its two beam lines is shown in figure 1. The drive beam generates 30 GHz power, while the main beam probes the accelerating field in the 30 GHz accelerator. Both beams are generated by S-band RF-photo-injectors. The RF-photo-injectors have photo-cathodes illuminated by a common short pulse (8 ps fwhm) laser. The cathodes and the laser system are described in [3].

The main beam operates with a single bunch of 1 nC charge. A second bunch, with a variable delay relative to the first, can be added later to allow wakefield studies in the 30 GHz structures. Before being injected into the 30 GHz accelerator the main beam is accelerated to 46 MeV in an S-band travelling wave structure. This is necessary to obtain a small enough geometric emittance to fit into the small acceptance of the 30 GHz accelerating structures which have a beam aperture of only 4 mm diameter. Magnetic spectrometers before and after the 30 GHz accelerator are used to measure the beam energy. The details of the 30 GHz accelerator are described in [4].

The drive beam RF-photo-injector is a 3-cell design optimised for high charge acceleration [5]. The nominal charge is 640 nC in 48 bunches with a bunch spacing of 10 cm. The photo-injector accelerates these bunches to 6 MeV. The photo-injector is followed by two short travelling wave S-band structures optimised for high-charge acceleration [6]. These structures are also used

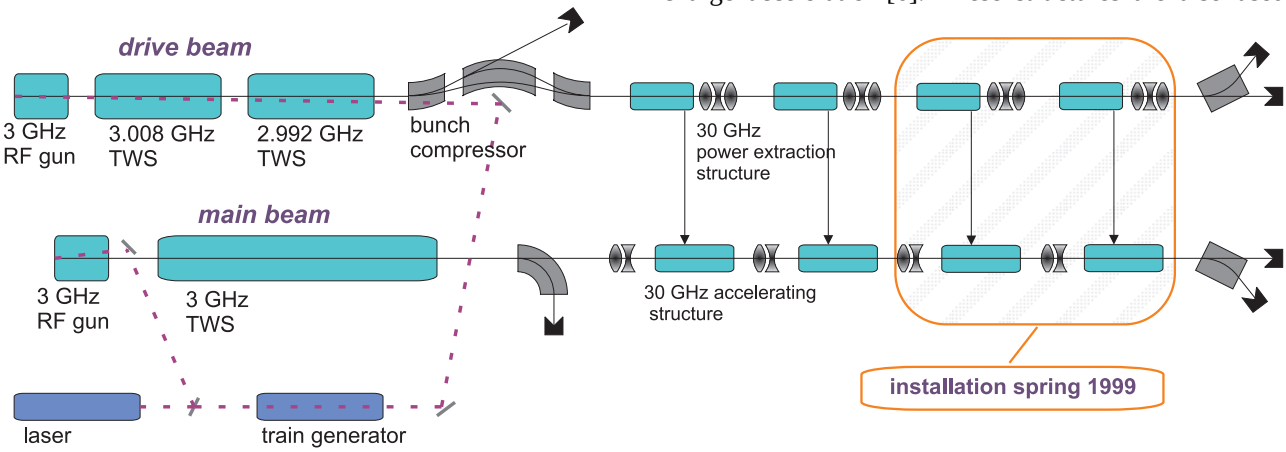

Figure 1: Layout of CTF II (TWS=travelling wave structure)

* Present address: Stanford Linear Accelerator Center, Stanford, California

for beam-loading compensation, as described in below. As a result of the counteracting longitudinal RF focusing and space-charge defocusing forces, the bunch length after acceleration is about 8 ps fwhm for the nominal charge. A magnetic chicane, together with proper phasing in the accelerating structures, compresses the bunches to ≤ 5 ps; this is needed for efficient 30 GHz power production. The first magnet of the chicane is also used as a spectrometer magnet. After bunch compression, the beam is injected into the 30 GHz decelerator [4] where a part of its energy is converted into 30 GHz power. A downstream spectrometer magnet measures the energy of the beam after power extraction.

2 DRIVE BEAM ACCELERATION AND BEAM LOADING COMPENSATION

The nominal drive beam train of 640 nC during 16 ns extracts 2.2 GW of power from the two 3 GHz accelerating sections. The related energy has to be provided by the energy stored in the accelerating structures. For this reason, the structures are operated at a high field (design 60 MV/m, achieved 36 MV/m) and their geometry is optimised for a low r'/Q (2.2 kΩ/m) to maximise the stored energy. Nevertheless the energy drop due to transient beam-loading would be 17.5 MeV at nominal charge. Since such an energy spread is neither acceptable for the bunch compression nor for the transverse matching into the 30 GHz decelerator, a two-frequency beam-loading compensation is used. The two accelerating structures operate 7.8 MHz below and above the drive-beam bunch repetition frequency of 2998.6 MHz. This introduces a change of RF phase from bunch to bunch which allows an approximate compensation of the beam-loading. Due to the curvature of the RF wave, a residual energy spread remains, leading to somewhat lower energies of the early and late bunches compared with bunches at the center of the train. This effect is visible in figure 2, which shows a longitudinal phase-space image of a 24 bunch train with a total charge of 120 nC. This is taken with a streak camera from a transition radiation screen in the first drive beam spectrometer. A plot of the calculated energy distribution is shown for comparison. For a 48 bunch train the total energy variation from bunch to bunch due to this effect is 7%. Without beam loading compensation it would be 30% for the nominal charge. By using two frequencies, the single bunch energy spread introduced in the 1st structure is compensated by the 2nd structure. However, using correct phasing and a slight reduction of the field amplitude in the 2nd structure, it is possible to introduce a correlated energy spread in the individual bunches which is approximately equal for all bunches. This is essential for bunch compression in the magnetic chicane. Adding a correlated energy spread to allow for bunch compression, the energy spread with beam loading compensation increases to 14%.

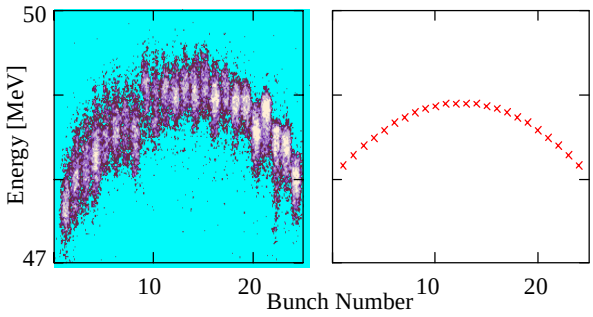

Figure 2: Longitudinal phase space with beam loading compensation. Left side: measured; right side: predicted.

3 TWO BEAM ACCELERATION AT 30 GHZ

In June and July of this year two-beam acceleration was tested by simultaneously passing the drive beam through the 30 GHz decelerator and the main beam through the 30 GHz accelerator. At present two power extraction structures are installed in the 30 GHz decelerator. Each power extraction structure is connected to one 30 GHz accelerating structure of the main beam. One of the power extraction structures is an older prototype (soon to be replaced) and gives about half the power of the other. The numbers quoted below for power and accelerating field refer to those measured with the newer structure. The following quantities were measured: drive beam charge before and after the decelerator, drive beam bunch length [7], main beam charge and bunch length, drive beam momentum before and after the decelerator, 30 GHz power (input, reflected and transmitted) for each of the two accelerating structures and main beam momentum. Table 1 summarises the performance achieved in comparison with the design goals. As already experienced in CTF I, no RF breakdowns were observed in either the 30 GHz waveguide networks or the structures. The 30 GHz power production is limited for the moment by the drive beam charge which can be transported through the decelerator.

		design	achieved
drive beam	maximum accelerated charge	640 nC	755 nC
	acc. charge giving max. 30 GHz power	640 nC	475 nC
	max. charge through decelerator	640 nC	374 nC
	number of bunches	48	48
	bunch length fwhm	5 ps	5 ps
30 GHz power at output of power extraction structure		71 MW	27 MW
30 GHz power pulse length		14 ns	14 ns
mean accelerating field in 30 GHz acc. structure		95 MV/m	59 MV/m

Table 1: Nominal and achieved performance.

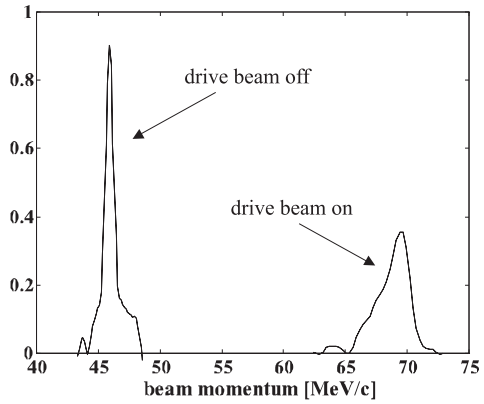

Figure 3: Momentum spectra of the main beam measured with drive beam on and off.

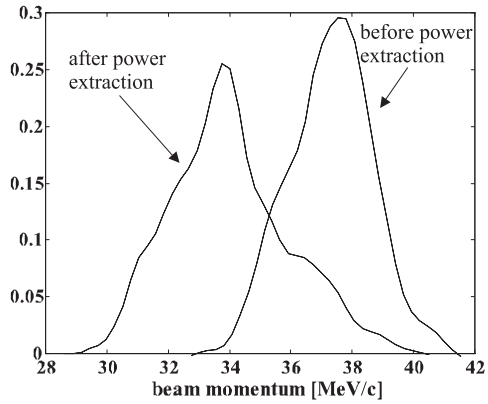

Figure 4: Drive beam momentum spectra measured before and after the 30 GHz power extraction structures.

Possible reasons for the still unsatisfactory transmission at high charges include the gradient in the drive beam accelerator which is still below the design value, transverse matching problems and various problems with the laser system.

Figure 3 shows energy spectra of the main beam measured downstream of the 30 GHz accelerator with and without 30 GHz acceleration. The larger energy spread of the accelerated beam is caused by laser energy jitters and by the bunch-length of the main beam, which is 6 ps fwhm corresponding to a phase extension of 65o at 30 GHz. Figure 4 shows the drive beam energy spectra before and after passage through the 30 GHz decelerator. These spectra were measured with a drive beam charge of 400 nC and a transmission of 85% in the decelerator. The measured power and acceleration are compatible with the values expected from theory. However, the precision of this comparison is presently limited by the beam losses in the decelerator.

4 SINGLE BUNCH EXPERIMENTS

The drive beam accelerator of CTF II can also be operated in single bunch mode. This mode of operation allows the study of the dynamics of single bunches with high charges. Recently a single bunch of 112 nC was produced and accelerated. Effects leading to emittance growth in the magnetic bunch compressor were studied experimentally [8]. The single bunch mode of operation is also used for beam monitor testing [9].

5 CONCLUSION AND OUTLOOK

The CTF II has demonstrated the principle of two-beam acceleration at 30 GHz. Although not all the design specifications have been met until now, the accelerating gradients achieved are already well above those in more conventional electron accelerators, and the charge and beam current obtained from the drive beam accelerator are unprecedented for RF-photo-injectors.

For the coming year it is planned to add two more power extraction and accelerating structures. A test with a special power extraction structure of considerably higher shunt impedance is foreseen, which will allow to generate even higher power than with the standard structures. This power will be used to explore the as yet unknown gradient limits of 30 GHz structures.

To improve the quality of the drive beam a new RF-photo-injector [10] and an idler cavity are under construction. The new gun will improve the drive beam quality while the idler cavity will reduce the residual energy spread of the beam loading compensation scheme.

Abstract

Hardware R&D on the C-band (5712 MHz) RF-system for an electron/positron linear collider started in 1996 at KEK. During two years R&D, we have developed two 50-MW C-band klystrons (TOSHIBA E3746 #1, #2), the "Smart Modulator", the traveling-wave resonator (TWR) and the cold model of the rf-pulse compressor [1,2]. A C-band accelerating structure, which uses the choke-mode cavity, is under development. Its HOM-damping performance will be tested at ASSET beam-line in this year. Since the C-band system is designed to accelerate high-current beams at a high accelerating gradient of 36 MV/m, there are various applications in the future beside the linear collider. For example, we can build an injector for the SR-ring in a limited site-length. Additionally, since the C-band components are compact, it has a big potentiality to be widely used in various medical and industrial applications, such as an electron-beam radiotherapy machine, or a compact non-destructive X-ray imaging system.

1 INTRODUCTION

The e^+e^- linear collider is a large-scale project. In the main linac for two beams, we need more than 7000 accelerating structures, 3500 klystrons and their pulse modulators. Therefore, the hardware has to meet the followings:

(1) Highly reliable,
(2) Simple,
(3) Low construction cost,
(4) Reasonably power efficient and
(5) Operationally ease.

The above list provides a guideline and boundary conditions to our R&D works. Among the system parameters, the choice of the drive rf-frequency plays the most important role concerning to the system performance as well as the hardware details. We proposed the C-band frequency as the best choice to meet all of the demands listed above [1].

2 SYSTEM DESCRIPTION

Figure 1 shows a schematic diagram of one unit in the main linac rf-system. The deigned value of the accelerating gradient in ref. [1] was 32 MV/m. It is now 36 MV/m, which has been increased by a new idea concerning the RF pulse compressor (see later) and improved shunt impedance in the accelerating structure. The required number of unit for 500 GeV c.m. energy was reduced to 1800 units (it was 2040 units).

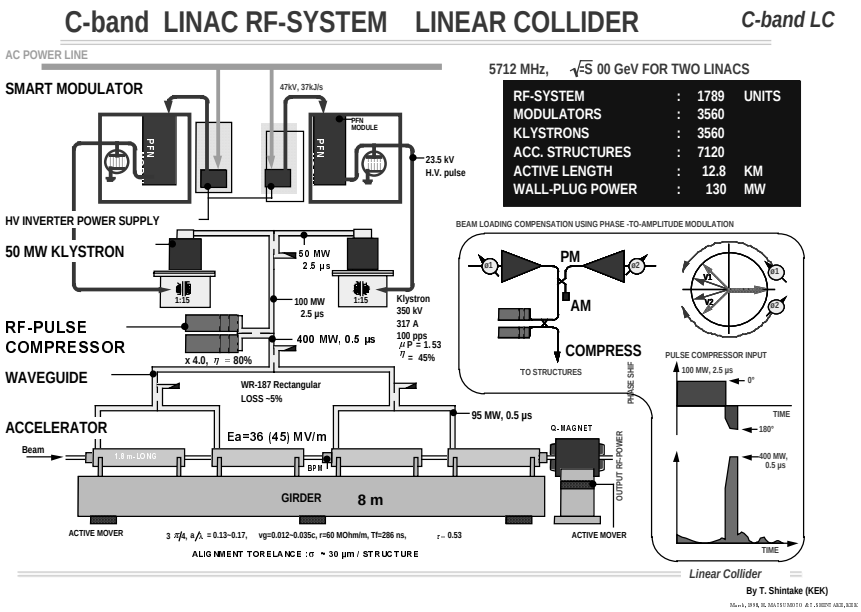

Fig. 1 One unit of the C-band RF system.

3 PROGRESS ON HARDWARE R&D

3.1 Waveguide Components

Since this is the first project to use the C-band frequency as the beam acceleration, no high-power waveguide component of vacuum-tight design was available in the market. We newly developed various waveguide components, including a ceramic window, at EIA-WR187 size (Fig.2). [3] We assembled a traveling-wave resonator (TWR), and tested it up to 90 MW of the accumulated power with 2.4 μsec pulse-width. No difficulty concerning to the high-power operation was found at this power level.

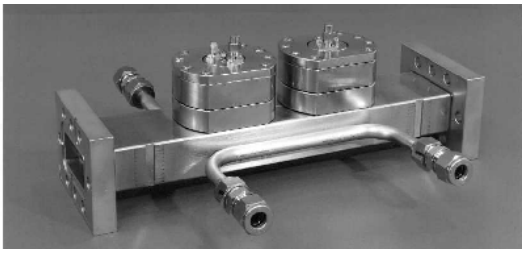

Fig.2 C-band waveguide component (Bethe holecoupler).

3.2 RF Pulse Compressor

The authors have proposed a new type RF pulse compressor in 1996 [4]. It can generate a flat output pulse from an energy-storage cavity of 1 meter long. It eliminated the long pipes required in SLED-II type compressor. To compensate ringing response associated with the multi-cell coupled cavity, the amplitude modulation is applied on the input RF power. In 1997, we demonstrated generation of a flat pulse using a cold model pulse-compressor cavity (Fig. 3, Fig. 4). The energy gain of 3.25 was obtained [5].

To improve the power gain, we started a study on a new idea: recovering rf-energy from the front part of the modulator pulse. A phase modulator is used to compensate a phase slip in the klystron. Since the pulse-compression cavity acts as the energy storage, the rf-energy in the front part is accumulated and contributes to the output energy.

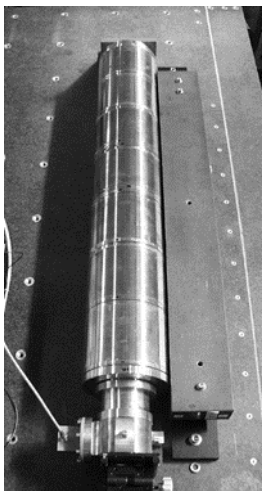

Fig. 3 Three-cell pulse compression cavity.

A tentative test showed enhancement of the power gain of 1.3 [6]. To apply this idea in the practical accelerators, we need to develop a RF feedback module (IQ-modulator and demodulator, a microprocessor and a solid-state RF amplifier of 500 W output level). This RF feedback module will be also useful in various accelerators to compensate the beam loading effects, such as in a beam buncher system or a rf-gun to generate a stable beam into FEL oscillators.

3.3 C-band Klystron R&D

In 1996 FY, we developed the first tube E3746 #1, which employed conventional design: the single-gap output structure and the solenoid focus. It generated 50 MW power into 1 μsec width at 20 pps repetition [7,8]. We continuously operated the klystron at C-band test-lab until the second tube being ready.

In 1997 FY, we developed the second tube E3746 #2. This is an upgrade version of the first klystron, in which the single-gap output structure was replaced with a newly developed 3-cell traveling-wave output structure shown in Fig. 5. The second tube generated 54 MW peak power in 2.5 μsec at 50 pps. The power efficiency was improved to 44%. Fig. 6 shows the output waveform from the second klystron. Details are reported at this conference [9].

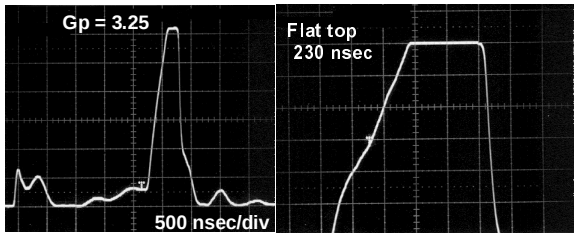

Fig. 4 Flat-top rf pulse compression using 1-m long 3-cell delay-line.

Recently we have developed an advanced calorimetric method for the absolute rf-power measurement. To eliminate uncertainty in flow-rate measurement of cooling water, we introduced an electric heater in the cooling water system. Since we can accurately determine the dissipation power on the heater by VI product, this method enables to determine the absolute power accurately.

3.4 Smart Modulator (Klystron Power Supply)

The C-band klystron uses a high-voltage pulse of –350 kV peak and 3.5 μsec width. The conventional PFN line-type pulse-modulator is suitable to generate this pulse, and no essential difficulties are expected. Therefore, R&D work was focused on reducing cost and improving reliability. In 1993, Prof. M. H. Cho and Prof. H.

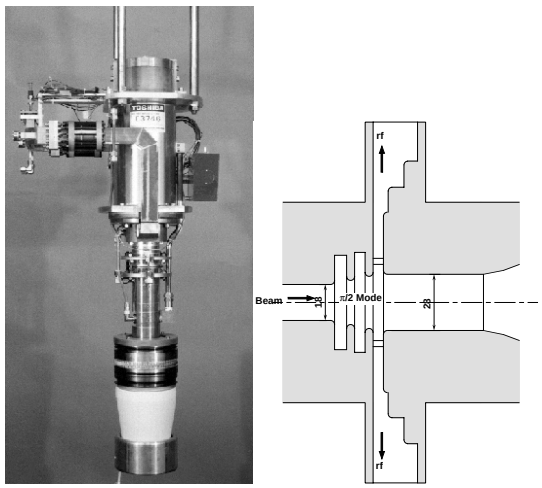

Fig. 5 The C-band klystron: TOSHIBA E3746 #2, and its traveling-wave output structure..

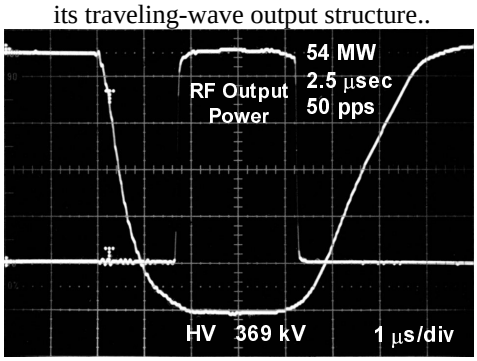

Fig. 6 RF output power of the second E3746 C-band klystron.

Matsumoto proposed a concept of “Smart Modulator”, which is an ideal modulator: simple, compact, reliable and low cost. As the first step, we developed a prototype of the smart modulator, which is

1. Direct HV charging from an inverter power supply.
2. No deQ-ing circuit.
3. Much smaller size than conventional modulators.
4. Uses existing reliable circuit components.

The developed smart-modulator is shown in Fig. 7. The main cabinet size is 1600x2000x1200 mm only, which is now running daily driving the 50 MW klystron [10,11,12].

Fig. 7. The smart-modulator (white box at upper-right), the C-band klystron (middle), and the C-band members.

3.5 Accelerating Structure

A C-band accelerating structure is under development at MITSUBISHI heavy industry [13]. It uses a special rf cavity called the choke-mode cavity, which strongly damps all higher-order-modes using microwave absorbers made by SiC [14]. The rf power for the beam acceleration is confined in the main cavity by means of a choke-filter. Figure 8 shows the structure under fabrication. It uses Matsumoto-coupler for symmetric field at input/output coupler. To align beams on its center, two RF-BPMs will be mounted at both ends, and one HOM pickup will be used at middile. The basic performance of the RF-BPM was tested at FFTB-beam line, and 25 nm of resolution was measured [15]. The RF-BPM in Fig. 8 is the upgraded version, which does not have the common-mode leakage. The HOM damping performance will be tested at ASSET beam line of SLAC in this year.

4 FUTURE R&D

The first stage of the R&D was successful. For the next step, in order to examine the system performance under a realistic situation, one-unit of the C-band system has to be installed and tested with beam in an existing machine, such as KEK-B injector. Daily operation will tell us what we should do next.

ACKNOWLEDGMENT

We thank Mr. Kazuharu Nishitani for his various contributions to build the experimental equipment. We thank Profs. H. Sugawara, G. A. Loew, W. Namkung and Prof. G. A. Voss, for their encouragement to our work. We also thank all contributors to this project.

THE DRIVE BEAM DECELERATOR OF CLIC

A. Riche, D. Schulte, CERN, Geneva, Switzerland

Abstract

In the Compact Linear Collider (CLIC) a high-current, low-energy beam will be decelerated in a chain of power extraction structures to produce the RF-power necessary to accelerate a low-current, high-energy beam in the main linac. The transverse dynamics of the decelerated beam is discussed, based on results of the programs WAKE [1] and PLACET [2]. The very large energy spread and strong transverse wakefields as well as the high group velocity of these fields and the considerable length of the bunch train are important factors. Static and dynamic imperfections are considered including ground motion. The choice of parameters for the structures is investigated. A promising beam-based alignment technique is presented that makes use of a low emittance beam.

1 INTRODUCTION

CLIC [3] is based on a two-beam scheme. The RF power used to accelerate the main beam (at $30\,\mathrm{GHz}$) is produced by a second high-current low-energy beam (drive beam) running parallel to the main one [4], which is decelerated in power extraction structures, to produce the RF power.

Each drive beam decelerator is on average $767\,\mathrm{m}$ long and contains 550 power extraction structures. The train producing the power consists of 1824 bunches. Along the train the bunch charge increases over the first 320 bunches and then stays constant (at $17.6\,\mathrm{nC}$). This charge ramp is necessary to compensate the beam-loading in the main linac [5]. In the following simulations, the charge of the first bunch is assumed to be half of the charge of a bunch on the flat top. Within the ramp the bunch charge increases linearly with the bunch number.

Depending on the beam-loading compensation in the drive beam accelerator, the ramp may be different from the model used and the flat top may be followed by a tail of bunches with decreasing charge. However, first simulations indicate that the different ramps have little influence.

The bunches are separated by a distance of $2\,\mathrm{cm}$, have a length of $\sigma_z = 400\,\mu\mathrm{m}$ and have normalised transverse emittances of $\gamma\epsilon_x = \gamma\epsilon_y = 150\,\mu\mathrm{m}$. The initial energy is $E = 1.2\,\mathrm{GeV}$ and the initial energy spread is assumed to be $\sigma_E/E \approx 1\,\%$ RMS [6]. During deceleration the energy spread increases to about $90\,\%$ of the initial energy.

2 MODULE LAYOUT

To simplify the longitudinal matching of the drive beam decelerators and the main linac they both consist of modules of equal length. A main linac module contains up to four structures—one to four of which can be replaced by quadrupoles if necessary. A drive beam decelerator module consists of two structures, quadrupoles and beam position monitors (BPMs) forming a FODO-cell. Each drive beam structure has an active length of $0.8\,\mathrm{m}$ and feeds two main linac structures, its total power is $512\,\mathrm{MW}$.

In modules where main linac structures are replaced by quadrupoles, decelerator structures will be replaced by drifts or special types that feed one structure only.

3 STRUCTURE MODEL

Here, only on the so-called four-waveguide structure [7] is considered. The inner bore of the structures is cylindrically symmetric, except for the four longitudinal waveguides that are cut into the surface.

The longitudinal and transverse wakefields can each be described very well by a single mode. These modes have almost the same frequency—longitudinally it is $30\,\mathrm{GHz}$, transverly it is $24\,\mathrm{MHz}$ lower.

In contrast to most structures in accelerators, the group velocities of the longitudinal and transverse modes $\beta_{\parallel,\perp}$ are comparable to the speed of light—e.g. $\beta_\parallel \approx \beta_\perp \approx 0.44c$.

The maximum, minimum and mean energy of each bunch is shown in Fig. 1 at the end of the decelerator.

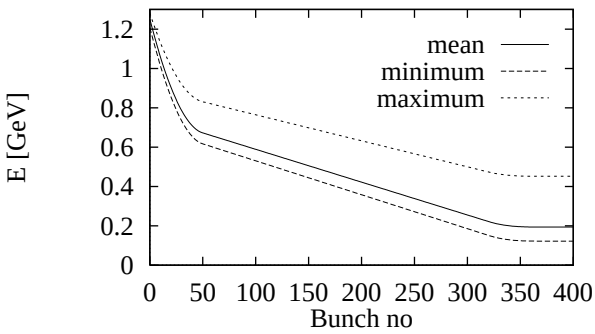

Figure 1: The final minimum, maximum and mean energy of each bunch as a function of the bunch number. Only the first 400 bunches are shown, on the flat top the values are constant.

4 LATTICE

The lattice consists of simple FODO-cells with a quadrupole spacing of half a girder length or $1.115\,\mathrm{m}$. Ignoring the additional drifts or special structures, each decelerator consists of 275 modules supporting 550 structures. For the same normalised emittance the maximum envelope in a periodic lattice is given by the particles with the lowest energy [8]. The lattice is scaled to have constant beta-functions for the lowest energy. The dependence of the final envelope on the final energy is shown in Fig. 2. A phase advance of $\Delta\Phi = 88°$ per cell was chosen. Larger phase advances reduce the sensitivity to transverse wakefields but increase the maximum transverse beam size. The three-sigma envelope of the beam is shown in Fig. 3. It shows the adiabatic undamping due to the decreasing energy.

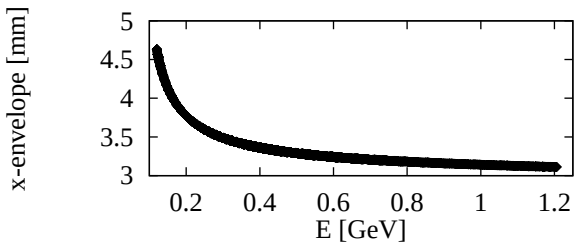

Figure 2: Final beam size versus final energy in the drive beam.

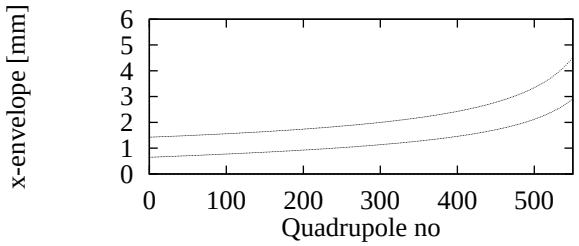

Figure 3: The envelope of a three-sigma beam along the decelerator in the focusing and defocusing quadrupoles.

5 STABILITY

In order to find the optimum iris radius a of the decelerating structures a scaling law for the longitudinal and transverse wakefields was derived using three different structures with $a = 10,\ 12$ and $20\,\mathrm{mm}$. The wakefields were found to scale as $\hat{W}_\perp \propto a^{-5}$ and $\hat{W}_L \propto a^{-3}$. The group velocity remains about constant.

Simulations were performed for different values of a and Q, ignoring the field non-uniformity. The layout of the decelerator was kept constant. In order to achieve the same power and initial-to-final energy ratio, the charge per bunch and initial energy were adjusted. Figure 4 shows the maximum amplitude reached by a three-sigma particle. The initial beam offset was $\Delta x = \sigma_x$. As can be seen, larger radii lead to a more stable beam. For very small values of Q, the envelope is larger at large radii, just because the emittance is larger due to the smaller energy.

The maximum charge per bunch is fixed by the drive beam injector to about $20\,\mathrm{nC}$. The parameters are thus chosen to be $a = 12\,\mathrm{mm}$ corresponding to $R/Q = 31\,\Omega/\mathrm{m}$. The necessary output power of $P = 512\,\mathrm{MW}$ can then be provided by $q \approx 17.6\,\mathrm{nC}$. The achievable Q is 50 [5].

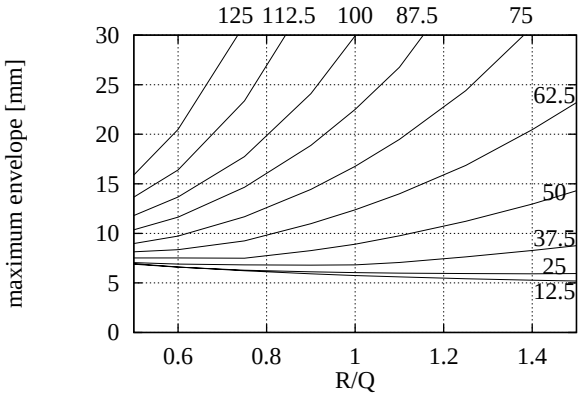

Figure 4: The maximum envelope of a three sigma beam with an initial offset of one sigma for different four-waveguide structures. The radius was varied to achieve different values of R/Q. The curves correspond to different Q-values.

6 NON-UNIFORMITY OF THE FIELD

The waveguides lead to a variation of the longitudinal field with the transverse offset r and ϕ. This in turn gives rise to a transverse kick

$$\Delta p_\perp(r,\phi) = \Delta p_{z,0} \sum_{k=1}^{\infty} 4k \frac{r^{4k-1}}{a^{4k}} \frac{\lambda}{2\pi} \sin(2\pi s/\lambda)$$
$$c_k[-\vec{e}_r \cos(4k\phi) + \vec{e}_\phi \sin(4k\phi)]$$

Here, $\phi = 0$ lies in a symmetry plane in the centre of a waveguide.

In the simulation only $k = 1$ and $k = 2$ are taken into account. The higher-order terms will cause a significant field only at large radii due to the $(r/a)^{4k}$ dependence.

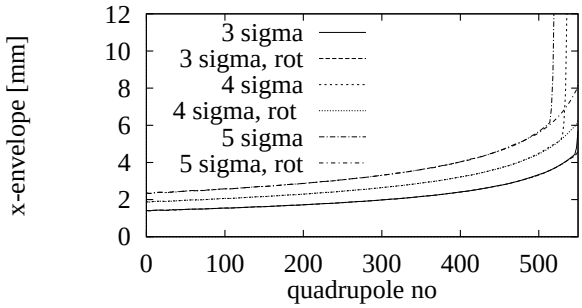

Figure 5: The envelope of an on-axis beam with and without rotating the structures at the focusing quadrupoles.

Figure 5 shows the envelopes for on-axis beams for particles with Courant-Snyder invariants $A_x^2 = c^2\epsilon_x$ and $A_y^2 = 0$. In this symmetry plane the forces are purely radial. The three-sigma particles barely pass. The situation improves significantly if every second structure is turned by 45° to get a cancellation of focusing and defocusing deflections. Here, the term with $k = 2$ may become important since it is not cancelled, but even the five-sigma particles turn out to be stable.

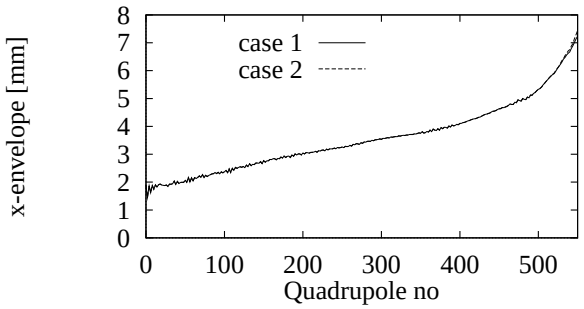

Figure 6: The envelope for a three sigma beam with an initial offset of $\delta_x = \sigma_x$ with (case 2) and without (case 1) taking into account the non-uniformity of the field.

To see the effect of the non-uniformity in the presence of beam jitter, the envelope for particles starting with $A_x^2 = 3^2\epsilon_x$ and $A_y^2 = 0$ for a beam with an initial offset $\delta_x = \sigma_x$ is calculated, with and without taking the non-uniformity into account. If the structures are rotated as described before, the difference is negligible, see Fig. 6. The same behaviour is expected for $A_x^2/\epsilon_x + A_y^2/\epsilon_y \leq 3^2$, but this needs more investigation.

7 ALIGNMENT AND STEERING

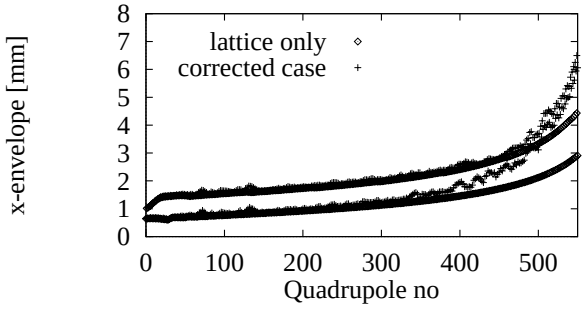

Figure 7: The envelope along the beamline after applying the ballistic correction.

Beam-based alignment is used to reduce the effect of the initial position errors of the beamline elements. One such method is the so-called "ballistic correction" [9], in which the beamline is divided into bins containing a number of quadrupoles and BPMs. The bins are aligned one after another in two steps that can be iterated if necessary. In the first step the quadrupoles in the bin are switched off. The beam is steered into the last BPM of the bin using a correction coil. The centres of the other BPMs are then shifted onto the beam trajectory—either using software or hardware. In the second step the quadrupoles are switched on and a few-to-few steering is performed. In this method, the beam has to be transported over some distance without focusing. This is not possible with the large emittance drive beam without major beam loss. Therefore it is necessary to use a low emittance beam such as, for example, the main beam after the damping ring. This beam has a bunch length of $\sigma_z = 300\,\mu\mathrm{m}$ and an energy of $E = 1.98\,\mathrm{GeV}$. Its emittance is less then $\gamma\epsilon_x \leq 2\,\mu\mathrm{m}$ in the horizontal plane. After aligning the BPMs, a simple one-to-one steering can be performed using the whole bunch train. The resulting envelope in a test case—not taking the non-uniformity into account—is shown in Fig. 7.

8 CONCLUSIONS

For a given type of power extraction structure it was found that increasing the aperture, and simultaneously decreasing the initial beam energy and increasing the bunch charge, improves the stability. Therefore the maximum beam current achievable by the injector has been chosen. The required output power then defines the structure aperture.

The non-uniformity of the longitudinal field effectively reduces the available aperture since particles at large radii are lost rapidly. Rotating every second structure improves the situation considerably, using a structure with a higher order of symmetry solves the problem. For example six-waveguide and eight-waveguide structures are under investigation.

With the present parameters a three-sigma beam is expected to pass the whole decelerator even if it has an uncorrected offset of one sigma at the beamline entry.

Further studies are necessary to understand the effect of the field non-uniformity on the correction scheme.

OPTICS ELEMENTS FOR MODELING ELECTROSTATIC LENSES AND ACCELERATOR COMPONENTS IV. ELECTROSTATIC QUADRUPOLES AND SPACE CHARGE MODELING

George H. Gillespie
G. H. Gillespie Associates, Inc., P.O. Box 2961, Del Mar, CA 92014, U.S.A.

Abstract

Optical models for a variety of electrostatic elements have been developed for the computer code TRACE 3-D. TRACE 3-D is an envelope (matrix) code that includes a linear space charge model and is primarily used to model bunched beams in magnetic transport systems and radiofrequency (RF) accelerators. New matrix models have been developed that allow the code to be used for modeling beamlines and accelerators with electrostatic components. These new models include a number of options for simulating: (1) einzel lenses, (2) dc accelerator columns, (3) electrostatic deflectors (prisms), and (4) electrostatic quadrupoles. A prescription for setting up the initial beam appropriate to modeling 2-D (continuous) beams has also been developed. The models for (4) are described in this paper and examples of their use are illustrated. The relationship between the 3-D (bunched beam) and 2-D (dc beam) space charge modeling is discussed and comparisons of numerical results to other calculations are presented.

1 INTRODUCTION

The TRACE 3-D program [1] is one of the standard codes used in the design of standing wave radiofrequency linacs and transport lines for high-current bunched beams. Considerable work has been done on extending the program to model a new array of accelerator problems, including wakefields [2], traveling wave structures [3], and electrostatic lenses [4]. This paper describes recent work at further extending the capabilities of TRACE 3-D.

2 ELECTROSTATIC QUADRUPOLES

Two electrostatic (ES) quadrupoles models have been developed for use in TRACE 3-D. One is a hard-edge model where the magnitude of the quadrupole field is constant over the quadrupole length and zero elsewhere. The second models fringe fields as linear functions that act over specified fringe field entrance and exit distances.

2.1 Hard-Edge ES Quadrupole

The first order optics for a particle moving in the field of an ES quad are the same as those for the motion in a magnetic quad using an equivalent field gradient B':

$$B' = 2V_o/(a^2\beta c) \quad , \qquad (1)$$

where V_o is the electrode voltage of the ES quadrupole, a is the radial aperture of the ES quadrupole, and βc is the velocity of the particle. The hard-edge ES quad model [2] in TRACE 3-D simply calls the hard-edge magnetic quadrupole subroutine using a gradient given by (1).

2.2 ES Quadrupole with Fringe Field

Electrostatic quadrupoles with fringe fields are often modeled in terms of a potential function of the form:

$$\phi(x,y,z) = + V(z)\,(x^2 - y^2)/a^2 \quad , \qquad (2)$$

where V(*z*) is a smooth function used to model the longitudinal variation of the quadrupole strength. The electric field is given by the gradient of ϕ: $\boldsymbol{E} = -\nabla\phi$. However, this electric field does not, in general, satisfy Maxwell's equation $\nabla\bullet\boldsymbol{E} = 0$. For the special case in which $V(z)$ is a piece-wise linear (or constant) function of *z*, then $\nabla\bullet\boldsymbol{E} = 0$ almost everywhere. The fringe field ES quadrupole uses a function $V(z)$ which rises linearly from zero to a maximum value V_o over an entrance length d_1, remains constant at V_o for a distance given by the effective electrode length *l*, and then decreases linearly to zero over an exit length d_2.

2.3 R-Matrix Elements and Example

A first-order 6×6 transfer matrix (R-matrix) is used to describe particle optics in the paraxial approximation. The elements of the R-matrix are computed directly from the electric fields using standard methods [4,5]. For the fringe field ES quadrupole, the region over which the fields act is divided into small steps of length Δz and four R-matrices are computed for each step: a drift matrix [1] of length Δz /2, a lens matrix which computes the quadrupole impulse, another drift matrix of length Δz /2, and a space-charge impulse matrix to model the linear space-charge forces (described in Section 3).

The non-trivial elements of the quadrupole lens R-matrix at location *z* are:

$$R_{21} = - R_{43} = - 2q\Delta z\, V(z)/(a^2\beta^2\gamma mc^2) \quad . \qquad (3)$$

Table 1 summarizes test TRACE 3-D calculations carried out for the hard-edge and fringe-field models with short fringe lengths, which are compared to magnetic quadrupole results. The fringe-field ES quad calculations required a maximum step size of $\Delta z = 0.1$ mm to obtain the results shown, whereas accurate results were obtained for the magnetic and hard-edge ES quads with $\Delta z = 2.0$ mm. Using the relation (1), the agreement is good between all cases.

Table 1. Comparison of quad fitting (matching) results (Example B of reference [1] without RF elements) for hard-edge ES quads, fringe-field ES quads (small d_1 and d_2), magnetic quads, and expected ES values from Eq. (1).

Quad Model	MMF (10^{-6})	Quad 1 (V_o or B')	Quad 2 (V_o or B')	Quad 3 (V_o or B')	Quad 4 (V_o or B')
Magnetic	2	- 20.2647 T/m	22.4726 T/m	- 19.6900 T/m	18.3534 T/m
Equation (1)	-	- 14.0189 kV/cm	15.5463 kV/cm	- 13.6213 kV/cm	12.6967 kV/cm
Hard-Edge ES	17	- 14.0189 kV/cm	15.5464 kV/cm	- 13.6214 kV/cm	12.6967 kV/cm
Fringe-Field ES	55	- 14.031 kV/cm	15.559 kV/cm	- 13.629 kV/cm	12.706 kV/cm

3 2-D SPACE CHARGE MODELING

Space charge is treated in TRACE 3-D as a linear force using the equivalent uniform beam model. The electric field components inside a uniformly charged 3-D ellipsoid, with semiaxes given by r_x, r_y and r_z, are [1]:

$$E_x(x,y,z) = (\kappa/\gamma^2)\,[(1\text{-}f(p))/(r_x(r_x+r_y)r_z)]x \quad , \quad (4)$$

$$E_y(x,y,z) = (\kappa/\gamma^2)\,[(1\text{-}f(p))/(r_y(r_x+r_y)r_z)]y \quad , \quad (5)$$

and

$$E_z(x,y,z) = \kappa\,[f(p)/(r_x r_y r_z)]z \quad , \quad (6)$$

where $\kappa=3\lambda I_b/(4\pi\varepsilon_o c)$, γ is the relativistic energy factor of the beam, and f(p) is the 3-D ellipsoidal form factor. I_b is average beam current, where each bunch passes a given point once per RF cycle (wavelength is λ). The form factor depends on $p=\gamma r_z/(r_x r_y)^{1/2}$: for p>1, f(p) is:

$$f(p) = [p\,ln\,[p+(p^2+1)^{1/2}]/(p^2+1)^{3/2}] - 1/(p^2+1)^{1/2} \quad . \quad (7)$$

Equations (4)-(6) for the bunched beam electric fields can simulate dc beam fields by taking appropriate limits.

3.1 Space Charge for Continuous Beams

For r_z much larger than r_x and r_y, the 3-D ellipsoidal beam bunch becomes elongated and the shape near the center approaches that of a 2-D beam with an elliptical cross section whose semiaxes are given by r_x and r_y. The electric fields in this case are obtained in the limit where p becomes very large. In the limit of large p, the 3-D ellipsoidal form factor becomes:

$$f(p) = [ln(2p) - 1] / p^2 \quad , \text{ for } p>>1. \quad (8)$$

The electric field becomes:

$$E_x(x,y,z) = (\kappa'/\gamma^2)\,[1/(r_x(r_x+r_y))]x \quad , \quad (9)$$

$$E_y(x,y,z) = (\kappa'/\gamma^2)\,[1/(r_y(r_x+r_y))]y \quad , \quad (10)$$

$$E_z(x,y,z) = (\kappa'/\gamma^2)\,[[ln(\gamma r_z/(r_x r_y)^{1/2}) - 1]/(r_z^2)]z \quad , \quad (11)$$

where $\kappa'=(\kappa/r_z)$. The field components (9) and (10) are of the same form [8] as those for a continuous uniformly charged, 2-D elliptical cross section beam, with semiaxes r_x and r_y, when the parameter $\kappa'=I_{dc}/(\pi\varepsilon_o\beta c)$. I_{dc} is the current for the continuous (dc) beam. Consequently, the transverse electric fields computed by TRACE 3-D are the same as those for a dc beam if the bunched beam current is related to the continuous beam current by:

$$I_b = (4/3)(r_z/\beta\lambda)\,I_{dc} \quad . \quad (12)$$

The longitudinal electric field (11) varies very slowly (logarithmically) with the transverse beam dimensions, and becomes small for large r_z. The bunch length r_z will not change due to the longitudinal space charge force if the total beamline length L over which the envelope equations are integrated is small compared to the initial r_z. Therefore, two conditions on the initial bunch length need to be satisfied so that the bunched beam space charge fields reduce to those for a continuous beam:

$$r_z >> (r_x r_y)^{1/2}/\gamma \quad \text{and} \quad r_z > L \quad . \quad (13)$$

Both conditions are achieved in the normal situation where the transverse dimensions are small compared to the beamline length, and one selects an initial value for the bunch length greater than L. The longitudinal emittance and Twiss parameters are:

$$\varepsilon_z = r_z(\Delta p/p) \quad \pi\text{-meter-radian} \quad , \quad (14)$$

$$\alpha_z = 0 \quad , \quad (15)$$

and

$$\beta_z = r_z/(\Delta p/p) \quad \text{meter/radian} \quad , \quad (16)$$

where r_z is in meters and $\Delta p/p$ is the momentum spread.

Using the formulas (12) and (14)-(16), the TRACE 3-D space charge fields reduce to those for a 2-D continuous beam when the conditions (13) are satisfied.

3.2 Comparisons to Semi-Analytic Calculation

The accuracy of the 2-D simulation has been verified using TRACE 3-D by comparing the space charge radial expansion of cylindrical beams with results for the semi-analytic solutions. Table 2 summarizes one comparison.

The space charge expansion of a zero emittance, cylindrical beam can be expressed in terms of Dawson's integral. For a beam with radius r_o and no divergence at z=0, the downstream r and z are related by [7]:

$$(z/r_o) = (2/K)^{1/2}\,(r/r_o)\,D[ln((r/r_o)^{1/2}] \quad , \quad (17)$$

where $D[\xi]$ is the value of Dawson's integral at ξ, and is available in tabulated form [9]. $K=2(I_{dc}/I_o)\,\beta^{-3}\gamma^{-3}$ is the generalized beam perveance and I_o is the Alfven current.

Table 2. Comparison of the simulated beam radius, for the space-charge expansion of 10 keV, 2 Ampere, dc (2-D uniform) e-beam, with the semi-analytic radius. The beam's initial phase space parameters are given in the text.

Length z (mm)	Drift Number	Drift Length	$\ln(r/r_o)^{1/2}$	Radius (mm) Semi-Analytic	Radius (mm) TRACE 3-D	Deviation (%)
1.6368	2	1.6368	0.02	10.00400	10.00400	0.00000
3.2750	3	1.6382	0.04	10.01601	10.01603	0.00020
8.2104	4	4.9354	0.10	10.10050	10.10057	0.00069
16.5869	5	8.3765	0.20	10.40811	10.40850	0.00375
119.6891	6	103.1022	1.00	27.18282	27.19945	0.06118
332.4853	7	212.7963	1.50	94.87736	94.94152	0.06763
548.5548	8	216.0694	1.70	179.93310	180.04664	0.06310
724.5571	9	176.0023	1.80	255.33722	255.49130	0.06034
976.9775	10	252.4205	1.90	369.66053	369.87306	0.05749

The Alfven current $I_o=4\pi\varepsilon_o[mc^3/q]=0.03335641 \times[mc^2(MeV)/q(e^-)]$ amps. The values $\xi=ln((r/r_o)^{1/2}$ shown in Table 2 were selected so that tabulated entries for D [ξ] could be used to determine the corresponding values of z/r_o. The perveance used (K=0.02986778) corresponds to a 2 amp, 10 keV beam with particle mass 0.511 MeV. A beamline of drift elements was constructed [10], whose lengths correspond to the intervals between the values of z/r_o. For a beam radius r_o = 10 mm, the resulting drift lengths and accumulated length z are given in Table 2.

The initial transverse phase space used values of $\varepsilon_x=\varepsilon_y=0.04$ π-mm-mrad, $\beta_x=\beta_y=2500$ mm/mrad and $\alpha_x=\alpha_y=0$. For the longitudinal parameters (14)-(16), initial values of $\Delta p/p = 5\times10^{-4}$ and r_z=100 meters were used. Simulations using I_b=0 confirmed that no beam expansion occurred due to finite transverse emittances.

The TRACE 3-D results shown in Table 2 used a radiofrequency of 2.998 MHz (λ just under 100 meters). Then, from Eq. (12), I_b=13.676 amps. The TRACE 3-D radii computed for this current agree with those from the semi-analytic calculation to better than 7 parts in 10,000. Other simulations to confirm the Eq. (12) scaling, and to explore limitations imposed by (13), were also performed with different λ, r_z, I_b, and with equal perveance beams.

4 SUMMARY

Optical elements for electrostatic quadrupoles have been developed for use in the TRACE 3-D code. A prescription for using TRACE 3-D to accurately simulate dc space charge effects has also been developed. Together with einzel lens [4], acceleration column [5], and deflector prism [6] models, TRACE 3-D has been expanded to model a spectrum of electrostatic systems.

ACKNOWLEDGEMENTS

The hard-edge ES quadrupole model was implemented by W. Lysenko [2] under CRADA number LA95C10203 between the Los Alamos National Laboratory and G. H. Gillespie Associates, Inc. The fringe-field ES quad model was developed using *PowerTrace*™ [10].

RECENT DEVELOPMENTS IN THE ACCELERATOR DESIGN CODE PARMILA*

H. Takeda and J. H. Billen
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

The PARMILA code, which originated in the 1960s for designing drift-tube linacs (DTLs), now designs and simulates the performance of many types of rf linear accelerator. The structure types include the DTL, coupled-cavity drift-tube linac (CCDTL) [1], conventional coupled-cavity linac (CCL), and several types of superconducting linac. This new code can handle multiple types of linac structures in a single run. This code features a more logically organized input sequence for the different linac structures and their properties. A PARMILA run can include sequences of beam-transport elements. In this paper, we describe the new user interface, highlighting the implementation of multiple rf structures. Also, we discuss the algorithm used for designing superconducting linac structures.

1 LINAC STRUCTURES

In designing a linac system, one first determines the types of linac (DTL, CCDTL, CCL, etc.). If a linac uses different rf structures, for example, one part of the linac requires a different number of cavities between focusing magnets then another, then we assign a new linac structure for that portion of linac. Starting from the low-energy end of the linac toward higher energy, up to 30 structures are allowed in an input file. The PARMILA code also calculates the beam-dynamics performance of the designed linac.

Each line of the PARMILA input file starts with a keyword, which in this paper we write in lower case letters in double quotes. At the beginning of the input file, we specify the global parameters on the "linac" line. Included parameters are: starting beam energy, bunch frequency, beam current, the beam particle mass and charge state. We specify whether the simulated particle distribution is read from a file created by another code (e.g. PARMTEQ [2] or a previous PARMILA run) with a "readdist" line, or if the distribution should be created anew by PARMILA according to data on the "input" line. After the global parameters for the whole linac are specified, each rf structure type starts with a "structure" line.

Figure 1 shows schematically the sections of a PARMILA input file. At junction between structures, the program keeps track of the ending state of beam characteristics in the linac. For typical room-temperature linacs, the inter-structure spacing is corrected so that the particle enters next structure with a correct phase. While the code designs the linac, it automatically creates a file of TRACE 3-D [3] elements which can be used for beam matching or optical element adjustment. For a multiple structure run, the sequence of rf structures follow the same order in the accelerator. Each structure is terminated as specified by a cell number on the "structure" line. Also, the particle distribution snapshots are stored in a file for later viewing with the DTLPROC postprocessor.

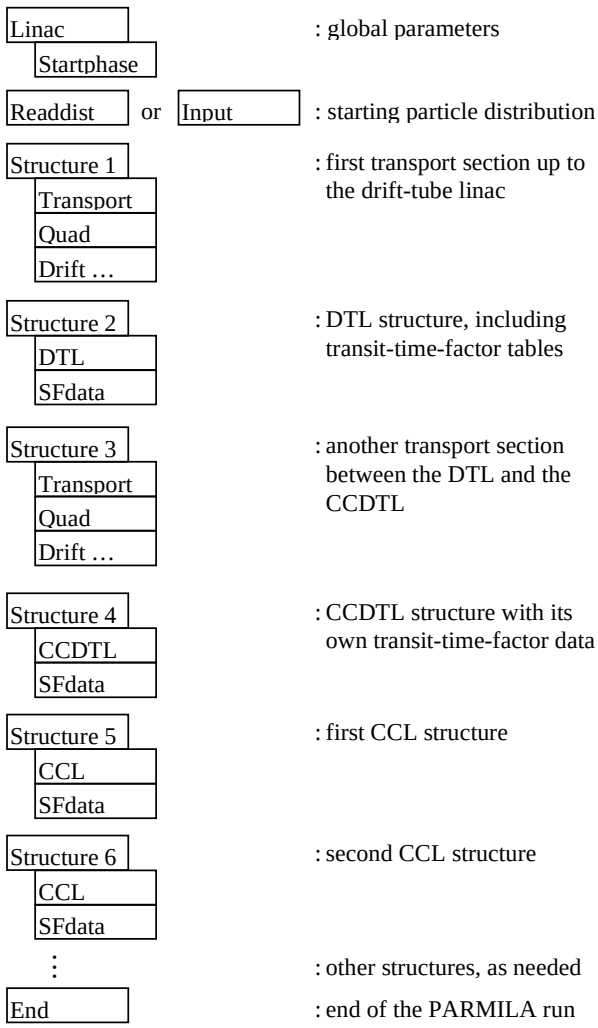

Figure 1. Schematic of a typical PARMILA input file.

2 INDIVIDUAL STRUCTURES

The keyword "structure" identifies and delimits the current linac structure. It includes the structure identification number, particle-dynamics termination cell number, frequency of the linac and the frequency used for the transit-time factors calculated by SUPERFISH [4]. All the phase coordinates of the initial particle distribution can be displaced by a specified amount if the rf module is driven by a separate power supply. Normally, one designs each linac structure one or more segments beyond the point where the beam-dynamics simulation ends. (Segments refer to contiguous sections of rf cavities, usually separated by focusing magnets.) This approach allows the code to calculate the distance between structures correctly. This can be specified by a design end energy parameter. For a CCDTL or CCL, one can design linac segments either with individual cell lengths proportional to particle velocity βc or with each segment made of cavities of identical length. In the latter case, the cell lengths are designed for a particle having the velocity $\beta_g c$, where the subscript g stands for geometrical.

One may specify several rf structure types such as "ccdtl", "ccl", "sc1", and "sc2". These keywords define parameters of a coupled-cavity drift-tube linac (CCDTL), a conventional coupled-cavity linac (CCL), or two particular types of superconducting cavity layout. For each of these structure types, PARMILA requires one or more tables of transit-time-factor data headed by one of the keywords "sfdata," "sfdatae," or "sfdataq." The three tables correspond to different boundary conditions imposed upon the fields in the bore tube at the edge of the cavity. The "scheff" keyword (for space-charge effects) specifies the initial space charge mesh size in each rf structure section. Once the particle dynamics starts (after a "begin" line), PARMILA adjusts the mesh size automatically to fit the extent of the particle distribution. An "output" keyword directs the code to store particle distribution snapshots at specified cell positions. The multiple structure run stops after encountering an "end" keyword.

3 TRANSPORT STRUCTURE

The "transport" structure type contains only beam optical elements. The code does not design an rf cavity layout for this sections an input file. A file can contain several "transport" sections, for example to match the beam's phase-space properties between accelerator sections. The user specifies transport elements such as "drift" and "quad" elements. After a "begin" keyword the code does the beam dynamics simulation through the specified optical elements. To assist designing the linac, PARMILA includes the transport elements in the TRACE 3-D input file that it automatically creates for the entire linac. A PARMILA run can consists only of a transport structure to simulate the beam dynamics. For a "transport" structure, the user can specify the starting design phase , if necessary.

4 CCDTL AND CCL STRUCTURE

The "ccdtl", or "ccl" line defines an rf structure of the same name. Both lines include data that specify the design termination energy, starting design phase angle, starting cavity field E_0, number of drift tubes per cavity (for the CCDTL), number cavities per segment, segment spacing, default quadrupole-lens parameters and other transverse focusing lattice settings. Other input lines ("extquad," "change") appearing after the "ccl" line or "ccdtl" line can be used to modify these default settings for specific rf cavities or magnets. There is considerable flexibility in the methods for defining the focusing magnet layout. For example, singlet or doublet quadrupoles can be placed a fixed distance from the end of each cavity segment, or each magnet location can be set individually. Also, their positions can be gradually moved within successive magnet spaces according to the beam velocity. The cavity field and amplitude can be set globally or automatically ramped using the "setramp," "e0ramp," and "phaseramp" lines. If one wants to maintain a constant real estate E_0T (accelerating field averaged over a transverse focusing period) across the segments, the "etfixed" line will compute the required acceleration.

After quadrupole and rf cavity definitions in the input file are the transit-time-factor tables. These tables list as a function of beam velocity βc several integrals computed by the SUPERFISH postprocessor SFO for a number of representative cavities. The "sfdata" table corresponds to symmetric cells, the "sfdatae" table is for cells at the edge of an internal cavity facing another cavity operated in the π mode, and the "sfdataq" table is for cell at the end of a segment where the electric field penetrates into the bore tube. The presence of these tables completes the linac design.

Once the linac is designed, one can modify the operating phase, amplitude, or quadrupole settings for a dynamics calculation. The "linout" line writes details of the designed linac to the output file. The "start" and "stop" lines tell the program the cell numbers on which to start and stop the beam-dynamics simulation. The "output" line specifies cell numbers for storing beam snapshots for later display by the DTLPROC postprocessor. If one simulates a well-matched 0-mA beam and saves the pseudo-particle coordinates at the center of each quadrupole magnet of a FODO lattice or a doublet lattice, the postprocessor DTLPROC can use the data to calculate the phase advance per focusing period along the linac.

5 SUPERCONDUCTING STRUCTURES

The "sc1" line defines a particular type of superconducting linac structure, which is characterized by

a missing segment at regular intervals. The "sc1" line includes number of cells per segment, missing segment interval, the energy gain per segment, the design end energy, design phase, segment separation and default quadrupole settings. The "sc2" line defines a superconducting linac structure, which is characterized by groups of cavity segments with quadrupole magnets between groups. The "sc2" line includes the energy gain per segment, segment spacing, number of segments between quadrupoles, and the lattice type: either a "singlet" lattice or "doublet" lattice. Like the room-temperature structures, the quadrupole settings for both superconducting layouts can be customized by "extquad" lines. The transit-time-factor tables used in the superconducting cavities are calculated by the SUPERFISH code for a number of beam particle velocities βc for the cavities with an identical cell length $\beta_g c/2$.

6 SUPERCONDUCTING LINAC DESIGN ALGORITHM

There are important differences between conventional room-temperature linacs and superconducting (SC) proton linacs now being proposed for some projects. In a SC linac of the type being designed for the Accelerator Production of Tritium project, multiple segments driven by the same power supply deliver equal power to the beam. Thus, each equally powered segment gives the same energy gain. Also, the segment spacing is fixed for large portions of the linac. Many cavity segments have identical lengths so that only a few different cavity shapes are manufactured for the entire linac. Unlike the conventional CCL, most cell lengths in the SC linac will differ considerably from $\beta\lambda/2$ (the distance traveled by a particle of velocity βc in one rf period). Instead of the usual phase difference of 180 degrees from cell to cell seen in a CCL, the phase changes may be tens of degrees larger or smaller than 180 degrees. By using active phase shifters, the rf power for each SC cavity segment can be driven independently. Within a segment, which consists of a series of coupled cells operated in the π mode, the relative rf phase between cells is fixed. Because of the usual large bore diameter in SC cavities, the fields in the end cavities extend out into the bore tube. This field penetration results in an effective shift of the electrical center from its geometrical center. The shift can be as large as ~2 cm for a 700-MHz cavity. These phase shifts are all included in the PARMILA code.

Because the lengths and positions of the of the SC linac cavities are predetermined, the design of the linac in PARMILA means finding the correct rf phase and the rf power at which to operate each segment. Because of the large phase slip from cell to cell, we trace a test particle through each segment recording the center-of-gap phases and energy gains of the particle. The code then requires two conditions simultaneously: 1) the energy gain must equal the design energy gain for the segment, and 2) the average phase must equal the design phase. This iterative process is performed by a two-dimensional optimization routine in PARMILA. After calculating the amplitude of rf electric field applied on one segment, and the entry and the exit phases of that segment, the code can compute the rf drive phase for the next cavity segment based upon the distance between segments and the difference between the exit phase of the upstream segment and the entry phase of the downstream segment.

7 SUMMARY

Format of PARMILA code input file was upgraded. The code can design and perform beam dynamics simulation of multiple linac structures in a single run including DTL, CCDTL, CCL, and superconducting linacs. Each linac structure is logically separated in the input file and the state of the beam at the end of each structure is transferred automatically to next structure type in the beam-dynamics simulation. Currently, a comprehensive PARMILA code documentation is in preparation.

Abstract

The Low-Energy Demonstration Accelerator (LEDA) injector is tested using the Chalk River Injector Test Stand (CRITS) radio-frequency quadrupole (RFQ) as a diagnostic instrument. Fifty-keV, dc proton beams are injected into the 1.25-MeV, CW RFQ and transported to a beamstop. Computer-simulation-code predictions of the expected beam performance are compared with the measured beam currents and beam profiles. Good agreement is obtained between the measurements and the simulations at the 75-mA design RFQ output current.

1 INTRODUCTION

To test the LEDA injector [1] under operating conditions, the ion-source extraction system is altered from a tetrode at 75 keV to a triode at 50 keV [2]. The rest of the 2.54-m-long LEDA injector is about the same as it will be when the initial tests of the LEDA RFQ [3] are made. We match the LEDA microwave-driven source H^+ beam (50 keV, 70-100 mA, >90% H^+ fraction) to the CRITS RFQ [4] using the two-solenoid, gas-neutralized low-energy beam transport (LEBT) [5] described in Ref. [6]. Two steering-magnet pairs provide the desired beam position and angle at the RFQ match point. Beam neutralization of 95-99% occurs in the LEBT residual hydrogen gas [7]. The RFQ accelerates the beam to 1.25 MeV and a simple HEBT transports that beam to the beamstop. The RFQ transmission and spatial profiles are measured as a function of injected current and LEBT solenoid excitations [2]. The expected beam performance is calculated using the computer codes TRACE [8] and SCHAR [9] to model the LEBT [10], PARMTEQM [11] to model the CRITS RFQ, and PARMELA [12] to model the HEBT.

2 INPUT PARAMETERS

The input H^+ beam parameters are determined from measurements on the prototype LEDA injector (Fig. 3 of Ref. 1) using a procedure described in [10]. A beam with 90-mA total current, proton fraction >90% (H^+ current >81 mA), rms normalized emittance ε_N = 0.146 π mm mrad, and α = -0.546 and β = 8.254 mm/mrad at 10% threshold is measured at the emittance-measuring unit (EMU).

Using TRACE [8] to drift the beam back along that 2.1-m long LEBT, from the EMU to the ion source, gives a predicted 6.98-mm-diam H^+ beam size, close to that of the 6.8-mm-diam ion source emitter, for an unneutralized current I_{eff} = 1.825 mA, α = 0.411, β = 0.215 mm/mrad, and ε_N = 0.146 π mm mrad (Table 1). Using these TRACE parameters as SCHAR* [9] input, and scaling them using $\alpha_{new} = \alpha_{old}[\varepsilon_{old}/\varepsilon_{new}]$ and $\beta_{new} = \beta_{old}[\varepsilon_{old}/\varepsilon_{new}]$, gives the measured ε_N to within 0.1% after two iterations. The resulting SCHAR-predicted input beam (Table 1) has ε_N = 0.134 π mm mrad. When SCHAR transports the beam parameters in Table 1 through the 2.1-m LEBT, the approximate phase-space shape at the 10% contour (Fig. 1) and beam profile at the video diagnostic (Fig. 2) result. Although the beam-profile data in Fig. 2 were obtained three days earlier than the phase-space data in Fig. 1, the source parameters were nearly identical for both data sets.

Table 1. TRACE and SCHAR input H^+ beam parameters.

TRACE (I_{eff} = 1.825 mA)	SCHAR (I_{eff} = 1.825 mA)
E = 50 keV	$v_o = 3.095 \times 10^6$ m/s
α = 0.411	r_{12} = -0.4131
β = 0.215 mm/mrad	$x_{max} = 4.271 \times 10^{-3}$ m
ε_N = 0.146 π mm mrad	$v_{x\,max} = 6.117 \times 10^4$ m/s

* $v_o = [2E/m_pc^2]^{1/2}c$, $r_{12} = -\alpha/[1+\alpha^2]^{1/2}$, $x_{max} = [\beta\varepsilon(6rms)]^{1/2}$, $v_{x\,max} = [\gamma\varepsilon(6rms)]^{1/2}v_o$

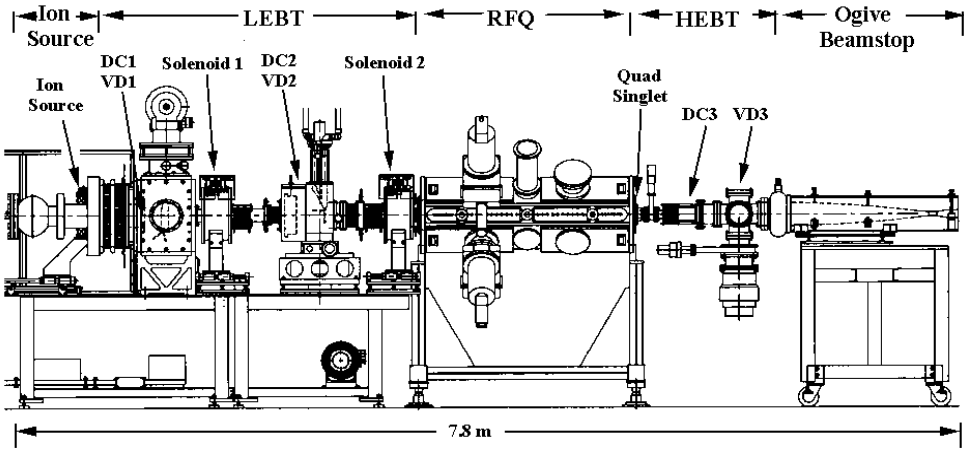

Fig. 3. The CRITS RFQ experiment beamline. The LEDA injector, ion source plus LEBT, is at the left. The CRITS RFQ is in the center, and the LEDA prototype ogive beamstop is at the right. The locations of the two LEBT solenoids (Solenoid #1 and Solenoid #2), RFQ exit quadrupole singlet, three Bergoz dc current transformers (DC1, DC2, and DC3), and three videocamera diagnostics (VD1, VD2, and VD3) are indicated.

lines. The LEBT dimensions are extractor to solenoid 1, 89.8 cm; solenoid 1 to solenoid 2, 138.4 cm; and solenoid 2 to RFQ match point, 25.6 cm. A beam neutralization of 98.0% (I_{eff} = 1.825 mA) is used. SCHAR predicts no proton beam loss in the LEBT. Using SCHAR input files, PARMTEQM predicts that the best match to the RFQ (Fig. 4) is obtained for $B_{sol\ 1}$ = 2100 G and $B_{sol\ 2}$ = 3675 G, giving ε_N = 0.169 π mm mrad at the RFQ match point. The actual $B_{sol\ 1}$ setting for the measurements, 1940-2010 G, is close to the SCHAR prediction whereas the actual $B_{sol\ 2}$ setting, ~4000 G, is 10% higher than the SCHAR prediction. The $B_{sol\ 2}$ setting is underestimated because of the absence in the SCHAR model of the un-neutralized section of beam transport just in front of the RFQ. Most of the SCHAR-calculated emittance growth (26.2%) is due to spherical aberrations in solenoid #1 (6.0%) and solenoid #2 (15.1%). The non-linear, space-charge-induced emittance growth is low (3.4%).

To obtain the 75-mA design RFQ output current requires operating the proton source at ~1200 W microwave power, 50% higher than used to obtain the SCHAR input parameters given in Table 1 (~800 W). The result is a larger-diameter beam at VD1 (Fig. 5) than in the case of the prototype LEBT measurements. At the ~1200 W power level the measured beam profile at VD2 (152.6 cm from the source) is also larger than SCHAR predicts.

4 CRITS RFQ PARMTEQM SIMULATIONS

The SCHAR output file is used to generate a 5,000 particle input beam for the PARMTEQM computer code to calculate the RFQ transmission and output ε_N. The proton fraction can be as high as 95% [13], but plasma effects caused by beam interactions with the beam-pipe walls [2] reduce the observed DC2 current by ~5%. These effects offset each other, so we use the measured DC2 current for the PARMTEQM input current. The result (Case 2, Table 2) is transmission = 75.1% and output ε_N = 0.207 π mm mrad (Fig. 6) for 97.5 mA input beam current and known RFQ intervane voltage (70.4, 72.6, 74.4, and 68.5 kV for Cases 1-4, respectively [14]). The predicted CRITS RFQ output current for other measured input beam currents [2] and RFQ vane voltages are given in Table 2. The SCHAR input parameters in Table 1 for a 90-mA beam (measured just in front of the EMU) are used for all of the simulations summarized in Table 2. Although RFQ output currents of up to 100 mA were measured [2], we limit our analysis to just those cases that have a complete set of beam currents and profiles.

5 HEBT PARMELA SIMULATIONS

The PARMELA [12] model of the HEBT uses the CRITS RFQ PARMTEQM output files for input. PARMELA,

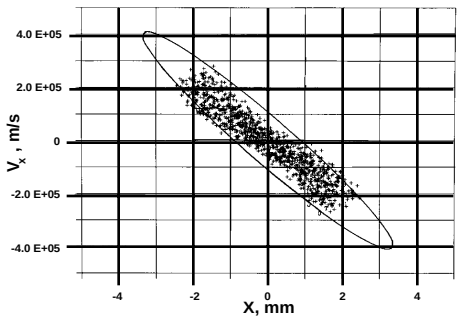

Fig. 4. SCHAR-calculated phase space (crosses) at the RFQ match point and the RFQ acceptance (curve) at 90-mA and 0.20-π mm mrad.

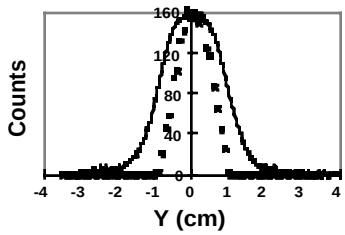

Fig. 5. Measured Hydrogen beam profile at VD1 (42.9 cm from the source) for case #2 in Table 2 compared with the SCHAR prediction calculated using the parameters in Table 1. Note the increase in the measured beam size over that in Fig. 2 as discussed in the text.

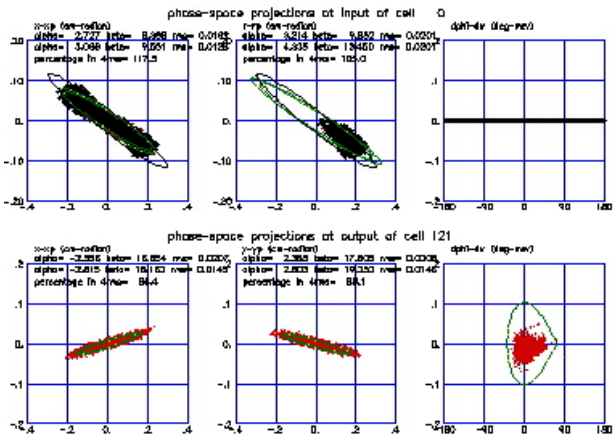

Fig. 6. PARMTEQM-calculated RFQ input (top) and output (bottom) phase space for Case 2 (Table 2).

set up to transport H^+ ions, predicts the beam transmission from the RFQ to the dc toroid (DC3 in Fig. 3), 57.5 cm downstream from the RFQ vanes, and also the x and y beam profiles at video diagnostic #3 (VD3 in Fig. 3), 87.7 cm downstream from the RFQ, for the known fields in the quadrupole singlet, located 7.8 cm downstream from the RFQ vanes. Table 2 lists the PARMELA predictions (note that the predicted beam loss between the RFQ and DC3 is small) along with the measured DC3 currents. Figure 7 shows the predicted x and y beam profiles at VD3 for Case #2.

Table 2. Results of the LEBT, RFQ, and HEBT simulations with SCHAR, PARMTEQM, and PARMELA, respectively. The measured LEBT beam currents at DC1 and DC2, the assumed PARMTEQM RFQ input current, the PARMTEQM-predicted RFQ output current, and the PARMELA-calculated and the measured HEBT current at DC3 are given in columns 2-7, respectively.

Case No.	Meas. LEBT current (DC1) mA	Meas. LEBT current (DC2) mA	PARMTEQM RFQ in current mA	PARMTEQM RFQ out current mA	PARMELA HEBT current mA	Meas. HEBT current (DC3) mA
1	123	94	94.4	70.33	69.95	74
2	124	98	97.5	73.18	73.16	76
3	123	96	96.0	75.11	74.96	75
4	138	102	102.1	71.98	71.61	90

6 DISCUSSION

There is good overall agreement between the measured beam currents and those predicted by the simulations for the 3 cases that have measured HEBT currents near the 75-mA CRITS RFQ design output current. These 3 cases are for the RFQ exit quadrupole singlet defocussing in x (Case 1), focusing in x (Case 2), and off (Case 3). The best agreement between the predicted current and the measured current is Case 3, but the best agreement between the predicted profiles and measured profiles is Case 2. The simulation of the 90-mA exit beam from the RFQ gives much lower beam transmission (DC2/DC3 = 70%) than the measured value (88%). It is likely that the beam input parameters in Table 1 are not as accurate a representation of the ~140 mA output beams (DC1) as they are for the ~120 mA beams. The measured and code-calculated RFQ transmissions are larger than those in [4] because of the steering and focussing flexibility of the LEDA LEBT (Fig. 3), features missing in the no-steering-magnet, single-solenoid LEBT employed in [4].

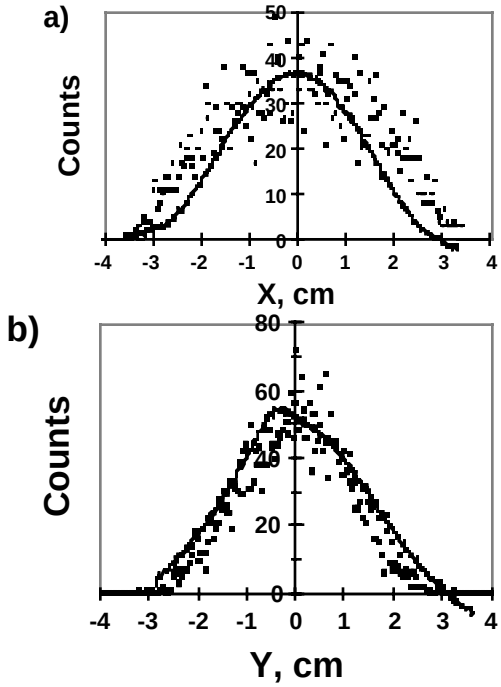

Fig. 7. PARMELA-predicted x (a) and y (b) beam profiles (squares) and the measured x and y beam profiles (lines) at VD3 for Case #2.

STUDY OF COMPENSATION PROCESS OF ION BEAMS **

A. Jakob*, H. Klein, A. Lakatos, J. Pozimski, L. Wicke

Institut für Angewandte Physik, University of Frankfurt, 60054 Frankfurt, Germany

Abstract

For investigation of space charge compensation process due to residual gas ionization and the experimentally study of the rise of compensation, a Low Energy Beam Transport (LEBT) system consisting of an ion source, two solenoids, a decompensation electrode to generate a pulsed decompensated ion beam and a diagnostic section was set up. The potentials at the beam axis and the beam edge were ascertained from time resolved measurements by a residual gas ion energy analyzer. A numerical simulation of self-consistent equilibrium states of the beam plasma has been developed to determine plasma parameters which are difficult to measure directly. The temporal development of the kinetic and potential energy of the compensation electrons has been analyzed by using the numerically gained results of the simulation. To investigate the compensation process the distribution and the losses of the compensation electrons were studied as a function of time. The acquired data show that the theoretical estimated rise time of space charge compensation neglecting electron losses is shorter than the build up time determined experimentally. To describe the process of space charge compensation an interpretation of the achieved results is given.

1 INTRODUCTION

Space charge forces within ion beams lead to a notable divergence of the beam ions and to a disadvantageously emittance growth. To enhance the maximum transportable current and reduce the increasing emittance during the transport of the ion beams in a Low Energy Beam Transport (LEBT) line, it is essential to reduce the space charge forces. Therefore space charge compensation of positive beam ions by electrons [1], which are produced by residual gas ionization, enhance the maximum transportable ion current.

Measurements by use of a residual gas ion energy analyser based on the detection of residual gas ions produced by the interaction between beam ions and residual gas atoms. The produced residual gas ions are radial expelled by the beam potential. Therefore the kinetic energy of the residual gas ions corresponds to the beam potential at the point of production under the assumption of negligible start energy. Hence the residual gas ions energy distribution contains all necessary information about the radial distribution of the beam potential and thus about the degree of compensation [2]. For investigation of the space charge compensation process a time resolved residual gas energy analyser with a channeltron was used [3].

Calculated beam potential by self-consistent numerical simulations [4] were compared with the potentials yielded from the measured spectra. The combination of simulation and measurement allows the determination of all relevant beam plasma parameters [5].

2 MEASUREMENT AND CALCULATION

Time resolved measurements of ions repelled radially by the beam potential passing an energy analyser [6] with an inserted channeltron were done to investigate the rise time of compensation of a periodically decompensated 10kV, 3mA DC He^+ ion beam [7].

The simulation of the self-consistent equilibrium states of the beam requires the temperature and the relative density of the compensation electrons at the beam axis as varying free parameters and radial distribution of the beam ions as input data. A CCD-camera was used to investigate the radial distribution of the beam ions by observing the light emitted by the intersection of the beam ions with the residual gas atoms (photon emission). In fig. 1 a CCD-camera profile measurement I(x) of an 3.9 mA He^+ ion beam is shown, the corresponding density profile $\rho(r)$ can be calculated via Abel inversion.

Significant advantages of this profile measurements in comparison to measurements by a flying wire beam profile monitor [5] are the high time resolution and that the CCD-camera is an undisturbing diagnostic instrument. Therefore there is no disturbance of the equilibrium state of the compensated ion beam due to the production of secondary electrons. In addition to the residual gas ion energy analyser the CCD-camera was used to estimate the rise time of compensation in the present experimental set up.

** Work supp. by BMFT under contract No. 06 OF 841

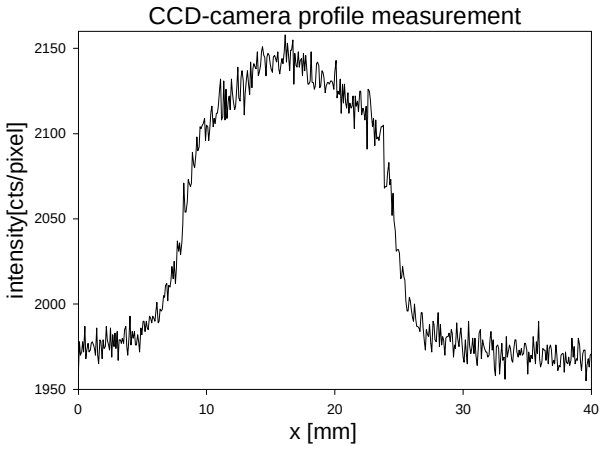

Fig. 1: Beam profile measurements by a CCD-camera. The exposure time was 2.5 s.

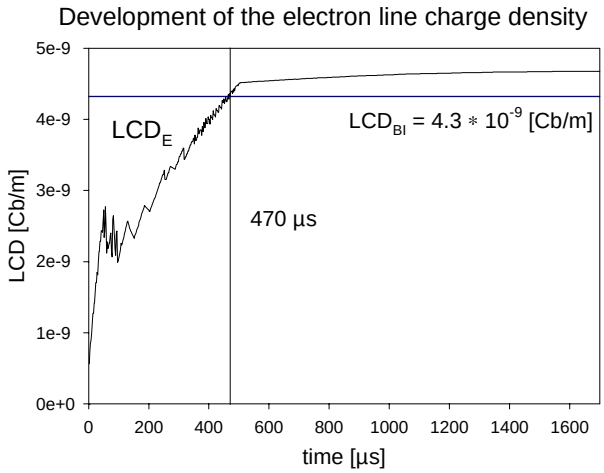

Fig. 2: Line charge density of compensation electrons and beam ions.

The minimum rise time of compensation τ can be estimated by a simple expression [5, 8], which is valid for idealized conditions (cylinder symmetry, electron losses neglected). Although the rise time of compensation determined by CCD-camera measurements are in good agreement with the calculated minimum rise time of compensation the evaluation of the residual gas ion energy analyser measurements shows that the compensation process is not finished at the minimum rise time mentioned above.

The following figures illustrate results gained from measurements for a residual gas pressure of $5*10^{-5}$ hPa, accordingly the calculated minimum rise time of compensation is 220 µs.

The determination of the plasma parameters, like the temperature of the compensation electrons (CE), the line charge density of the CE, the kinetic and potential energy of the CE by comparison of the simulation with the measured data reacts sensitive to fluctuation of the measured record. Therefore the measured data are fitted mathematically to smooth fluctuations of the measured data. The smoothed curves in the following figures show the appraisal of mathematically fitted measured data.

Fig.2 shows the development of the electron line charge density during the compensation process. The rise time of compensation is determined by the intersection point of the increasing electron (LCD_E) and the beam ion line charge density (LCD_{BI}) and is given by 470 µs.

The rise time of compensation estimated by the residual gas ion energy measurements exceeds the minimum rise time compensation τ by a factor of two due to electron losses, which is not taken into account in the above mentioned theoretical estimation.

Fig. 3 shows the evolution of the **e**lectron **c**harge **d**ensity (CD_E) during the compensation. The straight line indicates the CD_E on the beam axis, the dashed line is the CD_E at the beam edge. Fig. 3 clarify that the compensation process continues over the estimated minimum rise time of compensation τ of 220 µs. The minimum rise time indicates the time, which is needed to produce enough electrons (without consideration of electron losses) to compensate the space charge of the beam ions. With decreasing space charge forces during the compensation the electron losses increases continuously until an equilibrium state of electron losses and electron production is reached. The increasing electron losses yields to a prolongation of the compensation process up to 470 µs. Furthermore fig.3 and fig. 4 illustrate that redistribution processes are finished not until 1000 µs.

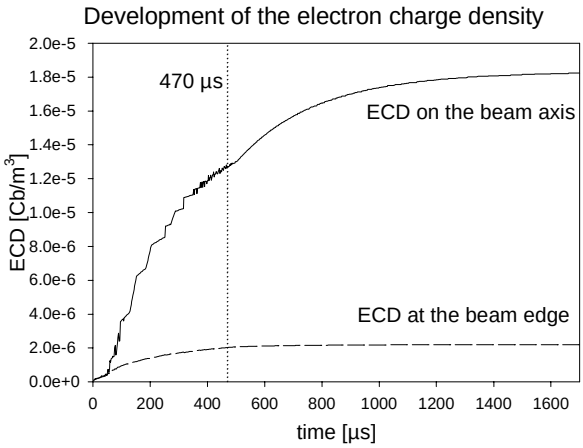

Fig. 3. Development of the electron charge density.

Fig. 4 shows the development of the kinetic (dotted line), potential (straight line) and total (dashed line) energy line density of the CE. The kinetic energy decreases continuously due to the dominant effect of decreasing temperature. The electron temperature decreases due to cooling processes by losses of „hot“ electrons. The maximum of the kinetic energy curve at 320 µs, represented in an antecedent presentation [5], which has not cleared till then, is an effect of the above mentioned fluctuations of the measured data. A new execution of the represented appraisal with smoothed measured records do not show this maximum.

From 80 µs on the potential energy exceeds the kinetic energy, hence the compensation electrons are trapped in the beam potential, this shows that the used theory and simulation is valid. Up to the maximum at 220 µs the potential energy increases, due to accumulation of produced compensation electrons in the beam potential, then electron losses and the decrease of the beam potential causes the progression of the energy. All three curves saturate after 1200 µs, then all redistribution-, production- and loss-processes reach an equilibrium state. The total curves shows clearly, that the energy still decreases, although the compensation process is complete. This effect is attributed to the above mentioned cooling process and redistribution within the ion beam, without a further accumulation of compensation electrons.

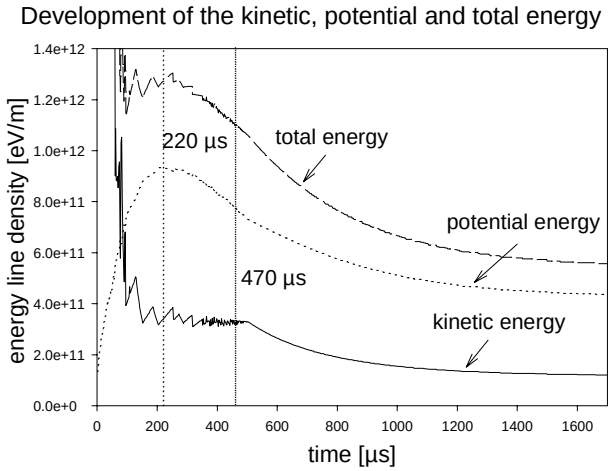

Fig. 4: Comparison of the development of kinetic, potential and total energy line density of the CE. The kinetic energy has a maximum at 220 µs. After 470 µs the compensation process is completed, after 1200 µs the development of the kinetic, potential and total energy line density saturates.

3 SUMMARY

The compensation processes of a periodically decompensated 10 keV DC He^+ ion beam has been investigated by usage of a time resolved ion energy spectrometer with installed channeltron. By application of an appraisal procedure of time resolved measurements using self-consistent calculations the rise time of compensation can be determined. A derivation by a factor of two was found between the experimentally detected rise time of compensation and the minimum rise time calculated for idealized conditions. The rise time of compensation was experimentally determined and has a value of 470 µs.

In the future work the time resolved residual gas ions measurements will perform on a pulsed ion beam, instead of a pulsed decompensated ion beam. For this investigation the gas discharge of the ion source will be pulsed directly.

DESIGN, ANALYSIS AND TESTING OF A HIGH THERMAL CONDUCTIVITY WAVEGUIDE WINDOW FOR USE IN A FREE ELECTRON LASER *

Abstract

Design, Analysis, and testing of a waveguide window with a goal of propagating greater than 100 kW average power operating at 1500 Mhz has been performed. This is made possible by the favorable material properties of Beryllia (BeO). Brazing the window to a soft copper frame and then brazing the frame to a KOVAR flange provides the vacuum seal. RF analysis combined with thermal/structural analysis shows the benefits of the material. The KOVAR flange with a CTE, coefficient of thermal expansion, that matches that of BeO enables a strong braze joint. RF testing to 35 kW has been successful, and higher powers will be tested in the near future. The basics of this design can be expanded to applications with lower frequencies and higher average power.

1 INTRODUCTION

The Free Electron Laser Facility being developed at Jefferson Lab requires much higher RF power throughput than is needed for their main facility. Much of the accelerator technology for the free electron laser is taken from the main facility which uses a two window design. The window design for the FEL consists of a room temperature warm window and a 2K cold window like the main facility. The warm window design from the main facility does not work at the power levels required for the FEL, therefore, Jefferson Lab initiated the development of a warm window using the cold window design as a baseline. In a corroborating effort, Northrop Grumman began developing a backup warm window design to enable greater than 100 kW average power operating at 1500 Mhz. The design was developed as a direct replacement in the FEL warm window location.

2 MECHANICAL DESIGN

The design evolved with the primary consideration to develop a backup warm window that would fit in the TJNAF envelope. Preliminary comparisons between alumina and beryllia windows showed that for standard grade material the high thermal conductivity of beryllia, shown in Table 1, resulted in low thermal gradients, and therefore low thermal stress within the window.

Table 1: Comparison of Thermal Conductivity's at 25C

Material	W/mK
Copper	380
Beryllia	300
SiC	270
AlN	240
Al	230
Mo	140
Alumina	20

To match the thermal expansion of beryllia, KOVAR was chosen as the flange material, minimizing thermal stresses in the beryllia during the braze cycle. A thin OFHC copper frame, .010 inches thick, between the beryllia window and the relatively stiff flange was added for strain relief. High thermal conductivity of the copper is also a benefit. Figure 1, shows a solid model of the window, the copper frame and the KOVAR flange. The KOVAR flange included a copper plating for high electrical conductivity.

The preferred BeO window geometry was an 'off the shelf' flat piece of Thermalox 995, .100 inches thick, from Brush Wellman. The thickness was chosen to keep the stress due to pressure low while using a stock size of standard grade material, ensuring repeatable material properties. Presently there is no multipacting coating on the window.

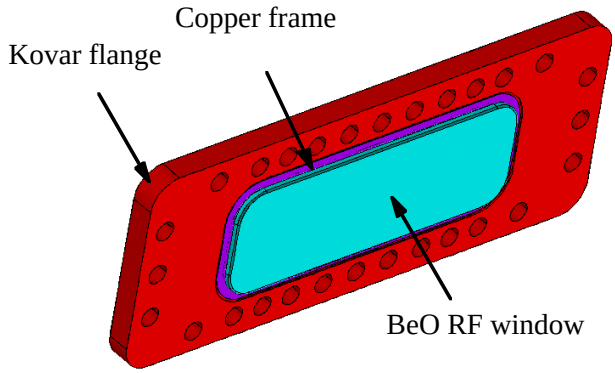

Figure 1: BeO RF Window, Flange and Frame

** Q. Shu now at AMAC, LLC, Newport News Va.

3 BRAZE PROCESS

A two step braze process was used, first the copper frame was brazed to the BeO window then the copper frame was brazed to the KOVAR flange. The following steps were used to attach the frame to the BeO window:

- Molymanganese metallization 1/4" wide around the surface to be brazed. Silk screen technique was used then fired at 1450 C.
- Nickel plate metallized area then sinter at 1000 C
- Nicoro ribbon is used with a (apprx. 15 lb.) weight on fixture brazed at 1050 C
- A nioro wire (20 mil O.D.) braze around the outer edge between the BeO and copper and fired at 970 C
- Helium leak check 1x 10-8 std cc/sec
- Light blasting was done with aluminum oxide particles

The second step of the process was to braze the copper frame to the KOVAR flange.

- Incusil-10 wire in a vacuum braze oven and fired to 750 C
- Mask the copper plated KOVAR and apply a light blasting with aluminum oxide particles to clean beryllia surface

4 RF DESIGN

RF analysis was used to determine the S parameters for the structure and to optimize the structure within the requirements set by the envelope and mechanical design. Table 2 compares the electrical properties of BeO with other standard grade candidate materials.

Table 2: Comparison of Electrical Properties

Material	Dielectric Const (1MHz)	Loss Tangent
Beryllia (Thermalox 995)	6.7	.0003
AlN	9.0-10.0	
Alumina	9.0	.0003

To optimize the structure with a .100 inch thick BeO window, metal "wings" forming an iris were added to the flange. These wings were added to both sides of the window as shown in figure 2. Results for wings on just one side were not acceptable. The following MAFIA RF analysis results were obtained for a wing width of .750", and a wing thickness of .100".

Table 3: S Parameter Results

S11 amplitude	S11 phase	S21 amplitude	S21 phase
.0066	87.30	.99956	-2.740

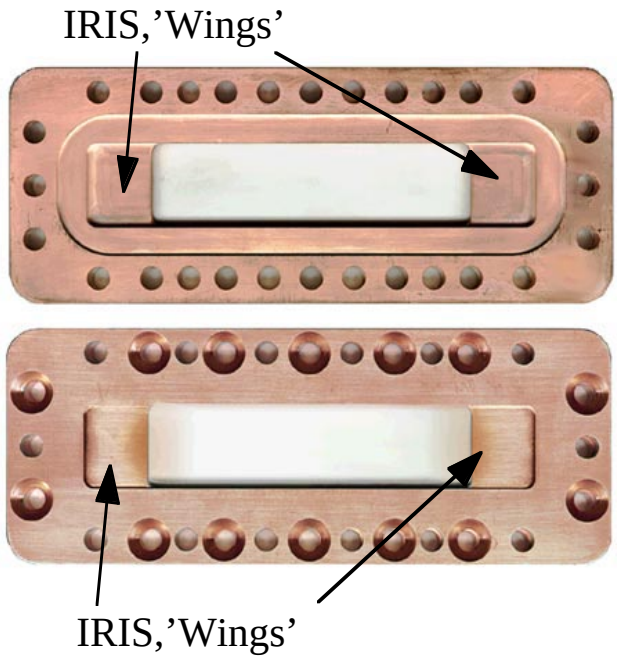

Figure 2: RF window and Iris('wings') and flange

After this configuration was selected, the power deposited into the ceramic and the fields in the waveguide were calculated. Contours of the heat deposited in the window are shown in figure 3 after scaling to a loss tangent of .0003 and 100 kW of through power.

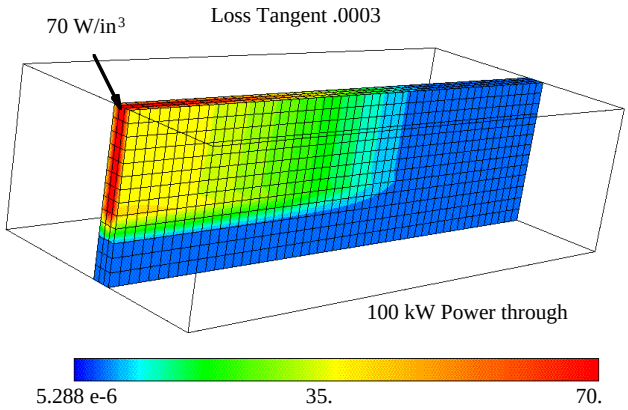

Figure 3: Heat loss contours determined by MAFIA

5 THERMAL ANALYSIS

The power loss distribution calculated in MAFIA was then mapped into an ANSYS finite element model. This model was used to determine thermal gradients and stresses in the window. Figure 4 shows the resulting temperature contours in the window, the frame, and the flange. On the edge of the flange a boundary temperature of 20C was set. The results show very small gradients in the window and a temperature rise of 29C between the window and the flange edge. These small thermal gradients result in small stress in the window.

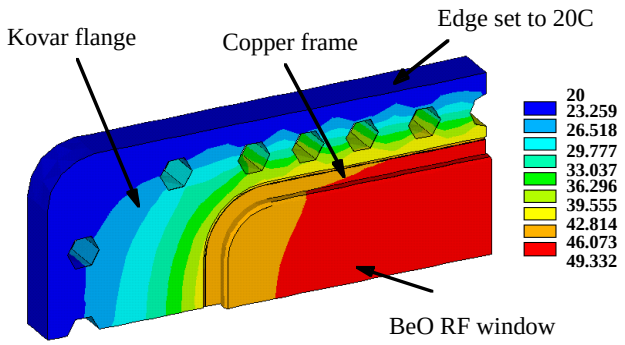

Figure 4: Temperature contours from ANSYS

6 RF TESTS

Thomas Jefferson National Accelerator Facility (TJNAF) provided the facility and manpower to test the window. Figure 5 shows the layout of the high power test. The space between the PN001 JLAB window and the BeO test window was evacuated by a 160 l/s Vac-Ion pump while the waveguide between the BeO window and the load was at atmospheric pressure. The window flanges were water cooled. The baseline pressure prior to testing was 1.4x10-9 torr. Temperatures at different locations of the waveguide and window flanges were monitored by thermocouples. Temperature of the BeO ceramic was measured by an infrared thermometer through a viewing port on the waveguide elbow. The waveguide between the two windows was equipped with a pick-up probe to monitor the electron current. A vacuum interlock and an arc detector interlock were used to prevent a catastrophic destruction of the ceramic. During the test, the incident and reflected powers, the vacuum pressure, the electron current, the temperature of the BeO ceramic and the temperatures of the window flanges were continuously monitored and recorded.

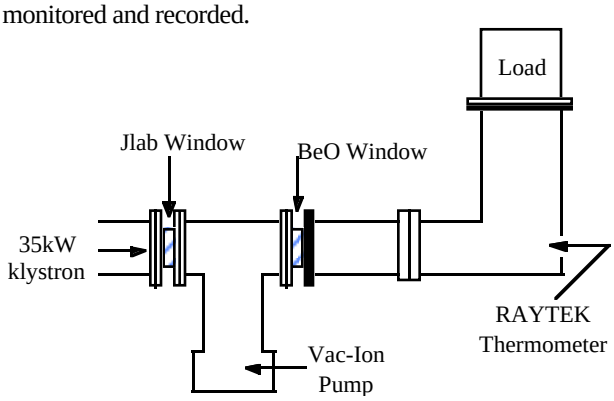

Figure 5: RF window test set up

Prior to applying high CW power, the windows were first submitted to high pulsed power (pulse length .01 ms - .1 ms, with a repetition rate of 100 Hz). Table 3 shows the temperature rise of the BeO ceramic as the power is increased. The temperature of the ceramic at zero power was 28C. The vacuum pressure increased to 9.4x10-8 torr at 35 kW and no electron current was detected.

Table 4: Temperature Rise In BeO Ceramic

Power (kW)	BeO Temp C	T(BeO)-27.7 ΔT C
0	27.7	0
5.04	35	7.3
10.1	40.8	13.1
15.1	45.7	18
20.2	51.2	23.5
25.2	58.2	30.5
35	70.9	43.2

The temperature rise between the coolant and the BeO window was much higher than expected from analysis. This could be from high losses in the braze material and/or poor thermal contact between the coolant line and the flange. This will be looked at more closely as additional tests are run.

7 CONCLUSIONS

Analysis shows that for the expected power lost in the window the goal of 100 kW of through power at 1500 Mhz is achievable. The high thermal conductivity of BeO results in low thermal gradients within the ceramic. Further tests are planned for 50 kW of through power. Modifications to the design which would include coolant nearer the ceramic would ensure lower ceramic temperatures. BeO as an RF window material shows promise based on the analysis and tests to date.

Abstract

A redesign of the basic cell configuration of the Damped Detuned Structure has been briefly reported in [1] where the cells are referred to as ellipsoidal cavities, and accelerator structures incorporating them are designated DDS 5 and DDS 6. This new structure type has been renamed RDDS 1, and the first of this series, RDDS 1, is presently under design and fabrication. The carefully sculpted cell profile (fabricated on computer controlled lathes at KEK incorporating diamond point machining) provides a 20% increase in shunt impedance which, when combined with other parameters, allows for a dramatic reduction in the RF power required for the NLC (Next Linear Collider). The detuning profile, damping manifold taper, and the cell to manifold coupling contant profile have all been carefully optimised so as to permit decoupling the cells at the ends of the structure from the manifolds while still adequately minimising the transverse wake. The decoupling is required in order to fit adequately matched terminations into the structure. The single structure analysis has been supplemented with studies of wake degradation arising from systematic fabrication errors and wake improvement obtained by combining manifold damping with structure interleaving.

1 INTRODUCTION

In the design of the NLC (Next Linear Collider) the heart of the system will consist of 4,752 X-band accelerator structures, each indiviual structure being 1.8025m in length. Any misalignment in the structure, or transverse motion of the structure over time, or beam misalignment from the electrical center of the structure will give rise to a transverse wakefield which will result in the beam being kicked off axis and can lead to a beam break up instability (as originally observed on the Stanford Linear Collider). In order to mitigate these effects, which may seriously degrade the beam emmitance, and hence reduce the luminosity of the beam, the transverse wakefield must be carefully controlled and damped. The method described herein, incorporates both detuning by gently tapering the iris parameters such that they follow an Erf function distribution and, damping the long range wake field, by coupling the wakefield out of the structure to a set of four manifolds which are located along the circumference of the accelerator structure.

In order to obtain the maximum efficiency of interaction, the shunt impedance is required to be maximised. The shunt impedance, R_{sh} is defined in terms of the potential across the structure V and, the power dissipated within the structure, P_d

$$R_{sh} = |V|^2 / P_d$$

In our current design, we maximise the $R_{sh}/Q = |V|^2/(2\omega U_E)$, where ω is the angular resonance frequency and U_E is the energy stored within the electric fields, so that we obtain a value that is 10% larger than that obtained over a set of pillbox cavities and, we enhance the Q value by 10%, both achieved by carefully shaping the contours of the irises and cavities. This together with a larger klystron pulse length, led to our initial design for RDDS with elliptical features having a 30% more efficient source-to-beam, or "wall plug", efficiency. In this design the average a/λ was approximately 0.171 (a being the radius of a particular iris). However, short range wakefield considerations has led to the iris being widened considerably in order to reduce the wake and, this leads to a 6% degradation in the overall efficiency. In this design the average a/λ is approximately 0.18. Furthermore, our initial design incorporated elliptically shaped cavities and irises. However, driven by mechanical engineering considerations, all shapes have been made circular. This reduces the efficiency by 1% or so, and at the same time it facilitates more rapid verification between the specified design and the fabricated cell.

Here we calculate the wakefield for the accelerator with a 30% improvement in efficiency the elliptical RDDS and, the RDDS with circular cells and cavities, which has an efficiency enhancement of approximately 20%.

2 WAKEFIELDS FOR CIRCULAR AND ELLIPTICAL RDDS

The wakefield in each 206 cell structure cannot be computed accurately, with a finite difference or finite element code as at present the memory and time requirements required to run the code are prohibitive and thus, we utilise a circuit model [3] and spectral function

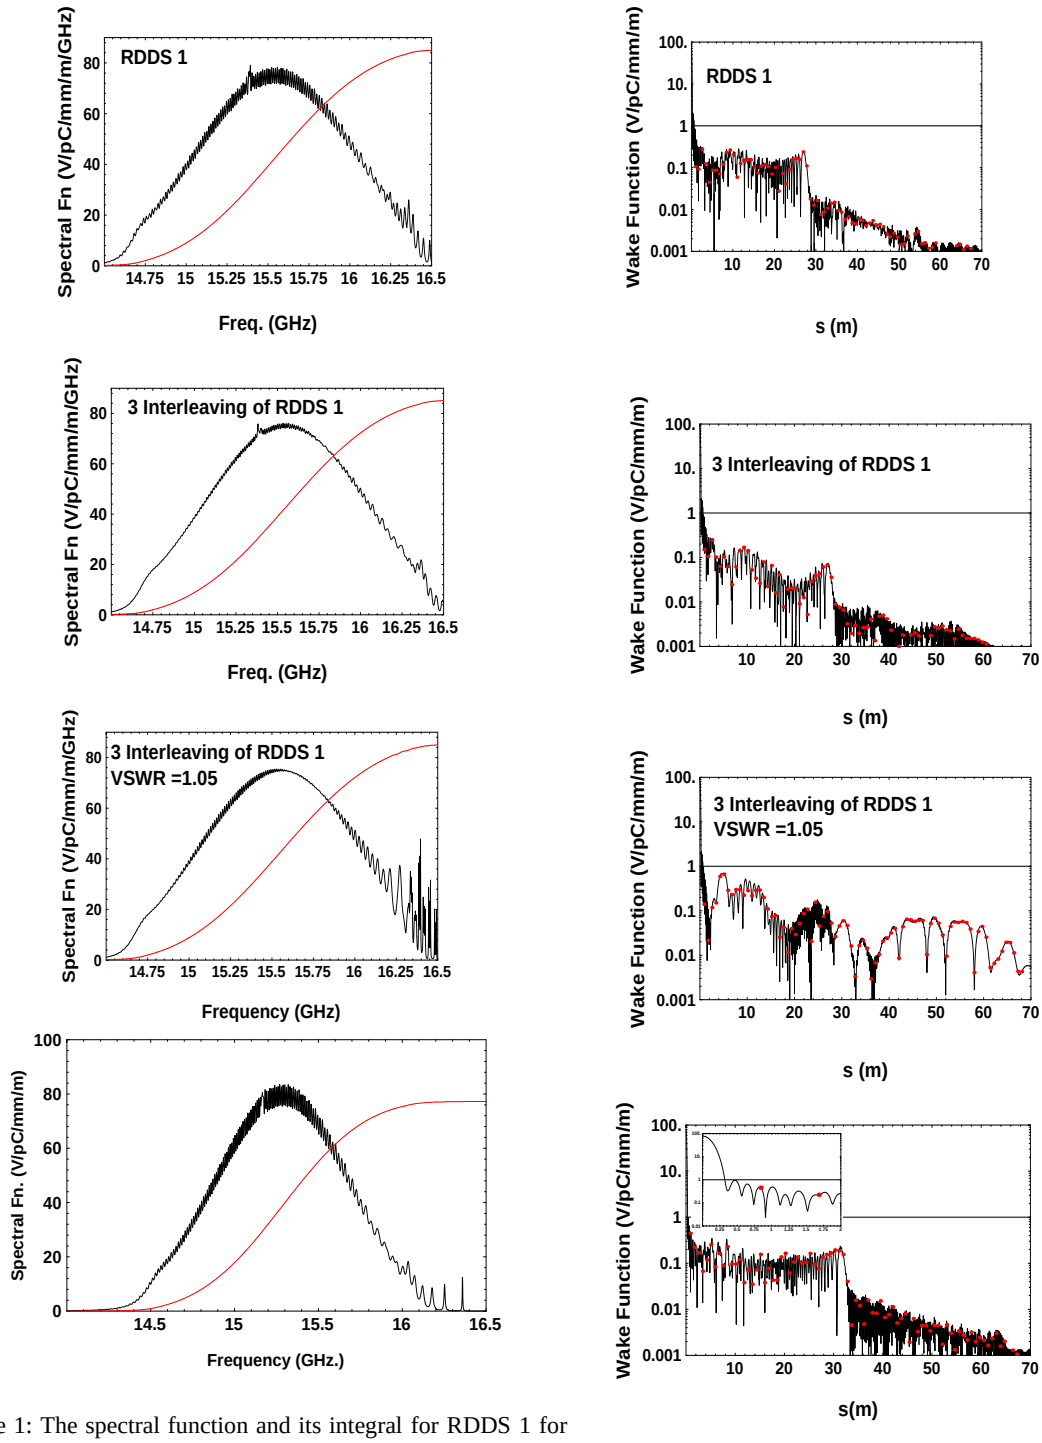

Figure 1: The spectral function and its integral for RDDS 1 for an initial design. The uppermost is the spectral function for a structure with perfectly matched HOM (Higher Order Mode) couplers and all cells coupled. The second is for series of three interleaved structures in which the synchronous frequency of each structure differs form its neighbor by 3.8 MHz. The third curve is for the case of three interleaved structures with six cells decoupled and a HOM load with a VSWR of 1.05. The fourth is for the most up-to-date design, RDDS1 with circular contours.

Figure 2: The wake function and its integral for RDDS 1. All wakes are the counterparts of the spectral functions given in fig. 1. The dots are located at the bunch locations. One V/pC/mm/m is indicated as beam emmitance considerations dictate that the transverse wake function, at the bunch locations, may not be larger than this value. The lowetmost curve is for RDDS1 with cicular features to the irises and cavities. The load has is assumed to have a VSWR = 1.

method [2] expressly developed for this purpose. The model we use assigns 9 parameters to each cell and this allows the dipole band of the brillioun diagram to be accurately described. The structure geometrical parameters have been designed to vary slowly in an adiabatic manner and thus we interpolate between, 5 cells to obtain the behavior of all 206 cells. The model we use incorporates many features present in the real structure as fabricated, viz., the non-perfect terminations of the manifolds in the higher mode loads and, the details of the coupling of the cells to the manifold (the modal composition of the accelerator is mainly TE at the low energy end and, it becomes progressively more TM towards the higher end of the structure). The spectrum function for a single elliptical structure is calculated and the coupling of the manifold to the structure is carefully optimised. The result of a final optimisation for the design with an $a/\lambda = 0.171$ is shown in Fig.1 for perfectly matched HOM couplers (higher order mode) and the wakefield corresponding to this spectral function is shown in Fig. 2. By interleaving the structures with structures whose central frequency is slightly shifted from their neighbours the wakefield is forced to decohere successively more so than a single structure. In Fig. 1 the spectral function is shown for three structures whose central dipole synchronous cell frequencies differ by 3.8 MHz from their neighbours, both with matched terminations to higher mode couplers and with terminations with a VSWR of 1.05 and with six cells decoupled either end of the accelerator structure.

The magnitude of the oscillations imposed on the spectral function is seen to be significantly reduced, particularly in the upper end of the spectral function. And, the wakefield is seen to be 3 times smaller in the region 0 to 30 m or so. Furthermore, the system is considerably stablised with respect to oscillations in the spectral function, on decoupling the last few cells. The last lowermost curve in Fig. 1 corresponds to the present RDDS with circularly shaped irises and cells. The spectral function corresponding to this latest design, is shown lowermost in Fig. 1. In this design, all ellipses have an eccentricity of 1 and the VSWR =1 of all loads in this preliminary realisation.

3 EFFECT OF SYSTEMATIC ERRORS ON THE WAKEFIELD

In the fabrication of the RDDS cells systematic, or repeatable errors, in the machining of the cells us likely to occur and in this section we consider the effect of such errors on the transverse wakefield. We consider a specific case, viz, a sinusoidal perturbation of amplitude 2MHz in the synchronous frequencies, in the central region of the structure (cells 75 through 125). The spectral function, illustrated in Fig. 5 is seen to be significantly modulated in the central region.

However, this significant modulation has little effect on the long-range wake function (Fig. 6). Although, for the first few bunches the wake field is slightly enhanced, it is a very small effect. We also consider random errors and, for a Gaussian spread in the synchronous frequencies with a σ of 10^{-4} (corresponding to approximately 1.5 MHz) the wakefield is largely unaffected.

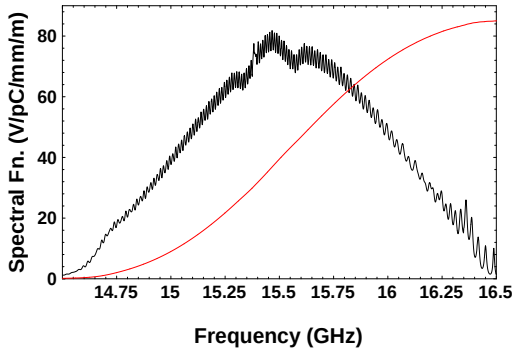

Figure 3: Spectral function for RDDS1 with all cells coupled and a perfectly matched HOM coupler. A systematic error in the fabrication is assumed to occur leading to a sinusoidal perturbation in the cell dimensions and the synchronous frequencies. The synchronous frequency perturbation has amplitude of 2 MHz.

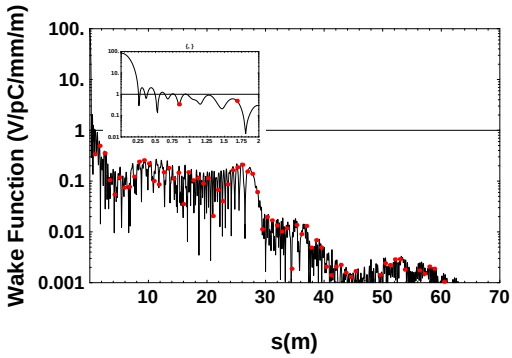

Figure 4: Wake function including the effects of a systematic fabrication error which results in a sinusiodal deviation in the synchronous frequency in the middle of the frequency band of the structure. Shown inset is the short-range wake in the range 0 to 2m.

Abstract

The fabrication technology of the high gradient superconducting(sc) cavities has been made much progress in the last 10 years. As a next issue, one has to develop a horizontal assembly method of sc cavities which makes no performance degradation in order to exhibit the excellence in the accelerator. Among many candidates of the cause with the degradation, here, the influence of breaking cavity vacuum after the vertical test and indium contamination effect are investigated.

1 INTRODUCTION

By the R&D of high gradient sc niobium cavities done at KEK so far, its technology level has come to the high gradient of 30 - 40 MV/m. Our next R&D target is to realize the excellence in the horizontal cryomodule. Performance of the sc cavity is very sensitive to the surface contamination, so generally speaking it is hard to reproduce the performance of the vertical test in a real accelerator. Really in the TRISTAN sc project, we observed a degradation in both Q value and the maximum accelerating gradient (Eacc,max) by the horizontal assembly. If the same degradation happens in the future advanced sc applications, the effect is very serious because the machines will be operated at 2K. The study of assembly method of cryomodule is an essential R&D issue.

2 HORIZONTAL ASSEMBLY

2.1 Horizontal assembly

In the TRISTAN sc project, after the vertical test of individual cavities, the cavity vacuum was broken introducing pure(6-N) and particle free (> 0.01 μm) nitrogen gas into the cavity for one night, then end flanges at the beam tubes were opened in the class 100 clean room and the remained scraps of indium used for the vacuum sealing on the flanges were carefully cleaned up. Two cavities were paired at the end flange of the beam tube with indium seal again. Blanket extension tubes were joined to each cavity at the other beam tube. After that, blanket flanges on the HOM ports were taken off and cleaned up indium scraps on the ports, then put on HOM couplers on them. The paired cavities were installed in the helium vessel of the horizontal cryostat outside of the clean room, then input couplers were put on the each port under a clean environment which was produced by a portable small clean booth. While this work, nitrogen gas was flowed the pair to prevent particle contamination from the outside. Then all the parts were assembled on the cryostat.

2.2 Degradation of cavity performance

After the horizontal assembly, the cavity pair was evacuated and cold tested. The unloaded Q value (Qo) was scattered after the horizontal tests and degraded in average as: 2.7×10^9 (vertical)→1.7×10^9 (horizontal).
This means that a surface resistance of 60 nΩ was added. $E_{acc,max}$ was also decreased as:
10 MV/m (vertical)→7 MV/m (horizontal).
However, the cavity performance in the accelerator did not change from the horizontal test.

2.3 Possible causes for the degradation

The degradation happens in the future application of sc cavities like a sc proton linac or TESLA, the influence is very serious. For instance, JAERI is considering a sc proton linac (600 MHz) for an intensive neutron source for the neutron science and nuclear waste transmutation. For this machine, electric power efficiency in the operation is an important issue, therefore 2 K operation will be applied. In this case the typical surface resistance of the cavities is about 10 nΩ. Adding 60 nΩ by the horizontal assembly, Qo value takes a figure down so that there is no meaning of the 2 K operation. The field degradation is also very serious for the machine. It is to be operated at Ep = 16 MV/m (surface peak field). The field limitation of 7 MV/m corresponds to 14 MV/m in Ep. There is no way for the operation.

One has to take a cure to prevent the degradation if he use the same assembly procedure. The possible causes of the degradation will be followings: 1) influence of breaking cavity vacuum, in other words particle contamination, or oxidation of niobium surface while the horizontal assembly, 2) indium contamination, 3) absorption gas, 4) contamination problem from RF accessories like input coupler or HOM couplers, 5) field emission, 6) multipacting so on. In this paper we investigate qualitatively used L-band single cell cavities with higher sensitivity on the issues 1) and 2) among these candidates.

3 INFLUENCE OF BREAKING CAVITY VACUUM

3.1 Effect of introducing N_2 gas

A concerning of breaking cavity vacuum is the particle contamination from the vacuum system or in the used N_2 gas. As a result the residual surface resistance (Rres) might increase or field emission happens. The faster N2 gas flow may bring the more particles into the cavity. In this experiment, flow rate of nitrogen gas was changed from 1.5 cc/min. to 900 cc/min. We used the vacuum

evacuation system presented in figure 1. The flow rate is adjusted by the valve(V2). Particles bigger than 0.01 μm size in the gas are eliminated by the final filter. By the particle counter measurement, manipulating of the final valve V2 produces particles, so it has to be handled carefully. The vacuum pressure of the sealed cavity is worse than 2-3 x 10^{-5} torr after the cold test (while cold testing the cavity vacuum is also sealed.). Prior to open the cavity valve V6, the space between V1 and V6 is evacuated to less than 1.5 x 10^{-5} torr, then V6 is opened. By opening V4 very carefully, it is checked whether the cavity was fully filled with N_2 gas. Vacuum evacuation

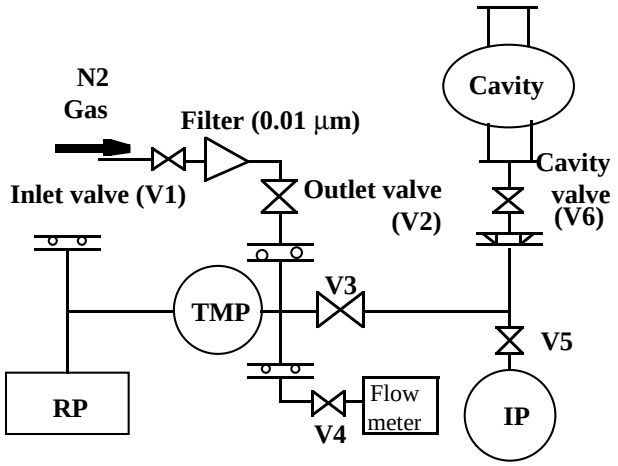

Figure 1: The used vacuum system for N_2 gas leak.

was started as soon as it was filled. Typical results of breaking cavity vacuum are shown in figure 2 on residual surface resistance and in figure 3 on field gradients. The summary is presented in Table 1. The concerned increase of Rres is not observed in the measurement error up to the flow rate of 900 cc/min. A clear field emission was observed from 20 MV/m at the flow rate 5 cc/min. but the other cases were not significant. That might be a mistake in manipulating the valves. Eacc,max decreases a little : 8 - 18%. This influence are too small to explain the degradation in the TRISTAN horizontal assembly.

Table 1: Summary of influence of breaking cavity vacuum with N_2 gas.

Flow rate of N2 [cc/min.]	Rres [nΩ] before / after (difference)	Eacc,max [MV/m] before / after (difference)	F.E at Eacc < 25 MV/m before / after
1.5	14.0 / 11.3 (-2.7)	31.3 / 31.8 (+2%)	No / No
5.0	7.7 / 4.8 (-2.9)	36.3 / 29.7 (-18%)	No / Yes from Eacc = 20
21.5	7.7 / 7.2 (-0.5)	40.3 / 34.2 (-15%)	No / No
120	12.1 / 14.4 (+2.3)	30.9 /28.4 (-8%)	No / No
900	5.4 / 7.4 (+2.0)	31.8 / 32.4 (+2%)	No / No

3.2 Influence of air exposure

Even nitrogen gas was flowed into the cavity while the horizontal assembly, there is a chance for the cavity inner surface to be exposed to the air. In this case, oxidation of niobium surface is concerned. A cavity once exposed to nitrogen gas in the experiment of *3.1* was exposed to the air by the same method as *3.1* for one day to one week

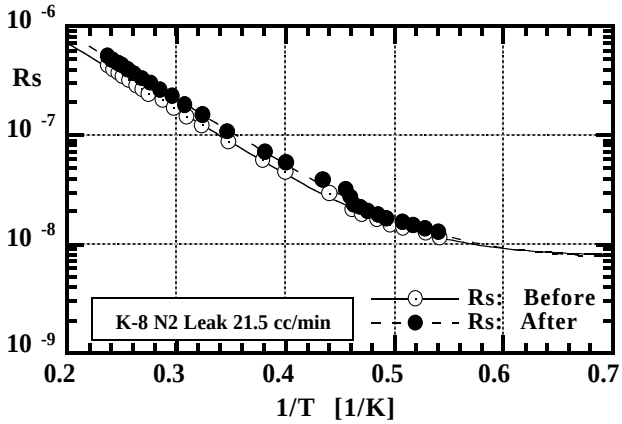

Figure 2: Effect on Rres with N_2 leak.

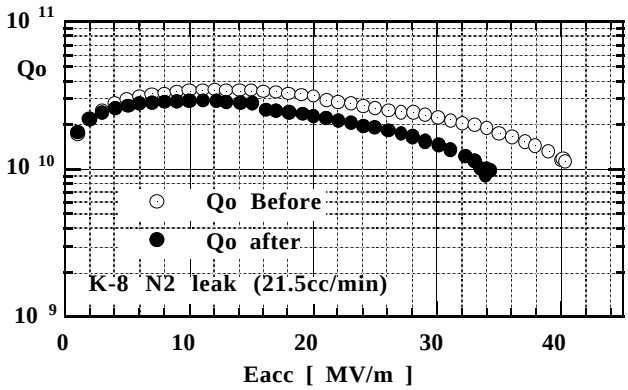

Figure 3: Effect on the Eacc with N2 leak.

Table 2: Summary of the effect of air exposure.

Exposed time	Rres [nΩ]	Eacc,max [MV/m]	F.E. onset field [MV/m]
0	7.4	32.4	29
< 45 min.	8.3	34.2	29
1 day	12.5	32.2	23
3 days	12.3	28.9	23
7 days	16.2	28.0	22

without disassembly. The results are summarized in Table 2. Only introducing the air into the cavity has no influence on Rres and Eacc,max but the exposure for one week produces the additional Rres of 8 nΩ and reduces the gradient by 9 % due to field emission. The onset point of field emission becomes lower with increased air exposure time. The exposure time of one day is enough for the horizontal assembly procedure. The resultant Rres of 5.1 nΩ and Eacc,max reduction of 0 % are too small to explain the degradation in the horizontal assembly. Especially the additional Rres is out of sight in the measurement error at 4.2 K because BCS surface resistance (100 nΩ at 500 MHz) is dominate in this

temperature, however, this additional Rres is very serious in the 2 K operation. It reduces the Qo value to about one half. Some cure might be need for this degradation with the 2 K operation.

4 INFLUENCE OF INDIUM CONTAMINATION

KEK has used indium wires or ribbons for the vacuum sealing of sc cavities. It has a high reliability but has a contamination problem by its scraps in disassembly. An experiment to see qualitatively the influence was carried out at CEBAF using a 1.5 GHz single cell cavity. In this experiment a flat indium fragment was attached intentionally on the cavity inner surface at the place 25 mm inside from the iris. The size was changed by four kinds : 35, 1.5, 0.5 mm^2 and no indium. After every measurement, the cavity was disassembled, soaked with nitric acid to eliminate the indium, then taken BCP(1:1:1) with a 30 μm material removal. The indium fragment was attached in the class 100 clean room after the surface treatment. The results are presented in figure 4 with the Eacc vs. Qo, in figure 5 on Rres and in figure 6 on the Eacc,max. Indium produces a big influence on both Rres and $E_{acc,max}$. The additional Rres and reduction of the $E_{acc,max}$ with the indium size (S; mm^2) are estimated from this experiment as follows:

Δ Rres (1.5GHz) =1.12 $\mu\Omega/mm^2$ · · ·(1),

$\Delta E_{acc,max} = 1 - \exp(-S/1.75)$ · · ·(2).

The thermal valance between a heating at the indium

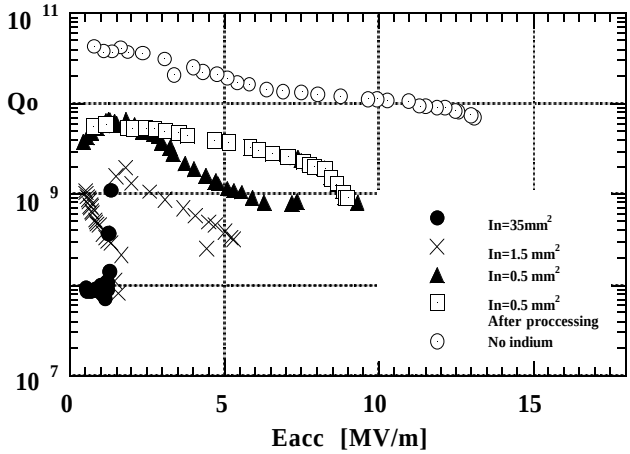

Figure 4: Indium size effect on Qo and Eacc,max.

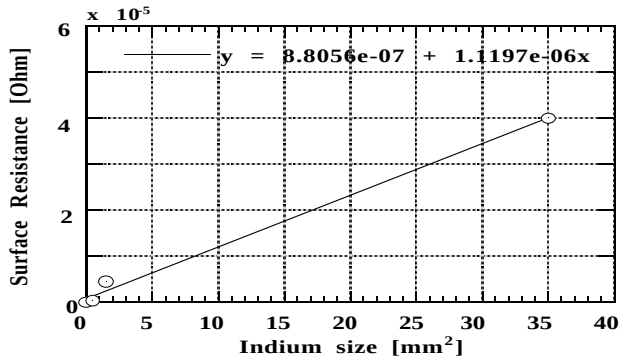

Figure 5: Increased surface resistance with indium size.

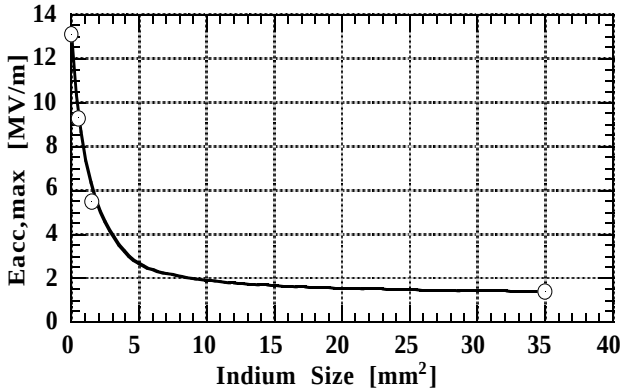

Figure 6: Limitation of field gradient with indium size.

fragment and the thermal conductivity of niobium determines the $E_{acc,max}$. Therefore the $E_{acc,max}$ does not depend on the frequency of the microwave. On the other hand, the sensitivity of the additional Rres of the eq. (1) depends on the rf frequency. For instance, from the definition and the scaling of rf frequency Qo value of 0.5 GHz cavity is presented by the Qo of 1.5 GHz cavity for the same Eacc as following:

$Qo(0.5GHz) = \omega_{1.5}U_{1.5}/(Pc_{1.5} + 1/9 \cdot P_{loss}(indium))$.

Here, U is a stored energy in the cavity, ω the angular velocity of microwave, Pc the intrinsic wall loss of the cavity, and Ploss(indium) the heating power at the indium. The 0.5 GHz cavity has the larger surface 9 times than the 1.5 GHz cavity, so the indium effect becomes small relatively to 1/9. Addition to it, the TRISTAN sc cavity is a 5 cell structure. The indium effect of eq. (1) should be changed for the TRISTAN sc cavities as follows:

$$\Delta \text{ Rres}(0.5\text{GHz}) = 1.12/(9\text{x}5)\ \mu\Omega/mm^2, \\ = 25\ n\Omega/mm^2 \qquad (3).$$

Suppose the reduction of 30% in Eacc,max by the TRISTAN horizontal assembly comes from the indium contamination, the size is about 0.6 mm^2 from eq. (2). Even if such an indium or scraps entered the cavity during cleaning the cavity flanges in the assembly work, it is not strange. The indium adds an additional Rres of 15 nΩ from eq. (3) and finally brings to field emission as presumed from figure 4 (▲ and ❒). A possible explanation of the performance degradation in the TRISTAN horizontal assembly is the indium contamination and the resultant field emission.

5 SUMMARY

Among possible causes of the cavity performance degradation in the TRISTAN horizontal assembly, the influence of breaking cavity vacuum and the effect of indium contamination are investigated. The former is not guilty with the 4.2 K operation but some cure is needed for the 2 K operation. The later has a serious effect on both Qo and field gradient. The degradation can be explained the indium contamination with the size about 0.6 mm^2, however, the other possibility should be investigated like contamination from cavity accessories or multipacting. The research program is now under going at KEK.

SIMULATION OF HIGH-AVERAGE POWER WINDOWS FOR ACCELERATOR PRODUCTION OF TRITIUM*

Abstract

Development of a robust, high-average-power (210 kW, CW) microwave transmission line system for the Accelerator Production of Tritium (APT) facility is a stringent engineering and operational requirement. One key component in this RF transmission system is the vacuum barrier window. The requirement of high-power handling capability coupled to the desirability of good mean time to failure characteristics can be treated substantially with a set of microwave, thermal-structural, and Weibull analysis codes. In this paper, we examine realistic 3-D engineering models of the ceramic windows. We model the detailed cooling circuit and make use of accurate heat deposition models for the RF. This input and simulation detail is used to analyze the thermal-structural induced stresses in baseline coaxial window configurations. We also use a Weibull-distribution failure prediction code (CARES), using experimentally obtained ceramic material failure data and structural analysis calculations, to infer probability of failure.

1 INTRODUCTION

The Accelerator Production of Tritium (APT) project is a Department of Energy (DOE) sponsored investigation into the feasibility of using linear accelerator technology (as opposed to traditional reactors) to produce tritium. A major technical issue is the design of vacuum barrier ceramic windows inside the RF transmission system. Specifications call for material transparent to microwaves at as much as 700 MHz and 500 kW, CW (actual operation will be at half that power). Compromise of the system results in vacuum breach and costly down time for the accelerator.

The objective of this analysis is to develop a simulation that will model the thermal and structural effects of transmission inefficiencies coupled to an atmospheric load to determine if, and more appropriately, when the ceramics will fail.

Since ceramics have much higher deviations in strength and wear properties than conventional structural materials, the output of the continuum, thermomechanical, Finite Element Analysis (FEA) will be coupled to a Weibull statistics code. Weibull analysis is performed with CARES (Ceramic Analysis and Reliability Evaluation of Structures) [1], a finite element probabalistic software developed by NASA. Probability of Failure (POF) is inferred from calculated Weibull parameters using data from four point bending tests on AL300 (97.6% alumina ceramic).

2 PHYSICAL DESCRIPTION

Two RF waveguide geometries are presented in this paper: (1) a generic, single window, design that has been used in experiments, and (2) one of the competing designs for the power coupler on the APT linac (courtesy of CPI Communications & Power Industries).

Electric fields from microwave transmission produce heat loads from imperfections in the electrical properties of copper and alumina. For the test geometry, there is active cooling from air flowing through the inner conductor and out across the window surface. The walls of the inner conductors, outer conductors, and t-bars are plated with copper (for electrical properties) and are otherwise aluminum and stainless steel. For the CPI geometry, the active cooling circuit is a more aggressive, water cool, in the inner conductor coupled with airflow between the ceramics. The conductors are copper and copper-plated stainless steel. The windows are kept in place by a brazed joint.

3 FINITE ELEMENT MODEL

The single window Finite Element (FE) model is built using 8-node bricks and 4-node shell elements and the CPI model is built as a 2-D axisymmetric simulation with 4-node quads. Using a 2-D axisymmetric simulation for the CPI geometry (as opposed to the 3-D implemented in the single window test case) is assumed from the observation that very little problem insight is gained from the addition

* The work was performed under the auspices of the U.S. Department of Energy by LLNL under contract W-7405-ENG-48.

of 3-D effects. There is geometric axisymmetry of the problem (in the region that we are interested) and our main concern is the stress state of the windows, not the entire system.

The heat deposition as a result of the electric field calculation along the walls of the inner and outer conductor and the ceramic is conservatively approximated to be axisymmetric with the maximum azimuthal values represented. The values of the electric field are calculated using a 3-D direct Maxwell equation solver. The values for power deposition are determined from the calculated electric field averaged over a RF cycle for the perfectly matched case.

Convective cooling is accounted for by computing heat transfer coefficients from correlations for fluid flow [2]. Enclosure radiation is accounted for in the vacuum cavities (in the 2-D axisymmetric case) using gray diffuse view factors. Natural convection and radiation exchange with the surroundings are accounted for on all outside surfaces.

The simulation is performed in two steps: (1) solution of the thermal profile from the given power load (using TOPAZ [3]) and (2) solution of stress contours throughout the window from the sum of thermal stress and mechanical stress from the vacuum pull (using NIKE [4]). These combine to give the thermal stress result.

4 RESULTS

There are three significant results presented here and each allow insight into to the fundamental physics of the problem.

4.1 Single Window Geometry

An experiment was performed at Argonne National Laboratory (ANL) [5] (using an EEV/WESGO AL300 ceramic) and is used for comparison with the test FE model. This experiment provides the temperature at the outer radius of the window and a temperature profile across the vacuum surface courtesy of an infrared camera. These experiments were done in the range of 1000 kW, CW at 350 MHz. The test FE model has been run and benchmarked to these experiments. This model helps us understand the significance of the cooling circuit in the stress distribution of the window. Running 1000 kW at 350MHz, the effects of too aggressive an inner conductor cooling without adequate attention to the air cooling across the window could be disastrous. It is discovered from varying the heat transfer coefficients (effectively changing the flow rates of air and water in the system) the stress is significantly effected. The results are seen in Figure 1.

It can be seen that as the heat transfer coefficient value on the inner conductor is decreased, the maximum principal stress in the window actually decreases. This is an important result - that less cooling results in less stress.

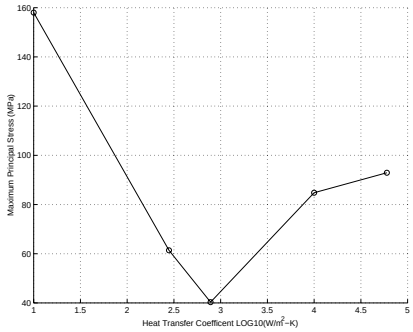

Figure 1: Maximum principal stress at various flow rates inside the inner conductor (window cooling held constant).

Conventional heat transfer rule-of-thumb would suggest the opposite, that less cooling will result in higher thermal stress. Further analysis shows that the magnitude of the face cooling is just as important. Figure 2 shows the variation of stress when the flow rates across the window are varied.

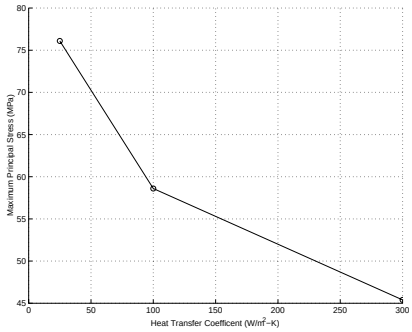

Figure 2: Maximum principal stress at various flow rates across the ceramic windows (inner conductor cooling held constant).

This geometry provided the first look of the effects of RF shields on the resultant heat load on the ceramic. These shields are place in the transmission line before and after the ceramics to prevent significant loading on the brazed joint. In preventing this build-up, the shield creates high electric fields at the same radial location in the ceramic (off the conductor walls). The resultant temperature peak, at a distance out from the inner conductor, results in high thermal loading in that position. This has been a significant influence in the temperature gradient driven thermal stress, because the peak temperature occurs away from the inner conductor wall, rather than directly at the wall, as theory would say. Couple that to the fact that the inner conductor is cooled to low temperatures, creates a strong temperature gradient right at the inner radius.

4.2 Dual Window Geometry

The CPI geometry includes a feature on the inner conductor that mitigates the aforementioned cooling issue (especially when using high flow rate water-cooling). The design features a thin-walled sheet of Oxygen Free

Electronic Copper (OFE-Cu) that the ceramic is directly brazed to. This plate is supported only at the ends, allowing the ceramic to expand, unconstrained, under a thermal load. The resultant stresses decrease by a factor of three over the ridged body assumption. Table 1 shows a comparison of the ridged and flexible support models with inner conductor and window cooling set at 60,000 W/m^2-K and 50 W/m^2-K respectively.

Table 1: Resultant principal stresses.

Maximum Principal Stress (MPa)	Ridged support	Flexible support
(σ_{mean}~250 MPa)	92.9	28.7

The implementation of flexible boundaries, although quite clever, leaves many questions lingering about the integrity of the brazed joint. Stresses in the copper plate are approaching the yield strength of the material and could create some fatigue problems in the long run.

4.3 CARES Predictions

CARES is a probabilistic, public domain software program that was developed at NASA Lewis Research Center. CARES calculates the POF for brittle ceramic materials from Weibull parameters and fatigue parameters for sub-critical crack growth. These parameters are calculated by CARES from test sample data.

Using data for WESGO AL300 ceramic [6], the probability of failure is calculated for extreme stress. Figure 3 shows the POF (as calculated by CARES) is only significant above 189 and below 273 MPa. Since our problem is the 30 MPa range (see Table 1), preliminary results suggest that the probability of failure will be quite low.

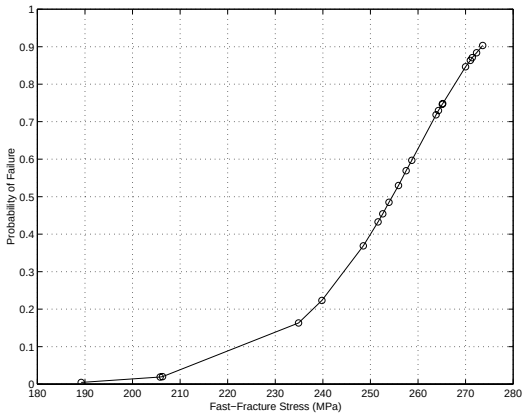

Figure 3: Probability of Failure in AL300 as a function of Stress State.

5 CONCLUSION / WORK IN PROGRESS

The analysis thus far has given much insight into the physics of the problem, significant design features, and their contribution to failure. From the aforementioned analysis we are able to infer trends in stress state when the cooling flow rates are changed. Thus, we are able to recommend optimum values to mitigate premature breakage due to thermally induced stresses. We also discovered that implementation of flexible boundaries for the ceramic vacuum barrier windows proved an excellent means of preventing thermal stress buildup.

Future analysis will be focused on continuing refinement of the current simulations to assure accuracy, as new experimental data becomes available in the coming months. More effort will be put on the interpretation of CARES results for fast-fracture as well as the failure time as a result of sub-critical crack growth (static fatigue). Other emphasis will be placed on the EEV design for the APT power coupler that was not treated here. A major feature of the EEV design is the use of an expanding outer conductor, rather than a shield, to protect the brazed joints. Preliminary results also suggest that the EEV design may not be plagued by the same cooling concerns because of the smooth distribution of power absorption in the ceramic (from the absence of shields) and the more than adequate use of air cooling across the window faces.

More future analysis will examine the structural response to the perfect mismatched case in the transmission (when the RF wave effectively encounters a short and is reflected back down the line) for both the CPI and EEV designs.

6 ACKNOWLEDGEMENTS

Completion of this analysis would not have possible without the contributions of colleagues at LLNL and LANL. The authors acknowledge stimulating discussions with Dr. A. Shapiro and Dr. C. Landram at LLNL, and Dr. B. Rusnak at LANL.

Abstract

The Intense REsonant Neutron Source (IREN) [1] with 200 MeV driver electron linac LUE-200 is being created at JINR by JINR, BINP and MEPhI. The average power of the electron beam will be 10 kW. For optional decision of a lot of problem we are planning to use a few test-installations (test-facilities). One of them is the Full Scale Test Facility (FSTF) [2] and the second one - the Electron Gun Test Facility (EGTF) at JINR. The JINR's operable installation (LUE-40 + IBR-30) [3], along its direct aim, also being used as the IREN's test-facility. The Electron Linacs of the Yerevan Physics Institute being planned to use as the IREN's test-facilities too. The description of the specified test-facilities is presented.

1 INTRODUCTION

The Intense Resonant Neutron Source (IREN) was designed and is being created at JINR by JINR, BINP and MEPhI. The IREN includes three main parts: the 200 MeV Electron Linac LUE-200 (beam average power will be 10 kW), tungsten target and plutonium booster-multiplicator [1]. On account of the IREN installation must be placed instead of the presently operating neutron source (IBR-30 and its driver - 40 MeV Electron Linac), the designed value of the accelerating gradient of the LUE-200 is chosen relatively high (35 MV/m) for providing the necessary energy and power of electron beam.

So far as the IREN must be instead of the operable facility (IBR-30 + LUE-40) it is reasonable to test, using test facilities, the most part of the IREN's equipment, and first of all the LUE-200 equipment, before its installation. For this purpose is expected to create some of those facilities at JINR and use existing facilities in BINP and YerPhI as well. The description of those facilities is given below. The program of works to be carried out at those facilities is also presented. Note that the possibility to provide the necessary accelerating gradient as well as the determination of the dark current are the principal problems for us.

2 FULL SCALE TESTING OF THE ACCELERATING SECTIONS

For full scale testing of the LUE-200 accelerating sections we are planing to use the special facility (FSTF) (see Fig. 1) at JINR (under construction [2]), as well as the BINP's available test-facilities. Since the BINP is the designer and producer of both - the accelerating sections and the SLED cavities - it is expected that the sections and cavities will be tested at the suitable BINP test-facilities in cooperation with the JINR representatives and get certificate of quality originally. At the FSTF the M-350 modulator for the 5045 klystron [4] was already installed, and klystron is being installed now. The M-350 modulator was created using of the M-250 modulator of the OLIVIN klystron station. This station was developed and created for the YerPhI linac and supplied to the JINR according to the agreement between JINR and Armenian government. All jobs on putting the modulator in operation are completed. The thermostat, cooling, monitoring and emergency systems are under construction. The vacuum system's equipment produced by the Vacuum Praha is ready for installation, and some of it is already installed.

The main problems to study at this facility are the obtaining of the expected accelerating gradient and measuring of the dark current. Along the accelerating section the scintillation detectors will be placed for measuring X-radiation induced in the section body by the dark current. Energy spectrum of the dark current and accordingly accelerating gradient will be measured in the usual way by magnet spectrometer. Moreover the RF-

power multiplier system, the waveguide elements, the LUE-200 control, monitoring and protection systems are expected to test at the FSTF. Note the another no less important role of this facility. It is expected that all the LUE-200 elements will be tested and get the certificate of quality on it before installation in the standard place.

3 ELECTRON GUN (EG) TESTING AND SETTING-UP FACILITY.

In Fig. 2 the EG test - facility layout is presented. The LUE-200 electron gun is under construction at JINR now. It was designed on the basis of the prototype created earlier at BINP for the F-factory. EG products the electron beam having the parameters: 200 KeV energy; 5 A pulse current at 0.25 μsec pulse duration. At the present time most of the EG parts are produced and its assembly being carried out. In addition to the electron gun the facility includes the following equipment:

- 100 cm length beam transport channel equipped with two focusing solenoid lenses and beam position correctors (transverse magnetic field coils);
- beam current monitor;
- beam position monitor;
- beam profile monitor;
- beam emittance monitor;
- magnet analyzer;
- auxiliary technological equipment.

The research program involves: cathode emission characteristics measurement, beam energy (total energy and energy spectrum) and space-angular (profile, emittance) electron beam characteristics measurement

4 TEST RESEARCH OF THE LUE-200 ELEMENTS AND RF SYSTEM DEVICES

The LUE-200 RF-system is based on two 5045 klystrons produced by SLAC. The RF-system includes the master oscillator, reference phase line, preamplifier, SLED system, and two waveguide feeds. The each waveguide feed provides incident and reflected power monitoring, RF-pulse envelope monitoring, phase monitoring (of the buncher and the accelerating sections RF channels relative to the reference phase), control and protection (on RF breakdown and VSWR in the waveguide feeds or the sections). The LUE-200 RF

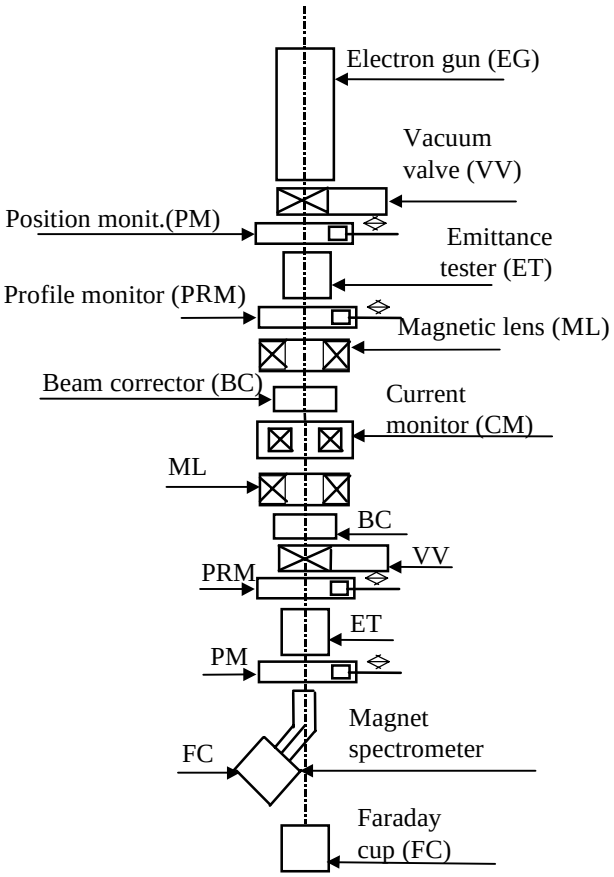

Fig. 2. Schematic layout of the EG test facility

system also includes high-power matched RF loads placed at the outputs of the sections. The RF system elements (except the SLED's cavities and the loads) were designed at MEPhI and produced by the ISTOK specialized manufacture. Some monitoring and RF-system control devices were designed at YerPhI and are being tested at the test facilities in Yerevan. When the testing will be finished that devices will be placed in own positions at the FSTF and at the LUE-200. Fig. 3 shows the layout of the IREN RF test-facility at YerPhI.

5 IREN MONITORING DEVICES

Within the project realization a number of basic principles on the IREN monitoring are being tested at the operable installation (LUE-40 + IBR-30) which is used as the IREN's test-facility. We try to build a stabile and reliable control system using free software base: FreeBSD and Linux operating system, free implementation of SQL server, HTTP server, etc. The use of the software which source codes are open gives us some advantage in comparison with commercial (and closed) software.

Such a monitoring system of the (LUE-40 + IBR-30) was created and put in experimental operation during the 1997-98. A set of pulse and continuous parameters are measured and stored with a real repetition rate 100 Hz. All the functions of the control systems (measuring, database storing, public access providing) are distributed between different UNIX workstations. Main attention is paid to provide a stability of the control system at emergency situations, such as AC power shutdown, network cable tearing, etc.

We also try to develop a software to provide an effective communication between personnel and users of the existing facility. All the information interesting for the users are available from the WWW, and WWW to SQL interface is used to access the databases.

6 CONCLUSION

The IREN project aimed to create the new JINR's base installation for fundamental research is being realized in the rigorous of the total crisis, caused by economic, political and social cataclysms of the recent years all over the territory of the Former Soviet Union. In spite of all the difficulties the IREN team does not lose hope to complete the project in the foreseeable future.

Work supported by .JINR Facilities Development Plan under contract .#0993. and partially by ISTC under contract A 087 at YerPhI.

CONSTRUCTION OF THE 8-GEV e^- / 3.5-GeV e^+ INJECTOR LINAC FOR KEKB

A. Enomoto, KEK e-/e+ Injector Linac Group*, and Linac Commissioning Group**
KEK, 1-1 Oho, Tsukuba-shi, Ibaraki-ken, 305-0801, Japan

Abstract

The KEK/PF 2.5-GeV linac has been upgraded since 1994 by upgrading the existing linac as well as extending it towards the upstream site. It has been almost completed and commissioned during May and June, 1998. This paper summarizes the construction status and the beam performance of the new injector.

1 INTRODUCTION

KEKB includes an 8-GeV electron (e^-) ring and a 3.5-GeV positron (e^+) ring, which has been under construction since the TRISTAN accelerator was removed. KEKB aims at a luminosity of 1 x 10^{34} $cm^{-2}s^{-1}$ with collisions between 1.1-A electrons and 2.6-A positrons.

One of the requirements of the injector linac is to deliver full-energy beams for both rings. The other is to increase the positron beam intensity to 0.64 nC (4 x 10^9 particles) /bunch with a repetition rate of 50 Hz. This positron intensity is ten-times as much as what the old linac produced, and when the beam could be injected without any beam loss, it takes 13.5 minutes to accumulate from 0 to a maximum charge of 26 μC, since the KEKB ring has a circumstance of about 3 km.

In order to achieve these requirements, the linac has been reconstructed and expanded [1]-[3]. For the energy upgrade, the number of accelerator modules was increased from 40 to 57, as well as the acceleration gain of each module from 70 to 160 MeV. The old positron generator was moved to a higher energy point of about 3.7 GeV from 0.25 GeV in order to increase the positron intensity.

2 CONSTRUCTION

The KEKB injector has been constructed since FY 1994 as a five-year program. Reconstruction of the old linac was finished by the end of FY1996; the linac expansion was constructed during FY1997 and the combination with the old linac was completed by the end of FY1997 (March, 1998).

2.1 Energy Upgrade of the accelerator module

In order to increase acceleration gradient, the rf source of the old accelerator modules has been upgraded from the downstream to the upstream using summer and winter shutdown terms. For increasing the rf peak power, the klystron modulator power was increased by twice, the 30-MW klystrons replaced by 50-MW klystrons, and rf pulse compressors (SLED: SLAC energy doubler) used. Including newly fabricated ones, 58 upgraded accelerator modules were so far constructed and the number of the remaining modules to be installed is only one.

	summer	winter	annual
-FY1994			5
FY1995		7	7
FY1996	12	15	27
FY1997	12	6	17
FY1998	1		1
		total	58

Among 58 accelerator modules, the SLEDs are not used in the most upstream module (pre-injector) and the accelerator module just after the positron radiator, in order to avoid any troubles due to electric breakdown.

2.2 High-power klystrons and modulators

The newly developed 50-MW klystrons are compact, size-compatible with the old 30-MW klystrons. They have been satisfactorily fabricated and installed according to the schedule described above.

Forty-seven klystron modulators were improved to double the pulse energy and 11 modulators were newly produced. The high-voltages applied to the klystrons were tuned so that the pulse width is 3.7 μs with ripples less than 0.3%. The high voltage control and the interlock monitor are made using programmable logic controllers.

During the linac commissioning in May and June 1998, the klystrons were operated at 25 pps and the output power was 38.6 MW in average of 55 modules with SLEDs; and corresponding calculated no-load accelerator gain was 164 MeV /module.

Matsumoto, S. Michizono, K. Nakamura, K. Nakao, Y. Ogawa, S. Ohsawa, T. Oogoe, T. Shidara, A. Shirakawa, T. Suwada, T. Urano, S. Yamaguchi
*2: N. Akasaka, A. Enomoto, J. Flanagan, H. Fukuma, Y. Funakoshi, K. Furukawa, N. Iida, T. Kamitani, M. Kikuchi, H. Koiso, K. Nakajima, T.T. Nakamura, Y. Ogawa, S. Ohsawa, K. Oide, K. Satoh, M. Suetake, T. Suwada

All the accelerator modules had been conditioned up to about ten-percent higher peak power, and the trip rate was low during the beam commissioning, ex., 0.31 times/klystron.hour during June 7 to 13. Since the operation started, two klystrons has been replaced owing to trouble in the output window and the gun cathode, respectively; and 4 more klystrons are to be removed during this summer shutdown in order to tune the focusing field again.

2.2 Low-power rf systems

The low-power rf systems have been extensively changed for the KEKB injector [4]. In order to synchronize the linac beam with the ring rf buckets within a requested precision of +-30 ps, the common factors between the linac and the ring rf frequencies were searched under the condition that the linac frequency was fixed and considering the ring rf bandwidth. The highest common factor was consequently chosen to be 10.38545 MHz, which is the 275 (11 x 5 x 5) -th subharmonic of the linac rf as well as the 49 (7 x 7) -th subharmonic of the ring rf (508.8872 MHz). This means the linac beam and the ring rf bucket are synchronized at 10.38545 MHz.

The subharmonic bunchers (SHBs), which produce single bunch beams from the gun beam pulses with a width of about 2ns, are to be operated at the fifth (571.2 MHz) and the 25-th subharmonic (114.24 MHz). For the former rf, a 10-kW solid-state amplifier was newly fabricated, however, for the latter, an old amplifier using vacuum tubes was still utilized with slight improvement.

The frequency of a master oscillator was chosen to be the fifth subharmonic (571.2 MHz). Using an optical fiber cable, the linac fundamental rf (2856 MHz) is transferred from a main-booster to sub-booster stations located at the upstream of every 8 accelerator modules.

For the SLED system, the sub-booster rf drive systems were improved so as to inverse phase at the latter part of the rf. The switching time is changeable. During the rf conditioning, it was set around 200 ns in order to avoid the rf breakdown.

Sub-booster klystrons were replaced by newly developed 60 kW klystrons in order to drive 8 klystrons instead of 4 klystrons in the old linac case. These klystrons are water-cooled. During the commissioning, the correlation between the rf phase shift and the cooling-water temperature was studied and measured 1 deg /0.1 deg.C. The temperature stability for the rf systems has been improved to be around 0.2 deg. by changing cooling-tour fan switching to continuous control of a 2-way valve.

2.3 SLEDs

So far 55 SLEDs has been operated. These SLEDs are of two-hole coupling type and are modified in order to facilitate handling in the existing linac: the tuner with smooth adjustments with the necessary resolution (2 kHz in resonant frequency); the drive mechanism of the detuner needle using solenoid. The radiation from the SLEDs is sufficiently low and the shielding is not necessary, though there are several SLEDs with relatively higher radiation. The tuners and the detuners are also well working.

2.4 Accelerator sections

About seventy 2-m sections, which are $2\pi/3$-mode traveling-wave structures, were fabricated using electro-plating method. One of them was tested up to 36 MV/m (21 MV/m is operational), where any limitation was not found. By the linac commissioning, all of the new sections were conditioned without any problem up to more than the operational gradient.

An accelerator section used just after the positron radiator is one meter long; the input coupler has two symmetric coupling holes in order to reduce electric field around the coupler and the input waveguides. This section is operated in the solenoidal magnetic field of 0.5 T and fed by an rf of about 30 MW, 1 μs without a SLED, producing an acceleration gradient of 17 MV/m. Rf conditioning for the accelerator sections used in the magnetic field was carefully performed. Consequently the klystron trip due to electric breakdown was hardly experienced during the commissioning for the positron beam in June. This was a drastic change from the four-meter sections which had been used in the old positron source.

2.5 Pre-injector

The KEKB injector requires the pre-injector to produce single bunches with a bunch length of about 10 ps (FWHM) and a charge of more than 10 nC. The gun is able to emit pulsed beams with a pulse width of about 2 ns (FW) and a peak current of about 10 A. In order to compress the gun beam to the single bunch beam, a 114.24-MHz SHB and a 571.2-MHz SHB were installed before the 2856-MHz bunchers. The gun beam energy was increased up to 200 kV (100 kV in the old electron linac) for suppressing space charge effect on the basis of a computer simulation. The pre-injector showed a good beam performance in the commissioning.

2.6 Positron production

The main improvement for the positron source was to replace 4-m accelerator section by shorter sections. In the KEKB injector, two 1-m sections and two 2-m sections were installed and rf pulses with shorter width are to be fed. This improvement was very effective for stable operation of the positron beam. The electron-to-positron conversion rate normalized by the incident electron energy was about 3.3%/GeV at the end of the linac.

2.7 Beam Instrumentation and control

One of the great progress of the KEKB injector from the old injector is to have developed a beam instrumentation system based on beam position monitors (BPMs)

which were installed at every location of quadrupole magnets [5]. The BPMs were widely utilized to tune linac beam in such cases as orbit correction and dispersion correction of the linac beam transport system.

The BPMs comprises stripline-type beam position monitors and associated signal analyzing systems. For solving man-power problem to develop a data acquisition system, 17 digital sampling oscilloscopes, which are of 5 GHz, 2 ch, and communicated with a VME computer, were distributed every half of the linac sector (typically 38.4 m). The signals are combined by combiners so that each peak is not overlapped and their peaks are measured using the oscilloscope functions and analyzed by VME. The position signals for one beam pulse are measured by a beam-trigger signal distributed to the monitor station. The position information from all BPMs is renewed every 1.4 second at present.

The other important monitor is a streak-camera system to observe the bunch structure of the linac beam [6]. The streak-camera system was also used in the old linac. However, it was not so easy to handle, because it consisted of separate devices, such as an optical system, a trigger and its delay system, a synchronization circuit between the trigger and the rf to reduce trigger jitters, as well as a streak camera proper. Further, air-Cherenkov light emitted by a beam was used as a light source into a streak camera; therefore, it has for a long time been used only for experiments.

Newly developed streak-camera systems are more simply arranged, computer controlled, and they utilize optical transition light (OTR) emitted from a metal mirror which can be easily inserted to the beamline. Thus four streak-cameras were installed after the pre-injector, after the linac arc, after the positron radiator, and the linac end. So far they were frequently used at the pre-injector as a real time bunch tuner.

2.8 Linac Alignment

All the buncher system are operated in the Helmholtz coil of about 0.1 T. In this low energy region, the alignment of the equipment was carefully checked; by changing the gun beam energy, the position change on beam screens was investigated. However the alignment has been still checked in this summer shutdown, because it was essential to use steering coils before the buncher during the commissioning.

The linac alignment has not been sufficient at present. One of the reason is the girder slide rollers were superannuated. They have been replaced during this summer shutdown. And the linac alignment will be selectively improved upstream of the positron radiator in order to increase the primary electron beam intensity.

3 BEAM PERFORMANCE

The linac commissioning was carried out as scheduled in May and June and the results near to the design were obtained as follows:

electron			positron	
	dsgn	achvd	dsgn	achvd
energy (GeV)	8	>8	3.5	>4
charge (nC/bunch)	1.2	1.5	0.64	0.6
energy width (% FW)	0.5	----	0.5	0.8
emittance (1σ, mm)	1.1	----	1.6	2.3

A remarkable feature of the linac commissioning was use of the beam instrumentation system and SAD (strategic accelerator design) computers in various stages of the beam tuning. Especially it was indispensable to tune high-current electron beams for positron production while suppressing emittance growth.

4 SUMMARY

(1) A linac upgrade was almost completed. A total energy of more than 8 GeV and average module gain of more than 160 MeV (20 MeV/m) were obtained.

(2) A positron beam near to the design quality has been achieved.

(3) To achieve a complete performance in the KEKB commissioning, the remaining issues, such as the linac alignment check, replacement of the old devices, and preparation for the 50-Hz operation, is to be still continued during this summer.

Abstract

A new grid pulser for a short pulse was installed in the electron gun system. The emission pulse length can be changed from 250ps to 1ns with the peak current of 1.6A. The single bunch operation in the storage ring was successfully achieved with the purity of 10^{-6} order.

1 INTRODUCTION

The SPring-8 is a third generation synchrotron radiation X-ray facility with a 1GeV linac, 8GeV booster synchrotron and 8GeV storage ring. We succeeded in the acceleration to 1GeV by the linac in August 1996, and in acceleration to 8GeV by the booster synchrotron in December 1996. In March 1997, the storage ring was accumulated the 20mA beam current with long life time. In May 1998, the storage ring was stored the electron beam with maximum current of 100mA.

SPring-8 linac with maximum energy of 1GeV is consisted of 13 high power klystrons(E3712,80MW) and 26 acceleration tubes[1,2]. The preinjector of the linac is composed of 200kV thermionic gun[3], two single-cavity prebunchers, a standing wave buncher and a high-gradient acceleration tube. The emission current from the linac has been produced various kinds of the pulse length from 10ns to 1μs and an energy of 60MeV, which are requested by the operation modes of the storage ring. We have been planned the 1ns emission of the linac for the efficient injection to the storage ring. Since this autumn, 1GeV storage ring(so called New SUBARU) which is under construction in SPring8 site will be also injected the 1ns emission from the linac. However, the 1ns emission have not been supplied in the 8GeV storage ring. Recently, the single bunched beam operation of the storage ring was achieved by using the new grid pulser(three fixed outputs 250ps,500ps,1ns).

2 PERFORMANCE OF GRID PULSER FOR SINGLE BUNCH EMISSION

The grid pulser system is shown in Fig.1. This system has three grid pulsers; a single-mode grid pulser(less than 1ns), a short-mode grid pulser (10-40ns) and long-mode grid pulser(1μs). The single-mode pulser has three outputs with the fixed pulse length of 250ps, 500ps and 1ns through the front panel N-type connectors, and the rise time of each pulse is about 200ps. These grid pulser are installed on the gun high-voltage deck. In order to achieve rapid exchange of the grid pulsers, the grid pulser system is connected with a coaxial rotary switch controlled remotely from the control room. The emission test was carried out with the 1ns pulse length of the single-mode grid pulser.

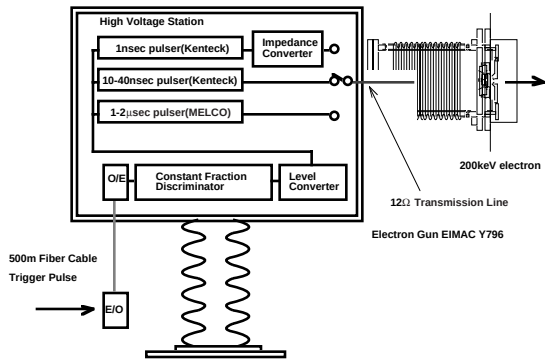

Figure 1: Schematic drawing of the grid pulser system.

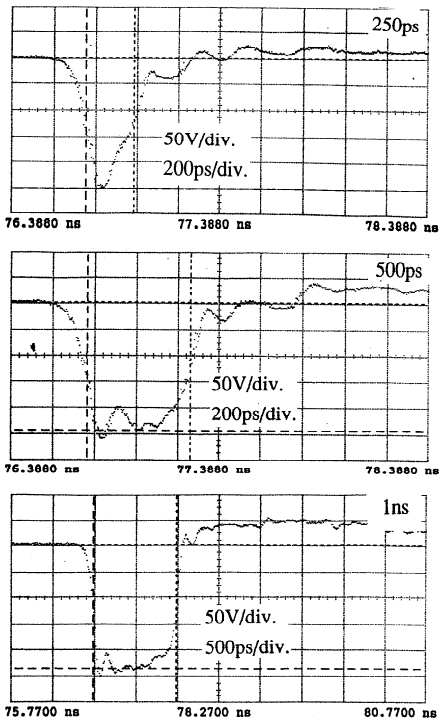

Figure 2: Waveform of three fixed outputs of single-mode grid pulser(250ps,500ps,1ns)

The external grid pulser trigger was transmitted through a single-mode optical fiber, which has low dependence on the room temperature, developed by Sumitomo electric industries. This fiber has a thermal coefficient for a delay of less than 0.4ppm. We use circuits made by ORTEL Co. as electrical-to-optical(E/O) and optical-to-electrical(O/E) converters, with a jitter of less than 2ps(rms) and a maximum frequency of 10GHz. The external trigger of grid pulser is synchronized both 508MHz(synchrotron, storage ring) and 60Hz(line frequency).

The waveform of the three fixed outputs of the single-mode grid pulser is shown in Fig.2. The peak-to-peak time jitter of three fixed output(250ps,500ps and 1ns) is 26ps, 28ps and 25ps, respectively. The relationship between pulser control voltage and pulser output voltage is shown in Fig.3. The output voltage of grid pulser is changed from 120V to 300V at the port of 1ns output.

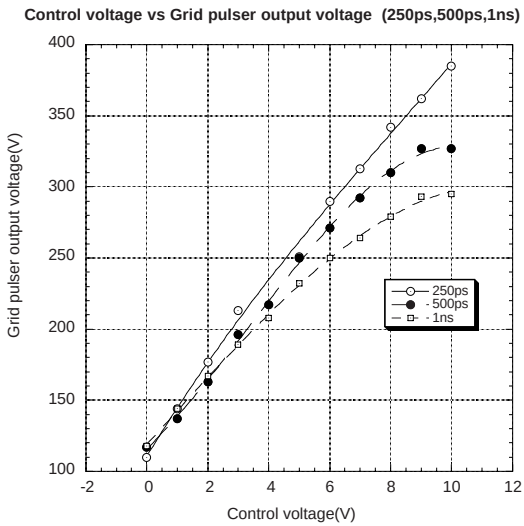

Figure 3: Control voltage vs grid pulser output voltage

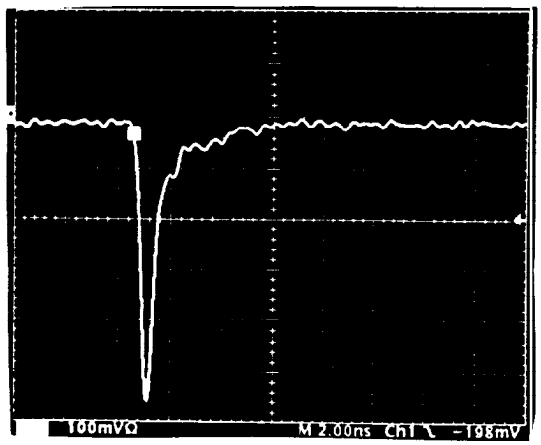
3 EMISSION & ACCELERATION TESTING

The waveform of the emission current from Y796 electron gun is measured by the SCM(wall current monitor) as shown in Fig. 4[4,5]. The maximum emission current is 1.6A with pulse length of 1ns.

Fig.5 shows the relationship between emission current and the output voltage of the single-mode grid pulser. The 1ns emission current shows the good linearity. We measured the characteristics of the 1ns beam which was accelerated up to the maximum energy of 1GeV. The beam position and shape were adjusted by checking screen monitors and the beam current was measured by wall current monitors. After fine adjustment of the beam transport, the transmission efficiency of the bunching section of linac was about 60%, and the transmission efficiency of the whole linac from the bunching section to an 1GeV beam dump was 95%. Using the chicane after the last acceleration tube, the energy spread and the beam energy was measured. The energy spread of beam was observed by the profile of screen monitor at the chicane center point(dispersion function 1m). The x-direction distribution of screen monitor at the chicane center point was 7mm. Consequently, energy spread of beam was within 0.7%.



286mA/div. , 2ns/div.

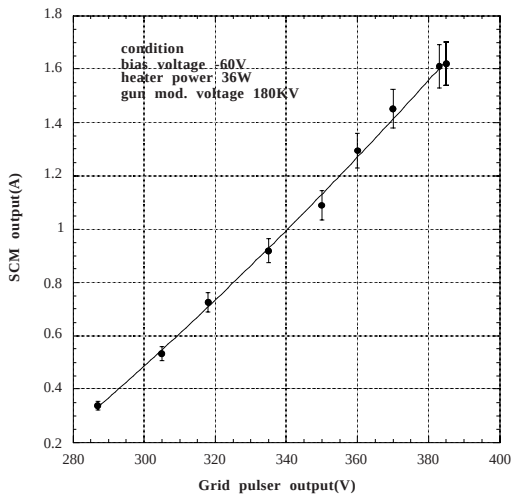

Figure 5: Relationship between grid pulser output and emission current

4 SINGLE BUNCH OPERATION OF STORAGE RING

We tried single bunched beam operation which accumulated the 1ns beam from the linac at the 21 buckets of the storage ring. Because Y796 cathode assembly was used for last 3 years, the grid was coated with Ba so that the grid emission has been increased. The current of the grid emission of 10^{-4} compared with the peak current of 1ns electron beam. By kicking the satellite

beam by the RF-KO of the synchrotron, the pure single bunched beam was obtained. The purity of the single bunched beam was observed by the technique of the optical measurement as shown in Fig.6. The purity of the single bunched beam was achieved to be the order of 10^{-6}.

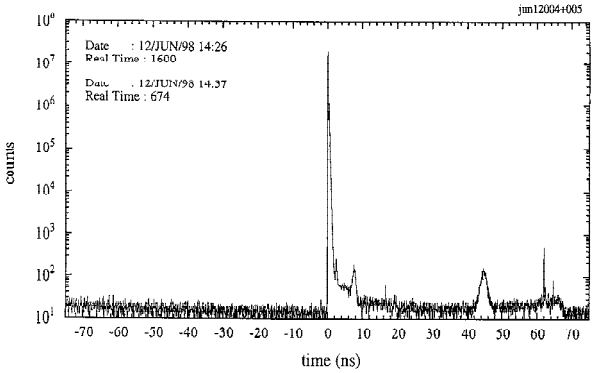

Figure 6: Measurement of single bunched beam of storage ring

5 CONCLUSIONS

We succeeded for accelerating the 1ns electron beam and accumulating the single bunched beam at the 8GeV storage ring. The grid emission was observed to be order of 10^{-4} compared with the electron beam. The purity of the single bunched beam of the storage ring was obtained to be order of 10^{-6} by means of eliminating the satellite beam by RF-KO of synchrotron.

PERFORMANCE OF AN *AccSys Technology* PL-7 LINAC AS AN INJECTOR FOR THE IUCF COOLER INJECTOR SYNCHROTRON

D.L. Friesel and W. Hunt, Indiana University Cyclotron Facility, Bloomington, IN, 47408

Abstract

An AccSys Technology Model PL-7 Linac is used to pre-accelerate H^- ions to 7 MeV for strip injection into a new 2.4 T-m injector synchrotron now being commissioned at IUCF. The Cooler Injector Synchrotron (CIS) is designed to inject over 10^{10} polarized protons or deuterons per pulse at 5 Hz into an existing electron cooled synchrotron-storage ring (Cooler) for nuclear research [1]. The linac, a 3 MeV RFQ coupled directly to a 4 MeV Drift Tube Linac, is designed to transmit over 1 mA of 7 MeV H^- ions to the CIS injection beam line with 85% transmission, 1 π mm mrad normalized emittance and 1% energy spread. Two 350 kW, 425 MHz rf amplifiers power the linac which accelerates variable pulse width H^- ions at duty factors up to 0.2%. We discuss the beam performance of this unique linac after a year of service as a synchrotron injector, and compare measured beam properties with calculations made during design and fabrication.

1 INTRODUCTION

Negative ion strip injection into the CIS booster synchrotron is required by the relatively low intensities ($\leq$ 5 mA) of polarized proton and deuteron beam ion sources. Strip injection and accumulation calculations for H^- ions on thin Carbon foils (2 – 8 μgm/cm^2) predict that a minimum energy of 5 MeV is required to achieve the intensity goals desired for Cooler injection, with higher energies yielding higher intensity gains [2]. This led to the selection of an AccSys Technology Model PL-7 Linac as the H^- pre-accelerator for CIS. The PL-7 linac design consists of a modified AccSys Technology 3 MeV RFQ directly coupled to a 4 MeV, 22 cell drift tube linac. Beam matching from the RFQ into the DTL is done internally at the RFQ exit and the DTL entrance. Indiana University and AccSys technology entered into an "Industrial Partnership" agreement whereby AccSys designed and built the accelerating structures and power amplifiers. IUCF supplied the source, LEBT, RFQ vacuum vessel, commercial hardware and some manpower support. Fabrication of the IUCF 7 MeV H^- linac, the prototype of the present AccSys Model PL-7 design (serial No. 001), began at AccSys in June, 1995 and was completed by December, 1996.

Construction of a booster synchrotron (CIS) to replace the IUCF cyclotrons as an injector for the Cooler [1] began in late 1994. Beam commissioning of the H^- linac pre-accelerator and the ring strip injection system began in January 1997 with a 25 keV unpolarized H^- beam and resulted in the injection, accumulation and capture of both 3 and 7 MeV protons in CIS. Construction of an intense pulsed H^- polarized ion source (CIPIOS) [3] also began in January 1997. Beam acceleration studies beginning in Nov. 1997 resulted in the acceleration of 10^{10} protons to 240 MeV by May 1998. Beam extraction and Cooler injection development will begin during the last quarter of 1998 and CIPIOS will deliver polarized H^- beam to CIS and the Cooler in the first quarter of 1999. The CIS lattice design [4], beam performance goals [5,6], and initial H^- beam strip injection and acceleration commissioning results were previously reported [7,8,9].

2 LINAC DESCRIPTION

Design specifications for the IUCF Model PL-7 Linac are listed in Table I, and were determined from modified versions of the linac design codes PARMTEQ and PARMILA. Beam measurements made during the last year, described below, are compared with these predictions. A layout of the PL-7 RFQ/DTL pre-accelerator is shown in Fig. 1, and details of the 4 vane RFQ and 22 cell DTL accelerating structures and 350 kW amplifier systems are provided in Ref.[7]. The RFQ

3 LINAC PERFORMANCE

For all measurements reported here, a ≤ 1.0 mA peak, 25 keV unpolarized H^- beam from a duoplasmatron source is focused at the entrance of an AccSys Technology model PL-7 Linac. Beam is matched to the Linac (RFQ) acceptance requirements (symmetric 1.3 mm beam radius and 125 mrad convergence half angle, normalized emittance of 1.0 π μm) via a Low Energy Beam Transport (LEBT) system consisting of three Einsel lenses, an x/y steering magnet and an electron beam sweep magnet. Diagnostics including a multi-wire harp, an emittance scanner and a beam stop were designed into the LEBT. Measurements of the 25 keV H^- beam properties at the RFQ entrance are $\varepsilon \leq 0.6\ \pi$ μm, $\alpha = 0.62$ and $\beta = 0.012$, well within the AccSys specifications. The small source emittance is not necessarily an advantage for the PL-7 linac, which was designed for an acceptance of 1.0 π μm. The new polarized source, however, will have a beam emittance more closely matched to the PL-7 emittance requirements.

The 425 MHz three stage power amplifiers for the linac must provide the required RFQ and DTL cavity fields with amplitude and phase stabilities of ± 0.5% and ± 0.2° respectively to achieve the 7 MeV H^- beam properties listed in Table I. Significant improvements to the frequency, phase and amplitude loops were required at IUCF to meet these specifications, which are critical to the injection performance goals for CIS. The frequency and phase loops operate to specification. Until recently, however, the cavity amplitudes were run open loop to achieve the RFQ and DTL required threshold fields because the amplifiers, based on the EIMAC YU-176 triode tube, had insufficient power to maintain stability with these loops closed. The amplifiers must typically run above 295 kW.

The performance of the linac was characterized by measuring the properties of the 7 MeV H^- beam using several diagnostic systems in the 9m transfer beam line between the linac and the CIS ring. The RFQ cavity field threshold (V_o) was determined to be 4.35 V on a diode attached to a small pickup loop by measuring the transmission of beam through the linac with the DTL turned off as a function of cavity field. Typically, beam transmission through the linac is 80%, although transmissions as high as 90% have been observed. Beam time-of-flight pickups in the 7 MeV transfer beam line are used to monitor the energy and energy stability of the beam from the linac. The orbit period of the strip injected proton beam in the CIS ring is also used to independently verify the energy of the H^- beam extracted from the DTL. At the measured DTL threshold diode voltage of 3.57 V, the rf capture frequency of an optimally stored proton beam in CIS is 2.09730 MHz (h=1), corresponding to a circulating proton beam energy of 6.990 MeV. The 7 MeV H^- beam emittance was measured to be between 0.6 and 1.0 π μm.

The FWHM energy spread of the H^- beam was measured to be ± 85 keV via elastic scattering from a 2.5 mg/cm^2 Au foil with planar Si surface barrier stopping detectors at 30° scattering angles. This slightly larger than the predicted value of ±75 kV by AccSys was caused by our inability to close the DTL amplifier cavity field amplitude loop. This is illustrated in Fig. 2. The upper trace is an oscilloscope display of the TOF energy measurement of a single 200 μsec long, 7 MeV H^- beam pulse from the linac. The two initial peaks in this trace are instrumental "turn-on" noise, while the energy fall off (≈200 keV) during the last 40 μsec is real and mimics the DTL cavity field amplitude fall-off with pulse length. The vertical scale for this trace is 100 keV/div. The lower trace is the intensity of strip injected proton beam in the CIS ring (0.2 mA/div), which exhibits a similar decrease with pulse length that is not evident on the H^- beam stop prior to injection. When amplifier upgrades allowed the amplitude loops to be closed, the TOF energy fluctuations were reduced to 25 keV, which reduced intensity fluctuations for strip injected beams.

These data illustrate the importance of stable linac cavity fields on the injection efficiency of protons into the CIS ring. The TOF energy monitor is continuously displayed during routine CIS operations to diagnose and correct linac (DTL) stability problems. Even with the DTL amplitude loop open, injection stability is quite acceptable for long running periods when the Linac is properly tuned and has reached thermal equilibrium after startup. With the loop closed, accumulated

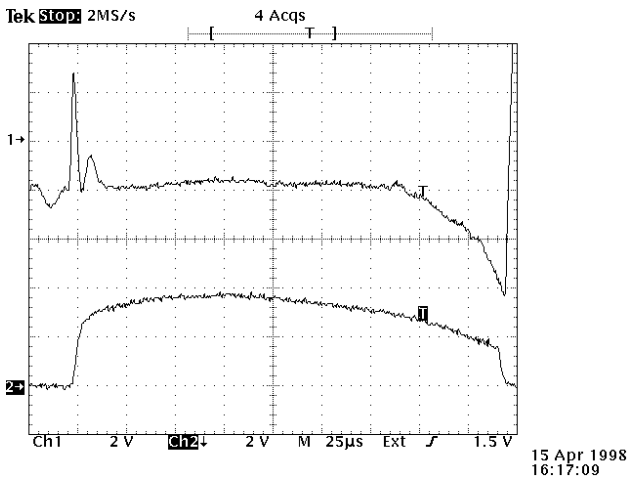

Figure 2. Scope displays of the 7 MeV H^- beam TOF energy (upper) and first turn proton beam intensity in CIS (lower).

and stored beam intensity typically varies by less than a few percent from cycle to cycle.

The focussing properties of the 7 MeV H^- beam exiting the linac were determined to be very close to the predictions provided by AccSys, which were used to design the transfer beam line optics that match the linac beam to the synchrotron acceptance. The beam line focussing elements and measured beam envelope are within 5 % of the values predicted using the optics code TRACE 3D, and beam transmission from the linac to the stripper foil in the ring is better than 85%.

4 BEAM INJECTION & RF CAPTURE

The linac delivers a 300μsec H^- beam pulse on a 4.5 $\mu g/cm^2$ stripper foil in the CIS at up to 5 Hz repetition rates for the injection and accumulation of 7 MeV protons. Two bumpers displace the ring equilibrium orbit onto the foil for strip injection and proton accumulation. Typically, an equilibrium accumulation of 8×10^{10} protons occurs in 200 μsec, after which the bumpers are turned off and adiabatic turn-on of a 1st harmonic rf cavity is started. Only about 2×10^{10} protons are rf captured and stored 2 msec latter because of the short 1/e beam lifetime (< 0.5 sec) in the 0.2 μTorr average ring vacuum. The captured beam bunch factor is 2.5 for an rf cavity voltage of 250 volts.

A schematic diagram of the RFQ, DTL and bumper fields, the linac H^- beam pulse and the injected proton beam accumulation relative timing required for optimal strip injection is shown in Fig. 3. We were surprised to find that the DTL cavity field must be at threshold before the 25 keV H^- beam from the source is injected into the linac or the DTL cavity field clamps to zero. This phenomenon was not observed when testing the linac at AccSys with protons. It is likely that stripped electrons produced in the RFQ cause multipactoring in the DTL which prevent its' rise to full field. This inconvenience was resolved by pulsing the source extraction HV in time with the RFQ cavity field, delayed by

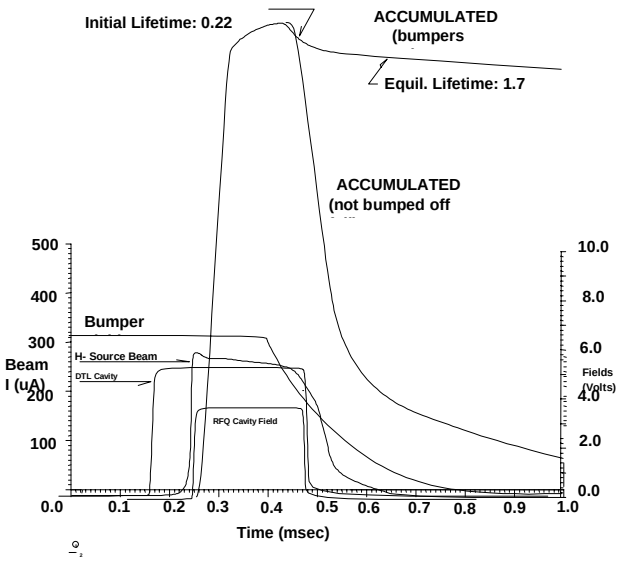

Figure 3. PL-7, bumper, and beam timing diagram.

as little as 30 μsec after the DTL cavity reaches full field. The RFQ pulse width must reside within the bounds of the DTL field anyway to insure that only 7 MeV H^- ions enter the transfer beam line, since 3 MeV H^- ions transmit through the Linac with equal efficiency as 7 MeV ions when the DTL cavity field is turned off.

5 CONCLUSIONS

The PL-7 linac has been used for over 1400 hours during the last year to inject 7 MeV protons into the new IUCF Cooler Injector Synchrotron. While some development of the RF amplifiers was required to achieve the guaranteed beam properties reported here, this linac has proven to be a reliable and stable source of 7 MeV H^- ions for strip injection into CIS. When delivered, the PL-7 linac was yet another new accelerator type introduced into the IUCF inventory. With continuous support from AccSys Technology, we have undertaken the effort to upgrade the amplifiers at IUCF ourselves to facilitate our understanding and maintainability of this system. The accelerating structures have proven to be rugged and reliable while the beam properties from this accelerator are reproducable to the point where no tuning of the transfer beam line and little tuning of the ring injection parameters are required to routinely achieve optimum strip injection performance. Turn-on during startup is usually quick (30 minutes), and once tuned up, the linac performs reliably for long periods of time, becoming invisible during other ring development activities such as beam acceleration and extraction studies. We are confident that these accelerator properties will be maintained as the CIS ring moves from developmental to operational status.

6 ACKNOWLEDGEMENTS

The work reported here was made possible by the skill and dedication of the technical and profession staff of IUCF, who were involved in all phases of this construction and commissioning effort. Clearly, this report could not have been made without the expertise and generous support of the professionals at AccSys Technology, Inc.

A 100 MeV SUPERCONDUCTING PROTON LINAC: BEAM DYNAMICS ISSUES

M. Comunian, A. Facco, A. Pisent
INFN Laboratori Nazionali di Legnaro, Legnaro, Padova 35020 ITALY

Abstract

Proton linacs with beam intensities between 10 and 120 mA in CW are under study in various laboratories, for applications that go from fundamental physics to energy production and nuclear waste transmutation. The majority of the projects consider, for energy above 100 MeV, the use of a superconducting linac, which is particularly convenient for "moderate" currents (10-50 mA). For the low energy part the situation is unclear, and the advantages of a superconducting structure have not been generally recognized yet. In this paper we consider a possible architecture for a 100 MeV linac based on independently phased resonators, and we give a first analysis of the beam dynamics issues, and the resulting cavity specifications. The flexibility of such a linac, for the use with different charge over mass ratios and beam currents, will be underlined.

1 INTRODUCTION

The interest for a superconducting proton linac covering the traditional DTL energy range has recently grown, in connection with various high intensity linac studies. We considered in this paper an Independently phased Superconducting Cavity Linac (ISCL) similar to those used for low energy heavy ions in many nuclear physics laboratories like ours, but at much higher beam intensity, and in a wider beta range. Development of cavities for this kind of applications has been done mainly at ANL[1], and other studies can be found in literature[2]. The high power coupler design and the beam losses control are specific problems related to the high beam power.

We show here a preliminary analysis at 352 MHz. Our attention is centered on beam dynamics issues: we determined a preliminary set of parameters that could help in cavity development. The classical chain of LANL programs (PARMTEQM, PARMILA…) was adapted to this specific problem so to have results based on well proven codes (especially for what space charge and initial distributions are concerned). We checked various approaches, like single and double gap cavities, 176 MHz and 352 MHz [3].

The most promising design for 30 mA beam current is based on the so-called “reentrant cavities”, that are modified pillbox, cylindrically symmetric and therefore theoretically dipole free.

2 THE ISCL

The linac was designed taking the main beam parameters used for TRASCO, the INFN-ENEA feasibility study for a waste transmutation Accelerator Driven System (ADS). In Tab. I we list the main specifications and the beam characteristics from the 352 MHz 5 MeV RFQ, with some emittance dilution in the matching line[4]. In the last two rows we specify the two main constraints of the independently phased resonators: the surface field and the beam loading per cavity. In particular the second constraint is specific of high current machines: in our case we want to feed each cavity with a single solid state amplifier and the limitation to 15 kW seems consistent with the present technology.

Table I: Main specifications of the linac.

Particle species		p	
Input energy		5	MeV
Output energy		100	MeV
Beam Current		30	mA
Duty cycle		100%	
Input RMS Emittance	Trans (norm)	0.4	mmmrad
	Long.	0.2	MeVdeg
Frequency		352	MHz
Maximum beam loading/cavity		15	kW
Maximum surface field		25	MV/m

3 THE REENTRANT CAVITIES

Various kind of superconducting resonators were developed or proposed for this β-range. Among them an attractive choice is a modified version of the reentrant cavities developed at Stanford [5]; in this early work the feasibility of low-β, single-gap niobium structures with good RF performance and no serious multipacting problems was demonstrated [6]. At the frequency of 352 MHz and in the presence of a relatively large bore, these cavities present many advantages: the axially symmetric shape avoids dipole field components; the single gap guarantees the widest velocity acceptance and the possibility of covering the full interval from 5 to 100 MeV with only one type of resonator; the simple geometry, which requires very few electron beam welds, allows for a low construction cost in the view of mass production. The maximum field achievable in superconducting cavities is usually limited by the onset of field emission; single gap structures, then, could

appear less attractive than multigap, high shunt impedance ones. However the relatively low energy gain per cavity which is required in our linac design and the low surface electric field ratio E_p/E_a of reentrant cavities make them perfectly adequate to the aim. The ISCL resonator characteristics, calculated by means of the program SUPERFISH, are listed in Tab. II. In fig.1 the shape of the new resonators and the design of the Stanford cavity are shown.

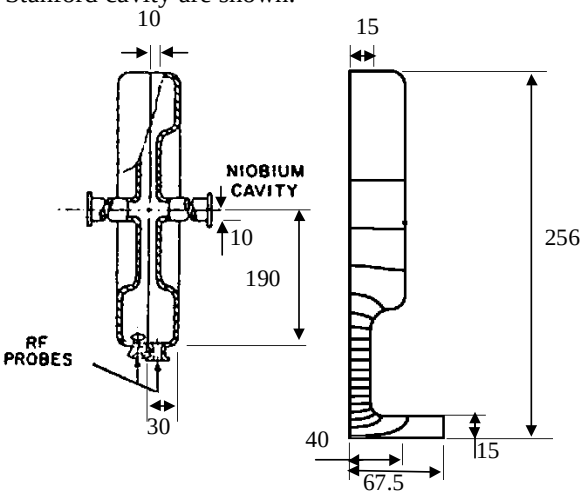

Figure 1: Reentrant cavity: the Stanford cavity (430 MHz [6]) and the proposed ISCL geometry (352 MHz).

H_p/E_a	32	Gauss/(MV/m)
$\Gamma=R_s\times Q$	82	Ω
R'_{sh}/Q	18	kΩ/m

4 BEAM DYNAMICS

We have chosen a FODO focusing structure with period $6\beta\lambda$. As the period becomes longer, a larger number of cavities can be installed between the quadrupoles. This design gives the advantage of an almost constant quadrupole gradient and beam envelope in the whole energy range. The zero current transverse phase advance per period is about 55 deg and the initial depressed one 45 deg. Moreover the adiabatic increase of the period makes the beam matching easier at the two extremes, with the RFQ and with the main linac.

The quadrupole parameters can be reached both by normal conducting and superconducting quads. Nevertheless, due to the lack of space, it is necessary to use superconducting quadrupoles installed inside the same cavity cryostat. A cost-effective design of such magnets is an open point.

The preliminary power consumption figures in Table III are rather conservative.

Table III: ISCL Parameters (30 mA).

Total length		65	m
Synchronous phase		-30	deg
Average acceleration		1-1.8	MeV/m

12.5 ÷ 28	2	30	60
28 ÷ 30	3	4	12
30 ÷ 55	3	18	54
55 ÷ 100	4	26	104
	Total	101	253

The linac has been simulated with PARMILA (standard PC version), using 10000 macro particles and about 700 elements (concatenated runs). Each cavity is represented by an accelerating gap. The structure of the linac, following the scheme of Tab. IV, is generated by an EXCEL workbook that writes the input files for PARMILA and reads the results preparing automatically several plots.

In Fig. 2 (upper part) the most significant parameters are plotted as a function of length. The transit time factor is in the range 50-98%. The voltage per cavity is chosen as to maintain a constant energy gain per linac length in the two linac parts; from the W plot the first (about 1 MeV/m) and the second (about 1.8 MeV/m) part of the linac can be distinguished. The plots of the surface field and of the energy gain per cavity show that the constraints are fulfilled.

In Fig. 2 (lower part) we plot the RMS envelopes, less then 1/7 of the aperture, and the emittances. Due to the non adiabatic change of the period structure some residual mismatch cannot be avoided. The emittance increase is acceptable, and can be partly seen heuristically as an exchange of energy (equipartitioning) between the longitudinal and the transverse degree of

* The BCS resistance is 58 nΩ.

freedom. The transverse degree of freedom is colder because the ISCL period is 6 times the RFQ period.

We have simulated currents up to 50 mA , and we did not see losses (10000 macro particles). Smaller losses must be investigated by other means.

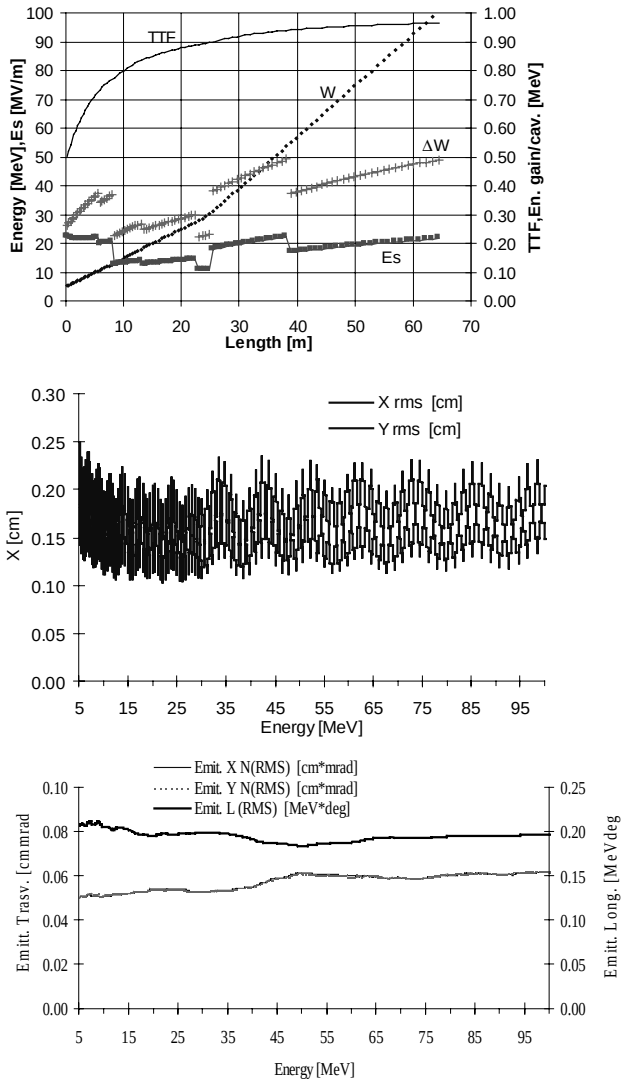

Fig. 2: Linac parameters as a function of position, RMS envelopes and Beam Emittance as function of energy.

5 DIFFERENT MODES OF OPERATION

The ISCL, in addition to a lower power consumption, has, with respect to a traditional DTL, the advantage of a considerable flexibility. It allows (see Tab. IV):

1. The compensation of the lack of performance of some cavities with the adjacent ones;
2. The use of the linac, with reasonable efficiency, at lower intensity keeping the CW characteristic of the beam;
3. If the linac is used as stand alone at low current (~1 mA) the field can be increased so to get almost 140 MeV of final energy (Exotic Beam production);
4. A moderate current of particles with q/A= ½ can be accelerated up to a final energy of 70 MeV/u.

Table IV: ISCL Operation modes (CW).

Particles	p	p	d	
Peak Current	30	1	<1	mA
Final energy	100	140	70	MeV/u
Beam Power	3	0.14	<0.15	MW
Mains Power	7	2	2	MW
Efficiency	41	7	7	%

6 CONCLUSION

We have designed a 352 MHz superconducting linac, able to accelerate a 30 mA CW beam up to 100 MeV, to be injected in the superconducting linac of a waist transmutation driver, but also able to accelerate, with good efficiency, 1 mA up to 140 MeV CW, as required for exotic beams production. Single gap axially symmetrical cavities (with a single design in the whole energy range) have been used. Many points of this design work are preliminary, but can be used as a base for cavity R&D.

STATUS OF THE SUPERCONDUCTING HEAVY-ION TANDEM-BOOSTER LINAC AT JAERI

S. Takeuchi and M. Matsuda

Japan Atomic Energy Research Institute, Tokai Research Establishment
Tokai, Naka, Ibaraki 319-1195 Japan

Abstract

An independently phased superconducting linac has been used over four years as the heavy ion booster for the JAERI Tandem accelerator at Tokai since its completion in 1994. This report describes the status of the resonator performances, especially the relief of Q degradation of hydrogen-polluted resonators by applying a sequential fast precooling method and other possible methods. A big air leak which happened to cold resonators is also reported.

1 INTRODUCTION

The superconducting heavy ion booster for the JAERI Tandem accelerator at Tokai is an indepependently phased linac composed of 46 superconducting quarter wave resonators, which are made of solid niobium and niobium-clad copper, and all of which optimum velocities are 0.1c[1]. There has been no resonator troubles resulting in cryomodule opening since the completion in 1994. Heavy ions of Ni, Ge, Se, Zr, I, Au and etc from the 20UR folded type pelletron tandem accelerator were boosted at accelerating fields of 3 - 5 MV/m per resonator and transported to the targets for experiments of nuclear or solid-state physics.

We have a problem called *Q-disease* that the resonators in the first four linac cryomodules suffer from hydrogen Q-degradation, which is due to significant hydrogen absorption during the electro-chemical surface treatment and precipitation of hydrides on the resonator surfaces during slow pre-cooling by the cryogenic system. A sequential precooling method was applied to the resonators to increase cooling rates across the temperatures from 130K to 90K in order to suppress the Q-degradation.

Recently, a big air leak happened in the linac due to a beam hit. This paper mainly reports the results of the fast precooling and the air leak accident. Our efforts to extract hydrogen from the niobium walls are also reported.

2 RESONATOR PERFORMANCES

2.1 Recovery of Q by Fast Precooling

We found that a severe Q-degradation happened to a resonator after it was cooled taking a long time between 130K and 90K[2]. The cooling rate of 10 -12 K/h by the cryogenic system is too slow and should be increased to 20 -40 K/h in order to moderate the Q-degradation. Fortunately, the cold helium gas was designed to flow into the cryomodules in parallel. The helium flow could be concentrated to a few cryomodules while the resonators in them were cooled down across the precipitation zone of 130K to 90K, and sequentially switched to others.

The first four linac cryo-modules which contain the resonators ill of Q-disease belong to seven cryo-modules cooled by a cryogenic system. We tried two modes of a three-modules-by-three-modules sequence and a two-modules-by-two-modules sequence. The cooling rates obtained by the two modes were 17 -27 K/h and 21-48 K/h, respectively. The reason that the rates were spread wide is that the four resonators are cooled in series in a cryo-module.

The low-field Q values of the 20 resonators measured after the two precooling modes as well as the normal precooling mode are shown in Fig. 1. Resonators of no.1 to no.16 are the ones in the first four cryomodules. The Q values were recovered to 65 - 80 % of the off-line test results by the two-modules-by-two-modules mode, except the two severely sick resonators no. 2 and 4. Those two resonators may need a treatment of hydrogen outgassing to recover satisfactorily.

Figure 2 shows the accelerating field gradients of the first 20 resonators measured at rf input of 4 watts after normal precooling in 1995 and after the two-modules-by-

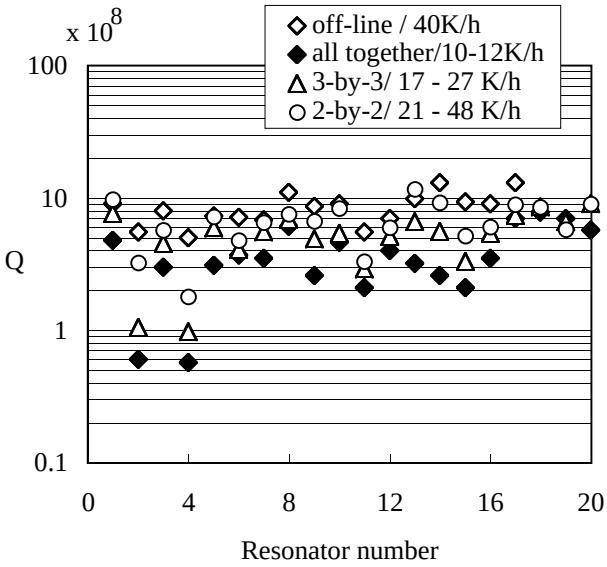

Fig.1 Low field Q of the first 20 resonators measured after four different precooling rates across the range of 130K to 90K; in the off-line tests, after the normal all-together precooling mode and after three-by-three and two-by-two sequential precooling modes.

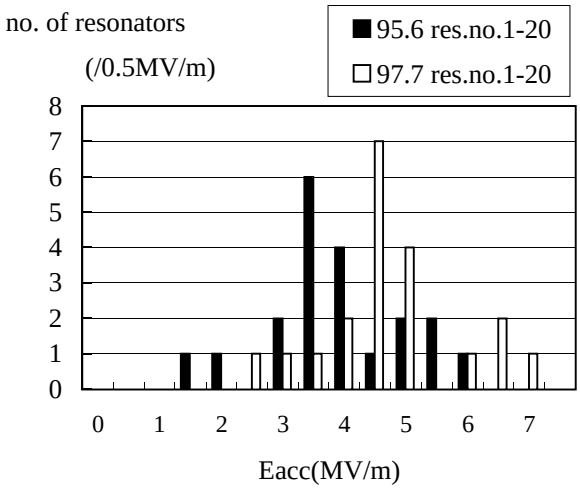

Fig.2 Histograms of the field gradients at rf input of 4 watts of the first 20 resonators measured in June, 1995 after normal all-together precooling mode and July, 1997 after three-by-three module sequential mode.

two-modules mode sequential precooling in 1997, as a histogram. The mean of the field gradients was recovered from 4.1 to 5.0 MV/m associated with the Q recovery.

The other 20 linac resonators which belong to the other cryogenic system have Q values between 0.6 and 1.2×10^9 so that the sequential precooling was not applied to them. In Fig.3, the accelerating field gradients of all the 40 linac resonators at 4 watts were shown as a histogram, which were measured at the same time together with the first 20 resonators. The overall mean value was 5.4 MV/m so that the originally designed value of 5 MV/m was attained.

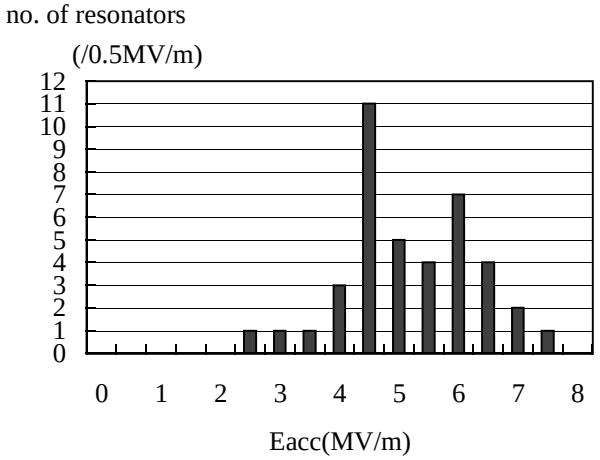

Fig. 3 Histogram of the field gradients of all the 40 resonators in the linac measured at rf input of 4 watts in July 1997.

2.4 Resonator Performances after Air Leak

A big air leak happened to the bellows between the first two cryo-modules on Sunday, May 31, 1998. The resonators were cold. The leak continued for about 12 hours untill the resonators were warmed across 80K. The pressure in the two cryostats were in the range of 10^{-1} Pa. The liquid level and helium pressure in the dewars were fortunately stable. The increase of the heat flow into the cryogenic system was about 23 watts, which was smaller than the refrigeration capacity per cryo-module of 28 watts. The resonators were once warmed up to the room temperature. The bellows had pin holes which seemed to be made by a sharp beam of 180MeV $^{32}S^{11+}$ of about 1 eμA. The leak rate measured later was 17 ml/s. Only from this rate, a lot of gas, as much as 1 kg, is supposed to be deposited on the cold surfaces of the resonators, the dewars and etc. From an additional fact that a big increase of leak rate have occured during the warming-up process, the deposition might be an order of 0.1 kg.

The accelerating field gradients of the resonators in the first two cryomodules are shown in Fig.4, in comparision with the data obtained before the leak(The sequential precooling was not applied to that machin time period, because of no demands for very high energies). The degradation of the resonator performances was not appreciably heavy, fortunately. They did not need heavy rf processing after the cool-down, either. It seemed that the niobium resonator surfaces were well protected from the gas deposition by the outer cans which have only two small beam holes of 25 mm in diameter.

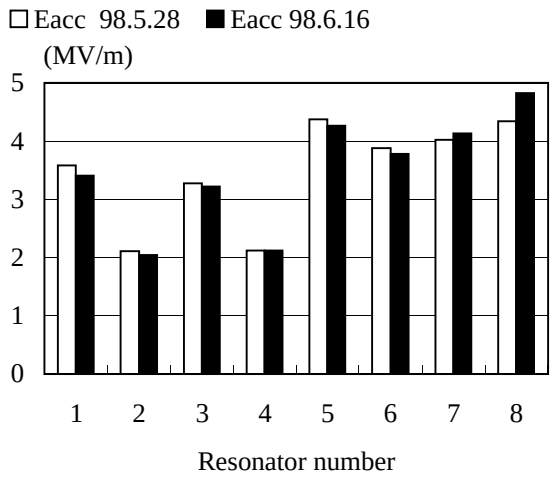

Fig. 4 Field gradients at rf input of 4 watts measured before and after an air leak trouble for the resonators on which air was deposited.

3 HYDROGEN OUTGASSING

It is idal to extract hydroden from the niobium walls by warming them up or by other methods if possible in order to cure the Q-disease. The quarter wave resonators are composed of a center conductor made of only niobium and an outer conductor made of niobium and copper and both conductors are welded together. It is, at least, possible to partially heat up only the center conductor.

3.1 Partial Heat Treatment

A spare resonators which was also ill of Q-disease was used to test the partial heating of the center conductor. A heater of 1.5 kW was set inside the center conductor, of which space is evacutated to 10^{-3}Pa. The top of the resonator was cooled by water. Lower 1/2 - 2/3 part of the center conductor was warmed up to about 600°C and hydrogen of an order of $1x10^{-3}$ mol was outgassed, which corresponded to a decrease of hydrogen content of 1 - 2 wppm in the niobium. The low field Q value measured after a slow precooling at a rate of about 12K/h was increased from 1×10^8 to 3.3×10^8 and the accelerating field gradient at 4 watt rf input from 2.7 MV/m to 4.0 MV/m. It looks worth applying this heat treatment to heavily hydrogen-polluted resonators such as the ones no.2 and 4.

3.2 Plan of ECR Plasma Surface Treatment

A method of hydrogen extraction without heating is wanted for the resonators made of bi-metals. Any of our attempts resulted in vain. Our next attempt is a plasma surface treatment utilizing electron cyclotron resonance at a micro-wave frequency. Gaseous elememts such as hydrogen, carbon and oxigen can be sputtered chemically from the surface[3]. We expect this method as a dry method of surface treatment for the superconducting niobium structures; that is, as a final surface treatment of rf superconducting cavities in place of heat treatment or high pressure water rinsing, or as a non-chemical surface re-processing method in case of heavy pollution.

A conceptional plan is illustrated in Fig.5. The ECR condition will be a frequency of 2.45GHz and a magnetic field of 0.09T. A resonator is co-axially placed in a solenoid. Investigations will be made with hydrogen, helium, oxigen or nitrogen gas.

4 OTHERS

4.1 Resonator control

Every resonator is controlled in a strongly coupled self-excited loop with phase lock and amplitude feed back functions. Six control modules made by Applied Superconductivity Inc. are used, each of which can control eight resonators. The rf power amplifiers were recently tuned up from 100 watts to 150 watts and moved close to the cryomodules in order to improve the stability at high field gradients. The resonator control is working well on the whole.

4.2 Cryogenic System

The cryogenic system is divided into two identical systems with refrigeration power of 250 watts. They have been working well except valve control troubles. The proportional valves are pneumatically driven and sometimes did not open as demanded. So that, an operator must make sure when time comes in a precooling period.

4.3 Beam Transport

The beam transmission was 40 - 100 % from the expectation in the past. After mis-alignment of 0 - 2 mm was found and fixed, the transmission was improved to about 80 - 100 %. An improvement was also given to the nine quadrupole doublet lenses placed between the cryomodules. They have now alternative focusing(F)-defocusing(D) planes as FD-DF-FD-DF- - -. The first four of them and the last four of them are simultaneously controlled, respectively, and the center one is turned off because there should be a beam waist point near the position. It made beam handling easier.

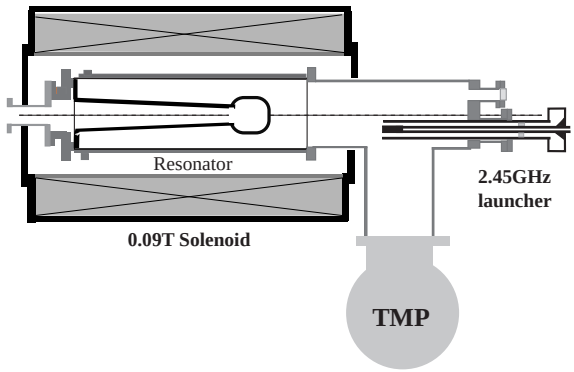

FIG. 5 Set-up plan of ECR plasma surface treatment for superconducting quarter wave resonators

5 CONCLUSIONS

The superconducting quarter wave resonators in the JAERI tandem superconducting booster have a mean field gradient of 5.4 MV/m, which is higher than the designed acceptance value of 5 MV/m, at the rf input of 4 watts, after carrying out the sequential fast precooling for the first 20 resonators. Resonator performances were found to be stable against a big air leak. Effective methods of hydrogen extraction from niobium are being investigated.

Abstract

The medium-energy beam-transport line of 2.7 m long for the JHF 200-MeV proton linac was designed. It consists of eight quadrupole magnets, two bunchers and two RF choppers, and has two purposes: matching the beam from the RFQ with the acceptance of the DTL; chopping the beam to produce a gap of 222 nsec between pulses of 278 nsec for the injection into the following rapid-cycling ring. The JHF proton linac is an intense beam accelerator with an average current of 0.2 mA in the first stage and of 0.8 mA for the future upgrade. Therefore, the key point in the MEBT design was focused on the control of the beam emittance growth in the beam line and the beam loss during transient times of the chopper. An RF deflector is utilized for the chopper owing to its characteristics of high deflecting field and compactness. The beam edge separation between the chopped and the unchopped beams reaches to 6 mm with a deflecting field of 1.6 MV/m. The field distribution (both E and B) of the RF deflector from MAFIA calculation is directly read into the modified TRACE3-D for the beam line design. The beam losses during RF transient times of the chopper, analyzed by both LEBT and PARMILA codes, are less than 0.08% at the exit of the 50-MeV DTL.

1 INTRODUCTION

In the JHF linac the beam intensity is high in terms of both the pulse current and average current[1]. Therefore, beam-loss control is a very essential requirement in the accelerator design. Beam-quality degradation mainly occurs in the low-energy sections. It has been realized that beam matching is of great significance for minimizing the emittance growth and avoiding beam-halo formation, which has been recognized as one of the major causes for beam losses[2].

The 500 μsec-long macropulses from the ion source need to be chopped into sub-pulses for injection into the following 3-GeV ring. After chopping, the macropulse consists of 278 nsec long pulses and 222 nsec long gaps in between the pulses. The chopped pulses should have a clean cut at the head and tail to avoid beam losses during injection into the ring. During the rise and fall times of the chopping field, however, there are some unstable particles, which are partially deflected; they may be accelerated to high energy and lost or get into the ring. Therefore, a fast-chopper design is being pursued in order to decrease the number of unstable particles.

The medium-energy beam-transport line (MEBT) between the RFQ and DTL has been designed to accomplish the two tasks: beam matching and chopping. It consists of quadrupoles, bunchers and RF deflectors. To conserve the beam quality, the line should not be too long and the beam needs to be well focused without large-amplitude oscillation. The line must also leave sufficient space for the beam diagnostics. The RF power requirement for the RF deflectors should be within the capability of the up-to-date solid RF power supply.

In this report, the design details are delineated. At first, the MEBT design is proposed in the second section. Section three describes the RF cavity of the deflector. The fourth section presents analysis of unstable particle. Finally conclusions are drawn out.

2 DESIGN OF THE MEBT

In order to describe the beam-deflection behavior, TRACE3-D[3] has been modified so as to include a new element: RF deflector. The field distribution in the cavity is calculated from MAFIA[4] and directly read into TRACE3-D. In this way, the fringe E&H fields beside the deflecting electrode can be taken into account.

The output beam from the RFQ is assumed to have the parameters listed in Table 1. Type A stands for the 30 mA case and Type B for the 60 mA case for upgrading in the future. The MEBT design is proposed with a total length about 2.7 m (Fig. 1). In the beam-profile plot at the bottom of the figure, the beam centroid offset in the x-direction by the RF deflectors is depicted by the dark curve. The beam dump will be positioned at the element 18 for the chopped beam. The design procedure has two steps. At first, the beam line up-stream of the element 18 is designed aimed at the largest separation between the unchopped and chopped beams at the element 18. Then, the unchopped beam is further transferred so as to match with the acceptance of the DTL.

Table 1. Input beam parameters at the MEBT entrance.

Parameters	Type A	Type B
I (mA)	30	60
$\varepsilon^{x,y}_{RMS}$ (πmm-mrad)	0.187	0.375
ε^{z}_{RMS}(πMeV-Degree)	0.133	0.266

* On leave from China Institute of Atomic Energy

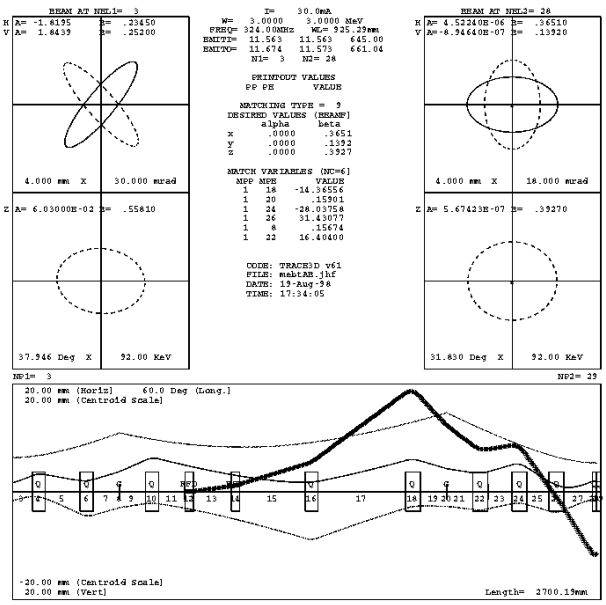

Fig. 1, TRACE3-D output of the MEBT for Type A. The up-left gives the input beam phase spaces and the up-right gives the matched beam with DTL. The bottom shows the beam profiles in the z, x and y directions respectively. The dark curve traces the beam centroid offset by the two RFDs. The element numbers are denoted under the beam axis.

The edge separation between the chopped and unchopped beam is 6 mm at the dump, when both of the RF deflectors have a deflecting field of 1.6 MV/m. This large separation is contributed from not only the two RF deflectors, but also the fourth quadrupole-element 16. The deflection is initiated by the two RF deflectors at an angle of 6 mrad for each, and is then amplified more than two times by the quadrupole. Downstream of the quadrupole, the deflection angle becomes 30 mrad. Owing to this reason, the RF deflectors do not require much RF power for an adequate deflection.

The first three Q magnets also contribute to the realization of the large separation. They should be adjusted for a small beam profile in the deflecting direction at the fourth Q magnet. Since the deflected beam centroid is more distant from the quadrupole's axis than is the undeflected beam envelope at the Q magnet it gives a larger defocusing to the deflected beam, but less defocusing to the undeflected beam. The first three quadrupoles should also keep the beam envelope in this section not too large in the y-direction in order to avoid any large emittance growth in this direction. In the RFD section, the beam size in the x-direction must be smaller than the gap between the deflecting electrodes so as to avoid beam losses on the electrodes.

In case that the beam emittance from the RFQ is larger than the assumed value for Type A, a relatively larger initial emittance between Type A and Type B for 30 mA beam was input into the designed beam line. The result shows that the same beam line is still applicable. Of course, the edge separation becomes smaller (about 3.6 mm for the input rms emittance of 0.25 π mm-mrad). But it is still sufficiently large for chopping the beam.

The beam emittance growth for the undeflected beam has been studied by means of PARMILA[5] simulation with 10,000 particles. Figure 2 shows the RMS emittance variation versus the element of the beam line. The beam has an RMS emittance growth of 7.7%, 9.5% and 4.8% in the x, y, z directions respectively.

The same beam line can also be used for input beam Type B. Only a very slight adjustment in the gradient of the Q magnets and the bunchers is necessary for large deflection and matching. For Type B, a higher deflecting field of 2 MV/m is needed to generate a 5-mm beam edge separation, due to the fact that the beam envelope is larger than that in Type A. The PARMILA run shows that the RMS emittance increases by 10%, 6%, 8% in the x, y, z directions, respectively.

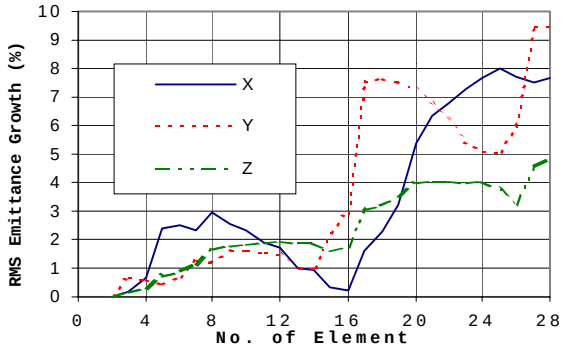

Fig.2. RMS emittance growth vs. the beam line elements for Type A.

3 RF CHOPPER DESIGN

A 324-MHz RF deflector cavity was designed and a cold model was tested[6]. The design philosophy is a low power demand from an RF power source and a fast rise time during pulse transient time. To hit the first target, the cavity geometry was optimized for maximum Z/Q_0 with MAFIA code under the limitation of the beam size; here Z is the transverse shunt impedance and Q_0 the unloaded Q value. To reach a fast rise/fall time, the cavity is heavily loaded by two coupling loops as input/output ports. Simulation with HFSS code shows the cavity can reach a very low loaded Q of 10 by means of two large loops with the size of 75×218 mm in the maximum-flux plane. To generate the deflecting field of 1.6 MV/m in the electrode gap, an input power of 22.2 kW is demanded from an RF power source, according to HFSS simulation. If the loaded Q becomes 15, the demanded power decreases to 14.8 kW. An additional power is needed to account for the deflection of the beam bunch with a half phase-length about 25° (see Fig.1). Therefore 1.2 times of power are required.

An aluminum cold model cavity was manufactured for demonstration of the low loaded Q. The results show a good agreement with the simulation: the measured Q_L=9.7.

4 ANALYSIS ON UNSTABLE PARTICLES

It is very crucial for the chopper to have as few unstable particles as possible during the RF rise and fall times. It is noted that the beam will not become totally unstable particles during the transient times because the scraper at the element 18 in Fig. 1 can stop some part of the particles in a beam when the RFD field is not at its full amplitude. To investigate the unstable particles during the transient times, PARMILA simulations with 5000 particles in uniform initial phase space were conducted. A particle scraper with an aperture of 20 mm in the x-direction is positioned at the element 18. As the RFD field increases toward its full value of 1.6 MV/m, the unstopped particle ratio in a bunch declines, as the curve shows in Fig. 3.

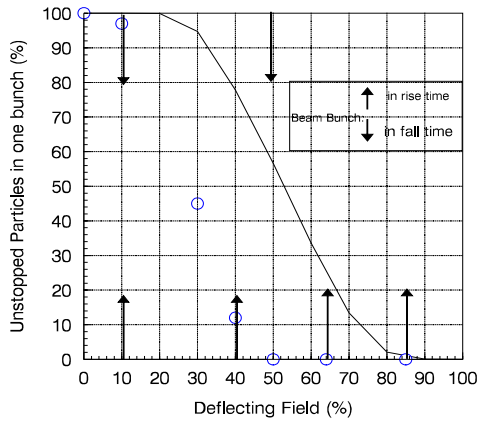

Fig.3 Unstopped particles ratio in one bunch vs. the deflecting field variation. The arrows indicate the bunch distribution during the RF rise and fall times. The curve indicates the ratios at the entrance of DTL and the circles those at the exit of DTL.

In order to obtain a quick rise and fall time, an improved method was proposed. The initial amplitude of the incident RF field to the cavity is 1.4 times the required full field. Some time after saturation, it is adjusted to one time the required full value. A rapid phase shift of 180^0 is added at the time just two or three periods before the power is turned off. These methods speed up the rise and fall times in terms of the required full field. Even though it needs an rf power two times higher, the solid RF power source is still within the commercially available range. Then, there are four micro-bunches during the rise time when the required full-field value is reached. Also only two bunches appear during fall time. These bunches meet the field amplitude, as denoted by the arrows in Fig.3.

When the field is more than 80% of the full value, the particles in a micro-bunch are almost totally stopped by the scraper. On the other hand, when the field is less than 30%, the unstopped portion of the particles can be injected into the acceptance of the DTL, according to TRACE3-D simulation. Thus only during the field-variation time from 30% to 80% of the full value, the beam will become unstable. However, not all the particles in the beam become unstable, because some of them can still be stopped by the scraper, as illustrated in follows.

During the rise time, two bunches at field of 10% and 85% amplitude do not become unstable beams. The other two bunches at 40% and 65% field amplitude partially contribute to the unstable particles. During the fall time one bunch is subjected to a field of 50%. Thus, for this bunch, only 58% of the particles become unstable. Totally, during transient times, the particles in 1.6 bunches become unstable at the exit of the MEBT.

A further investigation concerning the behavior of the transmitted unstable particles in the following 50-MeV DTL is conducted by means of the LEBT and PARMILA codes. Three scrapers are mounted in between the three DTL tanks with a slit full width of 6 mm. At the exit of the DTL, the ratio of the transmitted unstable particles is further reduced to less than 0.08% by the scrapers, as denoted by the circles in Figure 3. Also the scrapers do not block the unchopped beam.

5 CONCLUSIONS

The MEBT for the JHF linac is designed for matching and chopping the beam. The beam line is compact with a length of 2.7 m, owing to application of RF deflector. With the help of a quadrupole the chopper has a high deflection efficiency. The unstable particle ratio in the RF transient times can be reduced to less than 0.08% at the exit of the 50-MeV DTL.

Abstract

The first beam extraction from the 432-MHz DTL has been carried out in the test stand of KEK. Both MEBT and HEBT were assembled in the beam line for the beam test. The DTL has accelerated the 3-MeV H^- ion ejected from the RFQ up to 5.47 MeV. The measured ratio of the beam transmission is 91 %.

1 INTRODUCTION

The low-energy part of the 1-GeV linac for the Japanese Hadron Project (JHP [1]) has been constructed in order to establish the construction techniques and study the beam properties. (The scheme of the JHP is different from that of the Japanese Hadron Facility (JHF [2]) which was proposed recently as the modified version of the JHP.)

The test linac system consists of the H^- ion source, the radio frequency quadrupole (RFQ) linac and the short Alvaretz-type drift-tube linac (DTL). The beam-transport lines connect them. The high-power test of the DTL was completed in summer of 1994. The preparation for the beam study of the DTL was started since 1997, because the beam study of the RFQ had been completed.

2 SETUP FOR THE BEAM STUDY

The components of our linac system are as follows: 1) the H^- ion source; 2) the low-energy beam-transport line (LEBT); 3) the radio frequency quadrupole (RFQ) linac; 4) the medium-energy beam-transport line (MEBT); 5) the Alvaretz-type drift-tube linac (DTL); 6) the high-energy beam-transport line (HEBT). The layout of the linac system from the RFQ to the HEBT is shown in figure 1.

2.1 Ion source, HEBT and RFQ

The volume-productive ion source [3] supplies the H^- beam of the maximum 16-mA peak current. The extraction voltage of the ion source is 50 kV. The LEBT is composed of two solenoid magnets. The RFQ has the four-vane type structure. It accelerates the H^- ions from 50 KeV to 3 MeV. The resonant frequency of the RFQ is 432 MHz. The accelerating field of the RFQ is stabilized by the pi-mode-stabilizing loop. [4]

2.2 MEBT

The MEBT [5] consists of eight quadrupole electromagnets (Q-magnets [6]), a buncher and two steering magnets. All components of the MEBT are aligned on the same table. Thus, the alignment of the MEBT has been done by tuning the position of the table.

The buncher is a single-cell reentrant cavity. The gap length is 8.99 mm. The resonant frequency and measured Q_0 value of the buncher are 432 MHz and 21700, respectively. The maximum rf-power of 10 kW is supplied by the solid state power amplifier through the WX39D coaxial waveguide. The buncher is set in the middle of the MEBT. Two small steering magnets are installed between the QD1 and QF2.

2.3 DTL

The DTL has 18 drift tubes (DTs). The total length of the DTL is about 1.2 m. A permanent quadrupole magnet (PQM) is installed in each DT. The average field gradient of the PQM is 211 ± 1.3 T/m, which is about 20 % stronger than the design field (175 T/m). [7] The observed Q_0 value is 43500. It is about 90 % of the calculated value. The Q_0 value is sufficiently high. The measured

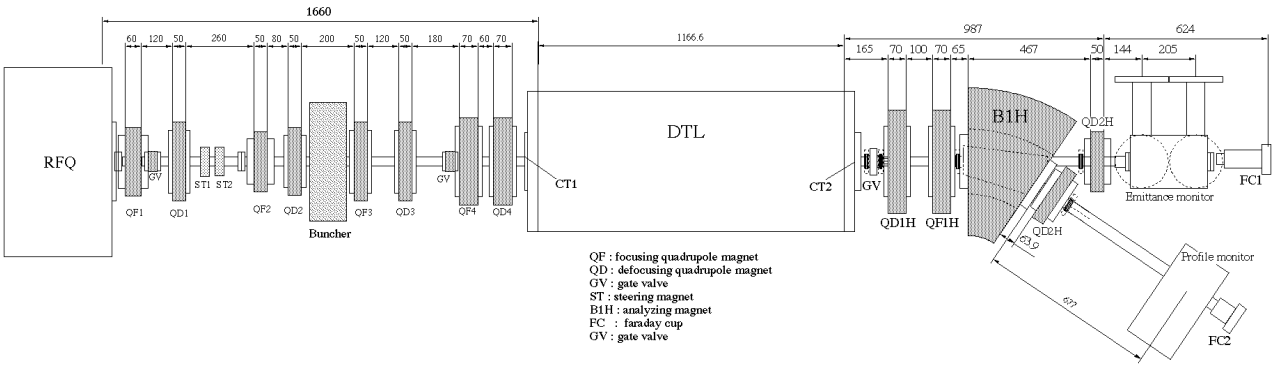

Fig.1 Setup of the DTL beam experiment

shunt impedance (Z) is 82 MΩ/m. It suggests a peak power of 128 kW for the 3-MV/m accelerating field. Thus rf-power of about 150 kW is required for the acceleration of 10-mA beam. The maximum electric field on the drift tube corresponds to 75% of Kilpatrick's limit. [8]

The accelerating field is stabilized by the eight post couplers. The field distribution stabilized by post couplers is sufficiently uniform (± 0.3%) and stable.

The current transformers (CT1, CT2) for the beam current measurement are installed in each end plate of the DTL.

2.4 HEBT

The HEBT consists of four Q-magnets, a bending magnet [9], a profile monitor, a transverse emittance monitor and two faraday cups. (We did not use the QD2H magnet between the bending magnet and the profile monitor.) The bending angle of the bending magnet is 34 degrees. The momentum distribution is measured by using a set of the bending magnet and the profile monitor. The effective area size of the profile monitor is 16 mm x 16 mm. The beam distribution is read by tungsten wires (0.1 mm in diameter) of 1-mm pitch.

The faraday cups (FC1, FC2) measure the total beam current. The FC1 works as the beam dump and the FC2 measures the beam current of the selected momentum.

3 MEASUREMENT

Because this study is the first beam acceleration by the DTL, the average beam current is reduced in order to minimize the beam loss. Then, the pulse length of the beam is reduced to 50 μsec, which corresponds to the rf-pulse length of the RFQ. The repetition rate is 10 Hz. Thus, the duty factor of the beam is 0.05 %. (The designed duty factor is 3 %.) The rf-pulse length of the DTL and the buncher are 200 and 140 μsec, respectively. The peak current of the beam, comes from the ion source, is about 13mA during the study. The coupling constant of the input coupler to the DTL tank has been increased from 1.0 to 1.25 (over coupling) against the beam loading by rotating the coupling loop before the beam experiment.

The DTL, MEBT and the HEBT were aligned in the RFQ beam axis by using a laser alignment system.

3.1 Tuning of the Parameters

The main parameters to be tuned are as follows: 1) The field strength of the Q-magnets of the MEBT; 2) The level and the phase of rf-field in the buncher; 3) The level and the phase of rf-field in the DTL; 4) The strength of the steering magnets. These parameters were tuned in order to maximize the beam transmission in the DTL and minimize the momentum spread of the beam ejected from the DTL.

The buncher requires the rf-power of 5.6 kW. The rf-power in the RFQ was adjusted to about 480 kW, which is an adequate power level for the standard operation of the RFQ. The rf-power level of the DTL is adjusted to 170 kW by parameter survey. Figure 2 shows the rf-field patterns for the DTL and the buncher

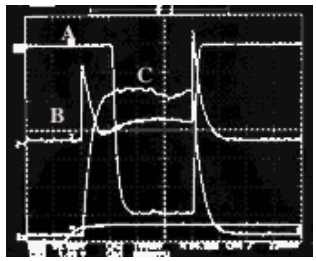

Fig. 2 Tank rf-field.
A: RF-field in the Buncher
B: Reflection from the DTL
C: RF-field in the DTL
(Abscissa: 50 μsec/div)

3.2 Beam Transmission

Figure 3 shows the output signals from CT1 and CT2. The upper line ("A" line) shows the beam current at the entrance of the DTL and the lower ("B" line) the output beam current from DTL. One vertical division corresponds to the current of 2 mA. It shows that the input and the output beam currents are 10.7±0.13 and 9.7±0.13 mA, respectively. Thus, the transmission of the DTL is 91 ± 2 % in this stage. Because the beam current from the ion source is 13±0.9mA and the transmission of the RFQ is 82.5%, the estimated beam current from the RFQ is 10.7±0.7 mA, which consists with the input beam current in the DTL. The reason for the missing beam of about 9 % is still unknown. We will check the followings in order to find its origin; 1) Transverse mismatching at the DTL entrance due to a 21-% excess in the strength of the PQM; 2) Alignment of the total accelerating system, especially, the Q-magnets of the MEBT; 3) a fraction of particles other than H^- ions.

3.3 Beam Energy

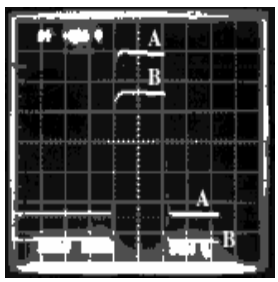

Fig. 3 Current monitor signal.
A: Incident beam into the DTL
B: Output beam from the DTL

Abscissa: 20 μsec/div
Ordinate: 2 mA/div

The beam momentum is measured on the profile monitor by changing the excitation current of the bending magnet in the HEBT. The beam momentum has been calibrated by using the beam from the RFQ without the acceleration in the DTL since the beam energy from the RFQ was already measured. The results (figure 4) include three kinds of data taken by changing the excitation current of the bending magnet. The abscissa is the energy of the beam. The Gaussian distribution curve has been fitted to the data in order to estimate the center value and the width of the kinetic-energy distribution. The averaged center value and the full width at half maximum of the

fitted curves are 5.47 and 0.21 MeV, respectively. The width of the distribution will be checked by the simulation.

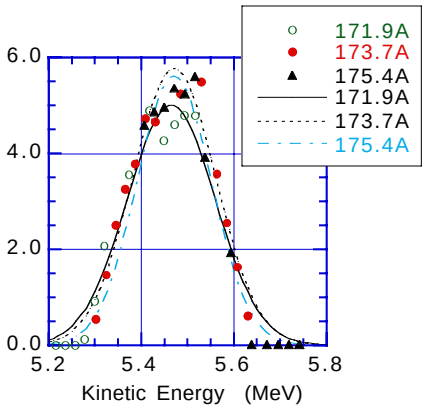

Fig. 4 Energy distribution of the beam from the DTL. Markers indicate the measured data. Gaussian curves are fitted to the data. The figures (171.9, 173.7 and 175.4) are the excitation current of the bending magnet used for the data taking.

3.3 Phase Dependence of the Beam Transmission

Figure 5 shows the variation of the beam transmission measured by changing the rf-phase of the DTL relative to that of the RFQ. The beam is measured by the FC2 after the bending magnet, which is adjusted by changing the excitation in order to collect the beam in the faraday cup FC2. The ordinate values are normalized at the maximum point. The width of the flat top of the plot is about 30 degrees. It is reasonable value, because the longitudinal bunch length of the beam from the RFQ is about 50 degrees and the acceptable longitudinal phase of the DTL is about 90 degrees.

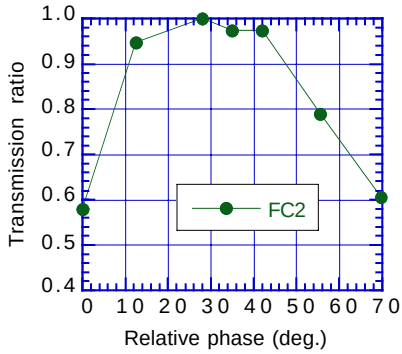

Fig. 5 Relative phase dependence of the beam transmission.

4 CONCLUSION

The first experiment of the beam acceleration by the 432-MHz DTL has been successfully performed in the test stand of KEK. The DTL accelerates the 3-MeV H^- ion ejected from the RFQ up to 5.47 MeV. Both MEBT and HEBT, assembled for the beam test, worked well. After the survey of the Q-magnet strength and the rf-pulse parameter for the tanks, the transmission of 91 ± 2 % has been obtained. The measurement of the beam emittance will be done soon.

5 ACKNOWLEDGEMENTS

We would like to thank Prof. M. Kihara for his continuous support. We also acknowledge Dr. A. Ueno and Dr. S. Fujimura for their useful suggestions for the operation of the RFQ and the ion source.

Abstract

At NIRS-HIMAC, 473 patients have already been treated using carbon beams by August, 1998. Therapy is scheduled in the daytime, while basic research is carried out during the nights and on weekends. Various ion species from Proton to Xenon have been used for basic research. Much effort was made to develop a time-sharing-acceleration system to well utilize the capability of three ion sources (PIG, 10GHz-ECR, 18GHz-ECR). Such recent developments in the injector are described in this paper. Several applications of linac beams with an energy of 6MeV/n are also briefly presented.

1 INTRODUCTION

Since 1994, HIMAC has been routinely used for both clinical trials of cancer therapy and basic research. Details concerning the HIMAC facility and its design philosophy have already been reported at linac and accelerator conferences [1, 2].

Taking account of an increase in both the number of patients and requests for basic experiments, it is necessary to effectively increase the available beam time and the kinds of ion species. During this year 16 themes in medicine, 64 in biology, and 47 in physics are actually being carried out in basic research. To answer these various requirements, a time-sharing-acceleration (TSA) scheme has been developed in the injector [3]. By using this scheme, three kinds of ion species can be simultaneously delivered from the injector to two synchrotron rings and a medium-energy (6MeV/n) experimental cave.

In order to expand the usable ion species, improvements in the ion sources have also been made. In order to precisely and actually measure the ion-stopping position in a human body, the application of positron emitter nuclei with a PET camera is in progress. A secondary-beam course was installed, and a preliminary test has been made for the production of ^{11}C by bombarding a thick beryllium target with high-energy ^{12}C beams through the reaction process of projectile fragmentation. The production rate of ^{11}C was around 0.2% and its purity 97%. A considerable increase in the primary beam is necessary to obtain sufficient intensity in the secondary beams for medical application; particularly developments in the ion sources are expected. Related improvements in the RF system of the injector are also necessary to stably accelerate heavy ions with an *e/m* of around 1/7, which corresponds to the maximum design value.

The above-mentioned developments in the injector are mainly discussed from the viewpoint of reliability; also, the status of some experiments in basic research using 6MeV/n beams (from the injector) are briefly reported.

2 TIME-SHARING ACCELERATION

2.1 Magnet

As previously mentioned, the purpose of this TSA-scheme is to simultaneously supply different ion species from three ion sources to three courses: two synchrotron rings and the medium-energy experimental course. Figure 1 shows a schematic drawing of the HIMAC injector. All of the DC magnets in the existing injector were replaced by pulsed magnets by the end of March, 1998. For designing these pulsed magnets, a response time of 100ms is necessary for the normal TSA operation, in which the injector is operated with a repetition rate of 3Hz at maximum and a typical pulse width of 1ms. Practical improvements and modifications concerning the beam diagnostic devices are under progress for routine TSA operation.

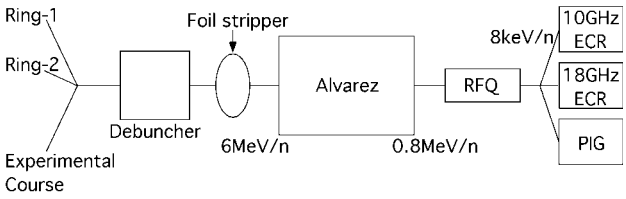

Fig.1 Schematic drawing of the HIMAC injector. Under TSA operation, one injector works as if it were three.

2.2 RF

An important point is to stably operate the RF system of RFQ and Alvarez cavities (100MHz) under different power levels, each of which corresponds to a different ion species (*e/m*). It is generally impossible to quickly control the tuning of cavities with mechanical tuners. In our case the highest power level is chosen; then, the tuning is optimized to this fixed condition. Although the cavities

are not precisely tuned for the other two power levels, the RF operation is now satisfactorily stable for *e/m*-values between 1/2~1/6. Careful tests are now under way in terms of the stability for the case of very wide *e/m*-values, such as 1~1/7.

Another RF problem was occasional sparks in the final amplifier for Alvarez at a high power level. This phenomenon seems to mainly originate in the reflected power from the loop coupler of the Alvarez tank when sparking occurs, and to be enhanced at the amplifier output-cavity. It was thus difficult to stably accelerate heavy ions with an *e/m* of around 1/7. Concerning this problem, an idea has been tested, which is to slightly detune the amplifier output-circuit seen by the feedline, in order to make its impedance smaller at 100MHz and to suppress the amplitude of standing waves (SW). Along this line, a cold test was carried out by adjusting the position of a short panel in the output cavity while observing the SW-signal through the directional coupler, as shown in Fig.2. All of the results, including a high-power test, show that a frequency shift by 0.32MHz from 100.93 to 101.25MHz allows the amplitude of sparks to be reduced down to 30% with no reduction in the RF-power transmission. RF-down times due to sparks has thus become rare; it is possible to stably accelerate heavy ions, such as Xe^{20+}, though small sparks may still occur in the tank.

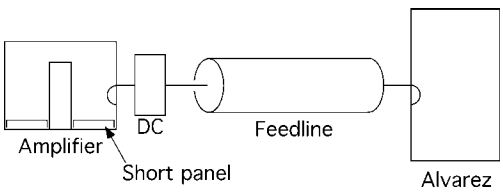

Fig.2 Schematic drawing between the final amplifier and Alvarez. A network analyzer is connected to a directional coupler (DC) to analyze the spectra of standing waves.

3 ION SOURCES

In the HIMAC injector, three ion sources have been operated in the pulse mode: PIG, 10GHz-ECR, 18GHz-ECR. All sources are normally operated at around 1Hz, according to the trigger pulses from synchrotrons; meanwhile the pulse width depends on the sources and elements. The detailed design of these sources has already been presented [4-6]. The present performance for typically-used ion species is listed in Table I. Each intensity is measured in front of the RFQ. In addition to Table I, several hundred eμA of N^{3+} and O^{3+} can also be easily supplied from three sources, though they are not usually used. Although the transmission efficiency between the source and RFQ is quite good for 10GHz-ECR (~70%), it has not yet been well optimized both for PIG and 18GHz-ECR, depending on the elements.

TABLE I. Typical peak intensities at the RFQ, in which the normalized acceptance is 0.6π mm·mrad. The transmission efficiency through the RFQ is about 93% for the below-listed intensity region.

PIG		10GHz-ECR		18GHz-ECR	
Elements	eμA	Elements	eμA	Elements	eμA
He^{1+}	550	H_2^+	360	Ar^{9+}	280
C^{2+}	650[#1]	C^{4+}	250	Fe^{9+}	35[#2]
Ne^{4+}	500	Ne^{4+}	350	Kr^{15+}	60
Si^{5+}	200[#1]	Ar^{8+}	200	Xe^{20+}	50[#3]
Ar^{7+}	300				

#1: by sputtering the graphite with (N_2+Ne) for C^{2+}, and the silicon single crystal with Kr for Si^{5+}.
#2: $Fe(C_5H_5)_2$ powder is used with O_2 for Fe^{9+}.
#3: abundance of ^{132}Xe is 27% and ^{84}Kr 57%.

3.1 PIG

In the typical production of Si^{5+} by PIG, the arc power is 6kW in peak (5A, 1200V), and the arc pulse width is 1.5ms; the duty factor is 0.15%. An extracted intensity of 400eμA has been routinely obtained by sputtering the silicon single crystal with Kr (~0.15cc/min). The stably-usable lifetime will be on the order of one week, depending on the arc power and elements; the recent results for Si^{5+} showed that it is 70hr with no adjustment. The electron bombardment power (~500W) to the upper cathode is stabilized in such a way that the error signal is fed back to the filament current, which is effective for stable operation in such a low-duty pulse mode. Figure 3(a) shows a pulsed beam-waveform of Ar^{8+}.

3.2 10GHz-ECR

Usually, carbon beams for radiotherapy are supplied from 10GHz-ECR with CH_4 (0.07cc/min); this source is basically maintenance free as long as gas materials are used. For the production of C^{4+}, the microwave power is about 500W with a pulse width of 8ms. An extracted intensity of around 350eμA has so far been routinely obtained owing to optimization for the position of the extraction electrode. A few hundred eμA of $^{13}C^{4+}$ and $^{36}Ar^{8+}$ are also produced for the nuclear physics experiments. Figure 3(b) shows a pulsed beam-waveform of C^{4+}.

3.3 18GHz-ECR

The production of heavy-metal ions has just started by using a newly-installed 18GHz-ECR with high extraction voltage (~60kV). For producing Fe^{9+}, $Fe(C_5H_5)_2$ powder has been preliminarily used with gas-mixing of O_2 (0.02cc/min). The lifetime is mainly subject to the amount of powder (0.15g at most), and the test results suggest that it is on the order of 70~80hr. Under the after-glow mode, a 45eμA of Fe^{9+} has been obtained from the source; the

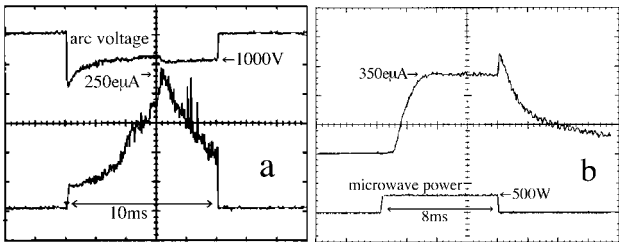

Fig.3 Pulsed beam-waveforms for PIG (a) and 10GHz-ECR (b). In such a low-duty pulsed PIG, the output of Ar^{8+} (highly-charged ions) is high during the early 6-7ms [4]. For the production of C^{4+} in the 10GHz-ECR, a smooth and rapid rising, and a clear afterglow-peak seem to be essential as an indication of stable operation.

microwave power is 1.2kW with a pulse width of 6ms. After its acceleration up to 6MeV/n, about 6eμA of Fe^{24+} or 10eμA of Fe^{23+} can be obtained by stripping through the thin carbon foil (100μg/cm^2). In the latter case, the usable intensity from the synchrotron is on the order of $1x10^8$pps. The pulse width of the afterglow peak is about 1ms, which is sufficiently long compared to the injection time (~160μs) of a synchrotron ring. The sextupole magnet was optimized in order to expand an ECR zone (size of plasma), which resulted in an improvement of the yield by a factor 2-3 for gaseous ions; hence, 750eμA of Ar^{8+} and 400eμA of Ar^{9+} can be obtained from the source. Careful cleaning and sufficient aging of the gas-feeding quartz tube are essential to well maintain the source operation.

According to the requests from basic research groups, Mg^{5+}, Ca^{7+}, Ti^{7+} will be produced by PIG, and S^{5+}, Cl^{5+}, Ni^{9+} by 18GHz-ECR. B^{3+} and F^{4+} will also be tested by one of three sources.

4 BASIC RESEARCH

Several groups in atomic- and bio-physics have conducted experiments using 6MeV/n heavy-ion beams from the NIRS-HIMAC injector linac [7].

The projectile charge (z) dependence on the electron-emission rate from Al-foil (300μg/cm^2) has been measured using fully-stripped ions (He~Ar). The forward enhancement and its strong dependence on z were observed; the ratio between the forward and backward was 1.67 for z=18. This would be due to much forward δ-electrons pulled by the strong Coulomb field of the projectile in the outgoing projectile direction.

Through collisions with fully-stripped ions, the total ionization cross sections have been determined for both atoms and molecules with a good accuracy by using a parallel-plate electrode. Another group made a similar experiment using a secondary-ion mass spectrometer (magnet type).

Pulse-radiolysis experiments were carried out using He^{2+} in order to measure the time-dependent yields of water-decomposition products by the scavenger method. The product yields were found to be smaller than those determined by electron beams.

The energy loss of Ar^{18+} in a Z-pinch helium plasma has been observed using a TOF method. The standard Stark-broadening diagnostics gives an electron density ranging from 4 to $5x10^{17}$/cm^3 for a helium plasma. The observed energy loss exceeds the value for cold helium gas, and agrees with the Bethe theory modified for the plasma.

The micro-structure of plasmid DNA (pBR322) irradiated with C^{6+} was analyzed using time-resolved fluorescence spectroscopy. The molecular behaviors of ethydium bromide (EB) intercalated between the base-pairs of DNA showed that the distance between the base pairs was expanded by 50% with the irradiation. The anticipated deformation in the double strand of the DNA has thus been proposed.

In order to strongly promote biophysical experiments, the dosimetory of C^{6+} beams has been conducted behind a thin Harvar (metal) foil with a thickness of 2.2μm and a diameter of 20mm. The results showed that the range of the beams was 14.2cm in air, and the long-time durability of this foil against the atmospheric pressure was satisfactory. A secondary-electron emission-type profile monitor (SEEM) has also been developed for irradiating biological materials, such as cells.

The authors would like to thank their colleagues at the Div. of accelerator physics and engineering of NIRS headed by Dr. F.Soga for many friendly discussions concerning injector linacs as well as their application to basic research.

PARAMETER STUDY FOR A HIGH CURRENT HEAVY ION LINAC*

G. Parisi, A. Sauer, H. Deitinghoff, H. Klein
IAP - Frankfurt University, Robert-Mayer-Str. 2-4, 60054 Frankfurt am Main, Germany

Abstract

In present scenarios of a heavy ion inertial fusion facility, a combination of linacs and storage rings has been proposed as a driver. After some funnelling steps, the main linac has to accelerate and focus an intense heavy ion beam (e.g. Bi^+, 400 mA) to a final energy of 10 GeV.

Using well known analytical formulae an attempt has been made to find a range of beam and structure parameters (e.g. frequency, shunt impedance, beam current, emittances, focusing scheme), in which the requirements on a DTL can be fulfilled. Beam dynamics aspects have been checked by numerical simulations.

1 INTRODUCTION

Since about 20 years, studies have been performed on inertial confinement fusion for potential application in energy production. Laser facilities, light and heavy ion accelerators and storage rings have been investigated as drivers; one study for a heavy ion driven fusion power system (HIBALL) was completed in the 1980's already [1]. Main progress has been achieved during the last years in the understanding of pellet dynamics after ignition, i.e. in the physics of extremely hot and dense matter, leading to new conditions for pellet ignition which impose also new requirements on the layout of the driver accelerator facilities. Progress and changes can nicely be seen in the proceedings of the Symposia on Heavy Ion Inertial Fusion, held every two years at different places, e.g. [2,3,4].

2 THE HIDIF STUDY

A combination of linacs and storage rings has been proposed by a European study group as an rf approach of a driver for a Heavy Ion Driven Ignition Facility (HIDIF) [5]. The scheme is shown in Fig. 1.

For pellet ignition, a beam energy of 3 MJ must be brought to the pellet within 5 ns, focused to spot sizes of about 1.7 mm radius. The ion species is Bi^+, the final ion energy was fixed to 10 GeV. These requirements determine mainly the driver layout and the beam parameters like beam current, beam emittance and pulse duration.

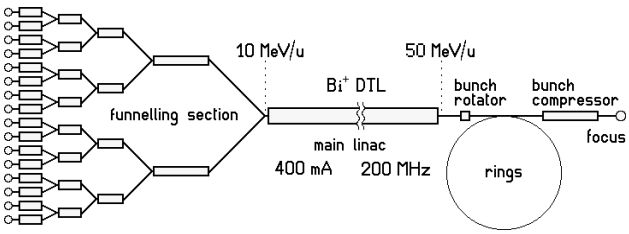

Figure 1: Scheme of the heavy ion driven ignition facility.

Since the capability of high current acceleration in a rf linac is limited, an array of rings and bunch compressors will be needed for the necessary current multiplication and pulse compression for the final focus. By tracking back the parameters needed at the final focus, limits on output conditions at the linac end are pre-given: beam current of 400 mA in a total transverse emittance of $4\,\pi$ mm mrad, and longitudinal maximum momentum spread of $\pm 2\times10^{-4}$ for 99% of the particles after bunch rotation for tolerable losses at ring injection. Following the scheme of funnelling [6] (already proposed for HIBALL) and taking some measured values for ion source currents and emittances, there are only few degrees of freedom for the choice of parameters in the layout of the main linac.

3 LAYOUT OF THE MAIN LINAC

Existing ion sources are not able to produce a current of 400 mA Bi^+: for a seven hole extraction, values up to 70 mA have been recently reported; with a lower extraction voltage, a 21 mA beam has been achieved within an emittance of $0.065\,\pi$ mm mrad (80% rms, norm.) [7]. Moreover, RFQs cannot accept such a high current; then beams from several sources must be extracted, accelerated and merged in a funnel tree as indicated in Fig. 1. In each funnel step the frequency of the linac and the current are doubled: assuming 3 funnel steps and including some losses at beam formation, an ion source current of 60 mA is required; for 4 funnel steps it is lowered to 30 mA.

The first accelerator will be an RFQ, which is able to capture, focus and bunch the beam even at high space charge forces. Its frequency is chosen with respect to the input ion velocity: an appropriate choice is 12.5 MHz, since one has about 1.2–1.5 keV/u Bi^+ with a dc post-acceleration of 250–300 kV after extraction; 60 mA are still accepted but already close to the RFQ current limit.

In the RFQ the dc current is formed to bunches of about $\pm 30^\circ$ phase width. Due to the high space charge forces in the beam, the initial bunch length will nearly stay constant, i.e. before the frequency can be doubled in the next step the ion energy should be increased by a factor of four to avoid dilution in the longitudinal phase space. With these assumptions one ends up, after 3 funnel steps, with 100 MHz for the main linac and an injection energy of about 3 MeV/u; or, after 4 funnel steps,

* Work supported by BMBF under contract 06OF841I.

with 200 MHz and about 12 MeV/u. The standard formulae of Mittag [8] show that in both cases the longitudinal acceptance is large enough to capture a beam with an rms emittance of 0.2 π°MeV/u without filamentation in the following acceleration to a final energy of 50 MeV/u.

Taking into account a 100 MHz DTL structure, the shunt impedance, which is a measure of the efficiency, drops already to the end of the linac. To improve the efficiency, a frequency jump in the main linac would be necessary, leading to a higher peak current and empty rf buckets. For a 200 MHz Alvarez type structure the effective shunt impedance changes only slightly in the whole velocity range; the technology is well proven in different laboratories. Therefore a preliminary layout for a 200 MHz DTL from 10 to 50 MeV/u has been made; the main parameters are summarized in Table 1.

The effective accelerating field E_oT is 2.8 MV/m; the average shunt impedance is 26 MΩ/m. For a total voltage gain of 8.4 GV, the length of the linac sums up to 3.4 km.

Table 1: Linac and beam parameters.

Mass number	209 (Bi+)	
Frequency	200.0	MHz
Current	400	mA
Number of cells	9775	
Total length (10-50 MeV)	3383	m
Min. aperture radius	1.6	cm
Max. pole tip field	1.15	Tesla
Electric field amplitude E_oT	2.80-2.88	MV/m
Total energy gain	40.0	MeV/u
Peak beam power, 60% chopping	690	kW/m
Peak dissipated power	320	kW/m
Average shunt impedance	26	MΩ/m
Transv. rms norm. emittance	0.176-0.183	π mm mrad
Long. rms norm. emittance	1.66-1.83	π ns keV/u

4 BEAM DYNAMICS ASPECTS

When generating the linac geometry, a drift tube aperture of about 1.6 cm radius came up; with a maximum pole tip field of 1 Tesla the transverse focusing turned out to be too weak for the FD or FFDD quadrupole configuration normally used. Going to a FFFFFDDDDD scheme, as proposed in [9], resulted in a maximum pole tip field of 1.16 T and a transverse phase advance of 35°–55° per period. Schemes from 3F3D to 7F7D seem to be possible too; no optimization has been done for these. In Fig. 2 the focusing scheme is plotted, showing a low flutter factor.

The normalized transverse emittance for proper ring injection of 1.3 π mm mrad is rather small. Assuming a safety factor of 10 between full and rms emittance, to reduce the risk of particle losses and structure activation, the required value of 0.13 π mm mrad has to be compared to the value of 0.06 π mm mrad measured directly at the ion source. This allows only a factor of 2 for the unavoidable emittance growth along the whole linac complex.

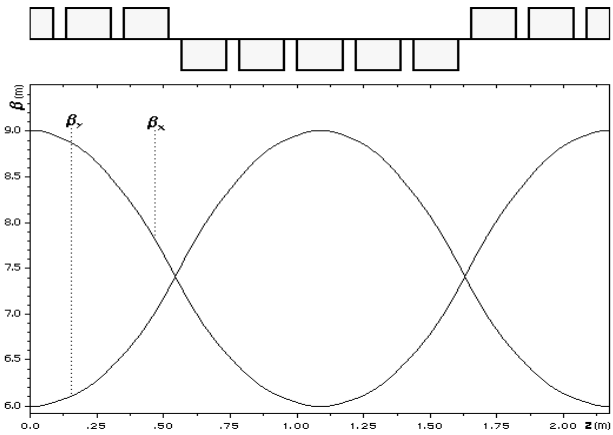

Figure 2: Chosen focusing scheme: plot of β_x and β_y.

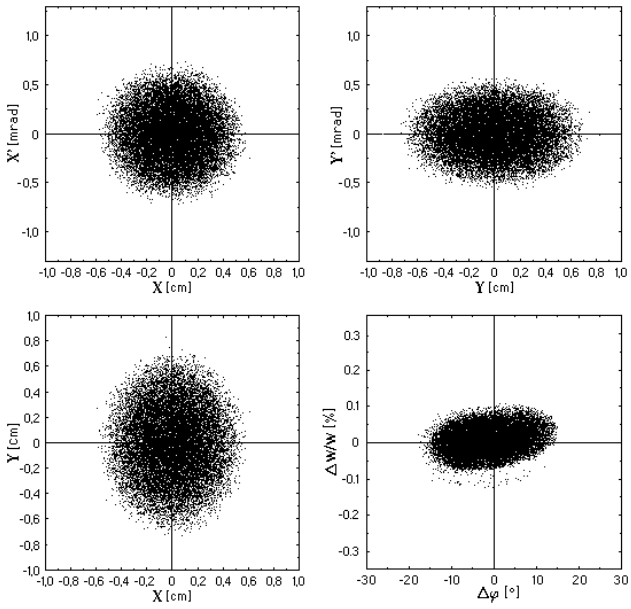

Figure 3: Output distribution at the linac end for 20,000 particles; 6D waterbag input, phase and amplitude errors.

Therefore particle dynamics calculations have been done with a 6D waterbag distribution including rf field amplitude and phase errors with an rms input emittance of 0.176 π mm mrad, allowing for some more emittance growth in the front part. It could be demonstrated that the requirements for ring injection can be fulfilled [10,11].

As an example, in Fig. 3 the output emittances at the linac end are plotted for the nominal design, including rf phase and amplitude errors. There is only a slight increase of beam size in the real transverse space. The energy spread in the longitudinal phase space is smaller than $\pm 4\times10^{-4}$ after debunching.

5 LINAC OPTION FOR TELESCOPING

An additional complication for the layout of the linac is the need to accelerate ions of different masses to the same momentum, to allow for "telescoping" of the different bunches in the final transport line. Telescoping is a

non-Liouvillean method: bunches with different ion species but same momentum are started with an appropriate delay time in a single beam line. The delay time and the velocity difference have to be chosen in such a way that the bunches fully overlap in real and momentum space at the end of the final transport, i.e. when hitting the pellet [12].

In the present scheme a mass difference of ±10% is required, which would correspond to the ions ^{187}Re, ^{209}Bi, ^{232}Th [5]. In Fig. 4 kinetic energy versus momentum is plotted for different masses for the velocity range of the main linac. At the design output energy for Bi (50 MeV/u) the momentum is 64 GeV/c; to get the same momentum, the kinetic energy for Re and Th must be 61 and 40 MeV/u.

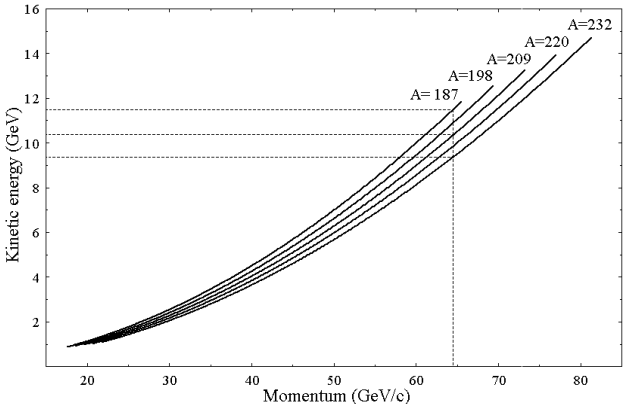

Figure 4: Energy vs. momentum for different masses.

But a DTL has a fixed velocity profile, accelerating all ions from the same specific input energy to the same specific output energy when the voltage is scaled accordingly to the mass ratios. Different velocity profiles can be obtained only if the frequency can be adjusted to the change in ion velocity, to fulfill the condition for synchronous acceleration. A large frequency variation of ±10% for an Alvarez type structure seems not to be realistic. Therefore the following concept has been investigated:

- the linac length has to be increased to accelerate the lightest ion to the higher required energy;
- the design mass has to be transported through the additional part only, keeping the beam bunched;
- the heaviest ion (which reaches the lower required energy already before the linac end) has to be transported through the rest of the main linac and the additional part.

For a mass 10% lighter than the design mass (ion energy difference of 20%) the linac becomes 20% longer; Th must be accelerated with a higher electric field E_oT of 3.1 MV/m and then transported without loss of beam quality through 1.6 km.

Preliminary beam dynamics calculations indicate that the beam can be transported through several DTL cells, when single resonators are installed in between the tanks, acting as rebuncher [11]. The time for switching all parameters between two pulses with different ion species is 0.075 ms. Any reduction in the required mass differences would simplify also the linac architecture and operation.

Table 2: Change of linac parameters for telescoping.

Mass numbers	187 (Re), 209 (Bi), 232 (Th)	
Number of new cells	1540	
Additional length	760	m
Electric field amplitude E_oT	2.4-3.1	MV/m
Momentum at output	64.3	GeV/c

5 CONCLUSIONS

From the point of view of particle dynamics, a conventional Alvarez type DTL can serve as main linac in the present HIDIF scheme. Some critical points exist: the alignment of drift tubes and quadrupoles in a 3 km long linac, the acceleration of ions with different masses to the same momentum at the linac end, the required peak power of about 1.1 MW/m. A higher beam current, as discussed for energy production, or a higher acceleration rate would increase this value. Beam dynamics calculations including errors and tolerances gave good results for the design ion Bi^+ and the linac layout of Table 1. The telescoping option must still be reconsidered.

6 ACKNOWLEDGEMENTS

The authors would like to acknowledge the good spirit of collaboration present in the HIDIF study group and the constant readiness for always open-minded discussion.

LUMINOSITY MONITOR OPTIONS FOR TESLA

Abstract

The feasibility of a luminosity monitor based on a radiative Bhabha, beamstrahlung photons or e^+e^- detectors, is investigated in the context of the TESLA [1] linear collider.

1 INTRODUCTION

During the normal operation of a linear collider, while the beam are in collisions, the detuning of the final focus optics must be controlled in such a way that the luminosity stays maximum. The required on-line tuning procedure should be the least invasive in order to lose the least luminosity up-time. The beam-beam deflection scan method in use at the SLC [2] allows one to measure the convoluted spot sizes of both beams with a limited impact on the machine operation. For TESLA [1] however, the large vertical disruption of the colliding beams (cf. Table 1), characterised by the disruption parameter $D_y = 33$, precludes the measurement of the vertical spot size by this method. However,

Table 1: TESLA parameters at the IP for $\sqrt{s} = 500$ GeV

Beam sizes	σ_x^*, σ_y^* [nm]	558 , 5
Emittances	$\gamma\epsilon_x^*, \gamma\epsilon_y^*$ [μm]	10 , 0.03
Bunch length	σ_z [mm]	0.4
Bunch population	N_e [10^{10}]	2.0
Number of bunch	n_b	2820
Bunch spacing	Δt_b [ns]	337
Luminosity	$\mathcal{L}$ [$10^{33}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$]	32
Beamstrahlung	δ_B [%]	2.5

the combination of beam-beam horizontal deflection scans ($D_x = 0.3$) and luminosity monitoring is a valid procedure to correct both horizontal and vertical aberrations. Luminosity monitoring, recently re-investigated at the SLC [3], offers the advantage that the beam aberrations can be measured in the vicinity of the optimum head-on collision parameters and that a relative measurement of the luminosity is sufficient for its optimization.

We study three options to provide such a measurement based on detecting either the bremsstrahlung leptons, the beamstrahlung photons or the e^+e^- pairs. We use the beam-beam program GUINEA_PIG [5] to generate these processes and track the trajectory of the low energy leptons, from pair creation or bremsstrahlung, through the coherent e.m. field of the opposite bunch. The bremsstrahlung cross-section is corrected for the finite beam size effect [4]. It can be artificially multiplied by a factor n_b which allows one, with a single beam-beam simulation, to track the bremsstrahlung particles and integrate the bremsstrahlung signal originating from n_b bunch-crossings assuming that the bunch parameters are fixed and their fluctuations can be neglected. This is a valid assumption since the bunch population is about 6 orders of magnitude larger than the bremsstrahlung one.

The e^+ and e^- bunches are replaced by 320 000 macroparticles with 6-D Gaussian distributions set by the beam parameters given in Table 1. The luminosity for the optimum parameters is about $3.2 \times 10^{34}\,\mathrm{cm}^{-2}\mathrm{s}^{-1}$ including a factor about 2.0 from the pinch effect. The statistical relative error on the luminosity is about $7.5 \cdot 10^{-5}$ from numerical origin. This is small enough to be able to identify, from the simulations, rate fluctuations of the order of 10^{-3} as physical fluctuations.

2 BREMSSTRAHLUNG MONITOR

Bhabha monitors are a well proven instruments for luminosity measurement at e^+e^- and e^-p colliders [6]. The radiative Bhabha process $e^+e^- \to e^+e^-\gamma$, also called bremsstrahlung has a much higher event rate at small angles than the elastic Bhabha process $e^+e^- \to e^+e^-$, and is more suitable for on-line monitoring. This rate can be measured by detecting the low-energy lepton emitted away from the intense beamstrahlung cone around the beam axis. Since they are strongly deflected by the opposite beam, the rate of the outgoing low energy bremsstrahlung leptons deflected at angles usable for a luminosity detector is enhanced. This more than counterbalances the finite beam size correction [4] of roughly 1/2 to the total bremsstrahlung rate. Because of its sensitivity to the beam-beam effect, the bremsstrahlung signal *within a fixed kinematical acceptance* is no longer an absolute measurement of the luminosity but it can still be used for measuring luminosity variations induced by beam parameter changes at the interaction point (IP) such that the horizontal beam sizes which control the beam-beam effect, are unchanged. This includes the most important vertical aberrations.

For this study the luminosity monitor, assumed to be a hollow disk around the beam axis with 24 mm inner radius. As shown in Fig.(1) its location, 8.5 m from the IP, is optimised for detecting about 40 GeV particles. The number of hits is about 550 with about 20 TeV deposited per side and per bunch crossing. Integrating over 10 bunch cross-

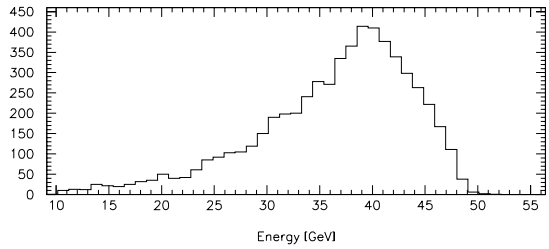

Figure 1: Bremsstrahlung energy distribution on luminosity monitor

ings and both sides leads to over 10,000 hits, enough to reduce the statistical error to the 1% level. The most important vertical beam parameters to be tuned are the beam matrix "rotations" which affect the vertical beam size, namely the vertical waist shift w_y, the vertical dispersion η_y and the yx'-coupling c_y. The definition of these aberrations and the beam matrices associated to them are given in [7]. Fig.(2) displays the results of luminosity optimisations obtained by varying the waist-shift w_y of the electron beam matrix, keeping the positron beam constant. The central configuration is such that

$$w_y^{(0)} = 0.9\,\beta_y^*, \quad \eta_y = c_y = 0 \tag{1}$$

for both beams. It is also the optimal configuration since, due to the pinch effect, the luminosity is maximized when both vertical waists are shifted by $0.9\,\beta_y^*$ in front of the IP. The gain in luminosity is about 16% with respect to the configuration where the waists are centered on the IP. In this figure, the calculated luminosity (right) is compared to the number of hits (left) from bremsstrahlung particles on the luminosity monitors, adding both sides. The scan involves 11 points and therefore a total of 110 bunch-crossings. The "optimum" luminosity as determined by the parabolic fit through the bremstrahlung rate, is less than 10^{-3} relatively smaller than the maximum of the calculated luminosity. This optimum can be determined equally well from the number of hits (counter) or from the energy deposited (calorimeter), and similar resolutions are obtained for the dispersion and coupling scans [7] as well.

In practice, each scan could be implemented with fast quadrupole pairs in the chromatic correction section (CCS) [8]. A vertical waist-scan like in Fig.(2) for instance, would be performed by symmetrically exciting the quadrupoles in the vertical CCS over 110 bunch crossings and measuring the luminosity for 110 monotonically increasing values of

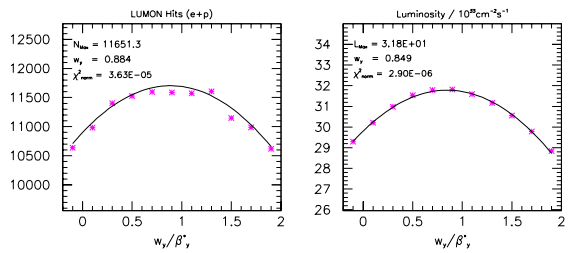

Figure 2: Scan of the vertical waist. Parabolic fits are drawn through the data points

the waist-shift w_y at the IP. In this way, a single TESLA bunch train with 2820 bunches would allow one to measure the vertical waist-shift, the vertical dispersion and the coupling of both beams, provided the implementation of the necessary excitations of the fast quadrupoles is manageable within one pulse.

3 BEAMSTRAHLUNG MONITOR

The beamstrahlung photons, with a ratio $N_\gamma/N_e \simeq 1.65$ for TESLA, provide a very strong signal which is directly related to the beam energy loss but less directly to the luminosity. In fact, this signal goes through a maximum when the two beams are vertically offset and deflect each other strongly. In order to decouple this effect from the luminosity optimization, we select the photons emitted in the $\pm 25 \times 5\mu\text{rad}^2$ forward cones whose intensities decrease with the beam offset. Fig.(3) shows the dependance of these intensities in the e^- (left) and the e^+ (right) directions on the e^--beam vertical waist (up) and dispersion (low). Unlike the bremsstrahlung, the beamstrahlung signal is not e^-/e^+ symmetric and signs which beam matrix is changing. As can be seen by comparing Fig.(3) to Fig.(2), the e^--beamstrahlung is not effective for the e^--waist tuning. Vertical dispersion, and $x'y$ the coupling as well, can however be tuned with a resolution better than 10^{-3} in terms of relative luminosity. In these scans, the 1% error in the intensity is due to the purely numerical limitation in the number of macro-photons, about 11,000, representing the physical photons contained in the forward cones.

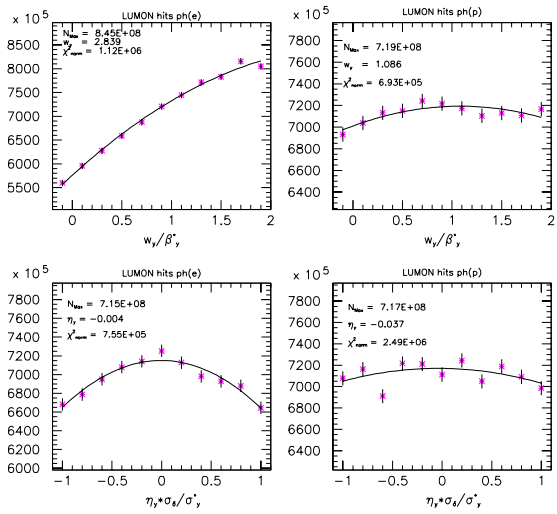

Figure 3: Beamstrahlung photon intensity per bunch-crossing vs. vertical waist (up) and dispersion (low)

4 $E^+ - E^-$ PAIR CALORIMETER

Inside the main mask a combined inner mask and luminosity monitor will be installed. This inner mask will be hit by a large number of pairs deflected by the beams. At small

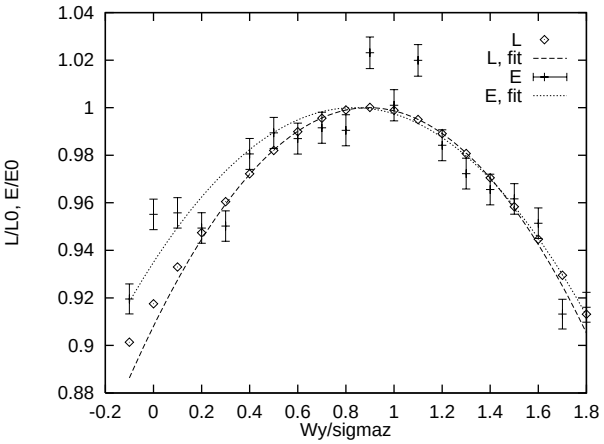

Figure 4: Scan of the vertical waist shift: energy deposited in the calorimeter and luminosity normalised to the maximal values.

radii it is covered with a low-Z material (graphite) to prevent the backscattering of low energy particles. At larger radii, where the background due to the deflected pairs is small, it will be used to measure the Bhabha events with larger angles. The rate of these events will be a few per second, much higher than those measured in the main detector for the reconstruction of the luminosity spectrum but too low for fast monitoring.

The total energy deposited by the pairs in this mask can be measured calorimetrically, but details have to be worked out. This energy is about $12000\,\mathrm{GeV}$ per bunch crossing and per side. This values varies from simulation to simulation due to physical and numerical effects. Running 25 cases with the same initial distribution (read from a file) but different seeds for the random number generators showed an RMS-spread of $1.2\,\%$ and $1.4\,\%$ for the two sides. This is in reasonable agreement with the expectation from the counting rate alone ($\approx\ 1.0\,\%$ from about 9200 hits). In practice one can expect significant contributions to the error from energy leaking out at the inner aperture of calorimeter and from jitter of the beam.

The scan was performed moving the waist of one beam, while the one of the other was about in the right position. For each point only a single bunch crossing was measured. The optimal position of the waist was determined by maximising the sum of the two signals, leading to $w_y = 0.83\,\beta_y^*$ (note that $\beta_y^* = \sigma_z$). The luminosity thus obtained is lower by a fraction of $4 \cdot 10^{-4}$ than the optimal value, which is reached for $w_y = 0.89\sigma_z$. The scan was repeated decreasing the positron bunch charge to $1.5 \cdot 10^{10}$ particles, increasing its horizontal emittance by $50\,\%$ and increasing its vertical emittance by $50\,\%$. In all three cases the luminosity for the found optimal waist position were smaller than the optimal by a fraction of about 10^{-3}.

In contrast to the bremsstrahlung process where the production of particles depends strongly on the luminosity and only weakly on the other beam parameters, the number and energy of pairs produced depends also on the number and energy of the photons produced by beamstrahlung. The deflection is however very different in the two cases. The beam particles which have emitted bremsstrahlung are still relatively high in energy and are focused by the oncoming beam. Most of the particles from pair production that hit the calorimeter are low in energy and are defocused by the same charge oncoming beam. Combining the two methods one could thus hope for reducing possible ambiguities.

5 CONCLUSION

We believe that a luminosity monitor will be a necessary instrument for the fast tuning of the collision parameters of TESLA. In this study we have shown that a radiative Bhabha counter or calorimeter can monitor the luminosity to a 1% resolution by integrating the bremsstrahlung signal over about 10 TESLA bunch-crossings, that is about 3.3 μs. The powerful beamstrahlung signal in a very narrow forward cone can also be used for tuning dispersion and coupling. A promising complementary option is a calorimeter in the masking system around the IP to measure the energy deposited by the pair-created e^+e^- particles. The 1% level can then be reached with one bunch-crossing.

With either monitor, scanning the usual vertical linear aberrations with about 10 points should permit to determine the optimal luminosity to better than 0.1% relative resolution. Implementing such scans within a single TESLA bunch train should be possible: it would reduce considerably the influence of beam jitter on the luminosity measurement errors.

THE CLIC 30 GHz TWO-BEAM TEST ACCELERATOR

I. Wilson, W. Wuensch, W. Coosemans, C. Achard
CERN, Genève 23,1211 Switzerland

Abstract

As part of the experimental effort to demonstrate the feasibility of the CLIC scheme, a 3 m long representative section of the CLIC accelerator has been constructed, installed in the CLIC Test Facility (CTF) and successfully commissioned with beam. Prototype 30 GHz components developed during the course of the CLIC study including accelerating structures, power generating transfer structures, and high power RF loads, have been successfully integrated with the micron-precision active alignment system, the vacuum system, the water cooling system, and the high power RF distribution system to produce a very compact two-beam test accelerator. This paper describes the layout and gives details of the important subsystems.

1 INTRODUCTION

A 3 m long 30 GHz two-beam test accelerator has been constructed and is presently operating with beam in the new CLIC test facility (CTF2). The test accelerator layout follows that currently foreseen for CLIC but has a higher density of quadrupoles - and consequently a lower RF filling factor - due to lower beam energies. The test accelerator is equipped with a prototype active alignment system in order to gain operating experience in a real accelerator environment. The bunched electron beams needed for the drive and main linacs are supplied by two separate 3 GHz linacs.

Since both CLIC and the test accelerator are composed of repeated two-beam 'modules', the construction of two fully equipped modules has enabled many of the technical difficulties of the full length linacs to be solved. All necessary subsystems including water cooling and vacuum have been included. The layout of a test accelerator module is shown in figure 1. Two such modules have been installed and a further two will be installed in 1999.

Prototypes of components developed in the course of the CLIC study have been used wherever possible. These include: accelerating sections, high power RF loads, main linac beam position monitors, main linac quadrupoles, support girders and the active alignment system. The power extracting structures are similar to those of CLIC but have a stronger coupling to the beam to compensate for the lower drive beam charge. Other components including waveguides, phase shifters, vacuum and beam line components were specially developed for the accelerator.

The test accelerator is shown in figure 2. Commissioning with beam started in the autumn of 1997. A maximum accelerating gradient of 50 MV/m [2] has so far been achieved and is currently limited by available drive beam charge.

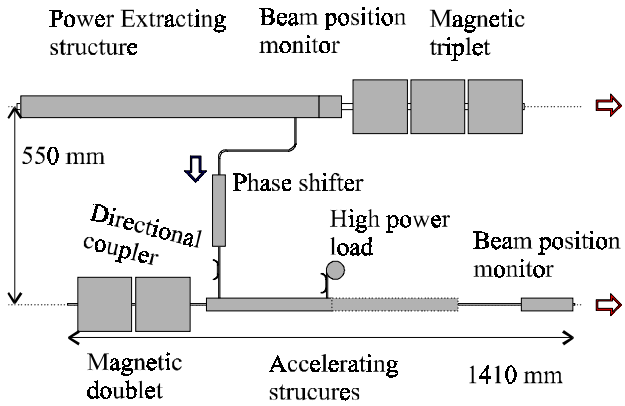

Figure 1: Schematic layout of one module of the main (lower) and drive (upper) linacs.

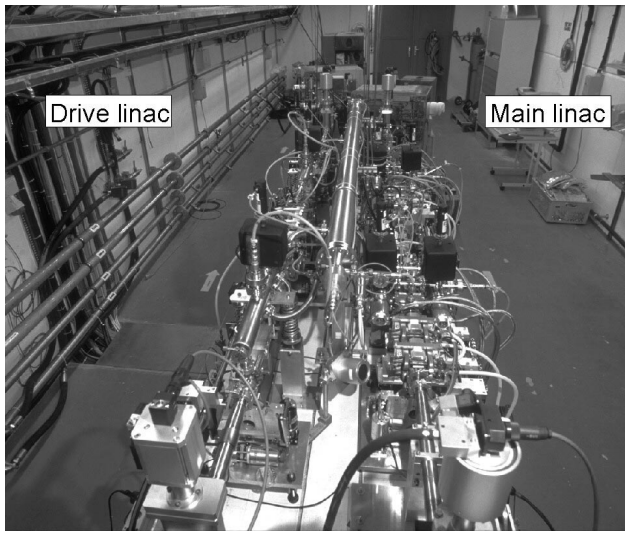

Figure 2: Downstream view of the test accelerator installed in the CTF.

2 RF SYSTEM

Each two-beam accelerator module has one power extracting structure, shown in figure 3, which feeds two accelerating sections. An extracting structure has four output waveguides - opposing pairs are combined to feed the two accelerating sections. For the moment all four output waveguides are combined to produce a higher

accelerating gradient for a given drive beam charge (but less total energy gain). RF power is combined in 'Y' junctions that are split in the magnetic field plane. The output of each accelerating section is connected to a high-power stainless-steel load which is vacuum pumped. The area around the accelerating section in the first module is shown in figure 4.

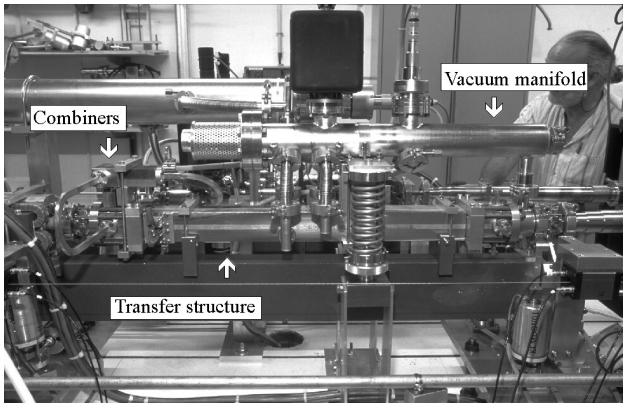

Figure 3: Installation around a power extracting structure.

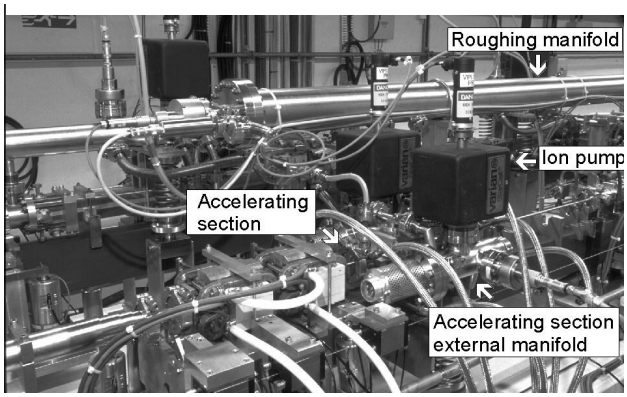

Figure 4: Installation around an accelerating section. The view of the section is obstructed by the vacuum manifolds.

The upstream ends of the power extracting structure waveguides are terminated with vacuum compatible loads containing ceramic absorbing elements. In order to maintain free movement of the support girders, all RF connections between components on the girders and those on the concrete support block contain lengths of flexible waveguide. These are made from copper plated commercially-available hydro-formed waveguide tube. The flexible waveguides also provide vibration isolation. The waveguide between the power extracting and accelerating structures contains a phase shifter.

Vacuum-tight high-power RF connections were made using a flange design with a flat face-to-face contact and a Helicoflex seal. There are no windows anywhere in the high power RF line. Low power signals are extracted from the high power system via vacuum-to-air 56 dB directional couplers before and after each accelerating section, providing calibrated incident, reflected and transmitted power signals. 1 mm diameter ceramic disks brazed into the coupling holes separate vacuum from air in these couplers. 12 m long WR-28 waveguide runs connect the outputs to the signal processing electronics in the klystron gallery.

3 BEAM POSITION MONITORS

A prototype 30 GHz resonant cavity BPM [4] with an integrated phase and charge reference cavity is installed in each main linac module. Common mode rejection is made in vacuum-compatible magic Ts. Position signals pass from vacuum to air-filled waveguide via alumina windows mounted on the difference ports of the magic Ts. Signal processing electronics is mounted in the klystron gallery.

A four-button BPM is mounted in each drive linac module. Each button electrode is connected directly to a coaxial vacuum-to-air feed-through. 20 to 30 cm lengths of standard flexible coaxial cable connect the BPM on the support girder to fixed semi-rigid coax fixed onto the concrete block.

4 ALIGNMENT SYSTEM

The entire accelerator is mounted on a concrete block that is grouted to the floor - a precaution that would only be meaningful in a proper stable linear collider tunnel. The block also contains niches where radiation sensitive alignment control electronics are mounted. All other components of the alignment system have been designed to be radiation hard

The test accelerator is actively aligned and held to within a few microns using a stretched wire system [3]. All beam line components other than quadrupoles are mounted on 1.41 m long (length of one module) silicon carbide support girders. The components are directly supported by ± 1.5 μm precision V blocks. Continuity of the beam axis from girder to girder to a similar precision is provided by a system of link rods that connect the ends of the successive girders. The link rods create articulation points at the beam axis intersections. The articulation points, and thus the linacs, are aligned by moving the ends of the girders with 0.1 μm step linear actuators, which are shown in figure 4.

Actuator movements are calculated from readings of the 0.1 μradian resolution tilt meters and the 0.1 μm resolution capacitive sensors of the stretched wire system. The vertical positions of the ends of the wires are measured by a hydrostatic leveling system.

Quadrupole doublets and triplets are mounted on independent platforms with their own wire sensors, tilt meters and actuators. The quadrupoles are referenced to the same stretched wire as the support girders.

The system operates in a closed feedback loop holding the linacs within an alignment window of ± 2 microns.

The end-station of the stretched wire system is shown in figure 5.

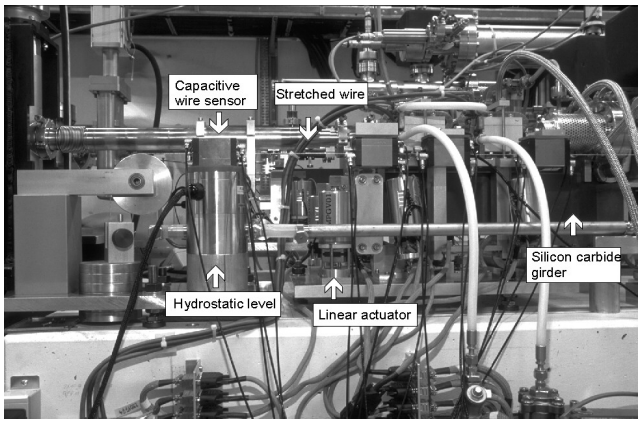

Figure 5: End station of the stretched wire system.

5 BEAM LINE COMPONENTS

The internal diameters of the main and drive linacs are 4 and 22 mm respectively. The main and drive linac beam pipes have been designed to present low transverse impedances. The drive linac beam pipe must also carry high image currents without arcing or heating locally. Maintaining these design objectives has been most difficult for the inter-girder articulations, which must also be flexible and vacuum tight. In the current design, the articulation points have a 1-2 mm beam pipe gap with a 50 mm diameter bellows placed around the gap region to contain the vacuum.

Connections between fixed drive-linac beam-line components are made using a flange design derived from the vacuum RF flange. The requirements for the RF flange, a small impedance mismatch and a high current capability, are identical to those of the drive-linac beam-line flange.

The prototype main and drive linac quadrupoles have internal apertures of 10 and 30 mm respectively. The resulting ± 2 mm clearances between the quadrupoles and the beam pipes allows the beams to be steered using quadrupole offsets. The field gradient in the main linac quadrupoles is 100 T/m.

6 VACUUM SYSTEM

The primary design challenges for the vacuum system are to provide adequate pumping to the very low conductance main linac beam pipe and to allow unconstrained movement of the alignment system. The design level of 10^{-8} torr has been achieved.

This vacuum level in the main linac is obtained by pumping each accelerating section cell with four 1 mm diameter radial holes. It is sufficient to pump only accelerating sections since in CLIC they make up most of the main linac length. Each accelerating section is pumped by a pair of local manifolds each of which contains a getter and an ion pump. The manifolds (weighing some 20 kg) are mounted on spring supports and follow girder movements with little applied force. Power extracting structures are pumped by a single local manifold also with a getter and an ion pump.

All of the local manifolds are connected via flexible tubing to a central roughing manifold, which appears prominently in all photographs of the test accelerator such as figure 1. After an appropriate vacuum has been reached the roughing manifold is isolated from the manifolds by valves. The accelerator can be isolated from the rest of the CTF with valves at the ends of each linac.

7 WATER COOLING SYSTEM

With average RF and beam power levels in the test accelerator a small fraction of those anticipated in CLIC, the water cooling requirement is less demanding. Nonetheless, the water connections must still remain sufficiently flexible when pressurized not to constrain the alignment system. Hydro-formed thin walled stainless steel tubing has been used to connect to the accelerating sections but the solution is unsatisfactory because the tubing is a vibration source. Latex tubing was later chosen for the quadrupoles and appears to function very well.

8 CONCLUSIONS

The successful installation and operation of the test accelerator represents an important step in the demonstration of the feasibility of the CLIC scheme. Difficulties of layout and assembly resulting from the high density of components of the 30 GHz accelerator have been overcome. The active alignment system has been successfully integrated with all the other subsystems, maintains alignment within a ± 5 micron window and operates reliably in a high radiation environment without any evidence of deterioration. A precise agreement between drive beam, generated power and main beam energy gain indicates that the RF system is functioning correctly.

Abstract

For future linear colliders, one of the essential techniques to get a sufficient luminosity is to accelerate multi-bunch beam of small bunch spacing. Beam loading voltage in an accelerating structure generates a large energy spread along the bunch train. This energy spread is critical for the lattice design and, if not properly compensated, induces emittance growth and in turn lowers the luminosity. A method to compensate for beam loading effects in a multi-bunch beam is under development at Accelerator Test Facility (ATF) in KEK [1]. We will report the beam tests for early injection and a phase to amplitude modulation method using multi-bunch beam of 2.8 ns bunch spacing. This energy compensation method compresses energy spread of multi-bunch beam by changing the input rf waveform properly into accelerating structures.

1 INTRODUCTION

A scheme of multiple bunches (87 bunches) being accelerated on each rf pulse is adopted in the Japan Linear Collider (JLC) design [2]. This scheme improves the energy transfer efficiency from wall plug power to the beam and luminosity of the machine. However, it results in turn significant beam loading. In JLC, an energy spread which is generated by the beam loading has to be reduced to a few tenth of a percent.

There are several possible methods to compensate the multi-bunch energy spread with keeping bunch spacing constant, such as ΔF method [3], ΔT method and so on. The ΔF method is to use one or more accelerator structures running at the frequency slightly higher and lower than the fundamental frequency and roughly in 90 degree out of phase from the acceleration. The ΔT method is to inject a beam before an rf pulse has filled in an accelerating structure. Power efficiency of ΔF method is higher than ΔT method, however this method is only adaptive in case that the energy of beam drops approximately linearly as a result of beam loading.

On the other hand, the transverse emittance dilution due to a random misalignment A_{rms} of quadrupole magnets with respect to the beam is estimated approximately to be

$$\frac{\Delta\epsilon}{\epsilon} \approx \frac{A_{rms}^2}{2\gamma_0\epsilon_0} \sum_i \gamma_i \beta_i k_i^2 (\frac{\Delta E}{E})_i^2 \qquad (1)$$

where $\gamma_0\epsilon_0$ is initial normalized emittance and γ_i, β_i, k_i and $(\Delta E/E)_i$ are Lorentz energy factor, beta function, focusing strength of quadrupole magnet and energy spread at the i-th quadrupole in the linac, respectively [4]. Since the emittance growth is connected to the energy spread at each quadrupole according to Eq. 1, energy spread correction should be done locally at each quadrupole. The ΔT method which compensates an energy spread in every accelerating structure is the local compensation, while ΔF method compensates it through several quadrupoles in average. In the low energy part in the linear colliders, the local correction method will be an important method where $\Delta E/E$ is not enough small.

2 PHASE TO AMPLITUDE MODULATION METHOD ($\Delta\phi - A$)

The most simple compensation of the beam loading in ΔT method can be done by injecting the beam before the rf pulse has filled the accelerating structure. If we use this simple early injection method, the beam current at which the energy compensation acts effectively is limited to some range, and acceleration efficiency will be poor. We apply

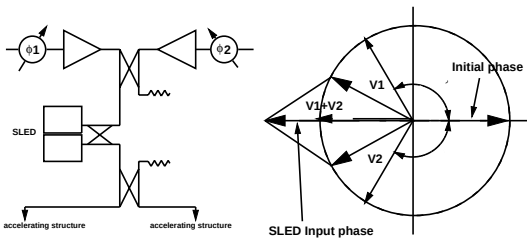

Figure 1: $\Delta\phi - A$ beam loading compensation

thus the amplitude modulation on the input rf pulse for the pulse compression. Therefore in case of using the SLED-I system [5], we can obtain the desirable slope of unloaded voltage by changing input rf waveform for SLED cavities. As discussed in Ref. [6], it is not a good idea to directly modulate the amplitude of the driving rf power to klystron. For a stable operation, a klystron usually needs to be used in the saturation condition. Thus, modulating the drive rf phase of klystron would be a better method. To modulate the amplitude of rf pulse for the SLED-I cavities at constant phase, two klystrons are needed. They run in saturation, keeping the input rf level constant. Then, we control their phases and combine the rf power from two klystrons by using a 3 dB hybrid combiner. Figure 1 shows a scheme in which the rf phases of two klystrons are rotated into opposite directions relative to each other. The sum of two

phase modulated rf makes amplitude modulated rf with constant phase, which is fed into the SLED cavities. The phase modulation of the two klystrons effectively realizes amplitude modulation using this method ($\Delta\phi - A$ method).

If bunch population of each bunch is not uniform, thus the energy spread of beam does not drop linearly with time. Even in the case of it, phase modulation to amplitude modulation ($\Delta\phi - A$) method can properly compensate by changing the speed of phase rotation.

3 BEAM TEST OF $\Delta\phi - A$ ENERGY COMPENSATION

To verify that the $\Delta\phi - A$ beam loading compensation scheme works as predicted, we performed preliminary beam test in the ATF injector linac of the damping ring. The ATF s-band linac consists of 80 MeV pre-injector, 8 regular accelerating units, two units of energy compensating structure for ΔF energy compensation. Each regular unit contains SLED-I pulse compression system and the compressed rf power is fed into the two accelerating structures. For this experiment, the first and second regular sections were used and a chicane to measure the multi-bunch energy distribution was constructed downstream from this two regular units. ATF linac accelerates a multi-bunch beam that consists of 20 bunches with 2.8 ns spacing.

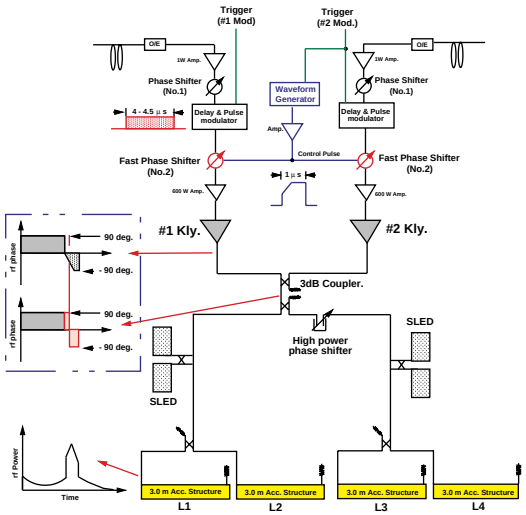

Figure 2: Experimental setup for $\Delta\phi - A$ beam loading compensation

3.1 *Experimental setup*

We preliminary tested $\Delta\phi - A$ method using two-klystron combination, Figure 2 shows the rf system of this experiment. It consists of two 85 MW klystron (TOSHIBA 3712), two dual-iris s-band SLED cavities, 3 dB hybrid combiner, high power wave guides, rf loads and an high power mechanical phase shifter. In this rf set up, rf power from the two klystrons were combined using 3 dB hybrid combiner, after that combined power was divided again to avoid a break-down at SLED cavities. High power mechanical phase shifter was used to adjust the relative phase between two rf units (L1,2 and L3,4 structures). Rf power is measured by using -70 dB Bethe-Hole coupler at several points which are each klystron out, the combined point, input of the SLED cavity and the entrance and exit of the accelerating structure. In the low level rf circuit, the 2856 MHz phase shifters (No.1) tune the rf phase of the input CW rf to the beam. By using Delay and Pulse Modulator, it is modulated into a short pulse with 4.5 μs width and the rf timing to klystron voltage is adjusted. The fast phase shifters (No.2) using varactor diode are used to rotate the drive rf phase. A control pulse with 1.0 μs width for the fast phase shifters is generated by an arbitrary waveform generator, and changes the rotating speed of drive phase. In this beam test, rotating speed of rf phase was changed at constant rate.

3.2 *Measurement system of the beam energy*

Figure 3 shows the layout of the beam line to measure the energy variation along the bunch train. For energy

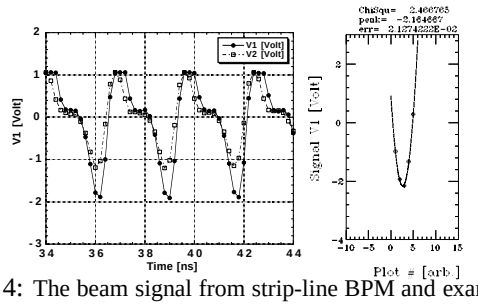

Figure 4: The beam signal from strip-line BPM and example of fitting to sample data

measurement, the horizontal chicane was installed down stream from the four regular accelerating structures which were filled amplitude modulated rf power. This chicane contains a strip-line-type beam position monitor (BPM) which is mounted at the center of the chicane to measure the beam energy. At this BPM, the horizontal dispersion function η_x is 50 mm. The multi-bunch beam signal from the BPM was measured by using a digital oscilloscope of real-time 5.0 GHz sample and a personal computer. A pulse height of each bunch signal was determined by a parabolic curve fitting to the sampled data. In this measurement, the position resolution was about 130 μm which was derived from three BPMs correlation and this position resolution corresponds to 0.26 % energy resolution. The position resolution was mainly limited by a systematic error of the fitting, so it may be improved using other functions for the fit. On the other hand, the only horizontal orbit of all bunches in the same pulse was measured using 7 BPMs in the linac, this measurement was free from the pulse-to-pulse energy jitter.

3.3 Preliminary result of beam test

In this experiment, the multi-bunch of 19 bunches/pulse accelerated with intensity of 0.82×10^{10} electrons/bunch at pre-injector exit. At the 80 MeV pre-injector, the energy of multi-bunch beam was compensated using the simple ΔT compensation technique (only early injection) to make the energy flat as an input of $\Delta\phi - A$ compensation section.

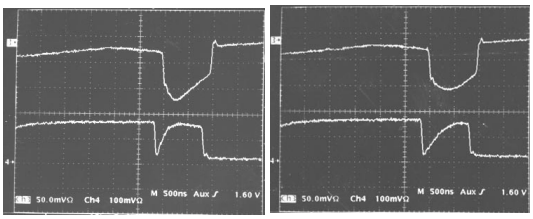

Figure 5: Rf waveform at the structure input (up) and the combined point (down) in different phase rotating speed. (right:90 deg./400 ns, left:90 deg./800 ns)

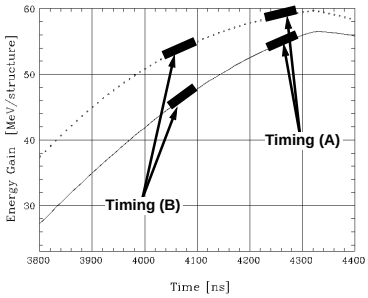

Figure 6: Calculation result of unloaded energy gain. Phase rotating speed are 90 deg./400 ns (dashed) and 90 deg./800 ns (solid)

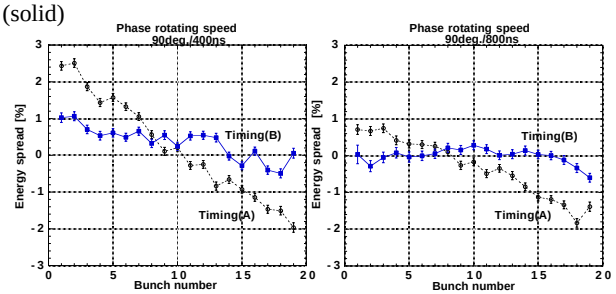

Figure 7: Measured multi-bunch energy spread with different phase rotating speed

We observed the difference of compensating voltage along the multi-bunch beam by changing the phase rotating speed and the relative timing of rf pulse to the beam in the two klystrons. Figure 5 shows rf waveforms at the input of accelerator and the combined point in the two cases of different rotating speed of drive rf phase. The calculation result of unloaded energy gain slope for the previous two different phase speed is shown in Figure 6. In this calculation, klystron output power is assumed to 20 MW which is the same value with the real beam test setup and the parameters of SLED cavities and structure are also the same. The two slopes of the unloaded energy gain curve are different by phase speed before first filling time of the structure. In the slow rotation case in which the phase speed is 90 deg./800 ns, the compensating voltage is larger than another case (see in Figure 6). Figure 7 shows energy distribution of multi-bunch beam in the two different rotating speed of drive phase and the two different beam injection timing to rf pulse which are shown as timing (A) and (B) in Figure 6. Assuming that the beam loss at $\Delta\phi - A$ compensation region was 10 % at the entrance of the first structure, the calculated beam loading voltage was about 2.7 MV/structure. Then the calculated energy spread with 90 deg./400 ns rotating speed are about 4.0 % at timing (A) and 1.8 % at timing (B), while in the another case with 90 deg./800 ns rotating speed they are about 2.8 % and 0.5 % at the each timing. From the Figure 7, the measured energy spread were 4.5 % (with timing A) and 1.5 % (with timing B) for 90 deg./400 ns, 2.6 % (with timing A) and 0.5 % (with timing B) for 90 deg./800 ns speed. The calculated values and the measured energy spread were consistent, so the amplitude modulation of the input rf acted to the multi-bunch beam so as to compensate the beam loading. However, the measured energy distribution inside the multi-bunch beam had a fluctuation from monotonous change. This fluctuation correlated to the intensity of each bunch. If we can measure the intensity variation along the bunch train and monitor the rf power correctly, the energy spread of multi-bunch beam will be minimized by setting the rotating speed of rf phase and injection timing as calculated. Its experiment is planed in this fall.

4 SUMMARY

The beam test of $\Delta\phi - A$ energy compensation was performed by using two klystron combination. Phase modulation of two klystrons was used to obtain an amplitude modulated input for the SLED. The modulation of accelerating waveform could be realized by modulating the amplitude of the SLED input. Energy gain of each bunch along a bunch train was changed by changing a rotating speed of an input rf phase, as a result the beam loading was compensated as expected.

5 ACKNOWLEDGMENTS

The authors would like to acknowledge the continuous encouragement of Professors M. Kihara, K. Takata, Y. Yamazaki. This experiment could not be performed without the help of Mr. D. Aizawa and E-CUBE corporation. We wish to thank these people for their help. The authors also appreciate to Drs. K. Egawa and M. Masuzawa of accelerator laboratory in KEK for the reason that they have readily lent us the dipole magnets.

Abstract

It is well established that operating frequencies in the 30-GHz range and higher are required to obtain the high accelerating gradients needed by linear collider systems that wish to probe center-of-mass energies significantly higher than 1 TeV. As an rf power source for high-energy linear colliders, relativistic klystron two-beam accelerators (RK-TBAs) have been shown theoretically to scale favorably to frequencies higher than X-band. To complement our studies of RK-TBA systems at 11.424 GHz, we are undertaking experimental tests of components at both 35 and 30 GHz. These studies will be conducted at the CEA/CESTA facility using the LELIA and PIVAIR electron linear induction accelerators (LIAs), respectively, and will concentrate on the interaction of the intense, modulated electron beams with rf cavity structures, compact induction modules, and permanent magnet quadrupole transport lattices. Details of the rf cavity design and the proposed experiments are discussed.

1 INTRODUCTION

To explore center-of-mass energies in the multi-TeV range with electron-positron linear colliders will require accelerating gradients of several hundred MeV per meter. Scaling of conventional, copper-based structure technology shows that this can be considered at operating frequencies around 30 GHz (Ka band) [1]. Among the myriad ways of producing pulsed, high-power microwaves to drive accelerating structures, RK-TBA technology has been shown theoretically to be one of the most efficient [2]. As a testbed for RK-TBA physics and engineering studies, the 11.4-GHz prototype RTA is currently being commissioned [3]. To complement these studies, we will conduct tests of rf output structures and bunched beam transport at 30-35 GHz. This work is conducted through a collaboration of LBNL personnel with groups at CEA/CESTA and CERN. This paper discusses these upcoming experiments, with emphasis on rf cavity design and measurements of longitudinal bunching.

2 TESTS ON LELIA

Since 1995, the induction linac LELIA at the CEA/CESTA facility has been used to produce a 2-MeV, 800-A, 60-ns beam modulated at 35 GHz by a free-electron laser. This work has been conducted with support of CERN to study the generation of a suitable drive beam to power CLIC Transfer Structures (CTS). Of equal interest is the possibility of using the modulated beam to drive inductively detuned rf structures in an RK-TBA. In this case, the rf properties of the cavities determine the longitudinal beam dynamics. Hence, measurements of longitudinal phase space bunching are important to make. Diagnostics techniques developed at CESTA have, for the first time, enabled us to directly view the electron bunching, and to capture the image with a streak camera [4,5].

2.1 Inductively Detuned SW RF Cavities

The first set of experiments will study the interaction of the modulated beam with standing wave rf cavities. Three different cavities are to be constructed and studied sequentially, one idler and two single-output cavities. We have modeled these structures with the Superfish, URMEL-T, and GdfidL codes [6]. The characteristics of the cavities are listed in Table 1.

	Idler	Low Q	High Q
f [GHz]	34-36	35	35
Q	363	6	45
R/Q [Ω]	45	45	45
P_{out} [MW]	-	0.7	5.0
E_{peak} [MV/m]	400	7	50

Table 1. Parameters of rf cavities.

The idler cavity has been designed to accept variable-radius 'tuning rings' in the inner pillbox region. These rings adjust the inner radius of the cavity to permit tuning the fundamental mode frequency over the range 34-36 GHz. The frequency of the cavity can be adjusted so that the longitudinal impedance seen by he beam is resonant, or detuned (capacitively/inductively). The idler cavity assembly is shown in Figure 2.

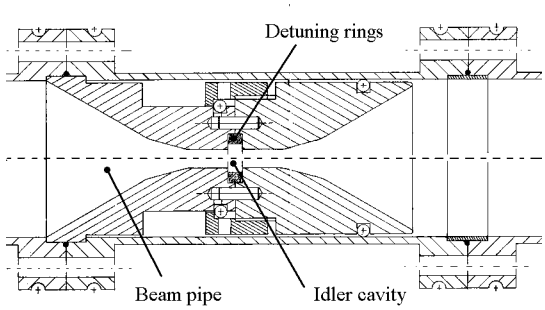

Figure 2. Idler cavity assembly.

The tuning rings will be manufactured by wrapping a layer of stainless steel (304SS) around a narrow spool that exhibits a slight taper. Individual rings will then be cut from this spool. This permits an accurate measure of the ring's inner radius, as well as differences in the radii between different rings.

The output cavities are designed with only a single output port. This port is attached to a connecting waveguide which is expanded to mate with standard WR-28 guide. Figure 3 shows a quarter of the geometry.

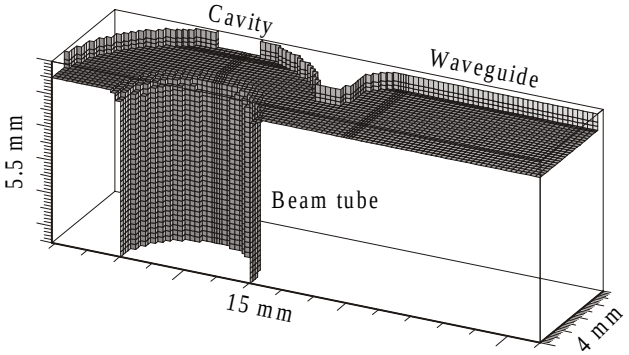

Figure 3. Output cavity quarter-geometry. The beam travels vertically through the beam tube.

This single output port can introduce an unwanted transverse impulse to the beam as it traverses the structure. The pillbox region of the cavity has been designed slightly off-center from the beamline axis to compensate for this. As a result, the linear variation of the longitudinal electric field has been strongly suppressed. A small quadratic variation is still present. However, any quadrupole interaction is slight. A cross-section of the longitudinal electric field distribution in the cavity midplane normal to the beam axis is shown in Figure 4.

The expected performance of these cavities is listed in Table 1. As can be seen, only a modest amount of output power is expected from these structures. These first experiments will concentrate mostly on beam dynamics issues: generation and transport of an intense, modulated beam through a narrow aperture cavity; and observation of the interaction of the cavity upon the beam. Later experiments may involve more sophisticated cavity designs, intended to produce rf output levels sufficiently high to drive accelerating structures.

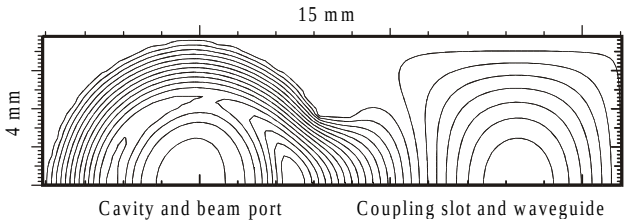

Figure 4. Cross-section of output cavity showing symmetrization of the modal longitudinal electric field.

2.2 Longitudinal Beam Dynamics Studies

Optical measurements will be performed to study the time-dependent beam-cavity interaction. Bunches will be extracted, and their longitudinal bunching characteristics measured. This allows us to make a comparison between our simulation codes and experiment. The primary measurement will be of the bunching parameter of the beam before and after it exits the cavity region. This will be compared with measurements of bunching when the beam is freely propagating. Simulation results of the evolution of the bunching parameter along the beamline following the FEL are shown in Figure 5. The cavity is located 28.5 cm from the end of the FEL. Measurements will also be made of the relative phase of the output rf power with respect to the FEL output.

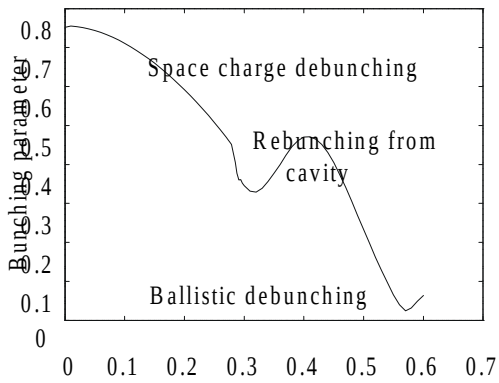

Figure 5. Evolution of the bunching parameter from the end of the FEL through the cavity.

2.3 Observation Of Bunching Characteristics

An optical diagnostic based on Cerenkov emission will be used to measure the bunching characteristics. The beam is stopped by a movable, fused-silica target. A gated CCD camera and a fast streak camera (2-ps resolution) will be used to collect and analyze a small part of the visible Cerenkov light. Figure 6 shows an example of the streak camera output, clearly displaying the bunching.

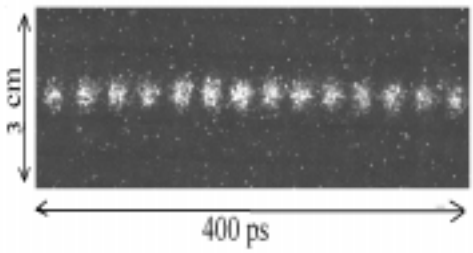

Figure. 6. Streak images of 35GHz bunches.

3 TESTS ON PIVAIR

The PIVAIR induction linac generates a nominal 7.2-MeV, 3-kA, 60-ns beam. These values make it very attractive as an injector for a 30-GHz RK-TBA system to power a multi-TeV linear collider. A preliminary point design for a multi-TeV-scale linear collider system using an RK-TBA driver and operating at 30 GHz has already been presented [7]. The RK-TBA drive beam architecture is shown in Figure 7.

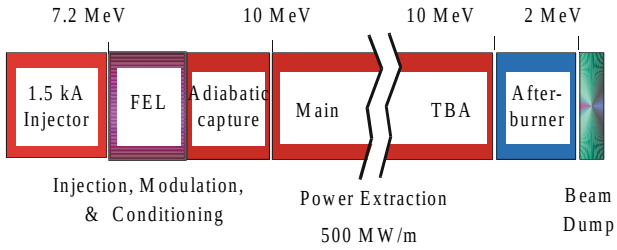

Figure 7. 30-GHz RKTBA architecture.

The front end of the drive beam injector for the Main TBA is composed of an electron gun and accelerator ('Injector'), a free electron laser ('FEL') to provide the modulation, and an 'Adiabatic capture' section to provide for bunch compression, additional acceleration, and other pulse conditioning. This latter effect may include shaping of the front-end current profile to provide a ramped current pulse. Power extraction and reacceleration then occurs in the Main TBA section.

A current proposal [8] seeks to use PIVAIR for TBA-related studies. An FEL to provide 30GHz modulation is to be constructed, followed by a beamline to support TBA studies. PIVAIR operated as a test stand thus will provide a valuable resource in the effort to examine beam dynamics and to test designs of beamline components for a high frequency RK-TBA. Of particular concern are the rf output structures and induction modules in the Main TBA section. Prototypes may be designed and then tested on the PIVAIR beamline, once a modulated beam is present.

4 CONCLUSIONS

Current experiments are studying the beam-cavity interaction in RK-TBAs at frequencies around 30GHz, ostensibly extending the utility of RK-TBA power sources to higher frequencies and to higher peak output power levels. These studies will enable us to more accurately predict and model beam dynamics in a large scale driver for a multi-TeV electron-positron linear collider.

5 ACKNOWLEDGMENTS

We wish to thank our collaborators in the CLIC group at CERN, and Colin Johnson and Walter Wuensch in particular, for their work in constructing the output cavities. SML also wishes to thank Warner Bruns for the time spent on extra development of the code GdfidL, which was used considerably in the cavity design. Work in the U.S. was performed under the auspices of the U.S. Department of Energy by LBNL under contract AC03-76SF00098, and by LLNL under contract W-7405-ENG-48.

HIGH CHARGE SHORT ELECTRON BUNCHES FOR WAKEFIELD ACCELERATOR STRUCTURES DEVELOPMENT*

M.E. Conde, W. Gai, R. Konecny, J.G. Power, P. Schoessow
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

The Argonne Wakefield Accelerator group develops accelerating structures based on dielectric loaded waveguides. We use high charge short electron bunches to excite wakefields in dielectric loaded structures, and a second (low charge) beam to probe the wakefields left behind by the drive beam. We report measurements of beam parameters and also initial results of the dielectric loaded accelerating structures. We have studied acceleration of the probe beam in these structures and we have also made measurements on the RF pulses that are generated by the drive beam. Single drive bunches, as well as multiple bunches separated by an integer number of RF periods have been used to generate the accelerating wakefields.

1 INTRODUCTION

In order to study and demonstrate the wakefield acceleration scheme and also the two beam acceleration concept, we have designed and constructed a facility called Argonne Wakefield Accelerator (AWA). The AWA consists of three major components: (i) a photocathode based RF electron gun capable of producing up to 100 nC (drive gun) followed by two standing wave linac sections for post acceleration, (ii) a second photocathode based RF electron gun capable of generating low charge short electron bunches synchronized with the drive bunches (witness gun), and (iii) an experimental section for wakefield measurements, in which the witness beam is accelerated by wakefields generated by the drive beam. We have obtained electron bunches of 10 - 100 nC with FWHM of 10 - 40 ps, which have been used for initial wakefield experiments in both dielectric loaded structures [1] and plasmas [2]. These unprecedented high-charge short-electron bunches, allied with the uniqueness of having two photocathode RF guns with adjustable delay between their beams, make AWA an ideal facility for the study of electron beam driven wakefield acceleration.

2 AWA ELECTRON GUNS AND LINAC STRUCTURES

Figure 1 shows a schematic of the AWA layout. The half-cell drive gun was designed to have a high accelerating field (92 MV/m at the photocathode surface) to allow the extraction of high charge electron bunches, and to produce a 2 MeV beam with the limited RF power available at the design time (1.5 MW at 1.3 GHz) [3]. The high intensity of the accelerating field in the gun permits the generation and acceleration of short electron bunches, without having to rely on magnetic pulse compression. Magnesium was chosen to be the photocathode material for its ruggedness and quantum efficiency (5×10^{-4}). The 2 MeV bunches generated by the drive gun subsequently

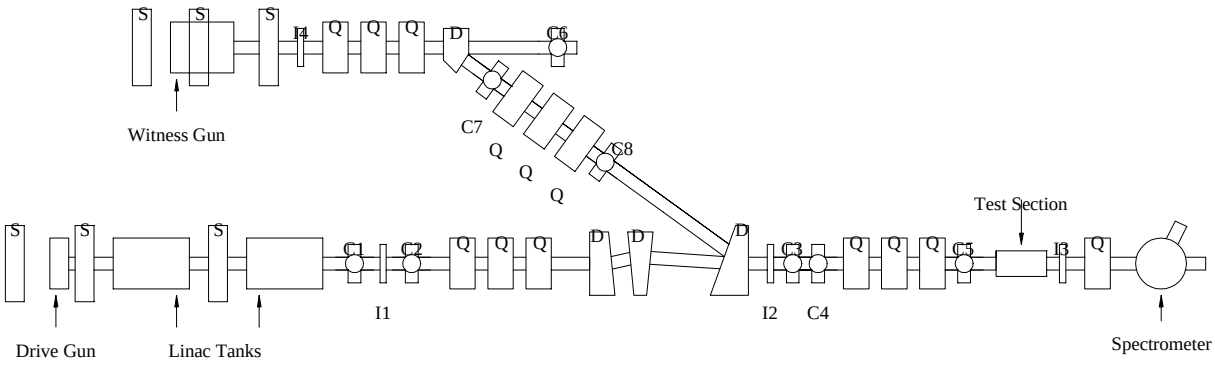

Figure 1: Schematic of the AWA experimental setup: S, Q, and D indicate solenoids, quadrupoles, and dipoles, respectively; the four integrating current transformers are labeled I1 through I4; the eight diagnostic ports are labeled C1 through C8.

*Work supported by the Department of Energy, Division of High Energy Physics, under contract W-31-109-ENG-38.

pass through two standing-wave, $\pi/2$ mode linac tanks (shunt impedance of 21.5 MΩ/m), increasing the beam energy to about 14 MeV. The linac structures have large irises (10.16 cm diameter) to minimize the generation of wakefields by the propagation of the high charge drive bunches [4]. The beam is then focused by quadrupoles and bent by three dipoles to allow for the injection of both the drive beam and the witness beam into the wakefield experimental section. The witness gun [5] is a 6-cell standing-wave $\pi/2$ mode structure that generates 4 MeV bunches of 300 pC. Its photocathode material is copper. The witness beam goes through combining optics and then through the wakefield device (plasma or dielectric structure) trailing the drive beam, thereby probing the wakefields excited by the drive bunches. Energy changes of the witness beam are measured by a spectrometer magnet located downstream of the wakefield experimental section.

The two RF guns and the two linac structures are powered by a single klystron (Thomson TH2022D; 24 MW, 4 μs pulses), via necessary power splitters and phase shifters. The laser system is comprised of a dye oscillator (496 nm) pumped by a tripled YAG, which is then followed by a dye amplifier, a doubling crystal and finally an excimer amplifier. This laser is capable of producing up to 8 mJ with 6 ps FWHM at 248 nm. The laser beam is then split and a small fraction of it (~ 15%) sent to the witness gun. There is an adjustable delay between the drive gun and the witness gun laser beams. This allows us to vary the delay between the drive and the witness electron bunches (obviously the RF phases have to be adjusted accordingly, in order to maintain the same launching phase).

3 DIAGNOSTICS AND BEAM CHARACTERIZATION

There are four integrating current transformers (Bergoz ICT - 082-070-20:1) installed on the beamlines to measure bunch charge at various locations as indicated in Fig. 1. Bunch length measurements [6] are performed using radiation emitted by the electron beam as it passes through a Cerenkov radiator. The Cerenkov light is sent to a Hamamatsu M1952/C1587 streak camera for pulse length measurements. Insertable quartz or aerogel plates are used as Cerenkov radiators. The aerogels require a more elaborate holder than the quartz plates, but offer several advantages. The aerogels need to be in a vacuum-tight holder which is inserted in the beam path. The electron beam enters our holder through a thin aluminum window (0.15 mm). It then traverses the aerogel (under atmospheric pressure) and emits Cerenkov radiation, which leaves the aerogel holder through a quartz window. Our aerogels have an index of refraction of 1.009, therefore the Cerenkov light is emitted at an angle of 7.4° with respect to the direction of propagation of the 14 MeV electrons. The light is then reflected by a mirror and leaves the vacuum chamber through a diagnostic view port.

Figure 2 shows measurements of pulse length as a function of bunch charge. In these plots the charge was measured by the integrating current transformer I1 (see Fig. 1), and the bunch length was measured using the aerogel radiator and the streak camera. In Fig. 2a we show a detailed charge scan in the range 15 - 35 nC and the corresponding FWHM of the pulses; many pulses were measured in this range and then binned in groups of 51. The plot shows the average value of charge and bunch length for seven bins, indicating that in this charge range the pulse length is almost constant, fluctuating between 15 and 20 ps. The plot in Fig. 2b shows a charge scan over a much wider range, but each point in this graph is the average of only three pulses. We have plotted the FWHM of the bunch lengths and also the 95% RMS values (this was calculated taking into account only the section of the pulse profile with intensity within 95% of the peak value, with the purpose of discarding the effect of the small background noise at the wings of the distribution). The ratio between the 95% RMS and the FWHM values shows that the pulses are not gaussian. The large fluctuation in the FWHM of the pulses also shows that the detailed shape of the temporal profile varies considerably from pulse to pulse. In all of these bunch length measurements the changes in bunch charge are accomplished by varying the laser pulse energy (either by purposely attenuating the laser beam, or due to

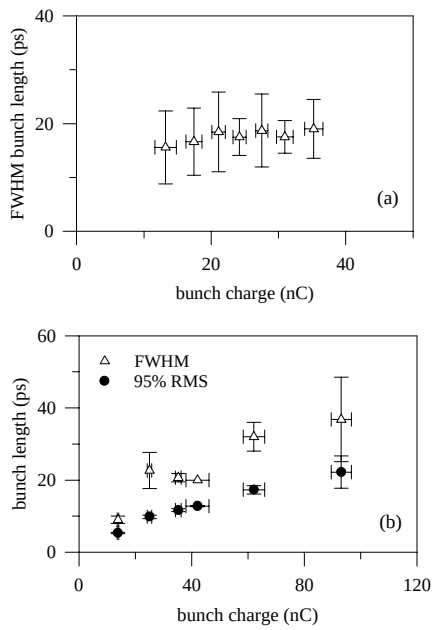

Figure 2: Measurements of electron bunch length as a function of bunch charge: (a) detailed pulse length measurement in the 15 - 35 nC range; (b) measurement over a wider range of charges, each point represents the average of three pulses.

the natural fluctuations in the laser power); when the change in the emitted bunch charge is large, it becomes necessary to readjust the solenoids and RF phases to compensate for the changes in the space charge forces.

4 WAKEFIELD MEASUREMENTS

We can map out the wakefields in a dielectric loaded structure by varying the delay between the drive bunch and the probe (witness) bunch. By measuring the change in energy of the witness beam, we obtain a direct measurement of the wake potential. This detailed mapping of the wakefields [1] was performed in a structure consisting of a hollow borosilicate glass cylinder ($\varepsilon \sim 4$) with inner radius of 5.0 mm and outer radius of 7.7 mm. Figure 3 shows the wake potential as measured from the energy change of the centroid of the witness beam as a function of the delay between the two bunches. The largest energy shift of the centroid is about 2.5 MeV/m (for drive bunches of 11 nC). Because the 2.5 mm FWHM length of the witness beam is a significant fraction of the wavelength of the wakefield (in this specific case the wakefield has an RF frequency of 15 GHz), the actual gradient is larger than the gradient measured from the witness beam centroid change in energy. By comparing the data with numerical simulations convolved with a Gaussian witness bunch shape, a true gradient of 3.6 MeV/m is inferred. Additional optimization of the laser injection phase and beamline magnet settings resulted in a gradient of approximately 6 MeV/m with a 20 nC drive beam intensity.

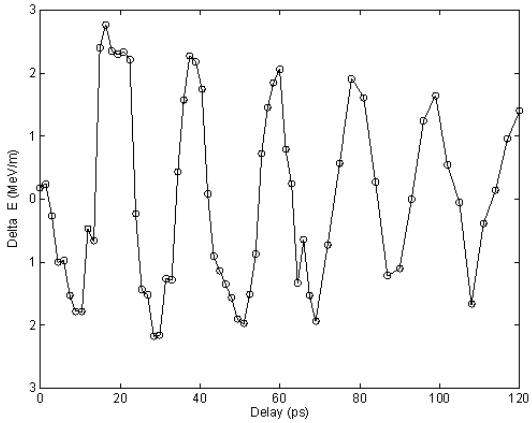

Figure 3: Wake potential measurement for a 15 GHz dielectric structure. Each data point is the change in the bend view centroid of the witness beam at the spectrometer 60° port.

5 DIELECTRIC WAKEFIELD TRANSFORMER

There are advantages in building a dielectric wakefield accelerator with two separate dielectric structures, in a transformer configuration. The drive beam generates an RF pulse as it passes through one of the structures. This RF pulse is coupled to the second dielectric structure (via a waveguide) where the witness beam is accelerated. The second tube has the same fundamental frequency but lower group velocity and transverse dimensions, thus providing an accelerating field step-up by compressing the RF pulse. Multiple drive bunches can be used, spaced by an integral multiple of the RF period, to provide a long accelerating pulse. Another advantage of having two separate dielectric structures is that the drive structure can be designed with sufficiently low transverse impedance to avoid beam breakup problems.

We have recently been designing and building dielectric wakefield transformers [7] operating at 7.8 GHz and also at 15.6 GHz. We have also succeeded in generating multiple drive bunches, by optically splitting and appropriately delaying the laser pulse to the drive gun. Figure 4 shows the envelope of the RF macropulse generated by a bunch train consisting of 4 bunches separated by 3.077 μs.

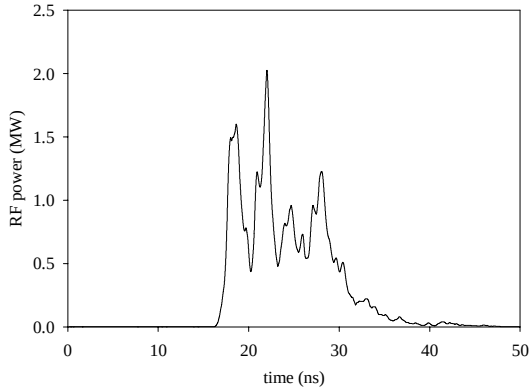

Figure 4: RF macropulse envelope for train of four drive bunches in a 7.8 GHz structure.

LASER SYSTEM FOR A SUBPICOSECOND ELECTRON LINAC*

R. A. Crowell, C. D. Jonah, A. D. Trifunac, and J. Qian
Chemistry Division
Argonne National Laboratory,
Argonne, Illinois 60439 USA

Abstract

At the Argonne Chemistry Division efforts are underway to develop a sub-picosecond electron beam pulse radiolysis facility for chemical studies. The target output of the accelerator is to generate electron pulses that can be adjusted from 3nC in .6ps to 100nC in 45ps. In conjunction with development of the accelerator a state-of-the-art ultrafast laser system is under construction that will drive the linac's photocathode *and* provide probe pulses that are tunable from the UV to IR spectral regions.

1 INTRODUCTION

From the start time-resolved investigations of fast chemical processes have been part of radiation chemical studies. Recent advances in accelerator technology are making it possible to generate subpicosecond electron pulses. Additionally, solid state laser development is making it more routine to generate subpicosecond optical pulses. A merging of these two technologies will provide an invaluable tool for probing ultrafast radiation induced processes. In this contribution the development of a state-of-the-art laser system that will be capable of both driving the photocathode of a subpicosecond linac and simultaneously and provide a widely tunable (UV to mid-IR) stroboscopic detection capability will be described

2 FEMTOSECOND LASER SYSTEM

2.1 Femtosecond Laser System

In order to generate subpicosecond electron pulses a state-of-the-art laser systems must be developed to drive the photocathode. The accelerator under consideration at Argonne National Laboratory requires the laser operate within very strict specifications[1]. The following key problems must be addressed:

- Development of an intense (>3mJ) 5ps UV laser pulse that is needed to drive the photocathode.
- A .1ps probe pulse must be derived from the same laser and be independently tunable from the UV to the IR.
- The UV pump and the probe laser pulses must be synchronized to the RF of the accelerator to within .5ps
- Development of novel, sensitive and specific detection techniques to make the fullest use of the potential information.

For the photocathode the laser must provide high energy UV (~260nm) pulses that can be varied in energy from .1mJ to 3mJ. The low UV pulse energy corresponds to operation of the accelerator in the low charge short pulse mode (i.e., 3nC, .6ps), while the high UV pulse energy corresponds to operation in the long pulse high charge mode (i.e., 45ps, 100nC) mode. In addition to variable UV pulse energy the UV pulsewidth must be made variable from 5ps to 60ps. Some of the laser pulsewidth and energy requirements are summarized in Table 1.

To make use of the full capabilities of the experimental system, the laser must also produce pulses with less than 0.1 ps duration with enough energy (~1mJ) to pump a series of widely tunable optical parametric amplifiers that will provide probing wavelengths from the UV to IR spectral regions. The laser is to operate from single shot to 60 Hz with a pulse-to-pulse jitter less than .5ps with respect to a 1.3 GHz master clock. *Minimization of the jitter is the is the most crucial and difficult aspect of the laser design.*

Table 1: Laser Energy and Pulsewidth Specifications

Linac Pulsewidth	Charge	Laser Pulsewidth	Laser Pulse Energy
.6ps	3nC	5ps	.1mJ
3.0ps	10nC	15ps	.3mJ
8.0ps	50nC	45ps	1.5mJ
45ps	100nC	60ps	3mJ

2.2 Generation of Intense UV Laser Pulses

A block diagram of the laser amplification scheme is shown on the following page. Briefly, a diode-pumped frequency-doubled Nd:YVO laser will be used to pump a femtosecond Ti:Sapphire (Ti:S) laser that will produce a

* Work performed under the auspices of the Office of Basic Energy Sciences, Division of Chemical Science, US-DOE under contract number W-31-109-ENG-38.

81.25MHz pulsetrain of 3nJ 50fs pulses centered at 800nm. The 50fs pulses will be passed through a grating pulse stretcher which will increase the pulsewidth to 500ps. This will reduce the peak power of the laser pulses enough to prevent optical damage in the following two stages of amplification (chirped pulse amplification). After the stretcher a polarizer-Pockels cell-polarizer combination will be used to select pulses out of the 81.25MHz pulse train at 60Hz (linac repetition rate).

The first preamplifier stage (AMP1) is a multipass (8 pass) Ti:S amplifier that will produce ~5mJ pulses at 800nm[2]. AMP1 is pumped with 50mJ pulses from a high power Nd:YAG laser (HP Nd:YAG). The output of AMP1 will be used to seed a power amplifier (AMP2) that will boost the energy up to >100mJ. AMP2 is also a multipass amplifier (4 pass) and will be pumped by 450mJ from a HP Nd:YAG laser.

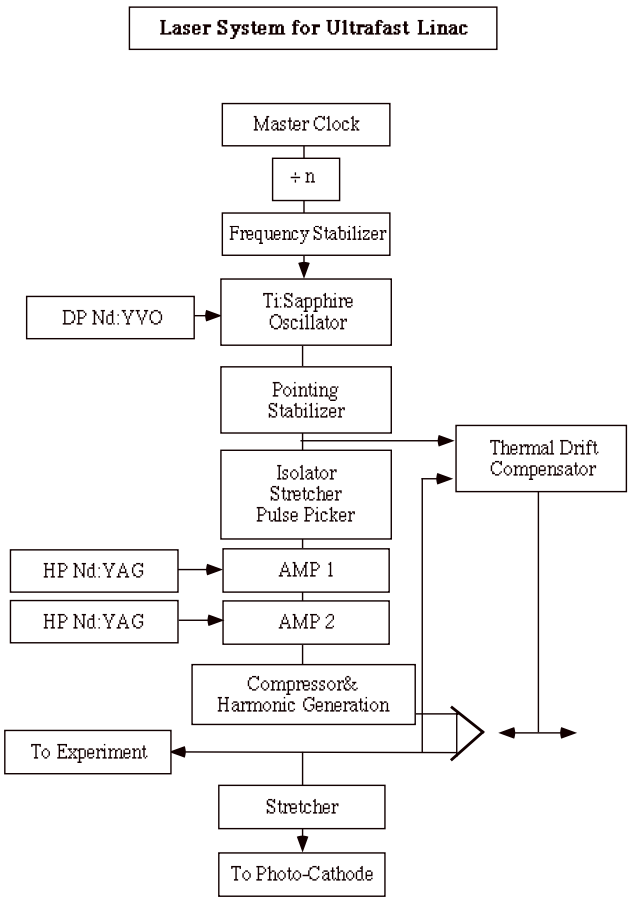

Fig. 1. Block diagram of the amplified femtosecond laser system. See text for details.

The amplifier output will be compressed in a standard grating pulse compressor to <.1ps and passed through a series of specially designed nonlinear crystals to generate the third harmonic at 260nm. The UV pulse energy is expected to exceed the required maximum of 3mJ. Dichroic mirrors will be used after the harmonic conversion step to divert the residual fundamental towards the optical parametric amplifiers while directing the third harmonic towards the linac cathode. Before illumination of the photocathode the UV will be temporally stretched by passing it through several centimeters of suprasil. The pathlength of the suprasil will be determined by the amount of UV pulse stretching that is required for the desired electron pulse charge and pulsewidth (see Table 1).

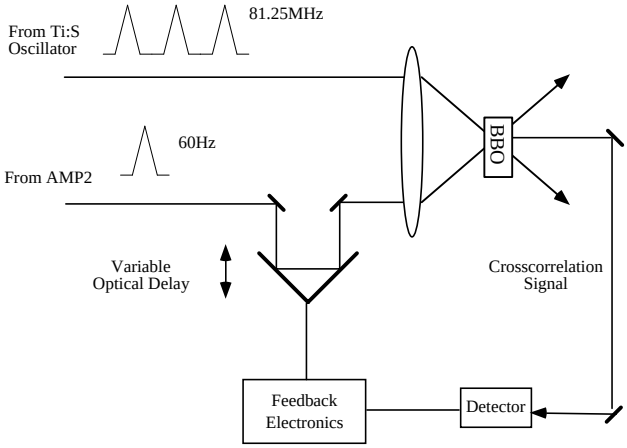

Fig. 2. Thermal drift compensation of the Ti:S amplifiers using the crosscorrelation technique. BBO (beta barium borate) is a nonlinear frequency mixing crystal. See text for details.

2.3 Minimization of Jitter

To generate .6ps electron pulses from a photocathode driven linac it is necessary to synchronize the phase of the RF that drives the photocathode and the UV laser pulses to within .5ps[1] of each other. The master clock for the RF will operate at a frequency of 1.3GHz. Expected sources for loss of synchronization will come from a variety of sources. Most importantly will be, drifting in the output frequency of the Ti:S oscillator, slow thermal drifting in the optical components, mechanical vibrations, and air currents.

The 16th subharmonic (81.25MHz) of the master clock will be used as a reference frequency for the Ti:S oscillator. Using commercially available electronics (Spectra Physics, Mountain View, CA) it is possible to reduce the jitter/synchronization out of the Ti:S oscillator to better than .1ps rms.

During the amplification process the synchronization will degrade due to the slow thermal drifting of the optical components and vibrations that result from mechanical and audio interference. To reduce effect of the slow thermal expansion and contraction of the optical components the pathlength that the laser pulse travels through the amplifier must be minimized. This dictated the choice to use a multipass amplifier design rather that a more efficient regenerative amplifier for AMP1. A multipass amplifier should reduce the path length by ~20m relative to a regenerative amplifier.

Compensation for slow thermal drifts will be actively achieved by passing the pulse out of the amplifiers through a stepper motor/piezo driven optical delay that will compensate for thermal drifts on a shot-to-shot basis (see Figure 2). The error signal for driving the optical delay will be derived from the crosscorrelation between the Ti:S oscillator and the output of AMP2 in a BBO crystal. This technique has been previously used to maintain subpicosecond synchronization between a Ti:S amplifier and an infrared optical parameteric amplifier[3]. Specially designed optical tables and evacuated beam tubes will minimize the sensitivity of the system to mechanical vibrations.

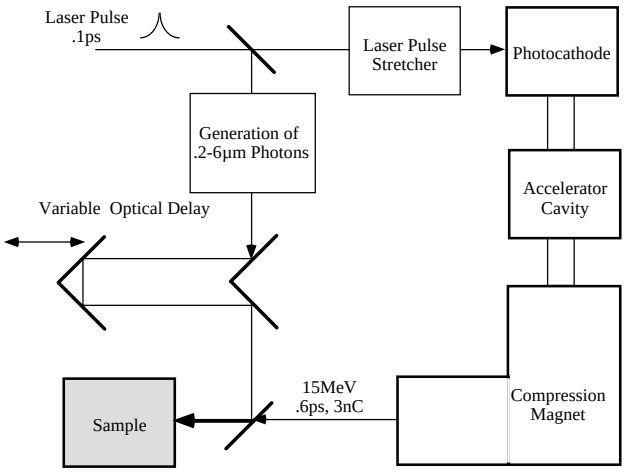

Fig. 3. Block diagram depicting a typical electron linac pump/laser probe experiment.

3 CONSEQUENCES OF LASER SYNCHRONIZATION

A significant advantage of this system is that the laser that "drives" the photocathode is inherently synchronized with the electron pulse, with very little jitter in the synchronization. This fact translates into considerable improvements in sensitivity and capabilities for detection schemes. Figure 3 shows a the setup for a typical pump/probe experiment in which the subpicosecond electron linac acts as pump source to initiate a radiological event that is subsequently probed by a laser pulse.

Detection schemes can now be based on laser produced interrogating light pulses as opposed to linac produced light pulses (Cerenkov radiation) that are presently used. Thus, the intensity and wavelength range will be available to develop new detection schemes for examination of transient species that are impossible to study at this time.

A new type of detection that will become available is transient infrared spectroscopy, which can be used to determine the role of excess thermal energy and vibrational energy transfer in radiation chemistry. In addition to providing a window through which to view the role of vibrational dynamics, the structural selectivity of infrared spectroscopy can be used to follow the progression of and identification of transient species. To this extent we have recently developed a unique optical parametric amplifier based on potassium niobate that is tunable throughout the chemically important 2.5-5.5 micron spectral region.

Other new types of detection under development include time resolved coherent spectroscopy (e.g., CARS, transient grating spectroscopy, photon echo spectroscopy), and time-resolved resonance Raman spectroscopy. Such techniques will provide new information on energy levels, lifetimes of transient species, collisional processes, coupling strengths, and diffusion processes.

4 SUMMARY

A femtosecond laser system for driving a subpicosecond photocathode electron linac has been described. The main design criteria center around the necessity to achieve .5ps synchronization between the high energy UV pulses and the phase of the RF that drives the photocathode. As a consequence of the synchronization between the linac and the laser a wide variety of sensitive detection schemes now become available for probing radiation induced chemical events on fast timescales.

Abstract

This preliminary feasibility study is based on the availability of the CERN LEP2 superconducting RF system after LEP de-commissioning. The option that is explored is to use this system as part of a high energy H⁻ linac injecting at 2 GeV into the CERN PS, with the aim of reliably providing at its output twice the presently foreseen transverse beam brightness at the ultimate intensity envisaged for LHC. This requires the linac to be pulsed at the PS repetition rate of 0.8 Hz with a mean beam current of 10 mA which is sufficient for filling the PS in 240 μs (i.e. about 100 turns) with the ultimate intensity foreseen for injection for the LHC.

The linac is composed of two RFQs with a chopping section, a room temperature DTL, a superconducting section with reduced beta cavities up to 1 GeV, and a section of LEP2 cavities up to 2 GeV. This study deals, in particular, with the problems inherent in H⁻ acceleration up to high energy and in the pulsed operation of SC cavities. Means for compensating microphonic vibrations in the SC cavities are considered, with the aim of reducing the final overall energy spread to the tight requirements for injection into a synchrotron. Other possible applications of such a machine are also briefly reviewed, that make use of its potential for working at a higher duty cycle than required for LHC alone.

1 INTRODUCTION

Most of the RF equipment of the CERN LEP-2 will be available after the year 2000. Among the possible re-uses of this valuable hardware [1-4] the realisation of a 2 GeV Linac injector for the PS is an attractive option with many benefits with respect to the present scheme for LHC injection [5].

As a result of the smaller emittance of the Linac beam and of the higher injection energy into the PS (at present 1.4 GeV), the LHC would profit from an increased brightness of the proton beam delivered by the PS injector complex. The peak beam intensity in the PS could be improved as well by filling the entire aperture. Beam losses would be reduced by the efficient charge exchange injection in the transverse planes, and by the chopped beam in the longitudinal phase plane. The injectors of the PS could be modernised and re-built with standardised equipment, with advantages in terms of reliability and maintenance.

Other potential applications of this facility at a higher duty cycle justify the use of SC cavities. They include: 1) neutron production with a spallation target, using the PS as an accumulator ring; 2) feeding a second generation ISOL facility for the production of radioactive ion beams; and 3) any physics application requiring intense secondary beams.

A small study group has concentrated on the main accelerator technology topics and on the most promising scenario. A first report indicating the feasibility of such a facility is being prepared [6].

2 PARAMETERS AND LAYOUT

The Superconducting Proton Linac, SPL, (Figure 1) is made of an H⁻ source, two RFQs with a chopper in between, a Drift Tube Linac up to 100 MeV and a superconducting section up to 2 GeV. The main design parameters are given in Tables 1 and 2.

Table 1: Linac Beam Parameters

Number of Particles / PS Pulse	1.5	10^{13}
Mean Linac Current during Pulse	10	mA
Pulse Length	250	μs
Repetition Rate	0.83	Hz
Filling Factor of Linac Buckets	½	
N. of Linac Bunches per PS Bucket	11	
SPL Micropulse (11 bunches)	59.6	ns
Chopping Factor	46	%
Mean Bunch Current (in an RF period, for a full bucket)	37	mA
Source Current	20	mA
Beam Duty Cycle (for PS filling)	0.021	%
Maximum Design Duty Cycle	5	%
Maximum Average Current	500	μA
Transverse Emittance, source exit, rms	0.2	μm
Transverse Emittance, PS input, rms	0.6	μm
Longitudinal Emittance (5 rms)	3	°MeV

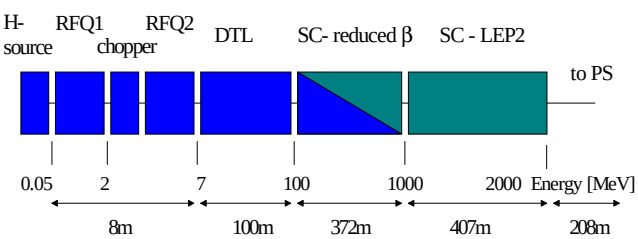

Figure 1: Schematic layout of the Linac.

Table 2: Linac structure parameters.

	W_{out} [MeV]	Freq. [MHz]	#of cav.	Power [MW]	# of klyst	Length [m]
RFQ1	2	176.1	1	0.45	-	2.3
RFQ2	7	352.2	1	0.5	1	4
DTL	100	352.2	29	5.8	6	99
SC - red. β	1027	352.2	152	13	19	372
SC - LEP2	2000	352.2	136	14.2	17	407
Line	2000	352.2	1	-	-	208
Total					43	1094

The facility is designed to provide 1.4 10^{13} particles at the exit of the PS, corresponding to the LHC beam-beam limit ("ultimate beam"). For a mean linac current of 10 mA, this number of particles can be obtained by injecting 110 turns into the PS, with a linac pulse length of ~250 μs. For the PS repetition period of 1.2 sec, the resulting linac beam duty cycle is only 0.021%. The injection energy into the PS, 2 GeV, has been chosen to use most of the existing LEP equipment, to improve transverse beam stability in the PS and to profit from the high accelerating efficiency of the LEP cavities at high energies.

The LEP RF frequency of 352.2 MHz is also used for most of the room temperature section. A significant number of klystrons with their power distribution systems can therefore be recovered, and a standard RF system can be used throughout the linac.

Due to the low duty cycle, the SC cavities need to be pulsed to minimise heat dissipation and wall plug power. The linac is foreseen for a beam duty cycle of 5%: up to this value the cryogenic system is dimensioned mainly to handle static losses and RF pulsing has no impact on the cryoplant. The main additional investment for this duty cycle comes from the shielding needed to cope with the higher activation due to losses in the linac.

The relative particle loss at 2 GeV and 5% duty must be smaller than 10^{-6}/m to allow hands-on maintenance; this is not a strong design constraint as a large fraction of the halo particles are transported through the large aperture of the SC cavities (>20 cm) and can be properly removed before PS injection.

An important design constraint is the high beam brightness needed by the LHC: this requires an emittance of 0.2 μm from the source because a factor 3 blow-up between the source and the PS has been conservatively assumed to account for space-charge, mismatch, and misalignment effects.

3 ROOM TEMPERATURE SECTION

The room temperature section is composed of a front-end (source, RFQs, chopper) injecting into a Drift Tube Linac (DTL). The 20 mA beam coming from the source is accelerated to 2 MeV by a 176.1 MHz RFQ. The beam is then chopped and injected, filling every other bucket, into an RFQ at double frequency (352.2 MHz), which brings the beam energy to 7 MeV. Matching to and from the chopper is performed by dedicated sections integrated in the first and second RFQ respectively.

A distance of 1.6 m is provided between the RFQs to house a wide-band electrostatic chopper of the BNL design [7] and some diagnostics. The chopper voltage required is 1.7 kV, and, to avoid partially filled buckets in the Linac, a 4.2 ns rise time is required: should it be too challenging, a chopper/antichopper line will be chosen.

The DTL has been divided in two sections. The first one (7-20 MeV) consists of one standard Alvarez tank, with FODO focusing. The second, up to 100 MeV, is of the separated-focusing DTL type, made of 28 8-cell tanks separated by 3 βλ drifts containing a quadrupole triplet. This structure offers higher shunt impedance and simpler mechanical construction than a standard DTL. Triplet focusing is preferred because of the resulting round beam inside the tank, which minimises the emittance growth due to RF defocusing. The transmission of the room temperature part is 99% (without taking into account stripping losses after the source) and the transverse emittance increase is 10%.

4 SUPERCONDUCTING SECTION

The superconducting part of the Linac consists of four different sections, with cavities optimised for beta 0.48, 0.6, 0.8 and 1. LEP-2 standard cavities (β=1) and cryostats are used between 1 and 2 GeV, while 5-cell cavities optimised for β=0.8 would be built and installed in the existing LEP-2 cryostats to cover the energy range between 450 MeV and 1 GeV [3]. Two additional sections of 4-cell cavities optimised for β=0.48 and β=0.625, arranged in shorter cryostats, cover the energy range between 100 MeV and 200 MeV, and between 200 and 450 MeV respectively. A development program is underway at CERN for the production of reduced-β (β=0.5 to 0.8) cavities with the niobium on copper technique [8]. In case the sputtering is not be feasible, the lowest beta cavities would be made of bulk niobium and the DTL energy increased up to 150 MeV. The layout of the superconducting part is given in Table 3.

Table 3: Layout of the superconducting section.

Sec.	Cryo stats	klyst rons	Cavi ties	cells / cav.	output energy [MeV]	length [m]	RF power [MW]
1	8	4	32	4	191	58	1.3
2	14	7	56	4	452	126	3.7
3	16	8	64	5	1027	188	8.0
4	34	17	136	4	2041	407	14.2
tot.	72	36	288			779	27.2

This layout makes use of 34 LEP2 4-cavity modules with their cryostats, i.e. 53% of the 68 installed in LEP. Including the cryostats used for the β=0.8 cavities, only 50 cryostats would be re-used, leaving some margin for reaching a higher linac energy if needed.

Due to the pulsed mode of operation, static cryogenic losses will dominate. Assuming a static loss of 180 W per 4-cavity module as in LEP [9], the 72 cryostats of the SPL would have an overall static loss of 13 kW, i.e. slightly more than the cooling capacity of a LEP-type cryoplant (12 kW).

The mean field used in this design is 6 MV/m although operation at a higher gradient should be possible in pulsed mode. The focusing for the superconducting section is provided by a doublet (two 400-mm long quadrupoles spaced by 100 mm) placed outside each cryostat. It has so far been optimised for zero current. For 40 mA the emittance increase is 45%, coming from the long focusing period at low (<1 GeV) energy and from mismatches between the different sections. A new layout for the low energy part and a more accurate matching should reduce the emittance blow-up.

5 ENERGY STABILITY

Mechanical vibrations in the SC cavities change their resonant frequency, leading to oscillations of the bunch in the longitudinal phase plane and finally to a pulse-to-pulse jitter in the mean bunch output energy. The effect of the vibrations can be greatly reduced by a self-excited loop and an RF feedback of the cavity voltage. For the SPL, a feedback scheme and calculation tools originally developed for the TESLA project [10] have been adapted for a proton beam. Since the correction is applied at the klystron input, the beam motion cannot be compensated completely when the klystron feeds several cavities as is the case in the SPL (8 cavities per klystron). In the simulations, the gains of the regulation loops are set to 100 and 500 respectively for the amplitude and for the phase. 20 % extra power is required for the amplitude loop and 20% for the phase loop.

The effect of the Lorentz detuning at 6 MV/m field is very small: the cavity phase can be cancelled by the feedback loops when the beam is injected, and the corresponding peak-to-peak energy error at 2 GeV is only 0.006 MeV.

The effect of mechanical vibrations has been studied assuming a pessimistic maximum cavity-to-cavity variation in resonant frequency of ± 40 Hz. The motions of the beam centre and the energy and phase errors at linac exit have been calculated for 500 uniform random distributions of frequency errors. The scatter in the position of the beam centre in the longitudinal plane at 2 GeV is shown in Figure 2.

Inside the single pulses, energy and phase are very stable (the period of the mechanical vibrations is much longer than the pulse length), while from pulse to pulse the rms energy variation is 0.3% (6 MeV). The energy jitter can be reduced to ± 3 MeV (total), by an energy-correcting cavity placed 200 m downstream, resulting in a good match to the PS bucket.

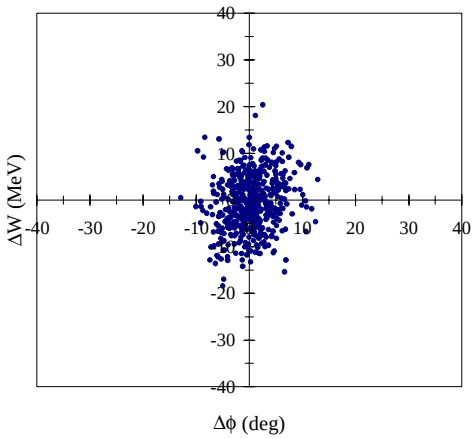

Figure 2: Relative position of the bunch centre in the longitudinal plane at 2 GeV for 500 random error distributions.

Abstract

The Heavy Ion Fusion Group at Lawrence Livermore National Laboratory has for several years been developing the world's first circular ion induction accelerator. This machine has recently been extended to 90 degrees, or 10 half-lattice periods(HLP) with full beam transport. In addition, induction cores have been installed on five of the HLP's, each with an independent arbitrary waveform pulser. An arbitrary waveform pulser for the bending electrostatic dipoles has also been enabled. Together, they have allowed the first attempts at coordinated bending and acceleration of the beam. The results of these first attempts will be reported on in the paper by examining the output of various diagnostic devices, such as the capacitive Beam Probes(C-probes), slit scanners, and the Gated Beam Imager(GBI).

1 INTRODUCTION

Currently, heavy ion beams are being pursued as a candidate for a driver of an Inertial Fusion(IFE) power plant. In such a power plant, ion beams would provide the input energy necessary to ignite small D-T capsules [1]. The accelerator for such a driver would need to accelerate space charge dominated ion beams to a total kinetic energy of a few GeV while providing pulse compression and be able to operate at a rate of ~5-Hz [2,3]. Usually the conceptual design of such a machine is linear, but an alternative concept, which may provide significant cost savings [4], is a circular machine, or recirculator. However, a space charge dominated, ion induction, circular machine has never been built before. Thus, the HIF Group at LLNL has been developing a small recirculator in order to investigate the validity of such a concept.

* This work has been performed under the auspices of the US DOE by LLNL under contract W-7505-ENG-48.
** Present Address: Stanford University, Palo Alto, CA 94305, USA

2 THE RECIRCULATOR

In order to validate the recirculator for an IFE power plant driver, coordinating bending and acceleration of the beam while maintaining transverse and longitudinal control beam brightness must be demonstrated [5]. Table 1 lists some important characteristics of the recirculator. In designing this machine, all of the important dimensionless beam parameters, such as perveance, were kept the same as a full scale driver machine. Each half lattice period(HLP) of the recirculator consists of a permanent magnetic quadrupole for focusing, an electrostatic dipole for bending the beam, and an induction core, or modulator, for acceleration and longitudinal compression. The dipole plates are designed to provide a 9 degree bend to the beam while the modulators are designed to provide 500-eV of acceleration.

Table 1: Recirculator Specifications

Circumference	14.4m	
Beam Species	K^+	
# of laps	15	
Max. Beam Radius	1.5 cm	
Beam Statistic	Lap 1	Lap 15
Beam Energy	80 keV	320 keV
Pulse Duration	4 μs	1 μs
Beam Current	2 mA	8 mA
Undepressed Phase Advance	78°	45°
Depressed Phase Advance	16°	12°

In the fall of 1997, the machine was extended from a 45 degree bend [6] to a 90 degree bend section. Figure 1 shows the current layout of the machine. Initially, a 4-μs beam pulse is injected by a source diode with an energy of 80-keV through a 1-cm diameter aperture which provides an initial beam current of 2-mA. Upon injection the beam enters an electrostatic matching section used to convert the uniformly expanding beam to an AG focused

beam. A short magnetic transport section follows which then leads to the 90 degree bend section. Following the bend section is the End Tank which houses several diagnostics (a Faraday cup, parallel slit scanner, and a gated beam imager) to measure beam quality. Also as part of the upgrade, magnetic induction cores were added to 5 of the 10 HLP's as shown.

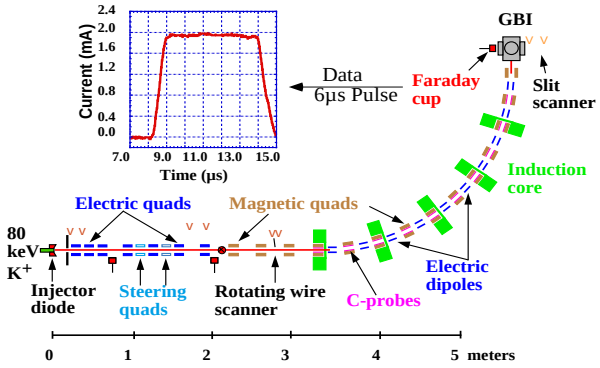

Figure 1: Current Recirculator Layout and Faraday cup data at 90 degrees.

The first attempts at beam transport through the 90 degree section were done with no acceleration and DC voltages (+/- 6.575-kV) on the bending dipole plates. Full current transport was achieved with less than 1% loss as measured by Faraday Cups. The RMS normalized emittance,

$$\varepsilon_{rms}^2 = 4\gamma\beta\left(\langle x^2\rangle\langle x'^2\rangle - \langle xx'\rangle^2\right)$$

for 90% of full beam current was also measured after 90 degrees. In the bend plane (x), the measured value is 0.045π-mm-mR while the out-of-plane (y) emittance is 0.068π-mm-mR. This compares to 0.021π-mm-mR measured directly after the source aperture. The growth seen is within the design specifications.

3 CAPACITIVE BEAM PROBES

In order to monitor the beam as it travels through the accelerator, a capacitive beam probe (C-probe), which measures the transverse beam position as a function of time, was also installed in each HLP as part of the upgrade. The C-probe [7] is a ceramic cylindrical shell whose inside is coated by copper. The copper coating is divided into four equal areas by divisions parallel to the cylinder axis. The C-probe is placed inside the beam pipe and as the beam passes through it, a charge is induced on each pad. The induced charge is a function of the charge centroid and the total current of the beam. Each signal is amplified and digitized through the computer control system and analyzed to obtain the charge centroid. Bench tests of the system, using a conducting rod to simulate the beam, have yielded a resolution of 70 μm [6].

Figures 2 and 3 show the x position and y position as a function of HLP number. HLP 0 corresponds to a C-probe in the straight section while HLP n refers to the C-probe immediately after the nth dipole plate. The different curves represent different applied voltages on the dipole plates. From the y position plot, the shot to shot repeatability of the measurement is clearly seen, while the x position shot demonstrates the sensitivity of the system to small perturbations. From tests characterizing the digitizing electronics, a systematic error of ~700-μm is estimated for each point. That systematic error should decrease upon adding some refinements to the algorithm that calculates the position.

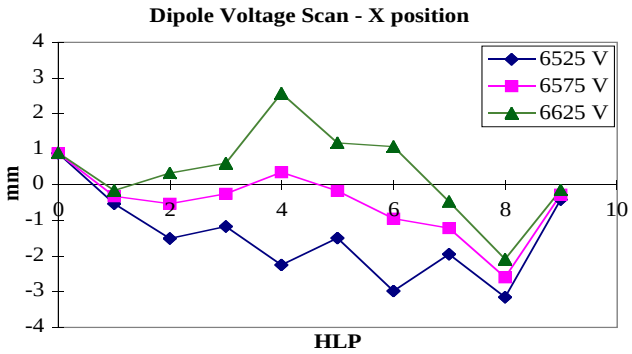

Figure 2: X positions as measured by C-probes for various dipole voltages.

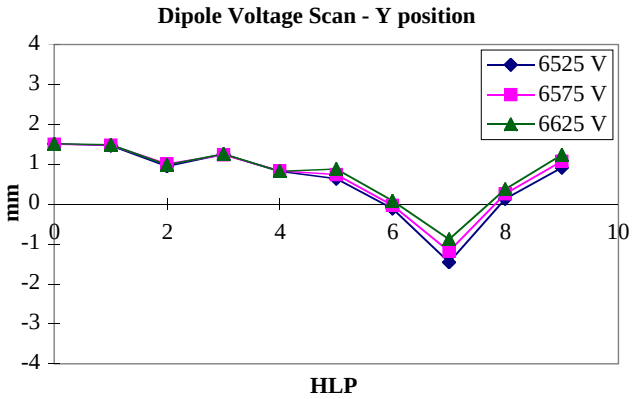

Figure 3: Y positions as measured by C-probes for various dipole voltages.

4 GATED BEAM IMAGER

In addition to beam position, the emittance growth of the beam as it travels through the bend section is of critical importance. In a full scale driver, the final beam pulse must be compressed to ~10 ns and a final spot size of a few mm. If the emittance is growth is too large, this final focus on the target will not be possible. Traditionally, a parallel slit scan has been used to measure the emittance of space charge dominated beams, but LLNL has developed a new device to measure the emittance, the Gated Beam Imager [8].

The GBI uses a pepperpot design in which the beam is incident on a hole with 100 μm diameter holes creating many beamlets. Each beamlet is emittance dominated and is allowed to drift to a micro channel plate(MCP). The MCP is coated with a thin layer of stainless steel, ~150

nm, which stops the ions and produces several few eV electrons per ion. After passing through the MCP, the electrons are proximity focused on to a phosphor screen. The light generated is focused and captured by a CCD camera that sits outside of vacuum. The image can then be analyzed to determine the emittance in both transverse directions. The MCP also allows time gating of the GBI to measure emittance as a function of time.

As of fall of 1997, the functionality of the GBI had been achieved, but there was still some slight discrepancy in direct comparisons between slit scanner data and GBI data [6]. After the analysis of the GBI images was changed to more closely mimic the slit scan, agreement between the two devices was achieved. At 90 degrees, the slit scan measurement yielded ε_x=0.045 and ε_y=0.068 π-mm-mR while the GBI yielded ε_x=0.043 and ε_y=0.065 π-mm-mR. Both of these comparison are well within the estimated 15% systematic error associated with each measurement.

5 ACCELERATION

In order for the acceleration of the beam to be controlled throughout the bend section, the voltage on the dipole plates need to be ramped up. For the full ring, the dipoles need to ramped from approximately 7-kV to 28-kV in ~240-μs. To meet this challenge, LBNL has developed a prototype dipole pulser [9]. This pulser delivers only the positive polarity, but the design can be used with only slight modifications to build a pulser for the negative polarity. Bench tests of the pulser system indicate that it delivers the necessary voltage ramp.

Currently, we are in the process of enabling the pulser on the 90 degree bend section. When connected the pulser provide voltages for the positive plates in HLP 6-10. The rest of the plates are operated with DC voltages. The initial test of the system has shown that is does not yet have the desired shot to shot repeatability at the low voltage level necessary on the initial lap. Figure 4 shows C-probe data from three successive pulses taken within a minute of each other. This clearly shows the variance from pulse to pulse. From the DC voltage data presented in figure 2, the pulse to pulse variance is less than 2%. Currently, we are exploring ways to modify the feedback loop of the pulser to obtain the necessary repeatability.

Presently the electronics for the modulator are just going through their initial implementation on the bend section. While the bench tests are very encouraging, there is no data to show at this time.

6 CONCLUSION

Lawrence Livermore National Laboratory is currently developing the world's first circular ion induction accelerator, the recirculator. This machine has been extended to 90 degrees with full current transport. The emittance growth in this bend section is well within the design requirements. The C-probe system has been enabled and has allowed for accurate beam position monitoring throughout the bend section and, the GBI has been fully reconciled with the more standard slit scanner. Initial test for the pulser to do the necessary ramping of the dipole voltage during acceleration have been performed. Currently we are performing the initial test of the electronics for the modulators. In the next month, we expect to make the first attempts at coordinating bending and acceleration.

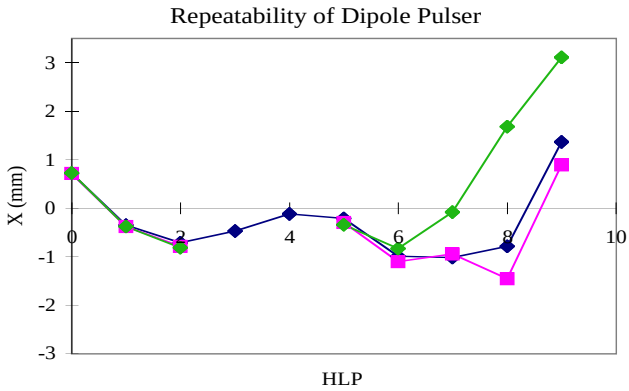

Figure 4: C-probe X positions for three consecutive pulses with dipole plates in HLP 6 through 10 connected to pulser.

Abstract

A linear accelerator for the new Munich high flux reactor FRM-II is under design [1,2]. This LINAC will be able to deliver intense beams of very neutron rich fission fragments from a target ion source located inside a through going reactor tube for the production of very heavy elements [3]. In order to obtain an efficient acceleration in the LINAC, charge breeding of the 1+ ion beam from the reactor to a q/A > 0.16 is required. The LINAC will work with 10% duty cycle with a final energy between 3.7 and 5.9 MeV/u. The LINAC of the Munich Accelerator for Fission Fragments (MAFF) will consist of an Radio Frequency Quadrupole (RFQ) accelerator, three interdigital H-type (IH) structures similar to the lead LINAC at CERN and two seven-gap IH-resonators for the adjustment of the final energy of the ions. In the present paper the concept, particle dynamics calculations and first cavity design calculations with MAFIA will be presented.

1 INTRODUCTION

Advanced radioactive nuclear beam facilities have a strong scientific case which is centered in three areas of basic science, namely Nuclear physics, Nuclear Astrophysics and the limits of the Standard Model. This physics and the application of neutron-rich fission fragment beams were discussed in [4]. With the ISOL (Isotope Separation On-line) technique intense high quality beams of radioactive ions can be supplied using very different reactions for the production: i) high energy protons, ii) fast neutrons and iii) thermal neutrons. The high neutron flux of a reactor and the high cross section of U^{235} for thermal fission (580b) allows to produce beam intensities comparable to those of stable beams which are used at GSI for the production of superheavy elements (SHE). The MAFF-Project at the new high flux reactor FRM-II at Garching will be the only facility world wide which uses this concept. A first realization of this concept was studied in the PIAFE project [5], which was stopped at 1. July 1998 for political reasons.

Compared to other radioactive beam accelerators under construction the MAFF project expects beam intensities (10^{11}/s) of fission fragments which are typically larger by a factor of 1000. Very intense neutron-rich ion beams accelerated to energies at the Coulomb barrier are of special interest for the production of very heavy elements. Fig.1 shows the calculated lifetimes for the elements Z=104 to Z=114 in dependence on the number of neutrons in the nuclei. The calculations are compared to measurements, which fit very well to the theoretical values.

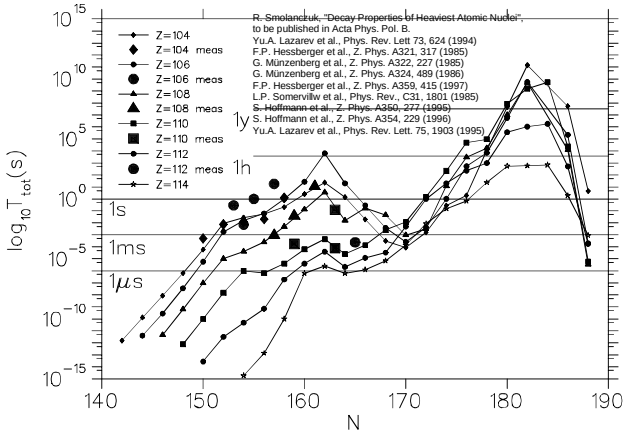

Figure 1: Calculated half-lifetimes for the elements Z=104 -114 in comparison to measurements [6].

In fig.1 is shown with very neutron rich isotopes as projectiles and implanted in a target very heavy elements with higher neutron numbers (165-180) can be produced, which lifetimes are extended to minutes and hours compared to the fusion products produced at GSI. The peak at lower neutron numbers (N=162) is derived from effects of magic shell closure.

2 ACCELERATION CONCEPT AND BEAM DYNAMICS

To achieve adequate final energies close to the Coulomb barrier several acceleration schemes have been proposed [2,7]. For MAFF the singly charged ions out of the reactor source will be injected into a high charge state ion source, presumably an electron cyclotron resonance ion source (ECRIS) and charge bred to an A/q < 6.3. The LINAC of MAFF is sketched in fig.2. The key parameters of the LINAC are shown in Table1.

2.1 The resonant structures

The LINAC consists on an RFQ which accelerates the ions from 2.5 keV/u to 300 keV/u which requires a rod

voltage of 59 kV for the present design which is similar to the REX-ISOLDE RFQ. First examination have been carried out [8] to use a quadrupole structure which is driven by an IH-resonator. Such an RFQ will be used for the high current injector at GSI. The booster LINAC consists of three IH-cavities where a jump in frequency is done at the second tank to reduce the length of the accelerator [2].

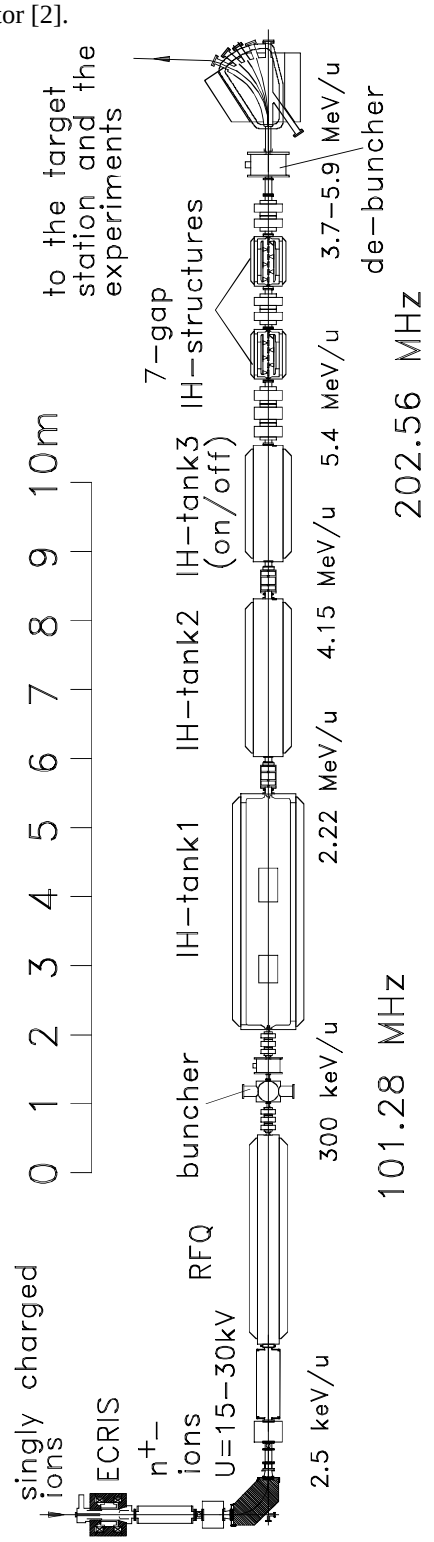

Figure 2: Lay-out of the MAFF LINAC.

Table 1: Key parameters of the MAFF LINAC

resonance frequency	101.28 / 202.56 MHz
injection energy	2.5 keV/u
final energy	3.7 - 5.9 MeV/u
A/q	< 6.3
max. duty cycle	10%
required energy spread at the target	<0.2 %
beam intensities	$4*10^{11}$ ions/s (^{91}Kr)
mass range (A)	75 -150
elements (Z)	Ni - Eu (28 - 63)

2.2 Variation of the final energy

The variation of the final energy over the large range of 2.2 MeV/u is done by using two 7-gap resonators and the tank 3 of the booster LINAC. So deceleration and acceleration is done at two different injection energies with the same 7-gap accelerators at 4.15 and 5.4 MeV/u. The 7-gap resonators of the MAFF-LINAC are IH-cavities in order to reach higher resonator voltages (2.1 MV) in comparison to the cavities used for REX-ISOLDE [9]. The 0°-synchronous particle structure is used in the beam dynamics, which means that the mean particle of the bunch will reach the center gap at 0° phase of the RF. The voltage of tank3 of the booster LINAC must be twice the effective voltage of the 7-gap resonators. In order to achieve the required low energy spread de-buncher is required after the second 7-gap cavity.

2.3 Beam dynamics

Beam dynamics calculations have been carried out to prove the possibility of the energy adjustment with only two 7-gap resonators.

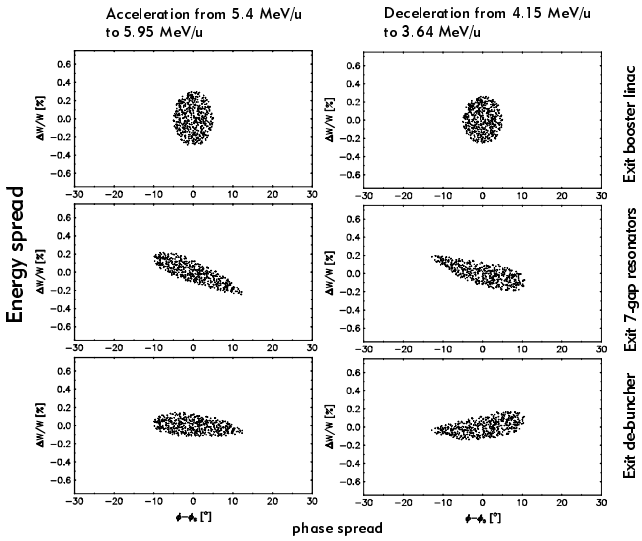

Figure 3: Development of the longitudinal phase space for the minimum and maximum energy of the MAFF LINAC

Fig. 3 shows calculations of the development of the longitudinal phase space of the beam from the exit of tank3 of the booster to the exit of the de-buncher. Table 2 summarizes the energies which can be achieved by deceleration and acceleration with both 7-gap cavities.

For the transverse emittances, the typical emittance of an ECRIS of about 0.6 π mm mrad (normalized) has been assumed. For the longitudinal phase space at the exit of the booster a phase spread of $\pm 5^{\circ}$ and an energy spread of +0.2% have been taken into account. From fig. 3 it can be seen that even in the worst case of maximum deceleration at lower starting energy the low energy spread at the exit can be provided.

Table 2: Achievable energies using the two 7-gap IH-resonators for deceleration and post acceleration.

E_{inj} [MeV/u]	E_{min} [MeV/u]	E_{max} [MeV/u]
4.15	3.64	4.77
5.4	4.78	5.94

3 CAVITY DESIGN AND MAFIA CALCULATIONS

The structures which will be examined first are the IH-RFQ and the 7-gap-IH-resonators. In order to get some cavity characteristics both resonator types have been examined by MAFIA calculations.

3.1 The IH-RFQ

The investigation of an IH-type RFQ at frequencies around 100 MHz is motivated by a higher shunt impedance compared to a 4-rod RFQ and that a direct rod cooling is not required due to a higher number of stems and herewith lower electrode currents. Fig.4 shows the 3m MAFIA model of the IH-RFQ. The parameters determined with MAFIA [8] are an R_p-value of 288 kΩm, a quality factor of 11657 at a frequency of 93.5 MHz, concerning a stem distance of 8 cm.

Figure 4: MAFIA model of the 3m IH-RFQ for the MAFF LINAC.

3.2 The 7-gap IH-resonator

The central issue of the MAFF-LINAC are the 7-gap IH-cavities. For the beam dynamics calculations a total resonator voltage of 2.1 MV have been assumed. For an incoupled power of 80 kW a shunt impedance of 110 MΩ/m is required to fulfill these requirements. Fig.5 shows the MAFIA model of one half of the 7-gap-IH-cavity. The cell length is 74 mm, the drift tube length 50 mm. The half shell radius is about 135 mm. The calculated quality factor is 15000, the shunt impedance about 300 MΩ/m. The calculated resonance frequency of the cavity was 225 MHz. Model measurements will done soon to prove the MAFIA calculations of the IH-RFQ and of the 7-gap cavity. Assuming the calculated values, the maximum resonator voltage of 2.1 MV can reached with low rf-power of about 50 kW.

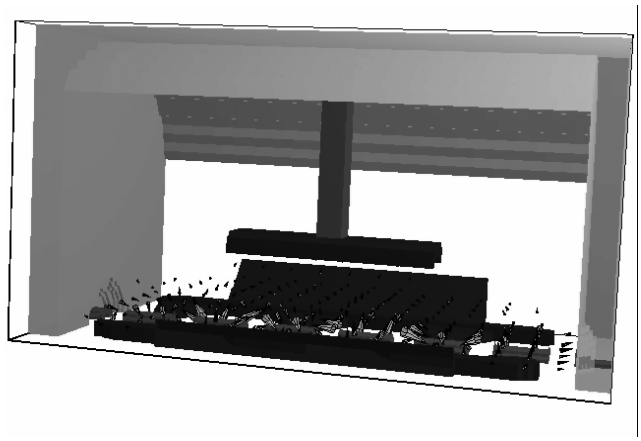

Figure 5: MAFIA model of one half of the 0.55m IH-7-gap resonator for the MAFF LINAC. Shown is the electric field of the TE_{111} mode.

Abstract

In a Radio Frequency Quadrupole (RFQ) linac, the electric field distribution is generated by four poles arranged symmetrically around a central z-axis. It's a customary practice to use a formulation based on cylindrical harmonics. That leads to inaccurate description of the fields near the boundary walls. Here, we present an analysis of errors based on an alternate numerical method to map the field correctly in the entire space between the vanes. This is especially important for high currents when the beam tends to fill nearly all available cavity-space [1]. The difference in the field-description and its effect on beam dynamics in a typical RFQ end cell will be presented. Two ways for calculating harmonic coefficients, the harmonic analysis and the fit to the cell geometry, are described.

1 INTRODUCTION

Radio Frequency Quadrupole (RFQ) linacs are widely used in the accelerator community. They have the remarkable capability of simultaneously bunching low-energy ion beams and accelerating them up to the MeV range. Several types of vane-tip geometries have been considered, and it is important to know the electric fields produced by these various geometries. In R.F.Q. linacs, the impedance in the beam zone is such that the electrodes can be considered as isopotential surfaces, and the vector potential can be ignored. Solving the Laplace equation in cylindrical coordinates, the electric potential seems to be able to be represented by the expansion:

$$U(r,\theta,z) = \frac{V}{2}\left(\sum_{p} A_{0(2p+1)} r^{2(2p+1)} \cos[2(2p+1)\theta] + \sum_{m,n} A_{nm} I_{2n}(mkr)\cos(2n\theta)\cos(mkz)\right)$$

The first eight terms give satisfactory accuracy [2]. Different methods are found in literature for calculating the coefficients of the expansion. The most common ones are the projection on the base [3] and the fit to the cell geometry [4,5]. This paper is a discussion on the accuracy that can be achieved with these two different methods.

2 CALCULATION OF THE ELECTRIC POTENTIAL IN A RFQ CELL BY TOSCA

We have first simulated the electric potential in a RFQ cell with the code TOSCA[1] (Figure 1).

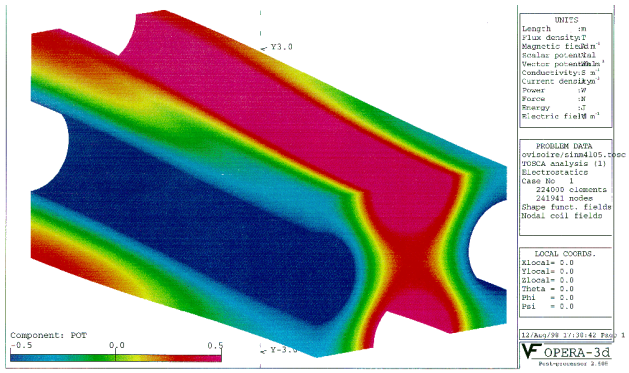

Figure 1: Electric potential in a RFQ cell.

This simulation will be the reference for validation and calculation in following stages. A typical RFQ end cell is chosen. The characteristics of the cell are:

- ρ = 0.89 (transverse radius of curvature)
- L_c = 11 (cell length)
- m = 2 (modulation factor)
- Sinusoidal profile in longitudinal direction

All distances are in R_0 units. The mesh of this simulation has been optimized for calculation of the peak surface electric field [6].

3 CALCULATION OF THE COEFFICIENTS BY PROJECTION ON THE BASE

To use the properties of harmonic analysis, we need to consider a limited space in which the boundaries satisfy the homogeneous conditions [7]. In cylindrical co-ordinates, the volume is a cylinder. The maximum value for the radius of this cylinder is "a", the minimum

[1] Vector Fields code for electromagnetic design

aperture radius. The coefficients can then be determined by the projection of the solution calculated by TOSCA on the lateral surface of this cylinder:

$$A_{0m} = \frac{16}{\pi V a^{2m} L_c} \int_0^{\frac{\pi}{2}} \int_0^{L_c} U(a,\theta,z).\cos(2m\theta).d\theta.dz$$

$$A_{n0} = \frac{8}{\pi V I_0(nka) L_c} \int_0^{\frac{\pi}{2}} \int_0^{L_c} U(a,\theta,z).\cos(nkz).d\theta.dz$$

$$A_{nm} = \frac{16}{\pi V I_{2m}(nka) L_c} \int_0^{\frac{\pi}{2}} \int_0^{L_c} U(a,\theta,z).\cos(2m\theta).\cos(nkz).d\theta.dz$$

Due to symmetry, only one quarter of a RFQ structure is necessary for the calculations. The results for the eight first order terms are shown in Table 1.

Table 1

A_{01}	A_{03}	A_{10}	A_{12}
0.9267	0.0012	0.6006	307.6125
A_{21}	A_{23}	A_{30}	A_{32}
-0.8337	-30753.6794	-0.0109	-7.0949

The difference between the real potential and the values obtained from the expansion derived coefficients is shown in Figure 2.

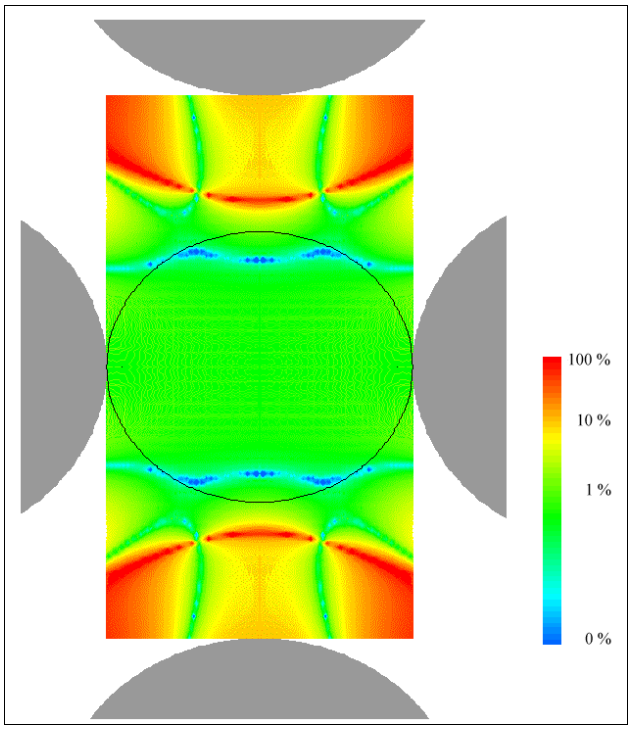

Figure 2: Difference between the real potential and the eight term potential. The accuracy is poor outside the cylinder used for calculations (black circle). A logarithmic scale is used.

It is apparent that the solution can't be extrapolated outside the volume used for integration. However, the accuracy is quite satisfactory with in the cylinder as is shown in Figure 3.

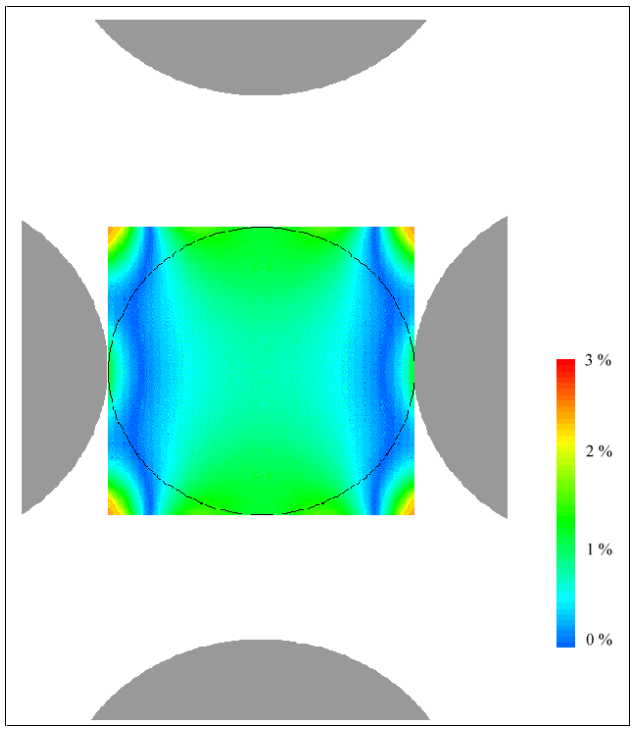

Figure 3: Same as in Figure 2 with a close-up view around the beam axis. A linear scale is used.

4 CALCULATION OF THE COEFFICIENTS BY FIT TO THE CELL GEOMETRY

The coefficients are calculated by the least-squares fit [8] using the isopotential surfaces defined by the conductors. This method is faster than the previous one for calculation of the expansion's coefficients. Table 2 contains the results of the fit obtained using the code MATHEMATICA[2].

Table 2

A_{01}	A_{03}	A_{10}	A_{12}
0.9587	0.0211	0.6064	3489.55
A_{21}	A_{23}	A_{30}	A_{32}
-0.5960	3493.32	-0.0093	-4.1060

The difference between the real potential and that obtained form the expansion using fit is shown in Figure 4.

[2] Environment for technical and mathematical computing.

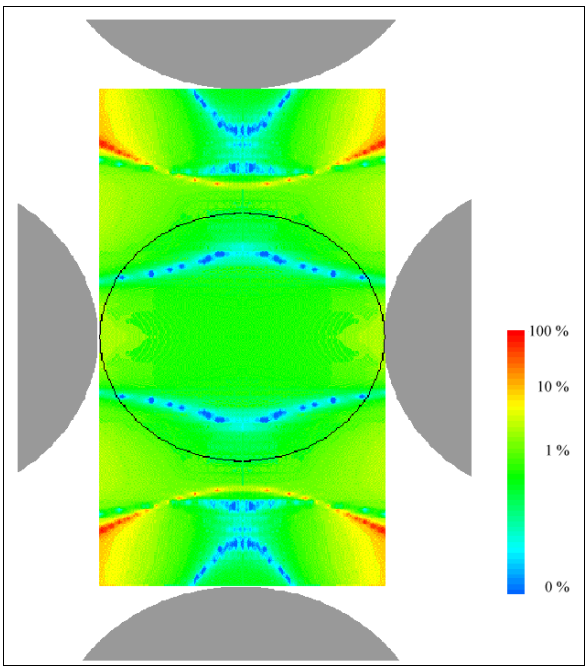

Figure 4: Difference between the real potential and the eight term potential with fit coefficients. A logarithmic scale is used.

The accuracy is better outside the cylinder used for projections (black circle). However, the deviation is about a few percent everywhere, which exceeds the tolerance for linacs (≈1% of maximum error).

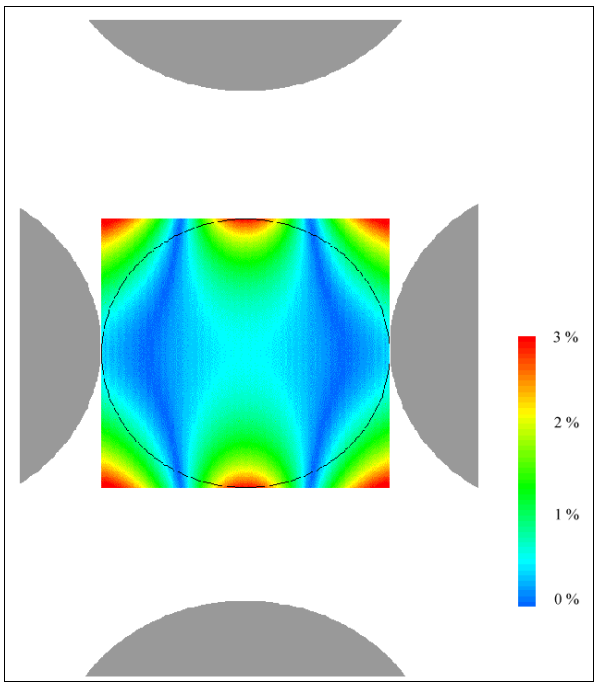

Figure 5: The same as in Figure 3 with a close-up view around the beam axis. A linear scale is used.

5 CONSEQUENCE ON BEAM DYNAMICS

In order to assess the influence of the difference induced by these two methods, beam dynamics simulation were done with particles that lay outside the cylinder of reference. 1035 particles of 1 MeV are uniformly distributed in a square with coordinates ($x = 0$, a; $y = a$, $m \times a$; $z = 0$) without any energy spread and zero transverse speed component for the injection. The transport is realized without any space charge and image effects. The intervane voltage is equal to 97 kV. The transmissions for three cases are summarized in Table 3.

Table 3

Real Fields	Projection	Fit
16.04 %	40.97 %	49.37 %

6 CONCLUSION

The projection on a cylindrical harmonic base gives the best accuracy of field around the beam axis. The fit to cell geometry by least-squares method doesn't give accuracy better than a few percent. However, regardless of the method used, cylindrical harmonics don't allow simulation with some accuracy in all region of the beam [2]. An alternative is to simulate the fields numerically. This is time consuming and needs a lot of memory to store the mesh for several cells. A good compromise would be to use 8 terms obtained by projection around the z-axis and a numerical mapping for the halo. A reduced mesh size is necessary in such case.

WAKE FIELD EFFECTS IN APT LINAC*

Sergey S. Kurennoy
LANSCE-1, Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Abstract

The 1.7-GeV 100-mA CW proton linac is now under design for the Accelerator Production of Tritium (APT) Project [1]. The high current leads to stringent restrictions on allowable beam losses (< 1 nA/m), that requires analyzing carefully all possible loss sources. While wake-field effects are usually considered negligible in proton linacs, we study these effects for the APT to exclude potential problems at such a high current. Loss factors and resonance frequency spectra of various discontinuities of the vacuum chamber are investigated, both analytically and using 2-D and 3-D simulation codes with a single bunch as well as with many bunches. Here we concentrate on two features specific to the APT linac: loss factors for the design $\beta < 1$ and CW beam structure.

1 INTRODUCTION

A wake-field analysis for a high-intensity accelerator includes wake computations, followed by calculations of loss factors and heating due to various elements of the vacuum chamber. The wake fields are typically computed with time-domain codes like ABCI [2] or MAFIA [3]. However, these codes are only applicable for ultrarelativistic bunches with $\beta = v/c = 1$. Two specific features of proton (or H^-) high-intensity linacs are essential for the wake-field analysis: first, β is significantly less than 1 for the most part of the machine, and second, the beam is either CW (in APT) or consists of macropulses containing many regularly spaced bunches (spallation neutron sources). Usual $\beta = 1$ estimates, while useful, can be quite different from those for the design β values, e.g., [4]. In particular, the resonance impedances and corresponding loss factors can strongly depend on β. Frequency-domain calculations can provide an answer for a given $\beta < 1$, but they require information on individual modes, and are typically limited to just a few lowest ones. In Sect. 2, we consider β-dependence of the loss factors for lowest modes in the APT 5-cell superconducting (SC) cavities.

Due to the CW beam structure, the beam frequency spectrum is concentrated only near the multiples of the bunch repetition frequency f_b. While the spectrum envelope is still defined by the bunch shape, it rolls off at frequencies many times higher than f_b, due to a very short bunch length. Therefore, an important question is whether any higher-order mode (HOM) has its frequency close to a multiple of f_b. The presence of such modes, especially at relatively low frequencies, can lead to undesired coherent effects. One can use time-domain computations with multiple bunches to answer this question. The idea is to apply a time-domain code with a few identical bunches at $\beta = 1$, but to set the bunch spacing s to $s = c/f_b$ for having the correct bunch repetition frequency. Since the resonance frequencies are essentially independent of β, so is a conclusion from such simulations. In Sect. 3 we compute the wakes in the APT 5-cell SC cavities varying the number of bunches in the bunch train, and look for coherent wake-field effects.

* Work supported by the US Department of Energy

2 LOSS FACTORS VERSUS β

For a Gaussian bunch of rms length $2l$, the loss factor k_s for the s-th cavity mode having the frequency ω_s depends on β as (see [4] for more details)

$$\frac{k_s(\beta,l)}{k_s(1,l)} = \exp\left[-\left(\frac{\omega_s l}{c\beta\gamma}\right)^2\right]\frac{|I_s(\beta,\omega_s)|^2}{|I_s(1,\omega_s)|^2}\,. \qquad (1)$$

Here $I_s(\beta,\omega) = \int_L dz\exp(-i\omega z/\beta c)E_{sz}(0,z)$ is the overlap integral, $\gamma = 1/\sqrt{1-\beta^2}$, and $E_{sz}(0,z)$ is the mode longitudinal electric field on the chamber axis.

For 5-cell APT SC cavities the lowest resonances are split into 5 modes which differ by phase advance per cell $\Delta\Phi$, and their frequencies are a few percent apart [5], see Table 1. MAFIA-computed on-axis fields of these modes [5] are used to calculate numerically overlap integrals in Eq. (1) and to find the loss factors for a given β. The results for the lowest monopole modes are presented in Table 1. We are mostly concerned about only these two resonance bands, since the higher modes are above the cutoff and can propagate out of the cavity depositing most of their energy in the beam pipes. Our results for the design values of β are in agreement with those obtained in [5]. Remarkably, the total loss factors for a given resonance band in Table 1 are lower for the design β than at $\beta = 1$, which is not always the case, see [4] for detail. The only exception here is the TM_{020} band for the $\beta = 0.82$ cavity, but it includes some propagating modes, and its contribution is very small.

Time-domain simulations with ABCI [2] give us the loss factor of a bunch at $\beta = 1$. The loss factor spectrum for the $\beta = 0.64$ cavity, integrated up to a given frequency, has two sharp steps, 0.5 V/pC near 700 MHz, and about 0.1 V/pC near 1400 MHz. They correspond to the two bands of the trapped monopole modes in the cavity, cf. Table 1. The totals for the TM_{010} and TM_{020} bands for $\beta = 1$ in Table 1 agree very well with the time-domain results.

The β-dependence of the loss factor for two TM_{010} modes — 0-mode and fundamental, π-mode — is shown in Fig. 1. Obviously, the shunt impedance (and the loss factor) dependence on β is strongly influenced by the mode field pattern.

3 MULTIPLE-BUNCH EFFECTS

Wake potentials of a train of a few identical Gaussian bunches passing through 5-cell APT SC cavities have been computed with the code ABCI [2]. Cavity parameters are given in [6], the bunch rms length was chosen to be 4.5 mm in the β=0.82 section of the linac, and 3.5 mm for β=0.64. While these bunches have β=1, their separation is set to s=0.85657 m, which gives the proper bunch repetition frequency f_b=350 MHz.

We study the loss factors for the 5-cell APT SC cavities as a function of the number of bunches N_b in the bunch train. The loss factor per bunch is expected to tend to a constant for incoherent wakes, but it should increase linearly when wakes are coherent. The coherent effects would occur if higher-mode resonances are close to multiples of f_b. The results for the transverse loss factor k_{tr} per bunch are shown in Fig. 2, both for β=0.64 and β=0.82 cavities. As one can see, k_{tr} reaches its asymptotic already for N_b between 5 and 10 in the case of β=0.82. This asymptotic value is, in fact, lower than k_{tr} for a single bunch. For β=0.64, however, we observe an almost linear growth up to N_b about 20, and only after that the transverse loss factor per bunch saturates. Therefore, in the β=0.64 cavity higher-order dipole resonances are closer to multiples of f_b than those for β=0.82. For comparison, the longitudinal loss factor per bunch for both cavities increases linearly as N_b increases. This is, of course, due to the fundamental accelerating mode of the cavity at 700 MHz. The maximal values of the transverse wake potentials also saturate as N_b increases, unlike the longitudinal ones, see [7].

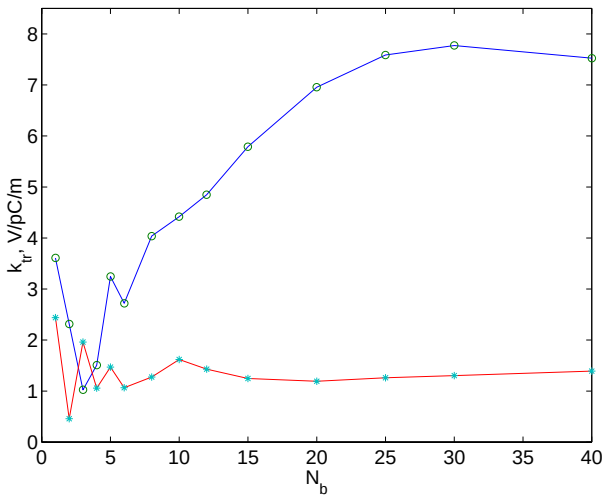

Figure 2: Transverse loss factor per bunch for 5-cell APT SC cavities versus the number of bunches: circles for $\beta = 0.64$, stars for $\beta = 0.82$.

As the number of bunches in the train increases, its frequency spectrum is getting more and more concentrated near the multiples of the bunch repetition frequency. Stronger peaks in the wake power spectrum for a relatively long bunch train indicate the frequency regions where the cavity resonances are close to multiples of f_b=350 MHz. To identify such frequency ranges we plot in Fig. 3 the power spectra of the wake potentials produced by a 30-bunch train in the cavities. The wake potentials have been calculated for 30 m after the leading bunch; they include about 60,000 points, and their Fourier transforms have been performed with $N = 2^{16} = 64K$. One can see a regular

structure of peaks at multiples of f_b, as well as a peak near 950 MHz, which corresponds to the band of the TM110 dipole mode [5]. Comparison of the wake power spectra for different N_b shows that the magnitude of this last peak decreases quickly as one goes to longer and longer bunch trains, since there is a smaller and smaller excitation at this frequency. Comparing relative peak heights in the frequency spectra shows where higher-order modes are close to multiples of the bunch frequency. Obviously, it is the strong peak near 1750 MHz — the multiple of the bunch frequency — that produces a coherent increase of the dipole loss factor in the APT SC β=0.64 5-cell cavity. Fortunately, its resonance frequency is close to the cutoff frequency of the pipe, which means this resonance can be effectively damped by HOM power couplers. Nevertheless, a more detailed analysis of this frequency range with frequency-domain codes is required to identify the corresponding eigenmode(s), and take its (their) properties into account in designing HOM couplers.

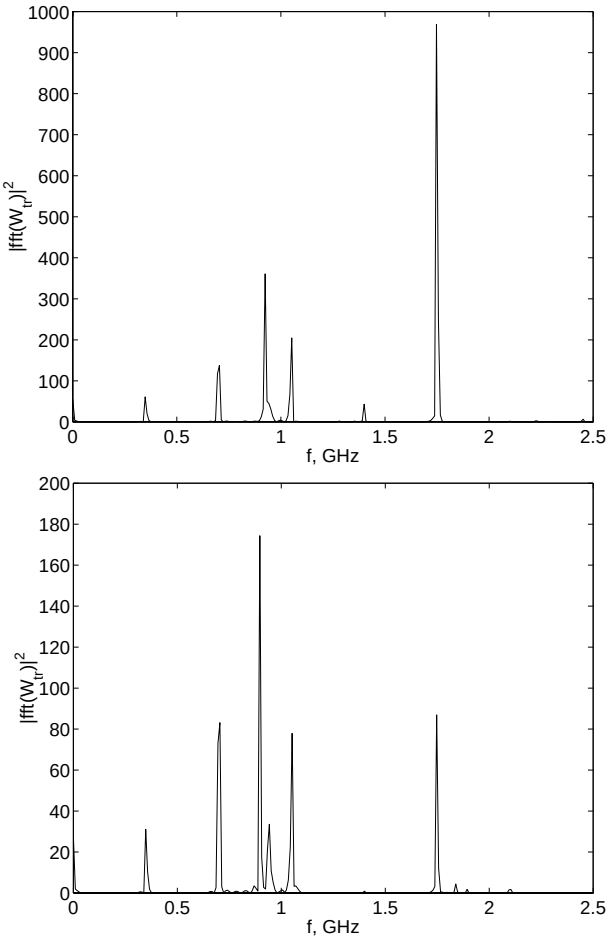

Figure 3: Power spectra of the transverse wake potentials for 30 bunches in the APT 5-cell cavities: $\beta = 0.64$ (top) and $\beta = 0.82$ (bottom).

Clearly, the potentially dangerous regions for the 5-cell β=0.64 APT SC cavities with respect to the dipole modes are around 1750 MHz and 1050 MHz, and for 5-cell β=0.82 cavities they are around 1750, 700, and 1050 MHz (but all those contributions are relatively weak). Also, some additional attention is probably required to the transverse modes near 950 MHz for β=0.64 and in the range 900–950 MHz for the β=0.82 cavities. While these frequencies are not close to a multiple of f_b, the corresponding dipole resonances are strong enough that their effects are observed even for rather long bunch trains.

A similar analysis has been performed for the longitudinal wakes, see [7] for detail. The power spectra of the monopole wakes are dominated by the fundamental mode at 700 MHz, but in a log plot one can see higher-mode peaks. There is one near 2100 MHz for β=0.64 cavities (since 2100 MHz is above the beam-pipe cutoff, one should expect a trapped monopole mode near this frequency), and two, near 1750 and 1050 MHz, for the β=0.82 case.

4 CONCLUSIONS

A simple approach to study HOM effects in cavities for CW or long-pulse non-ultrarelativistic ($\beta < 1$) beams is developed. Time-domain simulations with standard codes are applied to the bunch trains moving with β=1, but having a correct bunch repetition frequency f_b. As the number of bunches N_b increases, the details of the beam frequency spectrum, dependent both on β and N_b, become unessential since the cavity is excited mostly at multiples of f_b. This allows us to find potentially dangerous frequency ranges where HOM frequencies are close to multiples of f_b.

A further analysis with frequency-domain codes should be used to identify the modes in these frequency ranges. Computed fields of these HOMs are used then to calculate their loss factors for the design value of β and to take their properties into account in designing HOM couplers, if required.

Our main conclusion for the APT linac is that the only noticeable wake-field effect is the HOM heating of the 5-cell SC cavities. It has, however, an acceptable level and, in addition, will be taken care of by HOM couplers.

DESIGN STUDIES OF THE DARHT PHASE II INJECTOR WITH THE GYMNOS PIC CODE*

W.M. Fawley, E. Henestroza

Abstract

We have used the GYMNOS 2D (r-z) electro-/magnetostatic PIC simulation code to help design a high current, high brightness, 3.2-MV injector for the DARHT Phase II accelerator. GYMNOS is particularly noteworthy for its use of piece-wise linear approximations to curved boundaries within a regular orthogonal mesh, which aids in modeling complex surfaces. We present a number of comparisons between GYMNOS and EGUN results, both in terms of "coarse" parameters such as emitted current and beam envelope dynamics, and "fine" details such as the transverse phase space distribution.

1 INTRODUCTION

The DARHT Phase II accelerator is a 20-MV, 4-kA, induction linac to be built at LANL with a nominal pulse length of $2-\mu$s. This pulse will subsequently get chopped into four short duration ($\Delta\tau \sim 60$ ns) pulses which will then be focused onto a metallic converter for radiographic imaging purposes; a more detailed summary is available in Ref. [1]. Among the various challenging physics aspects of the injector and accelerator design is the need to produce a very low transverse emittance over the full temporal pulse width. At present, our goals for ε_n(edge) are $\leq 500\pi$ mm-mrad for the injector and $\leq 1200\pi$ mm-mrad at the x-ray converter approximately 20-m downstream of the accelerator. Success in this area for the injector requires, among other things, a very "quiet" and highly uniform emission surface, very careful design of the electrode geometry to minimize nonlinear electrostatic fields and to prevent unwanted electrical breakdown, and appropriate longitudinal shaping of the solenoidal magnetic field in the A-K gap and beyond to prevent radial oscillations of the beam from converting space charge energy into transverse emittance.

This paper presents the current status of LBNL/LLNL PIC simulations of the DARHT II injector with the time-dependent, azimuthally symmetric GYMNOS code[2] and compares its results with those obtained with the EGUN ray-tracing code[3]. GYMNOS is a fully relativistic, 2-1/2 D, electro- and magnetostatic code which uses an iterative ADI approach to solve the necessary elliptic field equations. Both electric and magnetic collective fields are determined, including the diamagnetic A_θ induced by beam rotation in external solenoidal focusing fields. GYMNOS employs the "Embedded Curved Boundary" (ECB) method[4] for representing curved boundaries via a piecewise linear approximation on a uniformly-spaced Cartesian mesh. The ECB method is far more detailed than simple staircase approximations to curved surfaces while remaining more computationally efficient than most adaptive mesh techniques.

We first discuss the overall injector geometry and compare the the steady-state GYMNOS and EGUN beam envelope results. We then examine details of the emission near the cathode/Pierce shroud boundary where apparent limitations of the simulation grid resolution and/or present ECB formulation results in difficulties when modeling extremely low emittance beams.

2 INJECTOR GEOMETRY AND FULL VOLTAGE CURRENT FLOW

In order to minimize the possibility of electrical breakdown in the 30-cm A-K gap, the present injector design uses a relatively large (10-cm radius), heated dispenser cathode surrounded by a Pierce shroud extending radially outwards to 40 cm. "Velvet" cathodes, while more robust in terms of insensitivity to vacuum contamination, are believed to produce too transversely warm and possibly insufficiently uniform emission to satisfy the high brightness requirements. The anode surface facing the cathode has a radius of curvature of 8 cm and 16 cm for r less than and greater than 20 cm, respectively. At a 3.2 MV potential drop, the peak electric field is approximately 162 kV/cm on the shroud and 189 kV/cm on the anode. The anode entrance opening radius asymptotes to 12.5 cm. Within the anode is a solenoid magnet, typically run at a current sufficient to produce a peak field of about 500 G to keep the beam well-confined radially as it drifts from the anode into the first accelerator cell magnets. Equidistant behind the cathode is an identical bucking solenoid to zero out any B_z field at the emission surface.

Given this configuration, the EGUN code predicts a steady-state beam current of 4.1 kA for a nominal injector voltage of 3.2 MV. The beam envelope radius smoothly shrinks down to approximately 7 cm as it passes into the anode opening and remains at that radius until it enters the first accelerator cell another 40 cm downstream. In these runs the beam rays were emitted at the 5 kV potential con-

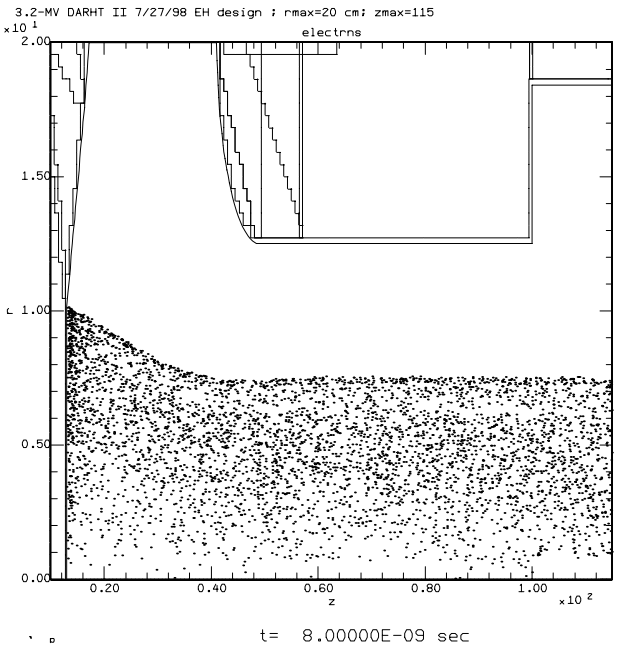

Figure 1: $r - z$ particle scatter plot from a GYMNOS simulation of the DARHT II injector

tour, approximately 4 mm downstream of the cathode surface, and very fine ($\Delta r = \Delta z = 1$ mm) gridding was used. More information on the design and EGUN results are available in Ref. [5].

GYMNOS runs with the same injector parameters show similar but not identical results. Since GYMNOS is a "normal" time-dependent PIC code, it is necessary to gradually ramp up the electrode voltages to minimize "shock" excitation of beam and electric field oscillations. We found that a 2-ns voltage risetime gave a smooth increase of emitted beam current and minimal radial bounces and/or particle reflection from virtual cathodes. The beam envelope evolution with z is quite similar to that predicted by EGUN. Figure 1 displays an r-z scatter plot of a GYMNOS simulation at $t = 8$ ns. Of the actual 100,000+ macroparticles in the simulation volume at this time, only ~10% are shown. For the simulation volume of 120 cm in z and 20 m in r, we used 126 and 45 grid points in z and r, respectively, leading to $\Delta r = 0.45$ cm and $\Delta z = 0.7$ cm.

Despite the good agreement in the beam envelope dynamics, there is a surprising disagreement in the magnitude of the emitted current with GYMNOS results being consistently $\sim 10 - 15\%$ higher. Some numerical tests have shown that while this discrepancy is insensitive to the grid cell size, there is an apparent sensitivity of I_{emit} to details of the macroparticle "birth" algorithm for space-charge limited flow. In each timestep GYMNOS places newly born particles within a "sheath" approximately one longitudinal grid cell wide downsteam of the emitting surface. As the sheath width is decreased by up to a factor of four, the total emitted current can change by some tens of percent. Since other tests at non-relativistic energies and previous GYMNOS modeling of ion injectors[2] showed

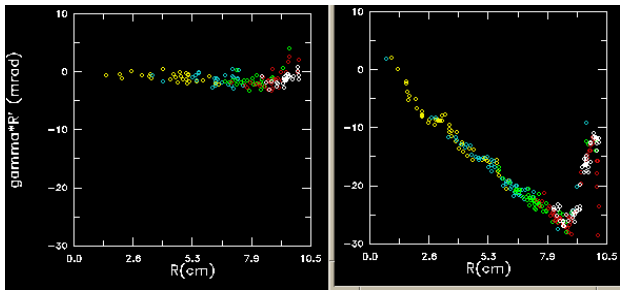

Figure 2: $r - \gamma r'$ snapshots at $z = 13.05$ and $z = 13.65$ cm for the same simulation shown in Fig. 1; the cathode surface is at $z = 13.0$ cm. Each plot includes particles within 0.05 cm of the nominal z position. The ordinate ranges from -30 to 10 mrad, the abscissa from 0 to 10.5 cm.

good agreement between Child's Law and the emitted current, we suspect that the emission algorithm need improvements for accurate resolution of the current sheath density and velocity profile for the relativistic injector energies relevant to DARHT.

3 PHASE SPACE EVOLUTION AND MODELING DIFFICULTIES NEAR THE CATHODE/SHROUD BOUNDARY

Given the high brightness wanted from the DARHT II injector, a great deal of effort has been spent on optimizing the gap geometry and solenoidal focusing profile downstream. At present, EGUN predicts that the normalized emittance jumps to approximately 1000 pi mm-mrad some 50 cm downstream of the cathode, stays this high for about one additional meter, and then (according further single-slice transport by the SLICE code[6]) oscillates and damps down to an exit emittance of ~500 pi mm-mrad at the exit of the first 8-cell block 5-m downstream of the cathode. These numerical values correspond to the "edge" emittance, defined as $4 \times \varepsilon_{RMS}$.

GYMNOS runs, which have been limited by CPU constraints to ~1 m of transport beyond the cathode, have shown consistently higher transverse emittance values, generally by a factor of 2-3X. After some development of post-processing tools to permit detailed investigations of particle dump "snapshots" (we cannot stress too highly how useful tools like these are in examining the fine details available in multi-dimensional PIC codes), we discovered that transverse phase space anomalies began appearing immediately downstream of the cathode surface. Specifically, a "hook" in $r - \gamma r'$ develops for $r \geq 9.0$ cm such that the smoothly increasing radial convergence for lesser values of r suddenly drops by a factor of two. An example of this behavior is shown in the $r - \gamma r'$ phase plots of Fig. 2, 0.5 and 6.5 mm downstream of the cathode. The equivalent normalized transverse emittance increase is close to 1000 pi mm-mrad within 1 cm downstream of the cathode, many times greater than found in the EGUN simulations.

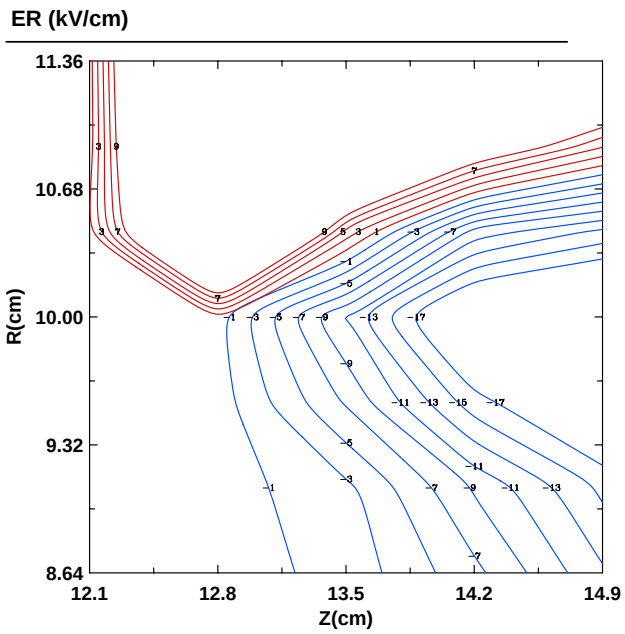

Figure 3: Contours of E_r near the outer radial boundary of the cathode. Between $r = 8.6$ and $r = 10.0$ cm the magnitude of this defocusing field nearly triples, leading to strongly nonlinear behavior in the electron beam's transverse phase space. Most of the nonlinearity occurs within $1 - 2\,\Delta r$ of the beam edge.

The origin of the hook drives from a strong increase in the defocusing E_r at radii just inside the cathode-Pierce shroud boundary. Inspection of the $r - z$ contours of the electrostatic potential show an enhanced "bowing" inward (toward smaller z) for $r \geq 9.5$ cm, one radial grid cell below the cathode/shroud boundary at 10.0 cm. At present, we believe the underlying cause for the bowing in Φ and nonlinear E_r dependence is a numerical artifact arising from a unwanted interaction of the 5-7 mm grid resolution, the sharp edge of the emitted beam, and the "kink" in the zero potential surface at the cathode-shroud boundary as modeled by the ECB formulation. We hope to find an appropriate solution that will not require decreasing the grid resolution to the 1-mm size of the equivalent EGUN calculations. Otherwise, the required number of grid points and macroparticles might jump by greater than an order of magnitude.

4 CONCLUSIONS

The underlying rationale for our use of GYMNOS in simulating the DARHT II injector behavior was to provide an independent check of both the EGUN results and overall physics design. Despite the problems discussed in the previous paragraphs, we note that GYMNOS does confirm that the injector design will produce ≈ 4 kA of emitted current together with a well-behaved envelope as the beam passes through the anode. While the GYMNOS results cannot confirm the high brightness EGUN runs, even with the present numerical limitations they indicate that the design is no worse than a factor of ~ 2 from the desired result.

EMITTANCE GROWTH FROM BEND/STRAIGHT TRANSITIONS FOR BEAMS APPROACHING THERMAL EQUILIBRIUM*

John J. Barnard and Bojan Losic
Lawrence Livermore National Laboratory, L-645, Livermore, CA 94550

Abstract

In certain applications such as heavy ion fusion, intense beams with large space charge tune depressions will be transferred from linear transport sections into bent transport sections. In some designs, such as recirculating induction accelerators, transport through bends will occur over thousands of betatron periods and in some driver designs the final transport through a bend will occur over tens of betatron periods. Over such distances, non-linear space charge forces are expected to produce particle phase space distributions which are close to thermal equilibrium, especially with respect to lower order moments. Here we calculate the properties of thermal equilibrium beams in bends assuming uniform focusing, as a function of two dimensionless parameters We also outline the calculation of the change in emittance for a beam that is initially in thermal equilibrium in a straight transport section, and that finally reaches thermal equilibrium in a bent system, using an energy conservation constraint to connect the two states.

1 INTRODUCTION

The conditions for equilibria of beams in a bent system were determined in ref. [1], under the assumption of uniform focusing and bending, with dispersion included through linear order in the equations of motion. The equilibria were determined by requiring that the derivatives of the second order moments with respect to path length vanish. A further assumption of this calculation was that space charge was distributed uniformly in an elliptical cross section, although as pointed out in refs. [2,3], distributions that are functions only of $x^2/\langle x^2\rangle + y^2/\langle y^2\rangle$ are also exact solutions to the moment equations of ref. [1], where x is the coordinate in the bend plane, y is the out-of-plane coordinate, and $\langle\ \rangle$ indicates average over the distribution.

Recently, in refs. [4,5] equilibrium distributions have been calculated that are fully self-consistent solutions to the coupled Vlassov and Poisson equations. Distribution functions which are functions only of the single particle transverse hamiltonian $h_\perp$ are solutions of the Vlasov equation, since $h_\perp$ is a constant of the motion. In refs. [4,5], the properties of a generalized KV distribution, (i.e. a delta-function of $h_\perp$) were investigated in detail. Although, the KV beam in bends is interesting because of its analytic tractability, beams which have equilibrated (e.g.due to space charge non-linearities), are likely to be better characterized by thermal equilibrium distributions. Although longitudinal/transverse coupling can be strong [6], it is of general interest to examine beams with distinct temperatures in the two directions.

The purpose of this paper, is to examine thermal equilibrium beams in bends with longitudinal temperatures which are not necessarily equal to the transverse temperatures (and hence the final temperature equilibration has not necessarily been reached.)

2 THEORETICAL MODEL

Equilibrium distribution functions f which satisfy the Vlassov/Poisson equations, for a system with constant focusing and bending radius have been found previously having the following form (refs. [4,5]):

$$f = f(h_\perp)\exp[-(\delta/\delta_0)^2] \tag{1}$$

where $2h_\perp = p_x^2 + p_y^2 + k_{\beta 0}^2(x^2+y^2) + 2g\phi - 2x\delta/\rho$. Here $f \equiv \mathrm{d}N/\mathrm{d}x\mathrm{d}y\mathrm{d}p_x\mathrm{d}p_y\mathrm{d}\delta$, is the number of particles per element of phase space, with the in-bend plane (horizontal) coordinate x, and vertical coordinate y, dimensionless momenta $p_{x,y}$ normalized to the design momentum in in the longitudinal direction $P_0 \equiv \gamma_0 m v_0$. The quantity $\delta = (P_s - P_0)/P_0$, is the fractional deviation of a particle with longitudinal momentum P_s from the longitudinal design momentum, and m is the particle rest mass. The quantity $k_{\beta 0}$ is the zero current spatial betatron frequency in the postulated uniform focusing channel, and ρ is the radius of curvature in the uniform bending field. The quantity ϕ is the electrostatic potential, and $g \equiv q/\gamma_0^3 m v_0^2$.

In this paper, we focus on the distribution of the form:

$$f(x,y,p_x,p_y,\delta) = f_0\exp(-h_\perp/T_\perp)\exp(-\delta^2/\delta_0^2) \tag{2}$$

Here, $T_\perp \equiv k_b\mathcal{T}_\perp/\gamma_0^2 m v_0^2$ where $\mathcal{T}_\perp$ is the comoving beam transverse temperature, k_b is Boltzmann's constant. The density $n(x,y)$ is given by:

$$n(x,y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y,p_x,p_y,\delta)dp_x dp_y d\delta \tag{3}$$

$$= n(0,0)\exp\frac{-1}{T_\perp}\left(\frac{k_{\beta 0}^2}{2}([1-\eta]x^2+y^2) + g\Delta\phi(x,y)\right). \tag{4}$$

Here $\eta \equiv \delta_0^2/2k_{\beta 0}^2\rho^2 T_\perp$, and represents the effects of dispersion in a bend on off-momentum particles, and $\Delta\phi \equiv \phi(x,y) - \phi(0,0)$. We find solutions to the non-linear poisson's equation $\nabla^2\phi = -qn(x,y,\phi(x,y))/\epsilon_0$ for which the beam pipe (radius r_p) is sufficiently far from the beam edge such that image forces can be ignored.

* Work performed under the auspices of the U.S. D.O.E. by LLNL under contract W-7405-ENG-48.

3 DIMENSIONLESS FORM OF MODEL

Without dispersion ($\eta = 0$) the beam density profiles in this problem recover azimuthal symmetry. In that case, the density profiles can be characterized by a single parameter (see e.g. [8]) which we define here as $\alpha_0 \equiv n(0,0)/n_{cold}$. Here $n(0,0)$ is the central density and n_{cold} is given by: $n_{cold} \equiv 2\gamma^3 m v_0^2 \epsilon_0 k_{\beta 0}^2/q^2$. The quantity n_{cold} is the density of a beam with focusing constant $k_{\beta 0}$, but at zero T_p and zero η.

When dispersion is added, the second dimensionless parameter η appears and all solutions may be characterized by the two dimensionless parameters α_0 and η. We define $X \equiv k_{\beta 0} x/T_\perp^{1/2}$, $Y \equiv k_{\beta 0} y/T_\perp^{1/2}$, $\Phi \equiv g\phi/T_\perp$, and $\Delta\Phi \equiv \Phi(X,Y) - \Phi(0,0)$. We may then cast Poisson's equation into the dimensionless form:

$$\frac{\partial^2 \Phi}{\partial^2 X^2} + \frac{\partial^2 \Phi}{\partial^2 X^2} = -2\alpha_0 \exp -\Psi. \qquad (5)$$

Here, $\Psi \equiv (1-\eta)X^2/2 + Y^2/2 + \Delta\Phi$. The boundary condition is $\Phi = 0$ at $X^2 + Y^2 = R_p^2$, where $R_p \equiv k_{\beta 0} r_p/T_\perp^{1/2}$ is the dimensionless pipe radius. Note that we have neglected the curvature terms in Poisson's equation, which is appropriate when $r_p << \rho$. Note also that R_p adds a third dimensionless parameter to the problem, but results presented here will be in a regime where R_p is large enough so that the beam parameters are nearly independent of R_p. We solve this equation numerically, using standard SOR techniques.

Once a solution is obtained, it is useful to calculate dimensionless moments of the density distribution:
$I_1(\alpha_0,\eta) \equiv \int\int dX dY \exp -\Psi$;
$I_{X^2}(\alpha_0,\eta) \equiv \int\int dX dY\, X^2 \exp -\Psi$;
$I_{Y^2}(\alpha_0,\eta) \equiv \int\int dX dY\, Y^2 \exp -\Psi$;
and $I_\Phi(\alpha_0,\eta,R_p) \equiv \int\int dX dY\, \Phi \exp -\Psi$. Here,the integration occurs over the interior of the beam pipe, $X^2 + Y^2 < R_p^2$, and the explicit dependence on α_0 and η is displayed. From these quantities, averages can be obtained: $\langle X^2\rangle \equiv I_{X^2}/I_1$, $\langle Y^2\rangle \equiv I_{Y^2}/I_1$, and $\langle\Phi\rangle \equiv I_\Phi/I_1$.

Using these integrals and averages, which depend only on α_0 η, (and in the case of I_Φ, R_p), we may calculate physical parameters of the beam. For example, the current $I = qv_0 n_{cold}\alpha_0 T_\perp I_1/k_{\beta 0}^2$, the perveance $K \equiv qI/2\pi\epsilon_0\gamma_0^3 m v_0^3 = \alpha_0 T_\perp I_1/\pi$, x-emittance $\epsilon_x = 4(\langle x^2\rangle\langle p_x^2\rangle - \langle x p_x\rangle^2)^{1/2} = 4T_\perp(I_{X^2}/I_1)^{1/2}$, and space charge parameter $S = 4K\langle x^2\rangle/\epsilon_x^2 = K/4T_\perp = \alpha_0 I_1/4\pi$. The rms tune depression $\sigma_x/\sigma_0 = (1/\langle X^2\rangle + \eta)^{1/2}$, and $\sigma_y/\sigma_0 = 1/\langle Y^2\rangle^{1/2}$.

4 RESULTS

Figure 1 displays a surface plot of the normalized beam density with a relatively large dispersion, and moderate tune depression. The beam has an apparent elliptical shape with a flattop similar to the thermal equilibrium beams in straight transport sections (cf. [8]).

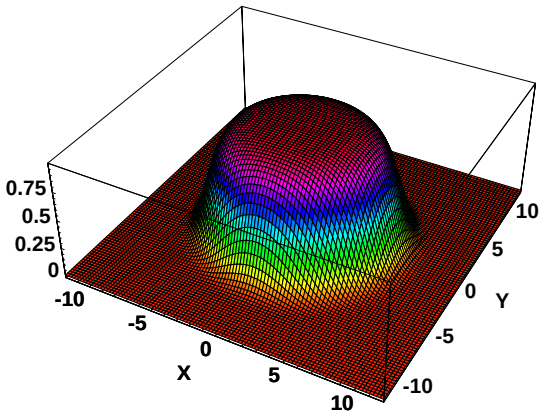

Figure 1. Scaled density $n(X,Y)/n_{cold}$ vs. X and Y for the parameters $\alpha_0 = 0.974$, and $\eta = 0.05$.

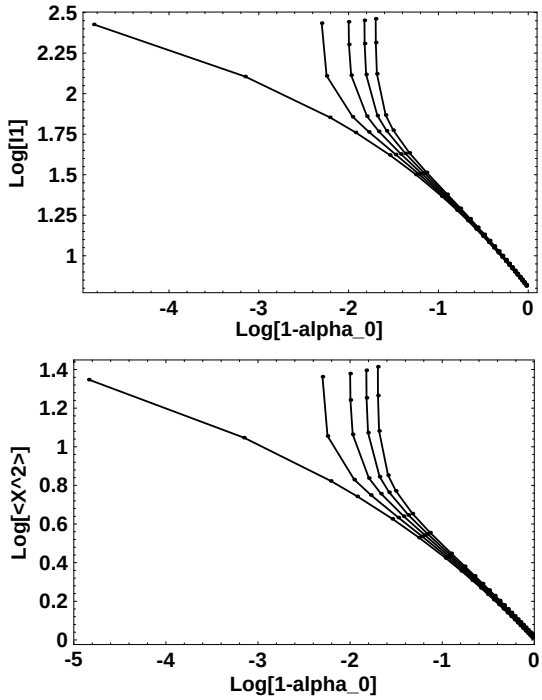

Figure 2. $\log(I_1)$ vs. $\log(1-\alpha_0)$ (upper) and $\log\langle X^2\rangle$ vs. $\log(1-\alpha_0)$ (lower) for five different values of η (starting from the left-most curve and proceeding to the right, $\eta =$ 0.00, 0.01, 0.02, 0.03, and 0.04).

The curves asymptote to $\alpha_0 = 1 - \eta/2$ for large space charge depressions (derivable from the envelope equations below with zero emittance), and I_1 tends to $2\pi/\sqrt{1-\eta}$, while $\langle X^2\rangle$ tends to $1/(1-\eta)$ in the limit of zero space charge.

5 EQUILIBRIUM EQUATIONS

In ref. [1], moment equations including dispersion were derived, and in ref. [9], the effects of images on a uniform density elliptical beam in a circular pipe were derived. The envelope equations with these two effects included (in addition to the usual external focusing, space charge and emittance terms are):

$$\frac{\mathrm{d}^2 a}{\mathrm{d}s^2} = -k_{\beta 0}^2 a + \frac{\epsilon_x^2}{a^3} + \frac{4}{\rho}\langle x\delta\rangle + \frac{2K}{a+b} + K\frac{(a^2-b^2)a}{4r_p^4} \qquad (6)$$

$$\frac{\mathrm{d}^2 b}{\mathrm{d}s^2} = -k_{\beta 0}^2 b + \frac{\epsilon_y^2}{b^3} + \frac{2K}{a+b} - K\frac{(a^2-b^2)b}{4r_p^4} \qquad (7)$$

Here $a \equiv 2\sqrt{\langle x^2\rangle}$ and $b \equiv 2\sqrt{\langle y^2\rangle}$. Setting $\mathrm{d}^2 a/\mathrm{d}s^2 = \mathrm{d}^2 b/\mathrm{d}s^2 = 0$, and transforming to the dimensionless variables, we find the equilibrium moments satisfy:

$$0 = -(1-\eta)\sqrt{\langle X^2\rangle} + \frac{1}{\sqrt{\langle X^2\rangle}} + \frac{\alpha_0 I_1}{2\pi\left(\sqrt{\langle X^2\rangle}+\sqrt{\langle Y^2\rangle}\right)} + \frac{\alpha_0 I_1\left(\langle X^2\rangle - \langle Y^2\rangle\right)}{\pi R_p^4}$$

$$0 = -\sqrt{\langle Y^2\rangle} + \frac{1}{\sqrt{\langle Y^2\rangle}} + \frac{\alpha_0 I_1}{2\pi\left(\sqrt{\langle X^2\rangle}+\sqrt{\langle Y^2\rangle}\right)} - \frac{\alpha_0 I_1\left(\langle X^2\rangle - \langle Y^2\rangle\right)}{\pi R_p^4}$$

It has been found that in all cases examined, that given I_1, and solving for $\langle X^2\rangle$ and $\langle Y^2\rangle$, these equilibrium equations accurately predict the moments derived from the SOR code, and the final term accurately gives an indication of the importance of image charge effects on the solution.

6 EMITTANCE GROWTH FROM BEND/STRAIGHT TRANSITIONS

As discussed in [1], if a beam abruptly enters a bend from a straight transport section, off momentum particles will tend to oscillate in x about centers which are displaced from the design orbit of the machine. This causes an envelope mismatch, and if the non-linear space charge forces are sufficiently strong to allow phase mixing and energy equi-partition between the x and y directions, then a new equilibrium will result. In ref. [1], the moment equations yield an exact energy invariant, when $k_{\beta 0}$ is independent of s, under the assumption that density is constant on nested ellipses ($n(x,y) = n(x^2/\langle x^2\rangle + y^2/\langle y^2\rangle)$). More generally, a dimensionless average transverse energy may be written:

$$H_\perp = \frac{1}{2}\left((1-2\eta)\langle X^2\rangle + \langle Y^2\rangle + \langle \Phi\rangle + 2\right) \qquad (8)$$

Because of the choice of normalization, it is the quantity $H_\perp T_\perp$ which is conserved. Note that the factor of 1/2 multiplying $\langle\Phi\rangle$ is necessary to correctly calculate the self-assembly energy from space charge. To calculate the the change in beam parameters from a straight/bend transition, we first calculate the current I and the transverse energy $H_\perp T_\perp$ of the beam in the straight section. Because we tabulate $H_\perp(\alpha_0, \eta, R_p)$ for fixed R_p we must account for the change in R_p as $T_\perp$ changes even though r_p remains fixed. But $H_\perp(\alpha_{0f}, \eta_f, R_{pf}) = H_\perp(\alpha_{0f}, \eta_f, R_{pi}) + (K/2T_{\perp f})\times(\ln R_{pf} - \ln R_{pi})$, where subscripts i, f indicate initial, final. For $k_{\beta 0}$ and r_p held constant, we find $T_{\perp i}[H_\perp(\alpha_{0i}, \eta = 0, R_{pi}) + (K/4T_{\perp i})\ln K/T_{\perp i}] = T_{\perp f}[H_\perp(\alpha_{0f}, \eta_f, R_{pi}) + (K/4T_{\perp f})\ln K/T_{\perp f}]$. For a finite value of η, we iterate $T_\perp$ and α_0, until the current and this relation for $H_\perp$ is satisfied. This allows calculation of all final beam parameters and using $\langle\delta^2\rangle = (1+\eta\langle X^2\rangle)\delta_0^2/2$, we may a posteriori, determine the initial value of δ_0. The change in emittance calculated using this algorithm agrees within numerical accuracy to the calculation done using the moment equations in ref. [1] and compared with simulations in ref. [7].

7 CONCLUSIONS

We have solved the self-consistent Vlasov Poisson system for beams in bends with thermal distributions, and with temperatures not necessarily equal in the longitudinal and transverse directions. We have characterized these beams by two dimensionless parameters α_0 and η and have graphed two of the quantities which characterize the solutions. We find that such beams have profiles which are constant on nested ellipses, to within numerical errors when the beam pipe is sufficiently large. This validates moment and envelope equations in refs. [1] and [3] for this class of beams. Emittance growth from bend/straight transitions, using energy and current conservation constraints was found to be the same as that calculated in ref. [1] again to within numerical uncertainties.

COUPLING SLOTS MEASUREMENTS AGAINST SIMULATION FOR TRISPAL ACCELERATING CAVITIES

Pascal Balleyguier, CEA/DPTA, 91680 Bruyères-le-Châtel, France

Abstract

At the LINAC96 conference, we presented a new coupling scheme for the Trispal CCL accelerating cavities: the "4-petal" slots [1]. It resulted from a MAFIA optimization in which we tried to maximize the shunt impedance. Since that time, we designed and built a mock-up for an accurate measurement of the Q-drop. Indeed, we achieved a good accuracy and reliability in Q-drop measurements, but the value was rather disappointing: -22.5% (+/-0.5), instead of 5% as predicted. As a consequence, the "4-petal" coupling scheme was abandoned, and we learned that local power losses computed by cavity simulation codes can be widely underestimated. Further simulation showed that improving the mesh resolution could give better results though we felt that only a more subtle meshing method (like triangular cells or partially filled cells) could lead to realistic values.

1 INTRODUCTION

The TRISPAL linac [2] will deliver a 40 mA CW beam of 600 MeV protons. Above 100 MeV, it will be made of 352-MHz π-mode coupled cavities. Their coupling slots had been optimized with MAFIA in a way to minimize the shunt impedance drop that they induce [1]. Starting from a "2-bean" configuration of slots inspired by LEP cavities [3], the optimization resulted in a new "4-petal" scheme, for which MAFIA predicted a -6 % Q-drop (about half that of the "2-bean" slots), with the same coupling coefficient. Moreover, this Q-drop was found to be approximately canceled by an improvement of R/Q, resulting in a quasi-negligible loss in shunt impedance.

These characteristics were weakly dependent on the resolution, and variations versus various geometrical parameters were rather coherent. For verification, the optimized geometry was also computed by other codes: Soprano [4] and Antigone [5]. Roughly, all the codes agreed about coupling factor and R/Q improvement. The Q-drop values were rather close too, except for the one computed with Antigone-H (-17 %) which seemed very pessimistic.

To settle the point of the Q-drop, a 1/3 scale aluminum alloy cold model has been build (fig. 1). The central part, which contains the coupling slots, can be removed for single-cell measurements. A major issue is to get a reliable Q value in spite of successive assembling and dismantling. The electrical seal is made of a 0.8-mm solder wire squeezed to 0.4 mm with a mechanical limitation that makes the contact quality independent of the tightening strength.

Coupling antennas were made of N connectors screwed outside each end plate (fig. 2) and did not need to be dismantled at changes of configuration (single or double-cell). The central stem of the connector was extended somewhat toward the cavity to make an on-axis electrical antenna, but the coupling remained low enough (<-25 dB) to neglect the external Q.

Fig. 1. The 2-cell cold model

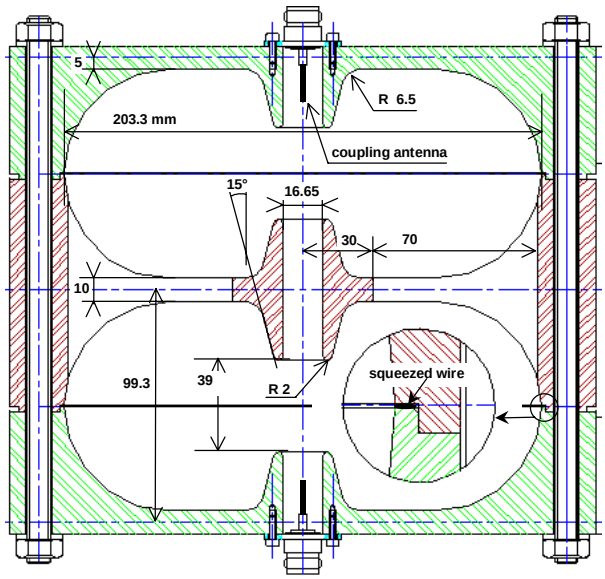

Fig. 2. Longitudinal section (transverse view on fig.4)

2 MEASUREMENTS VS. SIMULATIONS

In the MAFIA computation of the cold model, no symmetry is assumed in the center of the cell. So it represents a true double cell cavity, rather than infinitely long structure. We computed the coupling coefficient γ and the slot frequency drift α with the following

formulas:

$$\gamma = 2\frac{f_0 - f_\pi}{f} \quad , \quad \alpha = 2\frac{f_1 - f_0}{f},$$

in which f is the goal frequency (3×352 MHz). Indices π, 0 and 1 indicate the pi-mode, 0-mode and single cell cavity mode (i.e., a cell without any coupling slots), respectively. The factor two is to extrapolate the data to the case of an infinitely long structure with coupling slots on both sides of the cell as computed in [1]. The mesh used was exactly the same for the three modes, but in the case of a single-cell cavity, slots were filled with metal instead of vacuum. We used about 60000 points for a quarter of a cell, resulting in a 2.5 mm resolution in the vicinity of the slots.

Table 1 shows a +8 MHz systematic frequency error in simulation versus the cold-model that probably results from gap length and nose shape changes due to discretization. But this bias is constant, and should not alter relative differences. Indeed, α and γ computed values are close to the measured ones: the agreement is pretty good, from the coupling-factor and slot-frequency-drift points of view.

Table 1. Frequency and quality factor (4-petal).

	MAFIA	cold model
pi-mode (MHz)	1073.912	1064.415
zero-mode (MHz)	1081.556	1072.412
single-cell (MHz)	1088.948	1080.841
coupling γ (%)	1.45 (1.40*)	1.51
fq. drift α (%)	1.40 (1.42*)	1.60
Q pi-mode	11924	11340
Q zero-mode	12922	12938
Q single-cell	12236	12880
δQ_π (%)	-5.0 (-5.9*) (-16.9**)	-22.5
δQ_0 (%)	+11.5 (+11.3*) (+4.7**)	+0.9

(*MAFIA and **Antigone-H simulations in [1])

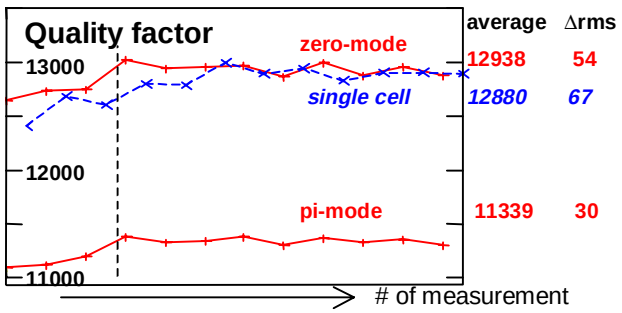

Fig. 3. Statistical variation of the measured Q.

The resistivity of the alloy (Al: 96%, Cu: 4%) was 51 nΩ.m, and the measured single-cell cavity Q was 12880, slightly above the computed value (12236). But, because of surface imperfection and seal losses, we should expect the measured Q to be 10% to 15% lower. We conclude that the MAFIA Q-value is probably underestimated, an effect that had already been established [1]. Anyway, as this bias is rather small and should be identical for the three modes computed here, the relative differences should not be significantly altered.

To estimate the quality factor reliability, we made a series of measurements alternating both configurations (single or double-cell) and changing the seal each time. The gradual Q improvement in the left-hand part of the curves (fig. 3) shows the improvement of the operator's skillfulness during the first measurements. Disregarding the first three points in each curve, the statistical variation on the measured Q is about 0.4 % r.m.s.. The accuracy on the mean value is then 0.15 %, leading to a 0.5 % absolute accuracy on δQ (see definition below).

Table 1 also gives measured quality factors against predicted ones. Here, relative variations versus single-cell mode (δQ) have been doubled by squaring the ratios to represent the case of an infinitely long structure with coupling slots at both sides of each cell:

$$\delta Q_\pi = \left(\frac{Q_\pi}{Q_1}\right)^2 - 1 \qquad \delta Q_0 = \left(\frac{Q_0}{Q_1}\right)^2 - 1.$$

We can see that MAFIA prediction of δQ_π is widely underestimated: -5 % instead of -22.5 %. Furthermore, we measured a very small δQ_0: +0.9 %, instead of +11.5 % as predicted. Other codes used in [1] gave results close to MAFIA ones, except for Antigone-H. This code predicts δQ values closer to measurements but still not very satisfactory.

3 BACK TO "2-BEAN" SLOTS

Previous measurements showed that the 4-petal slots did not yield the performance we expected from them. So, we built a new central-part for the cold model, with two classical bean-shaped slots. A single measurement (i.e., no statistics) in each configuration was performed this time. According to measured results (fig.4), the 2-bean slots are definitely preferable to 4-petal ones.

Unfortunately, we did not have time and material to make R/Q measurements with the bead-pull technique. Anyway, even if MAFIA predictions were right (the pi-mode R/Q variation versus single-cell is +5.2 % for 4-petal, and -0.2 % for 2-bean), the net result in shunt impedance would still be in favor of conventional slots.

For 2-bean slots, the simulated frequency is also 8MHz higher than measured, and a rather good agreement is obtained for relative frequency differences (table 2). The slot frequency drift α is pretty well predicted. The actual coupling factor is a little bit smaller than computed (1.27 % instead of 1.51 %). Perhaps the actual 5 mm radius due to the machining method, instead of right angles (at the slot corners), explains a part of this discrepancy. For linac designing, such a discrepancy is non-negligible and the slot width should be slightly increased in order to reach the desired 1.4 % coupling factor.

About Q-variations, this time the agreement between measurement and simulation is not bad. Apparently,

losses are inaccurate in the case of composite coupling (like 4-petal), and not in case of pure magnetic coupling (like 2-bean), but we have no explanation. This is a possible track for further investigations.

Table 2. The 2-bean coupling.

	cold model	MAFIA
pi-mode (MHz)	1069.976	1076.629
zero-mode (MHz)	1076.702	1084.604
single-cell (MHz)	1080.922	1088.554
coupling γ (%)	1.27	1.51
fq. drift α (%)	0.80	0.75
Q pi-mode	12083	13269
Q zero-mode	12959	14118
Q single-cell	12825	13928
δQ_π (%)	-9.2	-11.3
δQ_0 (%)	+2.8	+2.1

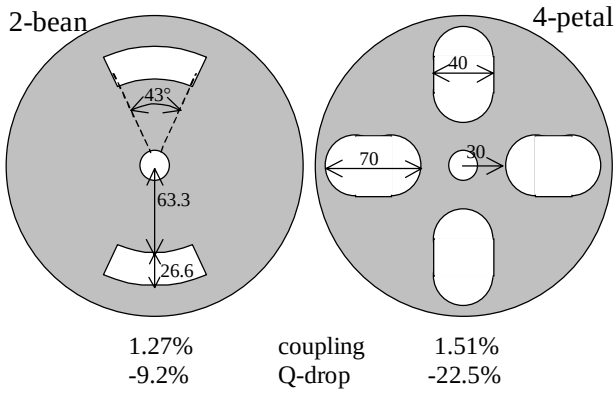

Fig.4. "2-bean" vs. "4-petal" slots (actual performances).

4 CONCLUSIONS

About the cold model: we managed to get a reliable quality factor in a cold model cavity, despite successive assembling and dismantling. Thus, we can estimate the percentage Q-drop induced by the coupling slots in an infinitely long structure, with an accuracy of ± 0.5. This accurate experimental data can be a benchmark for future codes.

About simulation: cavity code accuracy has been widely discussed until today (see, for example [6]). But most of the time, only the frequency or the on-axis field has been taken care of. The present study gives accurate experimental data involving the quality factor. We conclude that, at the present time, 3D codes tested here are not suitable for minimizing cavity losses.

In a closed vacuum-filled cavity, the quality factor is the ratio between two integrals: a volume integral (field energy) and a surface integral (losses). The first integral should be good, because if there were a bias in the whole volume, the resonant frequencies could not be predicted accurately. Thus, we probably should suspect the surface losses to be inaccurate. For a given field in the center of the cell, losses should be identical between a single-cell cavity and a multi-cell one, as long as walls are identical. Thus, only small areas in which surface currents are deviated by coupling slots (i.e., nearby the slot edges) should yield different losses. The discrepancy between computed and measured Q-drop is rather important though only small areas of the cavity walls may cause this difference. So, we suspect the local power dissipation to be very inaccurately computed in some cases, particularly in areas where the fields are strongly non-uniform.

Further analyses have been carried out at CST to explain the discrepancy between MAFIA results and measured ones. It appeared that the computed Q-drop would depend on the resolution, and be a little closer to experimental values with a much larger number of points. Anyway, no clear convergence was found, and the conclusion was that one should not try to get this kind of information from MAFIA at the present time. The future "Partially Filled Cells" algorithm, should lead to more accurate Q-drop values.

About Trispal: the 4-petal coupling slots must be abandoned. As we have no reliable way to optimize the slots, we will use the more classic 2-bean ones, which have proved to be not so bad.

Right now, we should take a great care when designing cooling circuits. If possible hot spots are suspected, a more important margin should be used. This remark is also valid for the Trispal RFQ design.

ACKNOWLEDGMENTS

The author thanks F.Appolaire who designed the cold-model, M.Fabry (from AMAFA) for having it built, and P. Hahne (from CST) for investigations with Mafia. The author is grateful to R.Wood (from LANL) for careful reading of the manuscript.

EXTERNAL Q STUDIES FOR APT SC-CAVITY COUPLERS

Pascal Balleyguier, CEA/DPTA, 91680 Bruyères-le-Châtel, France

Abstract

Coupling coefficients for the APT superconducting cavity couplers have been predicted using an improvement of the method previously developed for the French Trispal project [1]. We here present the method and a proof of the formula used to compute the external Q. Measurements on a single-cell copper cold model exhibited a very good agreement against simulation. Then, we established that the original coupler design lead to an insufficient coupling in β=0.64 cavities. Different solutions were proposed to fix this problem, like combining impedance discontinuities in the line and an off-centered disc end tip. Finally, it was decided to increase the beam tube diameter though it has some influence on the cavity end-cell performance.

1 INTRODUCTION

The superconducting accelerating cavity prototype for the Accelerator Production of Tritium project and its associated power coupler have been intensively studied in Los Alamos [2]. Among the main characteristics is the external quality factor of the cavity. This parameter determines the coupling between the cavity and the RF line that feeds it.

Some methods to compute the external Q already exist. In 1990, Kroll and Yu [3] proposed one based on a fit on a branch of Slater's diagram. Unfortunately, this method is limited to low Qext values (less than a few hundreds) and is not suitable for our purpose. The author of the present paper recently proposed a new method [4]. It has been improved since, and the resulting method in fact is equivalent in its principle to another one described in 1993 by Hartung and Haebel [5]. But our method differs both in the proof and in the practical way to operate. Moreover, we derive from it a procedure to compute fields and local power losses under operation in a cavity and its power coupler.

2 METHOD

Let us consider a lossless cavity initially containing some RF energy W at its resonant frequency ω. If this cavity is weakly coupled to an infinite line, this line drives out a certain RF power P and the energy stored in the cavity gradually decreases. The external Q then is:

$$Q_{ext} = \omega W / P .$$

Only a single mode is assumed to travel along the line. The power transported by the travelling wave along the line may be computed either from the electric or the magnetic field amplitude:

$$P = \frac{1}{2\eta} \iint_{\text{line x sect}} |E|^2 \, ds = \frac{\eta}{2} \iint_{\text{line x sect}} |H|^2 \, ds ,$$

assuming that η is the mode impedance. The stored energy in the cavity (assumed to be under vacuum) is:

$$W = \frac{1}{2} \iiint_{cavity} \varepsilon_0 |E|^2 \, dv = \frac{1}{2} \iiint_{cavity} \mu_0 |H|^2 \, dv .$$

We assume the line mode is a TEM, and that the dielectric is vacuum: $\eta^2=\mu_0/\varepsilon_0$. Then, the external Q can be expressed as:

$$Q_{ext} = \frac{\omega \iiint_{cavity} |F|^2 \, dv}{c \iint_{\text{line x sect}} |F|^2 \, ds} , \qquad (1)$$

F being either the electric (*E*) or magnetic (*H*) field. (If the line is not under vacuum and/or the mode is not a TEM one, a coefficient taking the line mode impedance into account has to be introduced in equation (1)).

Unfortunately, computing the Qext with the formula (1) would require the use of a dissipative code. Though such codes now exist, they are more difficult to use and much slower than non-dissipative ones.

Inverting the sign of time gives a second solution of Maxwell's equations that represents the same cavity slowly gaining energy from an incoming wave travelling in the line. According to the superposition theorem, we can add these two solutions (fig. 1).

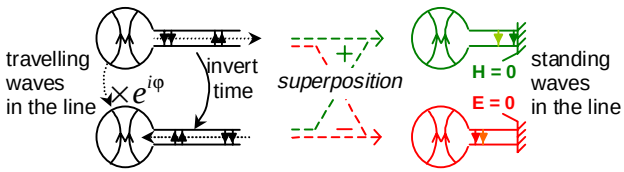

Fig. 1. Transforming a travelling-wave problem into a standing-wave one.

Inside the line, the two added travelling waves drive the same RF power P in either direction, and they interfere into a standing wave. Let us choose the reference plane at an electric field antinode: the standing wave field amplitude is there twice the one of the travelling waves. Inside the cavity, the two added fields have an arbitrary phase difference φ, so the amplitude of the resulting field is $|1+e^{i\varphi}|$ times the one of the original field. Using the same formal expression as in equation (1), we can define the quantity Q_1 as:

$$Q_1 = \frac{\omega \iiint_{cavity} |E_1|^2 \, dv}{c \iint_{\text{ref. .plane}} |E_1|^2 \, ds} = \frac{|1+e^{i\varphi}|^2}{4} Q_{ext} ,$$

where the suffix *1* indicates the resulting field after addition. This field is a pure standing wave in both the cavity and the line. The line can be terminated at the

reference plane with the appropriate boundary condition (perfect magnetic wall) without changing the fields, making this problem computable by MAFIA or any other cavity code.

Now let us use the superposition theorem again, but by subtracting the two solutions instead of adding them (the resulting fields will be noted with the suffix *2*). At the same reference plane, we now have a magnetic antinode which field amplitude is twice the one of the travelling wave. Inside the cavity, the resulting field is now $|1\text{-}e^{i\varphi}|$ times the original field. We define Q_2 as:

$$Q_2 = \frac{\omega \iiint_{cavity} |H_2|^2 dv}{c \iint_{ref.\,plane} |H_2|^2 ds} = \frac{|1 - e^{i\varphi}|^2}{4} Q_{ext}.$$

This problem can also be computed by MAFIA with the other boundary condition (perfect electric wall) at the reference plane. As for any value of φ, $|1+e^{i\varphi}|^2 + |1\text{-}e^{i\varphi}|^2 = 4$, we have then: $Q_{ext} = Q_1 + Q_2$.

So, two MAFIA runs (with the same mesh) are sufficient to predict the external Q. The reference plane position has no influence on the external Q and can be chosen anywhere in the line. Indeed, tests showed that the computed Qext was within a 0.5% variation when computed in double precision with different line lengths.

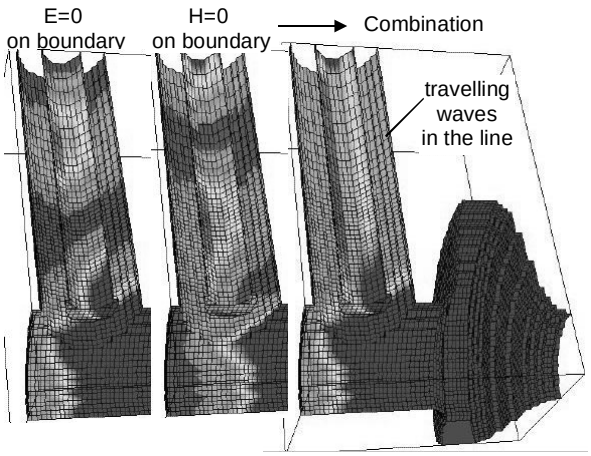

Fig. 2. Losses in the coupler under normal operations

Reciprocally, the travelling wave can be reconstituted from the two standing wave solutions in order to compute the fields in normal operation. For this purpose, one just has to combine the two standing waves solutions in quadrature phase. Before combining, one has to make sure that the electromagnetic energy at an arbitrary line cross section of the line is the same for the two waves.

This operation also permits to compute the losses in the coupler under normal (i.e. travelling waves) operation. As the solutions combine are in quadrature phase, the resulting losses is just the sum of the losses of the two solutions after normalizing them with respect to the energy density at the line end plane. As an example, the local losses in the final coupler (sect. 3) have been computed. As expected, we obtained a pure travelling wave with uniform losses along the line (fig. 2).

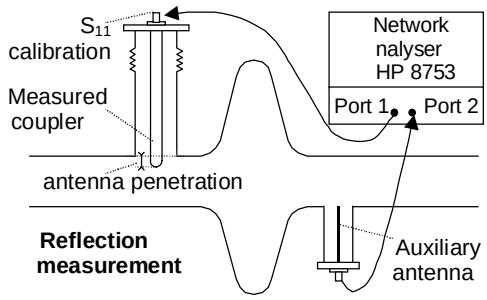

Fig. 3. Qext measurement in the 1-cell copper mock-up.

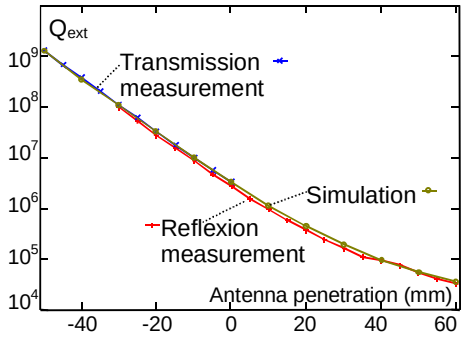

Fig. 4. Computed and measured Qext in the mock-up.

To prove the validity of this method, we tested it on a β=0.64 single-cell copper mock-up of APT cavities (fig.3). The coupling could be changed by moving the electrical antenna more or less into the beam tube. The Q_{ext} has been computed and measured (by reflection and/or transmission) for various penetrations of the coupler antenna. The result (fig. 4) shows an excellent agreement between simulation and measurements. The discrepancy of measurements versus simulation is <20 % for reflection and <7 % for transmission.

3 THE β=0.64 APT CAVITY

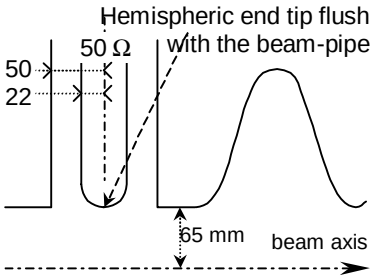
To cancel the reflected wave on the β=0.64 APT cavity, the external Q must equal the internal Q which is:

$$Q_{\text{int}} = \frac{\omega W}{P_{beam}} = \frac{\beta \lambda/2 \, E}{2 \, r/Q \, I \cos\varphi},$$

where *W* is the stored energy, P_{beam} the power gained, E=4.8 MV/m is the accelerating gradient, r/Q (single-cell circuit-definition)=17.1Ω, I=100mA is the beam current, φ=30° is the phase angle between the proton bunch and the RF voltage. The goal value is then: $Qext=0.22\times10^6$.
The cavity [6] has been simulated with the originally designed power coupler (fig.5). The computed Qext (assuming two couplers per 5-cell cavity) was: 1.5×10^6, which is off by a factor 6.7. With such a design, the antenna would have had to be pushed 26 mm into the beam pipe in order to reach the goal: this is not acceptable in a real accelerator.

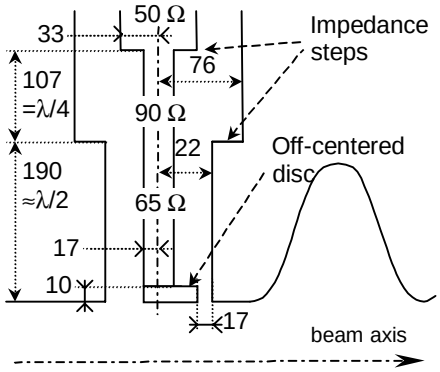
At first, we tried to increase the coupling, without modifying the cavity design, but only the coupler itself (fig. 6). Replacing the hemisphere antenna end tip with a disc was found to be efficient if the disc axis was shifted toward the accelerating cells. A further improvement was

obtained by introducing an impedance step in the coaxial line. Such a discontinuity generates a reflected wave that partially cancels the one at the antenna end, if the distance between the reflections planes is chosen suitably. It appeared that two such steps would be necessary: an impedance increase about λ/2 from the end tip, and an impedance diminution λ/4 further. These steps would also make the transition between the coupler dimensions and the feeding coaxial line, thus avoiding the use of a taper.



Qext=1.5×10^6 (–8.3 dB from goal)

Fig. 5. Original coupler design



Qext=0.22×10^6: goal achieved

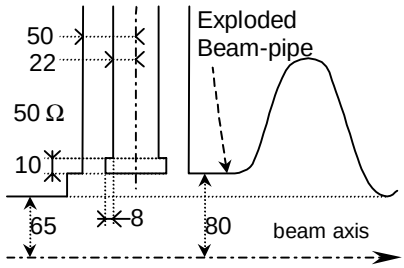
Fig. 6. Solution without cavity modification

However, the above solution only barely gave the necessary Qext and would have let no margin in case of unexpected behavior. For this reason, we preferred another one that consisted in expanding the end-cell beam-pipe radius from 65 to 80 mm. This change was rather soft because 80 mm is already the beam pipe radius of the β=0.82 cavities. Computations showed that such a beam-tube expansion would almost give the required Qext. In order to further improve the coupling, a 10-mm thick symmetrical disc was added at the antenna end tip (fig. 7). The Qext obtained (0.20×10^6) is even a little lower than required.

Such a modification in the cavity geometry has of course some influence on the cavity performance. First of all, the end cell profile has been adjusted to keep a 700 MHz resonance frequency. As well, the transit time factor is poorer with the enlarged pipe, and the geometric impedance (r/Q) drops by 19 %. But, as this happens only in the end-cell, the global cavity impedance is only 4 % lower, which is acceptable.

For a final adjustment, couplers will be tuned by adjusting the penetration into the beam pipe. The Qext has been computed versus antenna penetration, and the slope is 0.38 dB/mm around nominal position. So, a ±5-mm possible antenna adjustment will permit to vary the Qext within a factor 2.4.

The influence of a possible antenna tilt was simulated by a parallel displacement of the antenna in the z-axis direction. In fact, this effect is very small: 0.12 dB/mm. A ±1-mm misalignment can be compensated by a ±0.3-mm penetration of the antenna.



Qext=0.20×10^6: +0.6 dB more than goal

Fig.7. Final geometry

4 CONCLUSION

The Qext can be easily and efficiently computed by lossless cavity codes in frequency domain. The losses in the coupler associated with the travelling wave can also be derived from the same simulation.

The desired Qext in APT β=0.64 cavities has been obtained by expanding the beam-pipe. If necessary, an asymmetrical end tip and appropriate impedance steps could further improve the coupling.

The author thanks Brian Rusnak and all the coupler group for including me in their team during my stay in Los Alamos. I want to thank specially Frank Krawczyk for all his help, and Henri Safa for his suggestions about the possible ways to improve the coupling.

Abstract

PISCES II calculates Eigensolutions of any axi-symmetric cavity with 2.5D Finite Element Method and can handle periodic boundary conditions. Dipole and higher multipole solutions are obtained by hybrid finite elements. The accuracy of the frequency in a solution obtained from PISCES II is improved by use of higher order elements. In order to reduce the computation time, the Eigenvalue solver is improved.

1 INTRODUCTION

An RF cavity code with high accuracy is necessary for design with high precision. There are still some needs of an axisymmetric cavity because of its simplicity.

PISCES II can calculate all Eigensolutions in a cavity with axisymmetric boundaries including multipole modes[1,2]. Periodic boundary conditions can also be handled in this code.

2 FORMULATION AND FINITE ELEMENT MODEL

Because either $\vec{E}$ or $\vec{H}$ can be used as the field variable, only the electric field will be shown here. The differential equations to be solved are [3,4,5],

$$\nabla\times\nabla\times\vec{E}+k^2\vec{E}=\vec{0},\quad \nabla\cdot\vec{E}=\vec{0}\qquad (in\quad \Omega), \tag{1}$$

where $k^2=\omega^2\varepsilon\mu$. In vacuum space $k^2=\omega^2/c^2$, where c is the speed of light. Boundary conditions are

$$\vec{E}\cdot\vec{n}=0 \qquad \text{on magnetic boundaries } (\Gamma m) \tag{2}$$
$$\vec{E}\times\vec{n}=\vec{0} \quad \text{on electric boundaries } (\Gamma e) \text{ and} \tag{3}$$
$$\vec{E}_{right}=e^{i\varphi}\vec{E}_{left} \quad \text{on periodic ones } (\Gamma p), \tag{4}$$

where $\vec{n}$ denotes the outward normal on the boundary, and φ is the phase advance in the problem .

Because only the problems on axisymmetric domains are considered, we can assume $\sin m\theta$ and $\cos m\theta$ dependencies for E_r, E_z and E_θ components, and then the problem can be reduced to two-dimensional problem:

$$\vec{E} = (E_\theta \sin m\theta, E_r \cos m\theta, E_z \cos m\theta). \tag{5}$$

Then (E_θ, E_r, E_z) are functions of r and z only. The field variables are (rE_θ, E_r, E_z) for $m\geq 1$ and (E_θ, H_θ) for $m=0$.

Using Finite Element Method, Eqs. (1-3) can be reduced to a matrix form of a general Eigenvalue equation:

$$\boldsymbol{M}\cdot\vec{x}=k^2\boldsymbol{K}\cdot\vec{x}, \tag{6}$$

where $\boldsymbol{M}$ and $\boldsymbol{K}$ are large sparse symmetric matrices, and $\vec{x}$ is an Eigenvector[6]. Because of the hybrid elements, any spurious mode has zero-Eigenvalue and is well separated from the real modes. Usually several Eigensolutions starting from the smallest one but zero are of interest. Unfortunately, this Eigenvalue problem has many zero-Eigenvalue solutions, which correspond to the spurious modes, and thus special care should be taken. For axisymmetric solutions, such as TM0xx or TE0xx, the problem can be expressed by field variable of E_θ or H_θ, which has no zero Eigensolution.

3 PERIODIC BOUNDARY

The periodic boundary condition is implemented using Floquet's theorem[7]. Although $\vec{x}$ has to be a complex vector for this analysis, the final Eigenvalue problem to be solved can be rewritten as real and symmetric by splitting the component into real and imaginary part. Because of this technique, the Eigenvalue solver for the usual boundary conditions is used.

4 GENERAL EIGENVALUE SOLVER

Because Eq. (5) is a general Eigenvalue problem for large sparse symmetric matrix with many zero Eigenvalue solutions, special care had to be taken. The solver is based on the subspace method[8] and uses zero and upper filtering technique[9].

The zero filtering technique requires a rough estimate of the lowest Eigenfrequency(FLO), which can be obtained by the physical dimension of the problem. If FLO is not given by a user and solution with the second order element or multiple solutions are required, PISCES II evaluates FLO from a single mode solution with lowest order element starting with the "guess" value from the physical dimension.

Using similar technique, upper filter is also applied for acceleration of the convergence. If the upper frequency (FUP) are not given by a user, PISCES II uses the highest Eigenvalue in the subspace after it settled. In this case the FUP value is adjusted adaptively.

Because the method is based on the iterative method, initial vectors should be given at the beginning. For the problem with the lowest order element, the initial vectors are given by random numbers. Before starting with the second order element, the solution vectors are obtained from the lowest order element and "prolonged" to the

second order solutions by linear interpolation. Because fairly good initial solutions are obtained by this way and FUP is also available from the beginning, the solution time is reduced up to half comparing with direct start with the random vectors.

5 INPUTS TO PISCES II

A mesh data example for a sphere as shown in Fig. 1 is listed in Fig. 2. All the internal units are in SI. The first line contains a title with less than 80 characters. The second line is problem constants, where only the unit scale for cm is specified in the list. The options are explained later. The third line has three numbers, which are the number of nodes, the number of elements and the number of boundary points plus one for closure of the line. Node coordinates are specified being enclosed by brackets. Followings are the element data, which specifies the three coordinates of the vertices by the sequential numbers of the coordinate sets. The fourth positions are reserved. Then the boundary points are specified in the same way as above. Each boundary condition for a segment between n and n+1 boundary points is specified by a character constant. The encoding of the boundary conditions are listed in Table 1. The last group is the curvature data which specifies the radii of the segments in the same sequence as the boundary conditions. Zero in radius should read as straight line. Each group is read by free format read statement. The mid-line points will be generated in the code if the second order elements are needed. For a periodic boundary problem, the radial coordinates of both the left and right side nodes should coincide.

Table 1: The encoding of the boundary conditions

Code	Boundary condition
'A'	on axis (r=0)
'E"	on electric boundary (metal surface)
'M'	on magnetic boundary (symmetry plane)
'P'	left side boundary for periodic boundary
'Q'	right side boundary for periodic boundary

MESHNET program[10] can convert a TAPE35 data that is generated by LATTICE[11] to an input file for PISCES II. Because the curvature information is not included in TAPE35 data, the curvature data has to be added by hand or by NETREF (NET REFine) program.

Table 2 explains the major problem constants and their default values. Table 3 shows the encoding of the element type. For example, LMTYP=22, the second order nodal elements are used for axisymmetric modes (m=0) while the mixed linear edge/nodal element are used for multipole modes (m>0). For the default setting of LTYP=1, both TE0xx and TM0xx are obtained simultaneously at m=0 so that any mode is not missed in the solution. Although such Eigenvalue problem can be separated into two independent problems, it is solved altogether.

Table 2: The problem constants

name	Default	description

6 EXAMPLE

Figs. 5 and 6 show the relative frequency errors and CPU time as functions of the number of unknowns for the hemisphere problem shown in Fig.1 (r=10cm). The CPU time depends on only the number of unknowns, although the number of nonzero elements in the matrices are about twice. The second order solutions give better accuracy with doubled memory requirement.

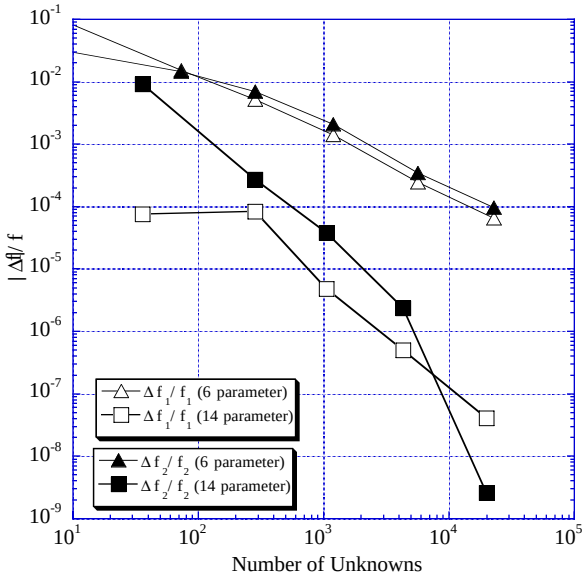

Fig. 5 Relative frequency errors of the second and the third lowest modes in a spherical cavity as a function of the number of unknowns.

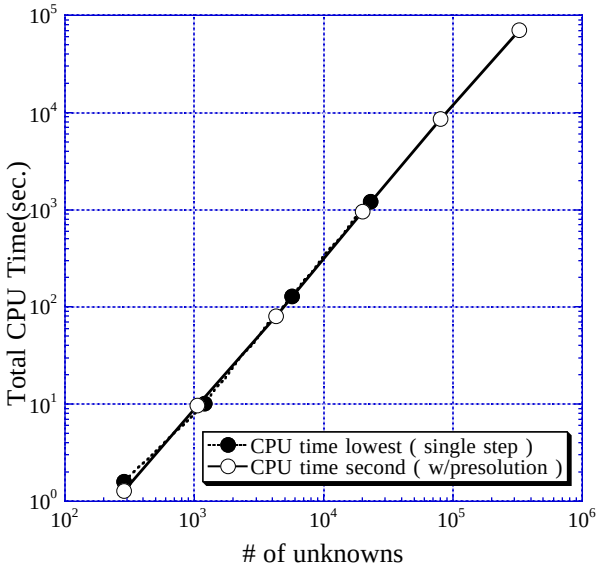

Fig. 6 CPU times as functions of the number of unknowns.

7 CONCLUDING REMARKS

After the improvement of initial vectors and parameters, the dipole problem with 324388 unknowns—23572 nodes, 46519 elements, 624 boundary points, 93662 point (including mid-line points generated internally)—takes about 20 hours for seven Eigensolutions. If FLO and FUP are given, the CPU time is reduced to about 70%. The most time consuming portion is the linear matrix solver. PCGM (Preconditioned Conjugate Gradient Method) with SOR as a preconditioner is currently used for the linear matrix solver. More efficient preconditioner will reduce the CPU time.

COMPUTING EIGENMODES IN HIGHLY LOSSY ACCELERATING STRUCTURES

S. Setzer*, T. Weiland
Darmstadt University of Technology, Fachbereich 18,
Fachgebiet Theorie Elektromagnetischer Felder, Schlossgartenstrasse 8, 64289 Darmstadt, Germany

Abstract

The numerical calculation of eigenvalues in structures containing high loss dielectric and permeable materials is of importance in the field of accelerators as well as in many other high frequency applications. While satisfying algorithms exist for loss free and small-loss problems, the numerical problem of highly lossy material insertion is still a big challenge. We examine the Jacobi-Davidson method that proves to be a rather suitable method for calculating a set of eigenvalues even in the case of highly absorbing materials. Furthermore, unlike the commonly used sub-space methods, this algorithm is not limited to calculate extreme eigenvalues only. It is also capable of finding the eigenfrequencies located around any user specified frequency. Another practical advantage of this method is the absence of parameters such as the upper limit for an eigenvalue spectrum.

1 INTRODUCTION

Many problems in the field of electroctromagnetic design require the determination of a set of eigenvalues and corresponding eigenvectors. In the absence of lossy dielectric and permeable material or even for small loss problems, existing algorithms are functioning satisfyingly. In the presence of highly lossy material new methods like the Jacobi-Davidson technique as shown in [1] must be used. This algorithm has been implemented in the eigenvalue module of the electromagnetic CAD software MAFIA which is based on the FI-Technique. Besides the basic theory we present results for typical accelerator components such as the preliminary model of a high order mode damped accelerating cavity built at Fermilab.

2 BASIC CONCEPTS

2.1 The FIT-Method

The formulations of the Finite Integration Technique (FIT) according to Weiland [2] provides a general spatial discretization scheme usable for different electromagnetic applications of arbitrary geometry. The so called Maxwell Grid Equations and the material relations are given in the following notation:

$$C\hat{e} = -\dot{\hat{\tilde{b}}} \quad (1)$$

$$\tilde{C}\hat{h} = \hat{\tilde{j}} + \dot{\hat{\tilde{d}}} \quad (2)$$

$$S\hat{\tilde{d}} = q \quad (3)$$

$$\tilde{S}\hat{\tilde{b}} = 0 \quad (4)$$

$$\hat{\tilde{d}} = \hat{\tilde{D}}_\varepsilon \hat{e} \quad (5)$$

$$\hat{\tilde{b}} = \hat{D}_\mu \hat{h}. \quad (6)$$

The geometry is discretized on a dual orthogonal grid system with the vectors of the electrical grid voltage $\hat{e}$ and the magnetic flux $\hat{\tilde{b}}$ located on the normal Grid G while the vectors of the electrical flux $\hat{\tilde{d}}$ and the magnetic grid voltage $\hat{h}$ are based on the dual Grid $\tilde{G}$. The analytical curl operator results in the curl matrices (C,$\tilde{C}$) and the divergence operator in the source matrices (S,$\tilde{S}$).
The presence of lossy dielectric and permeable materials can be included by introducing complex diagonal material matrices $\underline{\hat{\tilde{D}}}_\varepsilon$ and $\underline{\hat{D}}_\mu$. The eigenvalue equation can be obtained by combining equations 1 and 2 in the frequency domain with the now complex grid voltages $\underline{\hat{e}}, \underline{\hat{h}}$:

$$C\underline{\hat{e}} = -i\omega \underline{\hat{D}}_\mu \underline{\hat{h}} \quad ; \quad \tilde{C}\underline{\hat{h}} = i\omega \underline{\hat{\tilde{D}}}_\varepsilon \underline{\hat{e}}$$

$$\Rightarrow \underline{\hat{\tilde{D}}}_\varepsilon^{-1} \tilde{C} \underline{\hat{D}}_\mu^{-1} C\underline{\hat{e}} = \omega^2 \underline{\hat{e}} \quad (7)$$

2.2 The Jacobi-Davidson Method

The Jacobi-Davidson method as described in [3] is applicable to the standard as well as to the generalized eigenvalue problem with a complex system matrix. Here, we will only concentrate on the standard eigenvalue problem as it arises when using the FIT as presented above.
The idea of Jacobi-Davidson techniques is to generate a search subspace on which the projected eigenvalue problem of a now much smaller dimension is solved. This is the "Davidson" part and leads to an approximation for the eigenvalue and eigenvector of the unprojected problem. In the Jaccobi part of the algorithm, a correction equation is solved defining an orthogonal correction for the current eigenvector approximation. This correction is also used to expand the orthogonal search subspace.
Although no estimations of extreme eigenvalues are needed, there is a practical problem with the Jacobi-Davidson algorithm, namely the convergence towards a

* Work supported by DFG (GK-GRK 410/1)

specific eigenvalue. Usually one is interested in calculating a set of eigenvalues located around a user specified target which is more effectively done by using a modified method, the JDQR algorithm, as described in [4]. Here the Jacobi-Davidson method is used to generate a partial Schur-form for the standard eigenvalue problem. A explicit deflation technique is introduced which leads to a modified correction equation. After identifying the first eigenvalue, the speed of convergence towards the succeeding ones is increased by reusing already generated subspace information.

3 NUMERICAL RESULTS

The JDQR-algorithm, a modified version of the Jacob-Davidson method, has been implemented for rz-problems in the eigenvalue module of the electromagnetic CAD software MAFIA. As an example the preliminary design of a high order mode damped cavity developed at Fermilab [5] has been chosen. The damping of the unwanted higher modes excited by the beam itself is achieved by inserting rings of lossy dielectric and permeable material with $\underline{\varepsilon} = 5 - 5i$ and $\underline{\mu} = 100 - 3i$. The geometry of the cavity is shown in figure 1.

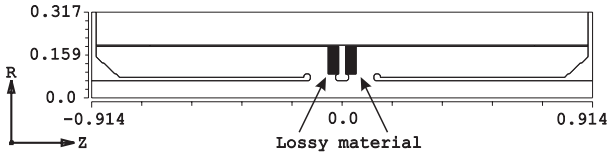

Figure 1: High order mode damped accelerating cavity

The first ten eigenmodes and the corresponding quality factors have been calculated , the results are summarized in table 1. To ensure that the lowest ten modes are identified, the user given eigenvalue target has been set to zero.

The speed of convergence for each eigenmode is depicted in figure 2. Usually, the identification of the first eigenfrequency takes more iteration then for the higher modes. This is due to the fact that subspace information generated for the first eigenvalue can be used to speed up the convergence of the following ones.

$Mode$	f_{re}/MHz	f_{im}/MHz	Q
1	54.608	0.657	41.56
2	63.723	15.888	2.01
3	64.833	16.357	1.98
4	87.578	1.902	23.02
5	98.203	36.505	1.35
6	98.278	36.606	1.34
7	137.547	53.701	1.28
8	137.630	53.829	1.28
9	171.255	52.872	1.62
10	171.340	53.066	1.61

Table 1: First ten Eigenmodes of a high order mode damped cavity

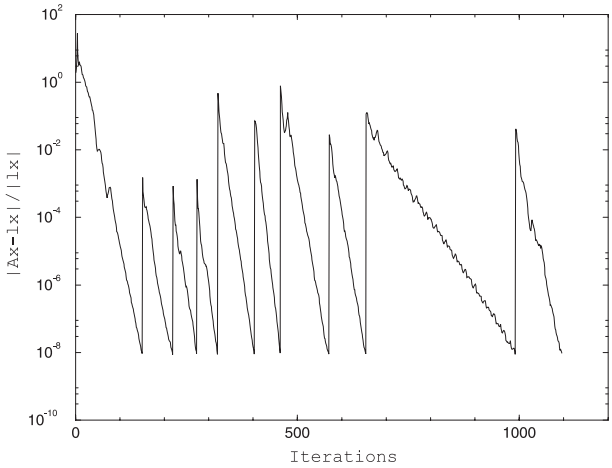

Figure 2: Relative error of eigenvalues vs. number of iterations

4 CONCLUSION

The Jacobi-Davidson method has proved to be a successful approach to the identification of resonating modes in structures containing highly absorbing materials. The algorithm is also capable of finding the eigenfrequencies located around an user given frequency which is useful for the examination of special frequency ranges. Another practical advantage of this method is the absence of parameters such as the upper limit for an eigenvalue spectrum.

SIMULATION RESULTS WITH AN ALTERNATE 3D SPACE CHARGE ROUTINE, PICNIC

N. Pichoff, J.M. Lagniel, S. Nath*
CEA-Saclay/DSM/DAPNIA/SEA,
* On sabbatical from LANL, Los Alamos, NM, USA.

Abstract

One of the major problems in the beam dynamics calculation dealing with high current linacs is the treatment of space charge effects. The widely used SCHEFF routine - originated and developed at Los Alamos, is often critiqued as being simplistic because of its inherent assumption of transverse symmetry. Here we report preliminary work on an alternate fully 3D space-charge routine for a bunched beam. It is a particle-in-cell approach based on numerical-calculation of the interaction between cubes (PICNIC). The principle underlying the method and the comparative results of simulation with SCHEFF and PICNIC are reported.

1 INTRODUCTION

Increase in the interest for high-current accelerators with very low loss-rate demands a high degree of confidence to the space-charge simulation tools. PARMILA is one of the more well known and widely used tools in the design of such accelerators [1]. Its space-charge routine, SCHEFF, is fast, but is not a fully 3D code. It assumes cylindrical symmetry around the longitudinal axis. We have written a new 3D space-charge routine, PICNIC, based on the same principle as SCHEFF, but making no assumption on the bunch shape. We made simulations with PARMILA, both with SCHEFF and PICNIC. Studies were done for the front section of the APT linac [2] (98 mA RFQ-output beam with energy form 6.7 MeV to 100 MeV) as well as in continuously linear focusing 3D channel (50 m, $k_{x0}=k_{y0}=k_{z0}=1\ m^{-1}$, with 10 space charge calculations per meter).

2 LIMITATION OF SCHEFF

In the SCHEFF routine the space is mapped with a 2D (r, z) mesh, r and z being respectively the radial and the longitudinal position in the beam. The number of particle in each elementary volume (a ring such that $r \in [r,r+\delta r]$ and $z \in [z,z+\delta z]$) is calculated, and the field induced by each ring, considered as uniformly charged, is computed at the mesh node. The field at each particle position is interpolated from that of the neighbouring nodes. Thus, SCHEFF is very well suited for transverse round-beam, but becomes increasingly inaccurate as when the transverse aspect ratio $\alpha = Y/X$, **X** and **Y** being respectively the x and y beam rms-sizes, differs significantly from 1, or when the beam has no cylindrical symmetry (e.g. in the RFQ output beam due to image charge forces).

In PICNIC, the space is mapped with a 3D (x, y, z) mesh. The number of particles in each elementary volume (cube) with $x \in [x,x+\delta x]$, $y \in [y,y+\delta y]$ and $z \in [z,z+\delta z]$ is calculated, and the field induced by each cube (considered as uniformly charged) is computed at the mesh node. The field at each particle position is then interpolated from those of the neighbouring nodes. No beam symmetry is assumed.

In figure 1 we represent the results of emittance-growth calculation of a non cylindrical ($X=Z=Y/\alpha$) beam (100mA, 6.7 MeV) in a continuously focusing channel ($k_{x0} = 1\ m^{-1}$). For both SCHEFF and PICNIC. The initial beam distribution is of type 8 in PARMILA (uniform); 9,000 particles are used. It clearly shows the problems with SCHEFF calculations for larger values of α. Simulations have also been done under the same conditions but with a transversally round beam ($X=Y=Z/\alpha$). In those cases PICNIC and SCHEFF give nearly the same results, i.e. those of fig.1.b.

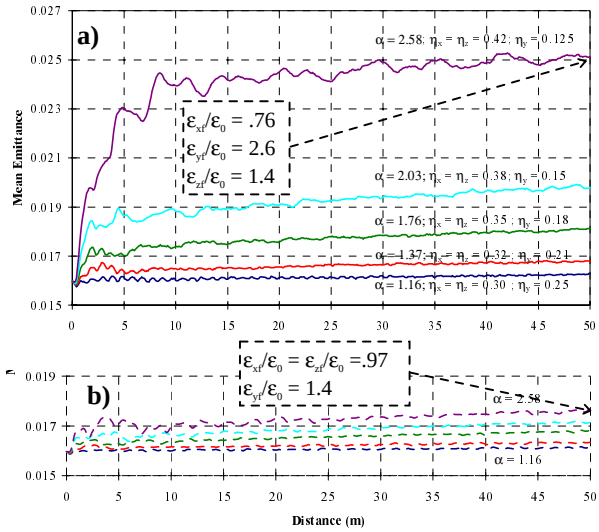

Figure 1: Emittance growth of non cylindrical beam in a continuously focusing channel. a) SCHEFF results, b) PICNIC results. We have Z = X.

The emittance growth observed at the beginning with PICNIC comes from the initial beam relaxation towards a space-charge equilibrium; the nonzero slope of the curves

is due to a poor statistics for this severely depressed-tune beam (see **§ 3.b**).

3 PICNIC PROPERTIES

a) Choice of the number of cells

With PICNIC, as with SCHEFF, one must choose number of cells ($\mathbf{N_c}$ is the half cell number) in each direction. The PICNIC mesh extends to ±3.5·X, ±3.5·Y and ±3.5·Z. Electric field at positions outside the mesh is calculated as that of a gaussian beam with the same rms-sizes. For example, a value of N_c=7 means step-size=.5X.

Figure 2 shows the transverse emittance growth versus N_c for 2 different particle number $\mathbf{N_p}$ (10K and 100K) for the APT linac at 100 MeV. It exhibits the existence of an optimised mesh number dependent on the number of particles used in the simulation.

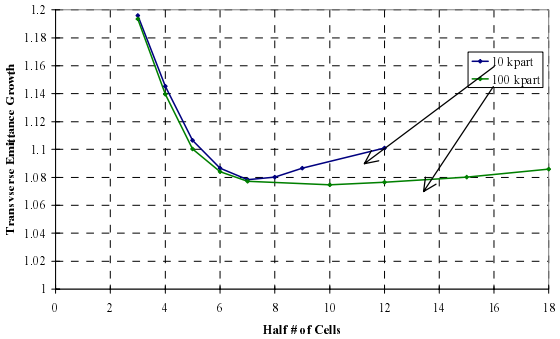

Figure 2: Emittance growth dependence on the number of cells and the number of particles.

When N_c is small, we have a lack of resolution inducing an emittance growth. When N_c large, the number of particles per cell is small inducing statistical noise and emittance growth, this is less sensitive with a higher number of particles. There is a optimum value for N_c, depending on N_p, which gives the best results. Choosing N_c=8 seems to be a good choice; it will induced an error lower than 1 %, whatever the particle number. However, results presented in **§4** in a continuous channel favour larger Nc.

b) Sensitivity to the statistics

When the beam is highly tune depressed, and the transverse and longitudinal temperatures are not the same (non-equipartionned), the rate of emittance growth per meter dε/dz in the direction with lower temperature depends on the number of particles. However, theoretically once at equilibrium (after some betatron periods), the beam should not undergo any emittance growth. This dependence on statistics is nearly the same with SCHEFF and PICNIC, it has been illustrated in fig. 3.

This results from an spurious exchange of energy between the "hotter" transverse direction to the "colder" longitudinal direction. This phenomenon has been demonstrated in [3]. A space-charge routine should therefore be validated in the context of "spurious collision" in order to avoid erroneous conclusion in term of equipartitioning. In all cases, however, it is better to work with large N_p. Even in such case, a very small emittance growth is observed. This is explained in **§4.c**.

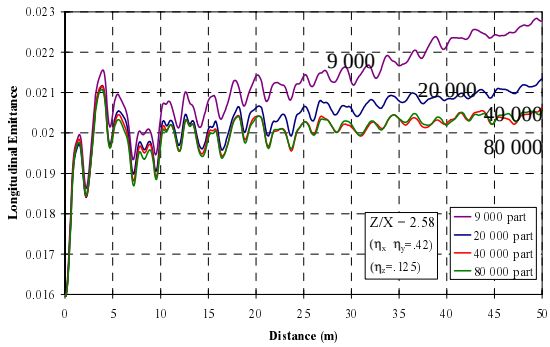

Figure 3 : Longitudinal Emittance growth of a highly tune-depressed beam, for different number of particles (PICNIC results) with X = Y = Z/2.58.

c) Computation time

Computation time for PICNIC and SCHEFF has been explored in terms of particles and cell numbers. They are represented in fig.4.

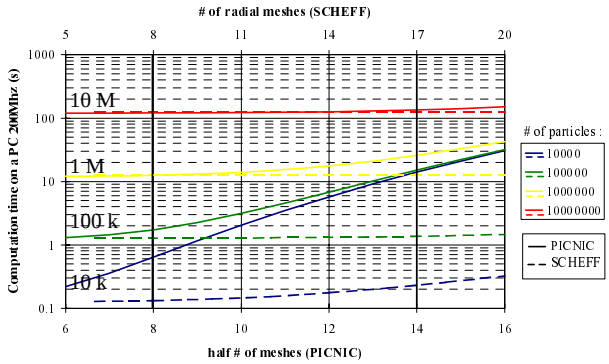

Figure 4: Space-charge computation time with a PC (fortran 77) for SCHEFF and PICNIC.

In a PIC code, one part of the computation-time depends linearly on N_p. It represents the time used to count the particles in the mesh cells (~10%), and to compute the field at each particle position (~90 %). This linear dependence can be seen when N_c tends to 0.

The other part of the computation-time depends on the method used to calculate the field at the mesh nodes. It depends only on N_c. For SCHEFF it is nearly proportional to N_c^4 and for PICNIC to N_c^6 ! New developments in PICNIC, not reported here, should reduce this part by a factor 5 to 10.

PICNIC computation-time is very reasonable with Nc=8. It is nearly the same as that of SCHEFF (with Nc=20) with more than 100,000 particles. Use of fully 3D

routines thus seems to be feasible even with a small computer (PC) !

4 LIMITATIONS

a) Highly tune-depressed beam emittance growth

The transport of a highly tune-depressed beam (η down to 0.1) has been studied in a continuous focusing channel with phase advance per meter without space-charge $k_0 = 1m^{-1}$. The initial beam is a uniform sphere (type 8), filled with 9,000 particles.

Simulations with PICNIC (fig. 5) and SCHEFF have shown a linear emittance growth, important for $\eta < 0.3$.

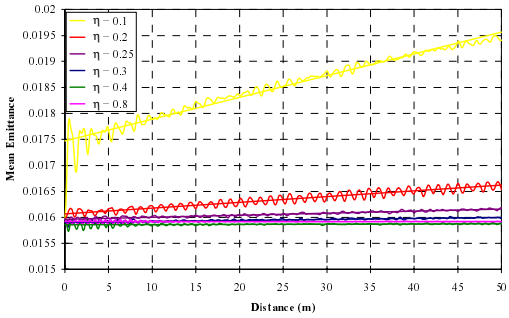

Figure 5 : Emittance growth observed with PICNIC for different tune depressions.

The growth rate (fig. 6) increases with the severity of tune-depression, and varies with the number of mesh: a large N_c seems to be better for η=0.2 (optimum for N_c=14).

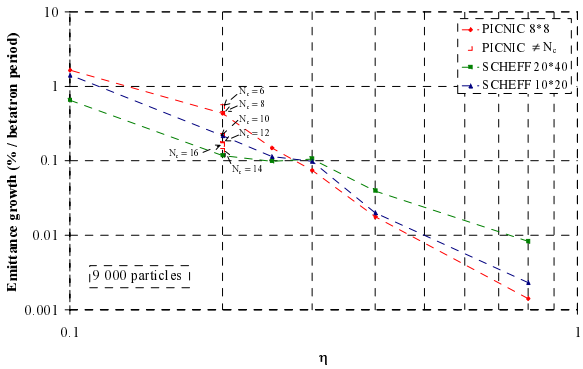

Figure 6 : Emittance growth rate in % per betatron period with depressed tune. Both PICNIC and SCHEFF results are shown

The origin of this observed emittance growth is under study. The growth-slope however quickly decreases when the beam density distribution is smoothed out. For example, the slope decreases by a factor ~3.5 when each cell is assigned the mean value of the neighbouring 27 ($=3^3$) cells with N_p=9,000 and N_c=8. It is independent on the initial beam distribution (as type 22 (~Water-Bag)) and the number of particles (up to 80,000).

b) Field calculation accuracy with small N_c

Figure 7 shows the space-charge field applied on the particles of a spherical Gaussian beam. Calculations were done with PICNIC and SCHEFF for 2 different N_c values and results are compared with the theoretical curve. With a too small value of N_c, the field is calculated as if the beam was less dense at the centre. This effect seems to be a common feature for all PIC routines; the same has been observed with the routine 3DPIC [4]. However, this seems to have a negligible effect on the emittance growth, but might change the space-charge equilibrium of the beam somewhat.

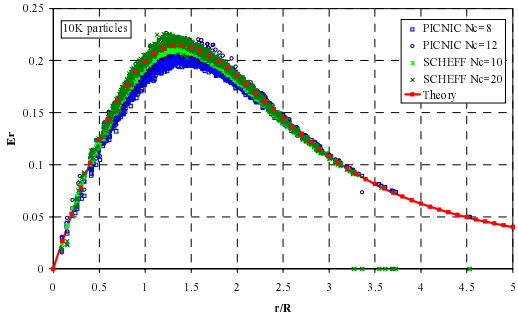

Figure 7 : Computed space-charge field on particles of a spherical Gaussian beam, compared with analytic prediction.

5 CONCLUSION

3D space-charge calculations appears to be realistic on a personal computer and PICNIC is a good candidate for this. It benchmarks very well with SCHEFF for test cases. It should be emphasised tha each space-charge routine needs to be carefully studied before application for appropriate parameters (i.e. N_c, N_p, number of space charge calculation per betatron period ...).

Some of the parameters could be used to quantify and compare the applicability of the routines, e.g. the coupling between directions (**§3.b**), the emittance growth per betatron period (**§4.a**), the computation speed (**§3.c**)... All these parameters depend on N_p and N_c (or parameters such as the screen distance in a PPI routine).

MUSTAFA-A TOOL FOR NUMERICAL SIMULATIONS OF THE BEAM BEHAVIOR IN A LINAC

G. Guignard, J. Hagel, CERN, Geneva, Switzerland

Abstract

MUSTAFA stands for **MU**ltibunch **S**imulation and **T**racking **A**lgorithm for **F**uture linear **A**ccelerators and provides an environment for tracking a multibunch beam accelerated in the linac of a collider. It is made of three parts: i) an interactive utility MBUNCH which allows to run the simulations, edit the input data, systematically vary some parameters, launch statistics on misalignment realisations and select the outputs, ii) the tracking program itself MBTR that includes magnetic focusing, acceleration, wakefields, misalignments and trajectory correction, and iii) a graphics facility called MOVIE that provides an animated representation of the transverse motion within each bunch of a train, either in the geometric space or in the phase space. While MBTR is written in FORTRAN, the other two codes are written in QUICKBASIC (MS V4.5). They run on PC Pentium computers in a stand-alone mode, independent of any network. Hence MUSTAFA is easily transportable and offers a unique graphics facility. It has been extensively used for multibunch simulations in the Compact Linear Collider scheme (CLIC) as well as for demonstrations of the beam behaviour in different stability or beam break-up conditions.

1 INTRODUCTION

The transverse oscillations of many bunches under the influence of longitudinal and transverse wake fields are of fundamental importance for beam stability in linear colliders. Since these oscillations are governed by many coupled forced-oscillator equations, their behaviour is generally complex and not yet completely understood. Simulation codes therefore are important to analyse the question of the bunched beam stability for various sets of linac parameters. MUSTAFA provides a user-friendly environment for such a tracking and result analysis. Only a short description of the three parts of MUSTAFA is given below and the potential user is recommended to look at the published MUSTAFA description and users' guide [1] for more details.

2 TRACKING CODE MBTR

The central piece of the MUSTAFA codes which have been written for beam tracking and multibunch simulations in a linac is the FORTRAN program named MBTR. This program is based on the MBTRACK codes [2], issued themselves from the single bunch tracking application MTRACK [3]. MBTR is a result of an evolution that followed the needs related to the CLIC studies and emphasizes portability as well as graphical visualization.

Since the beam of a linear collider is highly relativistic, the space charge forces can be neglected and the longitudinal positions along the bunches are fixed (no mixing). This has two impacts on the beam model. The absence of radial forces makes the use of a 3D-model with macro-particles unnecessary and each bunch can simply be longitudinally divided into elements with constant relative positions. The main parts of the numerical model are described below:

– The beam is a train of equidistant bunches. Each bunch is divided in turn into equidistant slices of width δ_z, small w.r.to the r.m.s. bunch length σ_z. Each slice is defined by the transverse positions of its center of gravity and its r.m.s. transverse dimensions deduced from the emittances. The charge per bunch is distributed in all slices according to a (truncated) gaussian distribution.

– Magnetic focusing is achieved by quadrupoles arranged in a FODO lattice that also includes drifts, accelerating structures, beam position monitors (BPM) and microwave quadrupoles (RFQ). There are two versions of the MBTR code which only differ by the way the focusing is scaled along the linac with the energy of the bunches. The first version called MBTRSCAL corresponds to a continous and adiabatic scaling (small steps not requiring any matching) while the second called MBTRSECT gives a more realistic lattice implementation, that approximates to the continuous scaling solution but is based on linac sectors with constant FODO geometry, joined by matching insertions.

– The RF system is characterized by a few parameters, such as the RF frequency of the fundamental accelerating mode ω_{RF} in s^{-1}, the RF wave length λ_{RF} in m and the maximum amplitude of the loaded acceleration gradient G_a in MV/m. The relative position of the bunch train with respect to the RF wave is defined by the phase ϕ_{RF} of the reference slice of the first bunch which is equal to zero at the peak of the wave. The phase ϕ_{RF} can be different in each sector and adjusted for optimum BNS damping. The relative phases of all the slices of the bunches are then calculated from this reference value and from the z-position of each slice resulting from the beam definition.

– Short-range wakefield Green's functions are computed with the code MAFIA [4] and defined as usual via the loss factors k_n and frequencies $\omega_n/(2\pi)$ of a large number of synchronous modes. The short-range, delta-function wake potentials are then given by the subsequent summation over these structure normal modes [5].

– Long-range wakefield Green's function is obtained either from an analytical approximation or MAFIA output data, that directly provides the field in the time domain, i.e. as a function of the distance behind a point-charge. Different models can be used. They all assume that beam loading in a train of bunches is compensated, but they differ by the

drop-off of the transverse wakefield behind bunch 1. Fig. 1 shows the Green's function of three particular models, two analytical ones based on piece-wise exponential decays and one numerical (termed here CG-DS) associated with individual damping of each cell and frequency detuning via linearly tapered iris dimensions. At the level of bunch 2, the wakefield is equal to 1 or 1.5 % of its maximum.

– The transport through the linac of the coordinates and geometrical emittances defined by the Σ matrix is done for every slice of each bunch, using the transfer matrices of the linac components. Hence, the slice emittance that includes the contribution of its off-set with respect to the average position of the train can be computed at any point s. Adding these contributions weighted by the slice population, gives the geometric emittance of a bunch or the whole train, depending on the selection. Calculating the (square root of the) determinant of Σ and multiplying by the Lorentz factor γ give the normalized bunch and beam emittances which are then used for further analysis.

– Trajectory correction is implemented in the presence of random misalignments of quadrupoles, accelerating structures and beam position monitors . It is based on a standard 'one-by-one' correction in which the beam is centred in a BPM by moving the preceding upstream quadrupole, taking into account the actual wakefields. A minimisation over several BPMs is also possible and errors in the measurements or in the displacements of the quadrupoles can be introduced.

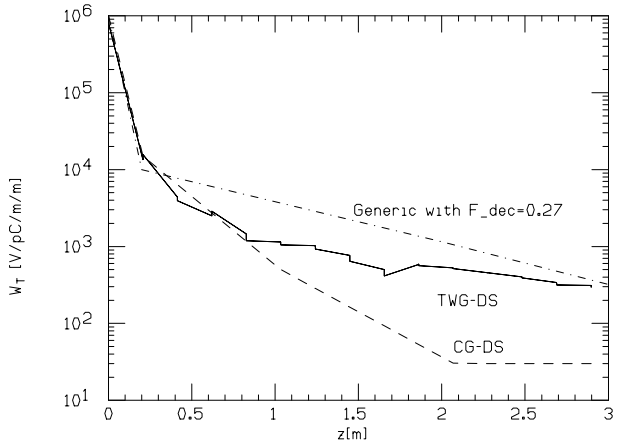

Figure 1: Long-range transverse wakefields in various CLIC structure models.

3 MBUNCH UTILITY

The MBUNCH program has been written to provide an effective and easy tool for working with the multibunch tracking code MBTR. It is fully menu driven and therefore self explanatory to a large extent, however, the basic parts are shortly described in this section.

MBUNCH handles the input and output of MBTR in an interactive way and allows to run the simulation code with specified input parameters. In addition, it postprocesses the output data providing both an online visualization of the results obtained and a statistical evaluation originating from many simulation runs. It also provides a link to the animated graphics facility which makes it possible to visualize a train of many bunches through the given linac. Finally MBUNCH gives the possibility to run either MBTRSCAL, the scaled lattice version of MBTR, or MBTRSECT, the sector lattice version of the simulation code (Section 2).

Like the simulation code MBTR, MBUNCH runs on IBM compatible PCs. It has been written using the language Microsoft Quickbasic V 4.5 [6] and is available in its executable form under the name MBUNCH.EXE. To run it efficiently together with MBTR and MOVIE, it is strongly recommended to use a PC with at least 16 Mbytes of internal RAM, a clock frequency of not less than 100 MHz, the available space on hard disk not being less than 30 Mbyte and a Pentium type processor. Although MBUNCH has been written under MSDOS (version 3.3 at least), WINDOWS 95 is well suited to run the code starting either in an MSDOS window or directly from Windows 95 Explorer.

The main menu of this program appears as:

```
****************************************
*  MUSTAFA -MULTIBUNCH SIMULATION      *
*      AND TRACKING ALGORITHM          *
*                                      *
*      G. GUIGNARD , J. HAGEL          *
*                                      *
*   (Version 1.0 , January 1998)       *
****************************************

Edit the input CLIC(SCAL)SECT.INP.... <===
Run the simulation ..................
Look at the output summary ..........
Look at the emittance graphs ........
Vary an Input parameter .............
Run the movie .......................
Save Results on Subdirectories ......
More ................................
End .................................

Pick an option via the cursor UP/DOWN keys
and  execute the command with the ENTER key.
```

The first command enables the user to interactively change the input file via the KEDIT editor and displays a copy. The second command runs the requested simulation and produces the following files: i) a summary of the results with the echo of the input data that can be displayed via command 3, ii) four files containing the orbits and emittances as functions of position s for the first, an intermediate, and the last bunch as well as the whole train (graphs previewed with command 4, see example in Fig. 2. Command 5 varies any single input parameter within specified limits and steps, providing four files [as under ii)] with the vertical emittance versus this parameter, that can be displayed. The next command initiates the 'movie' (animated graphics) described below and the last one stores all the generated files in a sub-directory for later use. Commands 4 to 6 open (mostly self-explanatory) sub-menus.

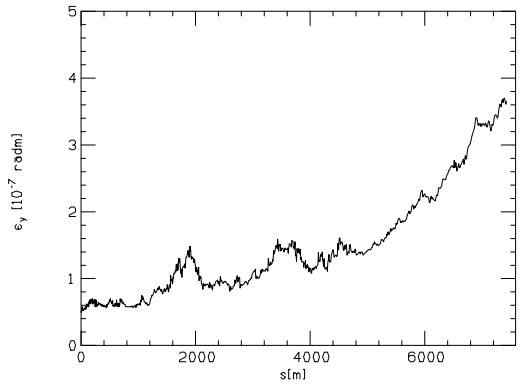

Figure 2: Vertical emittance growth averaged over a train of 10 bunches, along the 1 TeV linac, in the presence of a weak instability due to long-range wakefields

4 MOVIE FACILITY

The idea of the MOVIE code is to have a tool for direct visualization of transverse bunch oscillations as the train passes through all the parts of the linac. This helps to understand the instability mechanisms as well as the attempts to correct them. The MOVIE code shows the vertical oscillations (the most important for the flat beams of linear colliders) of all the slices of all bunches along the bunch coordinate z in the form of an animated graphics (real time corresponding to s). It uses an input file containing all the coordinates of all slices of all bunches along the entire linac (at every quadrupole position). This input file (CK.OUT) has to be created by the simulation code MBTR before MOVIE is run. Up to five bunches can be seen at any one time on the screen and it is possible during one run to scroll along the train using the right and left arrow keys. MOVIE van visualize bunches of up to 50 slices. The program MOVIE, as well as MBUNCH has been written using Microsoft Quick Basic (V. 4.5) [6] and can be run on any PC after importing and starting the executable file MOVIE.EXE. It can be run independently or via the MBUNCH utility which provides a comfortable way to launch it. The sub-menu for the 'movie' appears as:

```
   MOVIE SHOWING THE MOTION OF THE
        BUNCHES IN THE LINAC

Use the File CK.OUT created by the
stand alone program ................. <===
Use a different File ................
Run the Movie .......................
Preview the Frozen Pictures .........
Return to main menu .................
```

The proposed commands run the MOVIE facility from the last CK.OUT file created by MBTR simulations or from previously stored MOVIE-files with different names but the same extension. Command 3 initializes the animated graphics routine itself, requiring the full screen, using colors and displaying the bunch slice positions at successive quadrupoles at a nominal speed of 10 frames/s, giving the feeling of oscillating bunches with time when they travel down the linac (the related s-values appear on the screen).

The movie can be run with or without the subtraction of betatron motion, in the geometric- or phase-space, and offers on-line options to change the animation speed, stop on an image and save it in a file for later viewing with a graphics package. Figs 3 and 4 show examples of such frozen pictures in the geometric- and phase-space respectively, generated for a CLIC main beam. In the animated graphics, rapid succession of pictures of Fig.3-type gives the sensation of the oscillatory motion of the bunch tails. Colors are used to represent the particle gaussian distribution in a bunch (e.g. 'red' for the dense core and 'blue' for the tails).

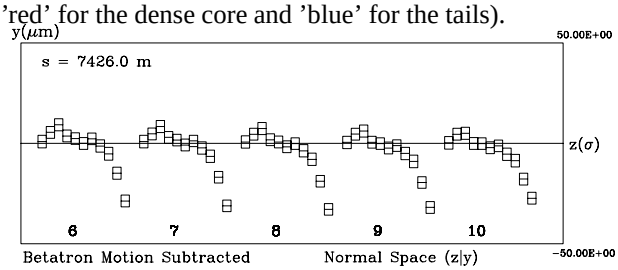

Figure 3: Vertical off-sets of the last five bunches at the linac end, for the same weak instability as in Fig. 2.

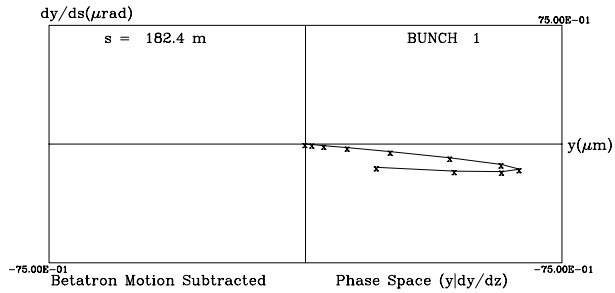

Figure 4: Vertical coordinate off-sets of bunch 1, in the phase space, at the linac beginning and with BNS damping.

5 CONCLUSION

The MUSTAFA programme 'trilogy' has proved to be user-friendly and very useful for both the design of the CLIC linear collider and the definition of the required parameters or tolerances. It also provides a practical graphic illustration of the possible single-bunch or multi-bunch instabilities. Its modularity makes additions easy and its portability has showed to be extremely convenient when movie-examples are projected during seminars or conferences. The code is available on request to any potential user.

SIMULATION OF HALO FORMATION IN BREATHING ROUND BEAMS IN A PERIODIC FOCUSING CHANNEL*

Zhibin Huang, Yinbao Chen
China Institute of Atomic Energy, Beijing 102413

Abstract

Halo formation in high-intensity axisymmetric beams in a periodic focusing channel is analyzed using particle-in-cell simulations. In order to explore self-consistently the fundamental properties of breathing round beams propagating in a periodic focusing channel, the initial phase-space distribution of a beam injected into a linac is adopted to be a sufficiently realistic distribution such as Gaussian, waterbag and parabolic. Numerical results such as halo intensity and emittance growth are obtained by means of multiparticle simulations.

1 INTRODUCTION

Recent interest in using high-current ion linacs for production of tritium, the transmutation of nuclear waste, etc. has enhanced activitities for halo study. It is necessary to understand mechanisms of intense-beam losses, especially, beam instabilities and halo formation, because machines must operate with a very low beam losses to avoid serious radioaction.

K-V distribution of particles in transverse phase space is used to adopt to predict the behavior of real beam in most theoretical studies [1,2]. Because K-V beam density is uniform, then space-charge forces are linear. Particle-core model has contributed to an understanding of the underlying causes of halo formation from mismatched beams [3-6]. In order to obtain more meaningful simulation results nonlinear particle-density distributions are adopted in a uniform channel [7-11], the codes calculating space charge have been replaced by those with more simple and accurate representation of practical distributions [12,13]. Moreover, it is important to understand the mechanism of halo formation in a periodic focusing channel, since the periodicity of the external field can cause a strong resonant instability [14,15]. The chaotic behavior caused by structure-driven resonance has recently been studied and connected with halo formation [16-19]. We had investigated the mechanism which enables some particles to escape from deep inside core in a uniform channel [11]. In present paper, we discuss the properities of halo formation in breathing round beams in a periodic focusing channel.

We first describe the simulation method in section 2, then apply the code to the phase-space distributions and obtain some simulation results in section 3.

2 SIMULATION METHOD

The Hamiltonian of the transverse motion is given by

$$H_\perp(r,r_\perp;z)=r_\perp^2/2+\kappa_z(z)r^2/2+q\phi(r,z)/\left(m\gamma^3\beta^2c^2\right), \qquad (1)$$

where m, q, βc denote, respectively, the ion mass, charge and longitudinal velocity, $\kappa_z(z)$, whose profile is shown in Fig.1, is the periodic function representing the variation of the focusing strength, and z is the distance measured along the beam line. $\gamma=\left(1-\beta^2\right)^{-1/2}$, $r=\left(x^2+y^2\right)^{1/2}$ is the distance from the z-axis in the transverse plane, and $r_\perp=\left(x'^2+y'^2\right)^{1/2}$ is the dimensionless transverse velocity with $x'=\dot{x}/\beta c$, $y'=\dot{y}/\beta c$, $\phi(r,z)$ is the space charge potential, which must meet with the Poisson eqution:

$$\nabla^2\phi(r,z)=-\frac{q}{\varepsilon_0}\iint f\left(r,r_\perp;z\right)d\bar{r}_\perp\,, \qquad (2)$$

where $f(r,r_\perp;z)=f(x,y,x',y';z)$ is the distribution function in the transverse nonrelativistic four-dimensional phase space.

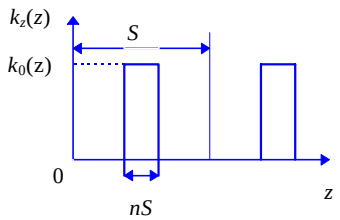

Figure 1: The profile of solenoidal periodic focusing field

All distributions that are function of the transverse Hamiltonian $H_\perp$ are stationary for a uniform focusing channel because $H_\perp$ is a constant of motion in this case. However, in the case of periodic focusing channels $H_\perp$ is no longer constant, and the only stationary state for which an analytic representation could be found is the K-V distribution. For a more general investigation one must rely on numerical simulations by means of adopting nonstationary distributions. Here nonstationary distribution functions used in computer simulation studies are defined as functions of the radius in four-dimensional trace space and not as functions of the Hamiltonian $H_\perp$. For a detailed discussion of nonstationary distributions see [20].

In order to compare different distributions on the same basis, we consider rms-equivalent beams which have the same perveance, rms radius, and rms emittance. To obtain the rms radius, we introduce the envelope eqution:

$$\frac{d^2a}{ds^2}+\kappa(s)a-\frac{\Lambda}{a}-\frac{1}{a^3}=0\ , \qquad (3)$$

where a, Λ and $\kappa(s)$ are dimensionless variables: $s=z/S$, $\Lambda=KS/\varepsilon$, K is the generalized perveance, ε the emittance and S is the periodic length of a single focusing cell, and $\kappa(s)=\kappa_z(z)S^2$. The matched normalized radius $a_0(s)$ can readily be derived from Eq.(3) when Λ and $\kappa(s)$ are determined. The vacuum phase advance over one axial period of such a focusing field is approximately given by $\sigma_0=\left[\int_0^1\kappa(s)ds\right]^{1/2}=\left[nk_0(z)\right]^{1/2}$. Then we notice that $a_0(0)$ corresponds to the minimum radius of a matched beam because the original coordinate is located at the center of a drift.

We determine the mismatched initial phase-space distribution $a_i=\mu a_0$, $a'_i=a'_0/\mu$, where a_0, a'_0 correspond to the matched one, and mismatch parameter $\mu\le 1$. The radial space-charge field of an axisymmetric beam can be calculated from Gauss law by counting the number of particles in cells of a finite radial grid which extends up to 5 times the beam matched radius. We monitor the total energy through the transport channel, and keep the total energy constant. Here we employ 10^4 particles and 100 radial meshes over the length $a_0=a_0(0)$.

3 NUMERICAL SIMULATION RESULTS

We take into account the transport channel with enough length so that the beam reaches saturated states before arriving at the exit. Here the filling factor n seen in Fig.1 is 40 percent of the length of a single cell.

If an input beam is perfectly matched to a transport system, there is no reason to expect the growth of a halo unless the distribution is intrinsically unstable against perturbation or there is structure-driven resonances. However, it is impossible to provide a perfect beam, actually, there is an inevitable initial mismatch which generates a halo.

We perform multiparticle simulations, to consider a beam as realistic as possible, several different types of initial phase-space distributions such as Gaussian, parabolic and waterbag distributions are adopted.

3.1 Emittance growth of various nonstationary distributions

To consider a beam as realistic as possible, several various initial phase-space distributions such as Gaussian (GA), parabolic (PA) and waterbag (WB) distributions are adopted to estimate emittance growth. Figure 2 shows emittance growth defined as the ratio of the final rms-emittance to the initial rms-emittance vs the cell number of the transport channel for tune depression η=0.4, which is defined by $\eta=\sigma/\sigma_0$, where σ is the space-charge phase advance over one axial period of such a focusing field and σ_0=75°, and different mismatch parameter (a) μ=0.7, (b) μ=0.8. From Fig.2 we can find that the more realistic the distribution is, the smaller the ripple of emittance growth changes through the transport channel.

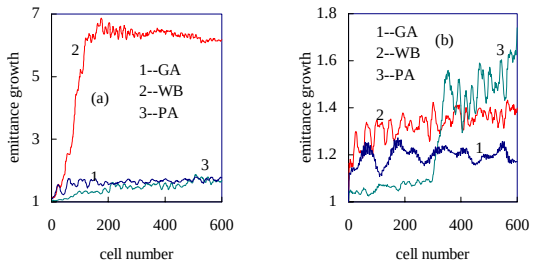

Figure 2: Emittance growth of various distributions vs cell number for (a) μ=0.7, (b) μ=0.8.

3.2 The structure-driven resonance

The periodicity of the external field can cause a strong resonant instability. Since the unstable particles can easily escape from the core getting a large betatron amplitude, it is necessary to investigate halo formation mechanism in the structure-driven instability. The instability growth rate increases with increasing σ_0, and at sufficiently high values of σ_0 there is an intensity threshold beyond which the beam is unstable for all values of $\sigma\to 0$ [20], that is to say, the second-order even mode occurs from the Vlasov equation perturbation analysis. For σ_0>90° and sufficiently large Λ, the envelope oscillations become chaotic for some mismatched beams [17].

Figure 3(a) shows emittance growth of rms-matched beams with Gaussian distribution, the phase advance without space charge is fixed at 105^0. We find emittance growth rises rapidly from η=0.23 to η=0.25, there is the region where the second-order even mode exists. The beam is trapped by the second-order resonance in the phase-space configuration shown in Fig.3(b).

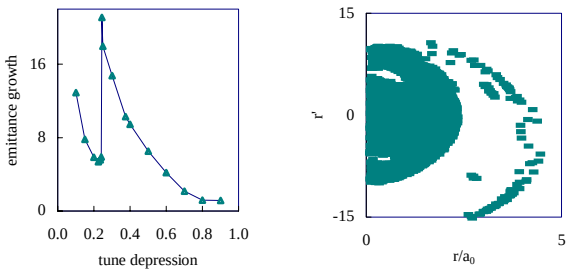

Figure 3: (a) Emittance growth of rms-matched Gaussian beams vs η and (b) phase-space distribution of rms-Gaussian beam at cell number=600 and η=0.245.

3.3 Halo intensity and the maximal radial extent

We firstly consider mismatched beams with Gaussian distribution, the phase advance without space charge is 65°,75°, 85°, respectively. The number of particles which go into the halo seen in Fig.4, gets rather small as mismatch parameter μ tends to 1.0. Here we define halo intensity *h* as the number of particles outside the boundary $r_b=1.75a_0$ divided by all of particles we employ.

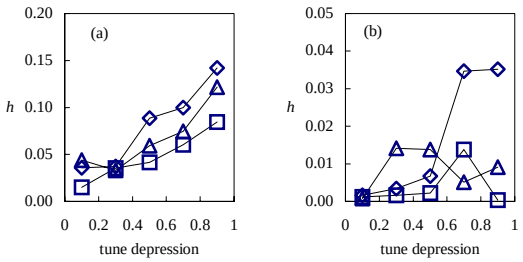

Figure 4: Halo intensity vs η for mismatch parameter (a) μ=0.6, (b) μ=0.8, with different σ_0: ◊-85°, Δ-75°, -65°.

In addition, let us look at Fig.5 where the maximal radial extent r_{max} has been displayed. It is obvious that the maximal radial extent is almost independent of σ_0, but the maximal radial extent is larger as mismatch parameter is lower than 1.0.

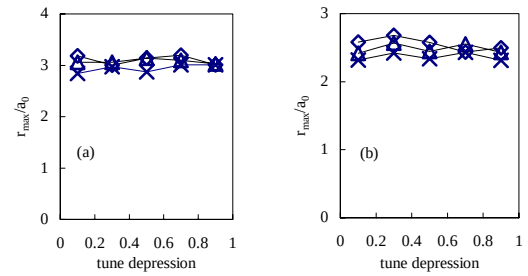

Figure 5: Ratio of the maximal radial extent to radius of matched beam vs η for mismatch parameter (a) μ=0.6, (b) μ=0.8, with different σ_0: ◊-85°, Δ-75°, ×-65°.

4 CONCLUSIONS

It has been confirmed that the periodicity of the channel induces resonant instibility in some region. There is no prominent emittance growth in the region when σ_0<90°, however, the strong instibility, especially the second-order resonance, occurs when σ_0>90°, and emittance growth is very large. Therefore, we do our best to set σ_0 at a value below 90° in a linear transport design. We can also set σ_0 above 90°, but we need to select the region where there is no resonance.

Simulation results show halo intensity and maximal radial extent are more increased as the magnitude of initial mismatch increases, and they is not dependent of the tune depression when σ_0<90°.

ACKNOWLEDGEMENTS

The authors thank professor Robert L. Gluckstern for helpful discussions and guidance. The authors also want to thank Dr. M. Ikegami for useful communications.

BEAM DYNAMICS IN A HIGH CURRENT SC PROTON LINAC FOR NUCLEAR WASTE TRANSMUTATION

G. Bellomo, P. Pierini,
INFN Milano - LASA, Via Fratelli Cervi, 201, I-20090 Segrate (MI), Italy

Abstract

INFN is studying a 100 MeV to 1.6 GeV high current (25 mA) proton linac for waste transmutation and energy production. The beam dynamics in the superconducting linac have been studied with multiparticle tracking codes. The results of this activity will be presented here, with a description of a simulation code that we are developing for space charge dominated beam dynamics.

1 THE LINAC DESIGN

INFN has started a two year program (TRASCO) for the design study and for R&D on components of a high power superconducting proton Linac for nuclear waste trasmutation. The status of the program is reported in a separate contribution at this Conference [1].

The 352 MHz superconducting linac, operating at 25 mA in the energy range 100-1600 MeV, uses five cell elliptical cavities designed for synchronous β of 0.5, 0.65, 0.85. The rationale of this choice, based on the efficiency of the cavities, has already been presented in Ref. [2].

The peak energy gain in the cavities, at the nominal synchronous phase ϕ_s=-30 deg, is 4, 6.5 and 10 MeV, respectively. The cryostats accommodate 2, 3 and 4 cavities in the three sections.

The transverse focusing is provided by a periodic array of quadrupole doublets, and the cavity cryostats are placed in the drift between the doublets. The lengths of the focusing periods are 8.0, 11.2 and 15.3 m.

The lattice parameters have been chosen so that the zero current phase advances in the first period of each section are close to 90 degrees and the tune depression is around 0.7.

The quadrupoles in each section have an almost constant gradient, so that the transverse phase advance is smoothly decreasing at approximately the same rate of the longitudinal phase advance.

The matching between sections is controlled with the gradient of the doublet at the interface and the tuning of the synchronous phases of the cavities close to the interface.

The rms beam sizes along the linac are shown in Figure 1. The input rms emittances are 0.4 π mm mrad and 0.2 π deg MeV.

Since the beam pipe radius is 100 mm the ratio between the aperture and the rms beam size is larger than 25 and reaches the value of 40 at the end of the linac.

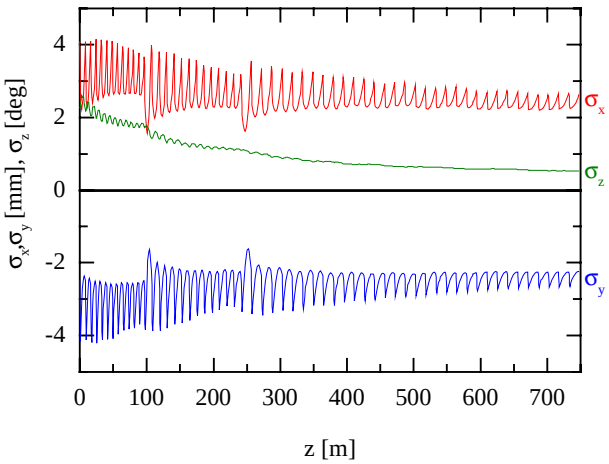

Figure 1: Rms beam sizes along the linac. On the positive ordinates: horizontal and longitudinal, On the negative ordinates: vertical.

2 MULTIPARTICLE SIMULATIONS

2.1 Initial results

Initial multiparticle tracking has been performed with a preliminary version of a code we are developing, using a limited number of particles (up to 5000) and space charge calculations via a direct point-to-point scheme. The results, reported at EPAC 98 [3], are summarized here.

For the rms emittances assumed in these simulations, 0.2 π mm mrad and 0.2 π deg MeV, an increase of 70% of the transverse rms emittances and a decrease of 40% longitudinal emittance was observed. The growth occurred mostly in the first linac section (100-200 MeV). Using as a guideline the equipartitioning criteria two alternatives were found to limit the emittance growth:

- a decrease of the period length of each section (this can be reached with 1, 2, 2 cavities per cryomodule in the sections, but results in a linac lengthening);
- an increase by a factor two of the transverse rms emittances. The beam sizes increase approximately by 50%, but the ratio aperture to rms is still larger than 20.

The latter solution, presented in Figure 1, has been chosen to be explored in more detail with the enhanced capabilities of the code, using up to 10^5 particles, and will be reported in the following subsection.

The first solution will be examined in the future, in connection with the foreseen increase of the current up to 50, or even 100 mA [1].

2.2 The multigrid code

A multiparticle beam dynamics code has been developed for the SC linac simulations. The particles are advanced through direct integration of the equations of motion along a beamline composed of quadrupoles, drift spaces and RF cavities.

The on-axis longitudinal field of the cavities is either assumed as an analytical expression for an ideal cavity or provided as an input. An iterative method to set the RF field phases of each cavity to the synchronous values, defined at the cavity center, has been implemented.

Space charge kicks are applied every few integration timesteps. A 3D space charge routine based on a fast multigrid[4] Poisson solver and a Cloud in Cell (CIC) charge assignment algorithm have been implemented in the code. The charge distribution is evaluated in the reference particle rest frame, using a CIC density smoothing algorithm. The Poisson equation for the electric potential is then solved on a square mesh (typically consisting of 33x33x33 points, extending at least to 6 rms) using a fast multigrid solver. The electric field in the rest frame is then computed from the potential, transformed to the laboratory frame and the corresponding kick, interpolated from the grid values, is applied to each particle of the beam.

Multigrid methods are surely among the fastest iterative methods for the solution of elliptic problems[4]. The model problem is represented on a series of coarser grids, obtained, for example, doubling the mesh size. Appropriate operators allow to "transport" the information (i.e. the source term, the residuals or an estimate of the solution) down one coarser grid level ("coarsening") or up one finer grid level ("prolongation"). The approximate solutions at each grid level are then used to form a better solution of the problem on the finest. The approximate solutions at each grid level are obtained with a few cycles (2-4) of an ordinary relaxation method (here the Gauss-Seidel algorithm).

The multigrid scheme makes use of the smoothing properties of relaxation schemes: the high frequencies (relative to the grid in use) of the error decay very rapidly. This, together with the use of a hierarchy of coarser and coarser grids, allows a very effective improvement in the convergence with respect of a standard relaxation scheme on a single grid, which has to face a poor performance with the smooth components of the error. V-cycle multigrid schemes converge (to 10^{-6} in norm) in 4 to 6 iterations, independently from the grid size.

A further acceleration in the convergence to the required accuracy for the space charge fields in a beam dynamics code is the use of the potential map evaluated in the previous space charge step, in order to have a better initial guess for the unknown potential.

The multigrid Poisson solver has been employed for beam dynamics simulations with up to 10^5 particles for the 750 m TRASCO linac, as reported in the following.

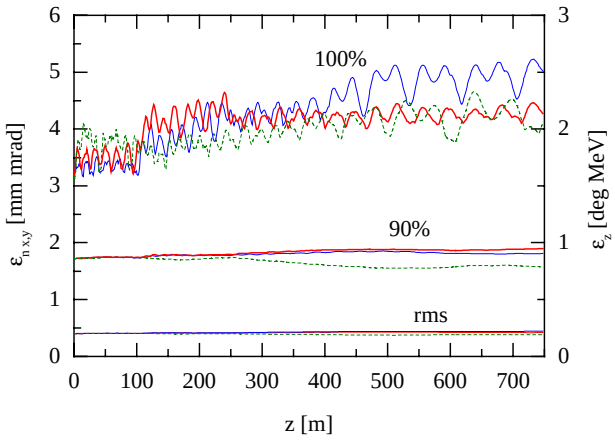

Figure 2: The rms, 90% and total (100%) normalized emittances along the linac. Solid curves (left axis): transverse emittances; dashed curve (right axis): longitudinal emittance. 10^5 particles in the simulation.

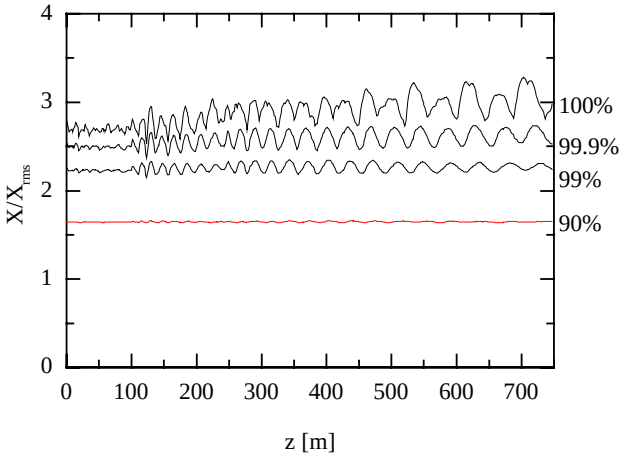

Figure 3: Ratio of the horizontal beam size to the rms value along the linac, for different beam fractions (10^5 particles in the simulation).

2.3 Matched beam case

The simulations with the multigrid code, using 10000 particles, have confirmed the results obtained with the point to point space charge routine. Simulations with 10^5 particles were then performed to explore in more details the tails of the beam distribution.

The simulations discussed here have been performed using a 6D waterbag distribution for the particle loading with a quiet random number generator [5]. However, more particle loading options still need to be implemented in the code, in particular the stationary distributions described in Ref. [6].

The input rms beam Twiss parameters and the matching conditions for the section transitions have been calculated with a linear space charge code [7].

The evolution of the rms, 90% and total emittances along the linac is plotted in Figure 2. The rms emittance growth is less than 10%.

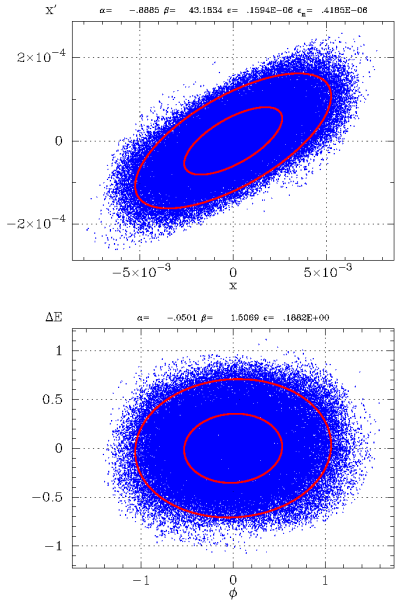

Figure 4: Transverse (upper) and longitudinal (lower) phase space projections at the end of the linac (1.6 GeV). Also plotted are the rms and the 90% beam ellipses. The simulation has been performed with 10^5 particles. Units are m, rad and deg, MeV.

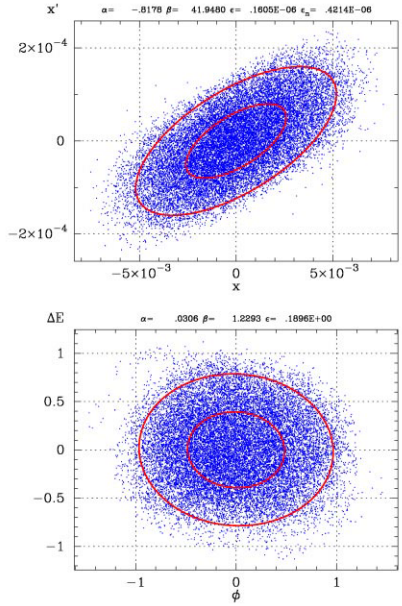

Figure 5: Transverse (upper) and longitudinal (lower) phase space projections at the end of the linac for an initial mismatched beam (10% in x,y and z). The simulation has been performed with 20000 particles. Units are m, rad and deg, MeV.

The increase of the total emittance is moderate (less than 50%), so that the ratio total/rms grows approximately from 8 to 12. The discontinuity at the interface between section 1 an section 2 (approximately at z=100 m) can be seen from Fig. 2.

The regular behavior of the beam is more apparent in Fig. 3, where we plot the ratio X/Xrms corresponding to various beam fractions. The 100% beam size is remarkably constant in the first linac section (up to z=100 m), indicating, in our opinion, a good matching of the beam distribution in the linac. In the second and third linac sections the betatron oscillation of the beam tails (99% and beyond) can be clearly seen, indicating a mismatch of the tails of the distribution. Similar plots can be shown for the vertical and longitudinal distributions.

A close examination of the phase space projections at the end of the beamline, see Fig. 4, show the formation of beam tails, in both the transverse and longitudinal planes. The deformation of the phase space is also evident looking at the beam fraction outside the 90% ellipses.

2.4 Initial beam mismatch

Simulations with a 10% mismatched initial beam (in a single plane and in all planes) have been performed with 20000 particles. No appreciable variations of the rms beam emittances have been observed. The total beam emittances increase by 20% with respect to the matched beam case, in agreement with similar calculations [8].

The phase space projections for a mismatch of +10% in the three planes are shown in Fig. 5; signs of filamentation in the longitudinal plane are barely visible.

3 CONCLUSIONS

The beam dynamics multiparticle simulations of the linac, using up to 10^5 particles, have shown a modest 10% increase of the rms emittances and a good behavior of the total beam sizes and distribution along the linac.

Initial calculations with mismatched input beams (10%, in one plane or in all planes) have shown a remarkable stability in the rms emittances, with no significant sign of halo development.

A revision of the linac design will be undertaken in the future to increase the current up to 50 mA and to explore the constraints imposed by the 100 mA operation.

SIMULATIONS OF THE NONLINEAR TRANSVERSE RF FIELD EFFECTS ON THE BEAM DYNAMICS IN LOW ENERGY X-BAND SW LINACS*

Sun Xiang and Lin Yuzheng
Department of Engineering Physics, Tsinghua University, Beijing 100084, PRChina

Abstract

The detailed beam dynamics simulations in a low energy X-band SW linacs are presented. The codes *CAV* and *TRACK* are developed. They are used to investigate beam dynamics in a model structure including the nonlinear transverse RF fields. Examples are given of the study of transverse effects in different cavity shapes and in different synchronous states. The results are compared and found to agree well with those from analyses.

1 INTRODUCTION

In ref.[1], we discuss the RF fielde nonlinear effects on the emittance dominated beam in low energy linacs analyticly. In low ernergy linacs, the initial phase region of captured particles is very large and usually in the decelerating region. From the simply theory, the nonlinear transverse effects on the beam is associate with the relative radial positon of particles, the nonlinear components of RF fields and the synchronous state between particles and RF fields. The RF nonlinear transvers effects on the beam and the emittance growth mainly occurs in the first cavity, especially over the decelearting phase region. These effects weaken quickly and vanish in the quasi-synchrous section and synchrous. In the symmetric π mode cavities, the nonlinear components of RF fields are least. But the nonlinear effects on the beam in an assymetric first cavity can be less than the beam with the same initial phase in a symmetric one.

A few formulas for longitudinal and transverse dynamics have been derived including bunching, accelerating and higher space harmonics. The results of the theory should be compared with the ones of simulation to test and verify this theory.

We mainly concentrate on the first cavity in simulation.

2 MODEL

A model linac structure is considered to compare the analysis of this structure by the methods in ref.[1] with the numerical simulation by *CAV* and *TRACK*. In order to amplify the effects of the nonlinear RF fields, a larger beam radius and RF power are chosen. This model structure opperates in *9300MHz* and consists of *8* cavities (shown in Fig. 1). The microwave power inputed in the structure is *1.1MW* and the initial *rms* normalized tranceverse emittance of the electon gun is *12.02mm.mrad*. The initial phase region of captured particles is from -150^0 to -30^0.

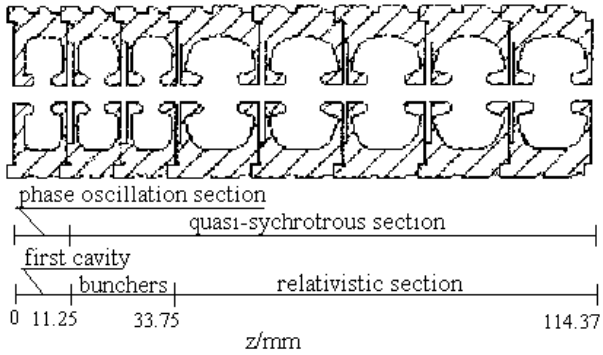

Fig. 1 Schematics of the model structure

3 DESCRIPTION OF THE SIMULATION CODES

The RF fields in the linacs are calculated by CAV. TRACK is coded by multi-particle tracking and calculates the beam dynamics including the nonlinear RF fields. It uses the time as independent variable and calculates the effects of Coulomb interactions among the electrons by variable-radius-disc model[2]. The electrons are emitted randomly with a profile that can be arbitrary distribution in radius. Both forward and backward particles are tracked. We introduce *power distribution factors* to TRACK to changing the RF field distribution conveniently.

4 EMITTANCE GROWTH

4.1 Emittance Growth Occurs in the First Cavity Mainly

The rms normalized emittances at the entrance of the model, at the exit of the first cavity, at the exit of the bunchers and the exit of the model are calculated separately. From simulation results (shown in Fig. 2), we can see the emittance growth due to RF nonlinear fields occurs in the first cavity mainly. The drop of emittance at the exit of the model whose initial phase is -150^0 results

*Work supported by the National Science Foundation of China

from the particles loss on the wall. So we concentrate on the first cavity when investigating the emittance growth.

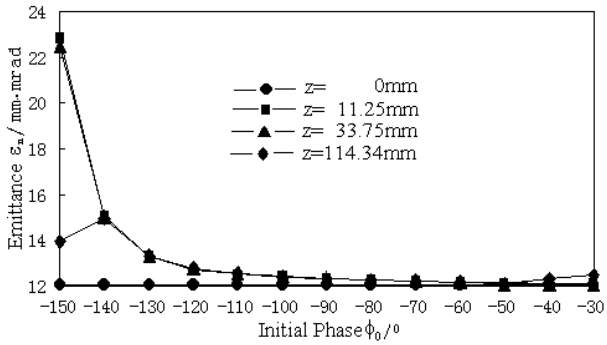

Fig. 2 Comparison of ε_n at different cross section

4.2 The Influence of the Cavity Shape

The nonlinear transverse effects on the beam is associate with the nonlinear components of RF fields which are deceded by the cavity shape. The RF fields in the assymetric cavity lift slowly along the axis and the decelearting for the particles in the asymmetric cavity is smaller than the particles with the same initial phase in the symmetric cavity (shown in Fig. 3). The emittance growth in the asymmetric cavity is smaller because the synchronous state of particles in the asymmetric cavity is better than in the symmetric cavity, even though the nonlinear components of RF fields in the asymmetric cavity is larger than in the symmetric cavity.

ε_{n1}*=22.81mm.mrad* at the exit of the symmetry first cavity as compared to ε_{n1}*=12.51mm.mrad* at the exit of in the assymytry first cavity at the initial phase ϕ_0*= -150*^{0}.

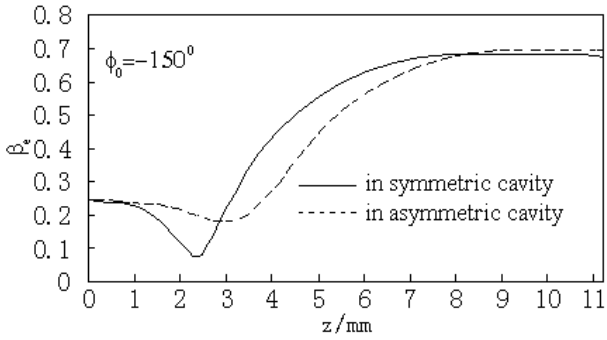

Fig. 3 Schematics of β_e in the different shape first cavity

4.3 The Influence of the Synchronous State

The synchronous state is associated with the initial phase, injecting voltage and RF field amplitude. The following ε_{n1} is the rms normalized emittance at the exit of the first cavity.

If the initial phase is near the sychrotrous phase (*0*^{0}), the sychrotrous state is better (shown in Fig. 4). ε_{n1}*=22.82mm.mrad* at the initial phase ϕ_0*=-150*^{0} as compared to ε_{n1}*=12.72mm.mrad* at the initial phase ϕ_0*=-120*^{0} in V_{inj} *=16.0kV* and P_0 *=1.1MW*.

If V_{inj} is higher, the sychrotrous state is better (shown in Fig. 5). ε_{n1}*=22.82mm.mrad* in V_{inj} *=16.0kV* as compared to ε_{n1}*=26.80mm.mrad* in V_{inj} *=14.5kV* at the initial phase ϕ_0*=-150*^{0} and P_0 *=1.1MW*.

If P_0 is higher, a_n is higher and the decelerating is larger, then the sychronous state is worse (shown in Fig. 6). ε_{n1}*=22.81mm.mrad* in P_0 *=1.1MW* as compared to ε_{n1}*=13.72mm.mrad* in P_0*=0.9MW* at the initial phase ϕ_0*= -150*^{0} and V_{inj} *=16.0kV*.

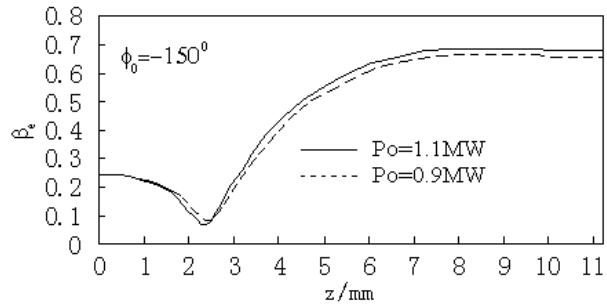

Fig. 6 Schematics of β_e in the first cavity for different P_0

5 COMPARISON BETWEEN ANALYSIS AND SIMULATION

The relativistic factor at the exit of the first cavity,

$$\gamma_1 = \gamma_0 + \frac{e}{m_0 c^2}\frac{\bar{\beta}_{e0}}{k}\left[\sum_{n=1}^{\infty} a_n \frac{Sin\left(\frac{n\bar{\beta}_{e0}}{\beta_{p1}}\phi_0\right) - \frac{n\bar{\beta}_{e0}}{\beta_{p1}} Sin(\phi_0)}{1-\left(\frac{n\bar{\beta}_{e0}}{\beta_{p1}}\right)^2}\right]$$

$$+\frac{e}{m_0c^2}\frac{\bar{\beta}_{e1}}{k}\sum_{n=1}^{\infty}a_n\left[\frac{-Cos\left(\frac{\bar{\beta}_{e0}}{\bar{\beta}_{e1}}\phi_0\right)Sin\left(\frac{n\bar{\beta}_{e0}}{\beta_{p1}}\phi_0\right)}{1-\left(\frac{n\bar{\beta}_{e1}}{\beta_{p1}}\right)^2}\right.$$

$$\left.+\frac{n\bar{\beta}_{e1}}{\beta_{p1}}\frac{(-1)^n Sin\left(\frac{\beta_{p1}}{\bar{\beta}_{e1}}\pi\right)+Sin\left(\frac{\bar{\beta}_{e0}}{\bar{\beta}_{e1}}\phi_0\right)Cos\left(\frac{n\bar{\beta}_{e0}}{\beta_{p1}}\phi_0\right)}{1-\left(\frac{n\bar{\beta}_{e1}}{\beta_{p1}}\right)^2}\right] \quad (1)$$

Corresponding, the phase at the exit of the first cavity

$$\phi_1 == \frac{k}{\bar{\beta}_{e1}}(D_1 - D_0) \quad (2)$$

where $D_0 = -\frac{\bar{\beta}_{e0}}{k}\phi_0$ defined in ref.[1].

After one cavity under the nonlinear RF fields,

$$\Delta\varepsilon_{xn} = 4\pi\left(\frac{1}{\beta_{p1}\lambda}\right)^3 |N(\phi_0)|\sqrt{\langle r^4x^2\rangle\langle x^2\rangle - \langle r^2x^2\rangle^2} \quad (3)$$

If the distribution of electrons is uniform distribution at the plane which is perpendicular to the axis,

$$\Delta\varepsilon_{xn} = 4\pi\left(\frac{R}{\beta_{p1}\lambda}\right)^3 |N(\phi_0)|\times 0.06R \quad (4)$$

where R is the envelope radius of beam.

For the first cavity,

$$N(\phi_0) = \frac{D_1 e}{m_0c^2}\frac{\pi^2}{2}\left(\frac{1}{\beta_{p1}} - M_0^2\right)\sum_{n=2}^{\infty}\frac{n(n^2-1)}{1-(nM_0)^2}[Cos(nM_0\phi_0) - Cos(\phi_0)]$$

$$-\frac{D_1 e}{m_0c^2}\frac{\pi^2}{2}\sum_{n=2}^{\infty}\frac{(n^2-1)a_n}{1-(nM_1)^2}\left\{M_1\left(\frac{n^2}{\beta_{p1}}-1\right)Sin\left(\frac{M_0}{M_1}\phi_0\right)Sin(nM_0\phi_0)\right.$$

$$\left.+n\left(\frac{1}{\beta_{p1}}-M_1^2\right)\left[-(-1)^n Cos\left(\frac{\pi}{M_1}\right)+Cos\left(\frac{M_0}{M_1}\phi_0\right)Cos(nM_0\phi_0)\right]\right\} \quad (5)$$

where $M_0 = \frac{\bar{\beta}_{e0}}{\beta_{p1}}$, $M_1 = \frac{\bar{\beta}_{e1}}{\beta_{p1}}$.

RF acceleration and RF effects on longitudinal phase space distribution γ_1 and ϕ_1 of analysis is in rough agreement with γ_1 and ϕ_1 of simulation (shown in Fig. 7 and 8). So is the RF field effects on transverse phase space distribution ε_{n1} (shown in Fig. 9).

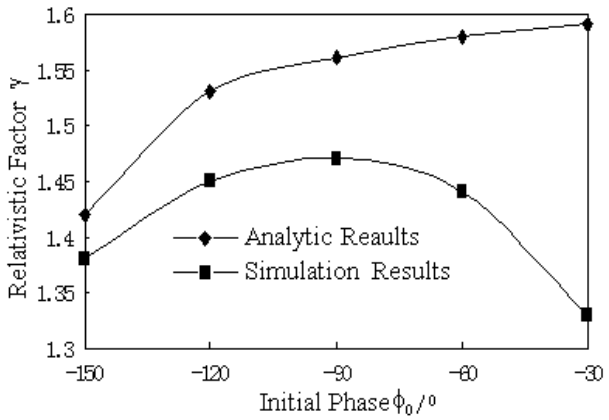

Fig. 7 Comparison of γ at the exit of the first cavity

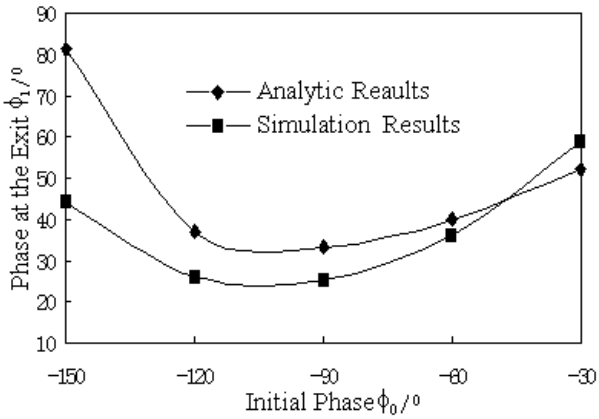

Fig. 8 Comparison of ϕ at the exit of the first cavity

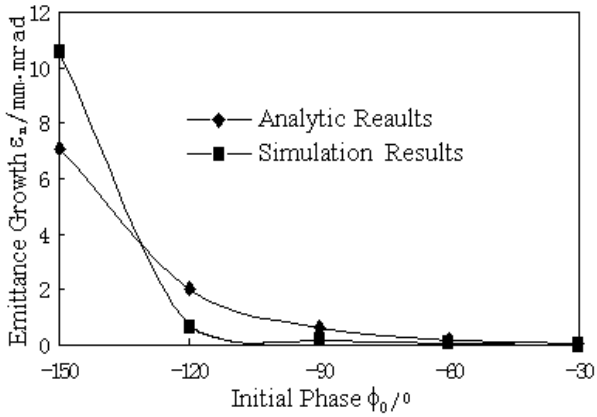

Fig. 9 Comparison of ε_n at the exit of the first cavity

6 CONCLUSIONS

A simulation to investigate the beam dynamics in the presence of nonlinear RF fields in a low energy SW X-band linac structure has been performed. The results have been compared and found to agree well with those from analyses. These programs *CAV* and *TRACK* should be useful in designing the low energy, high beam quality and high shunt resistance SW linacs opperating in higher frequencies.

A *6 MeV* X-band SW linac structure has been designed including the nonlinear RF fields and is presently under construction.

Abstract

RF guns have recently been very commonly used in high-energy research accelerators, as well as in various applications of accelerators such as FEL, because it offers significant advantages over the conventional techniques, which use electron guns and bunchers. In this paper, the novel structure of the RF gun, utilizing the π/2 mode, standing wave, on-axis coupled structure (OCS), is described. The new structure offers much higher group velocity and lower emittance over the structure that is commonly used. As a result, the new structure has a more stable operation for higher beam current without sacrificing beam emittance. Moreover, the structure offers unique characteristics in reduction of back bombardment for the application of thermionic cathodes in RF guns. The cavity structure and beam parameters were optimized by using EMSYS (2D) and MAFIA (3D). An overview of design detail and prototype structure, which can be used with either thermionic cathodes or photocathodes, will be presented.

1 INTRODUCTION

Since RF guns offer various advantages over the high voltage DC guns, many of today's electron injectors for physics accelerators and accelerators for FEL utilize this concept in order to obtain a higher brightness beam within a smaller space [1]. Although laser driven cathodes have been used in conjunction with RF gun, the complexity, the lifetime of cathode material, and cost have been the obstacles. Meanwhile, the RF Gun with the thermionic cathode offers a compact and low cost injector, but it suffers by pulse shortening due to electron "back-bombardment".

Here, we propose a new RF-Gun utilizes the π/2 mode, on axis coupled standing wave structure (OCS), that can offer highly stable, high current beam with lower emittance. The new structure can be used with both the photo cathode and thermionic cathode.

2 DESIGN CRITERIA AND CONCEPT

There are several very important criteria for designing RF guns, including:

2.1 The first accelerating cavity and the cathode for initial acceleration should be made electrically and mechanically as axis-symmetric as possible.

2.2 The accelerating field within the first cavity contains the least transverse components on an off-axis where the beam initially gains longitudinal momentum.

2.3 The amplitude and phase of accelerating field within the accelerating cavities should be stable with beam loading, frequency shift, and thermal instabilities.

2.4 Accelerating gradient must be as high as possible, but less than the RF breakdown and field emission threshold.

In order to satisfy these criteria, we have designed an S-Band RF Gun as shown in Fig. 1. The standing wave π/2 mode was chosen as the accelerating mode to satisfy criterion 2.3 [2]. The on-axis coupling structure (OCS) was used in order to satisfy criteria 2.1 and 2.2.

The selection of this mode and structure offers several other advantages, such as a) ease of machining the structure; b) ease of tuning; and c) flexibility of choosing the ratio of accelerating field in the first cell and the third cell.

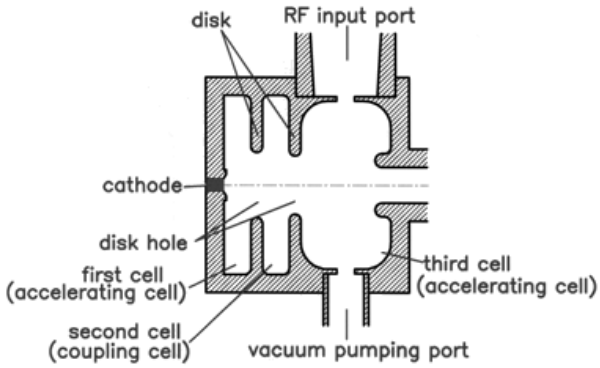

Fig. 1. Cross sectional view of OCS type RF gun

The RF input power will be fed to the third cell where a vacuum pump out-port is placed at the opposite side of the RF input-port in order to minimize the non-axis symmetry within the cavity as shown in Fig 1. A demountable cathode structure is designed by using a tungsten wire spring in the form of a toroid for RF contact. It employs an impregnated tungsten dispenser cathode for operation at around 1000°C.

Fig. 2 shows an equivalent circuit for three cavity couple resonator models with the nearest neighbor coupling (k_{12} and k_{23}) and the second nearest neighbor coupling (k_{13}). Assuming Q is very high, one can obtain the relation of the couplings and the amplitude ratio of the first and third cavity as:

$$\frac{k_{12}}{k_{23}} = \frac{|X_3|}{|X_1|} = \alpha$$

for $\pi/2$ mode operation. This indicates that one can choose any α by changing the radii of the coupling disk holes.

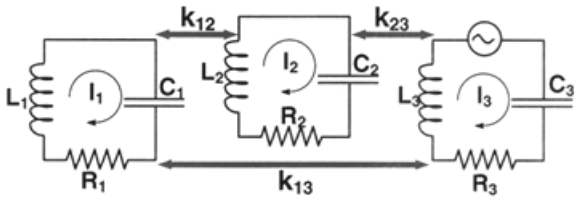

Fig. 2. Coupled resonator model for OCS type RF gun

3 NUMERICAL SIMULATION AND DESIGN OPTIMIZATION

The electromagnetic field profiles were computed using SUPERFISH and EMSYS. The beam dynamics were calculated by the 2D particle-in-cell (PIC) code EMSYS and 3D PIC Code (MAFIA).

Fig. 3 shows the relation of computed coupling coefficients, k_{12} and k_{23}, vs. disk hole radius in millimeters.

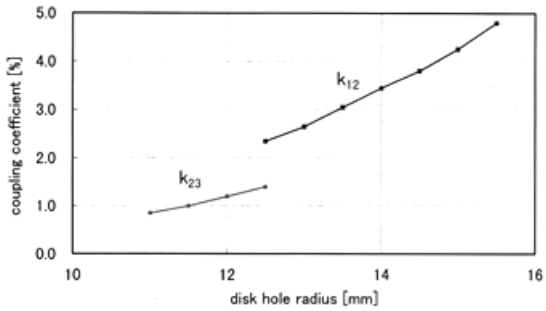

Fig. 3. Disk hole radii vs. coupling coefficients

Fig. 4 shows the dependence of output beam emittance and back bombardment power on coupling ratio α, assuming cathode diameter of 6mm and current density 16A/cm^2. In order to optimize the output beam energy spectrum, the length of the first cell and the second cell are varied along with α. A larger α offers lower back bombardment power, but aggravates the emittance of the beam, since the accelerating field on the cathode surface will be reduced. The optimum α will be around 2.5 and the normalized emittance is 12πmm·mrad. The average back bombardment power is about 1.1W, assuming the pulse width of 5μsec and a repetition rate of 10pps [3].

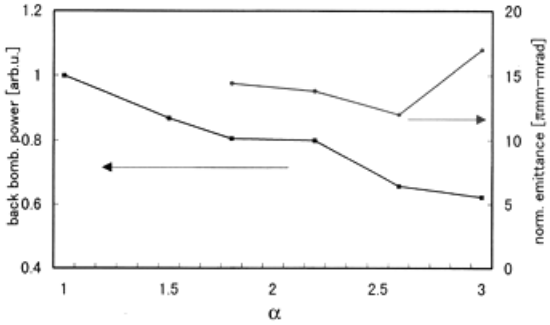

Fig. 4. Field balance (a) vs. beam emittance and back bombarding power

Fig. 5 shows the computed energy spectra of back bombarding beam for α=2.6 and for α=1.0. This figure clearly shows that the lower accelerating field within the shorter first cavity will generate much less electron back bombarding energy as 0.2MeV, compared to the back bombarding energy of higher accelerating field within the longer first cavity as 0.6MeV.

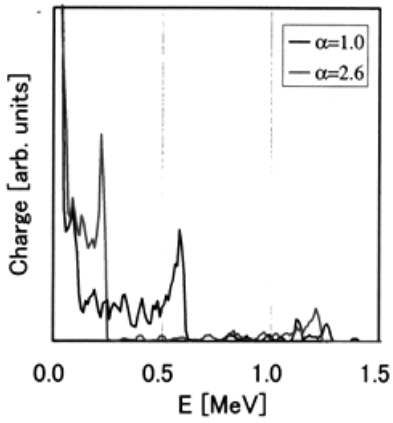

Fig. 5. Energy spectra of back bombarding beam

Fig 6 shows the radial distribution of back bombardment power density for α=2.6. The back bombardment power density is much higher in the center of the cathode due to the back bombarded higher energy electrons being focused by the radial RF field. This indicates that the back bombardment effect and pulse shortening will be completely eliminated by introduction of a hollow beam cathode with a Faraday cup of 2mm hole in the center of the cathode and a Faraday cup placed behind. Fig. 7 and Fig. 8 show an energy spectrum of output beam and energy spread as a function of time, respectively. The FWHM of the energy spectrum is about 25KeV and the charge contained during 10psec is about 0.17nC.

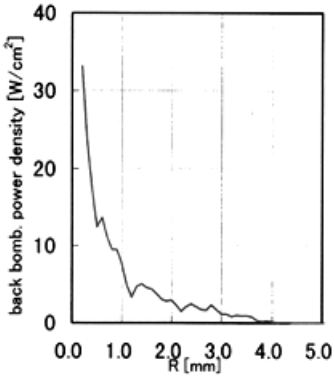

Fig. 6. Radial distribution of back bombarding power density

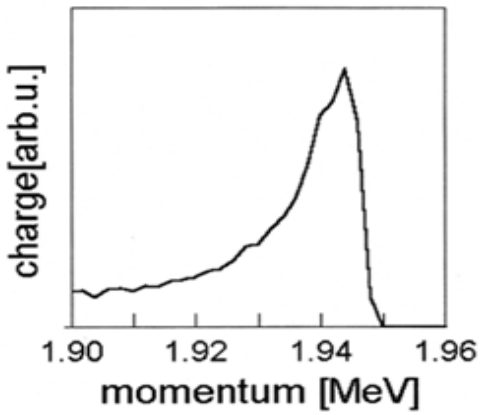

Fig. 7. Energy spectrum of output beam

4 CONCLUSION

The new on-axis coupled standing wave RF gun structure is presented. This structure offers numerous advantages over the RF guns, which are commonly used. It can be used with either the photocathode or thermionic cathode. Two prototype RF guns are under construction along with a hollow beam thermionic cathode with a beam dumper placed in the center of the cathode.

THE HIGH VOLTAGE SYSTEM FOR THE HIGH INTENSITY CERN PROTON SOURCE

C.E. Hill, M. O'Neil
PS Division, CERN, 1211 Geneva 23, Switzerland

Abstract

For the RFQ injector mounted on the CERN 50 MeV proton linac, the source needs to provide about 300 mA of 100 keV beam in pulses of 20 to 150 μs at 1 Hz. Although the high voltage supply is fairly conventional, a number of measures had to be taken to ensure not only the reliability of the source electronics, but also other equipments installed in the near vicinity. In view of the high current demanded from the source, a new and very simple form of beam load compensation was developed to stabilise the preinjector voltage to values acceptable to the RFQ.

1 BACKGROUND

The original 750 kV preinjector for the CERN Proton Linac (Linac2) used a Cockroft-Walton (C-W) high voltage supply with dynamic beam load voltage stabilisation [1]. In 1993, this injector was replaced by a Radio Frequency Quadrupole (RFQ) system whose injection energy was 90 kV. This voltage was chosen to be close to that of standard commercial high voltage power supplies whilst still allowing a small margin for injector column conditioning.

The ion source is a standard CERN Duoplasmatron with the steel body adapted to the length of the injector column. This two-section column uses two porcelain rings 300 mm diameter by 60 mm thick which were recovered from parts of the original CERN Linac1 preinjector [2]. The porcelains are glued with Araldite to the end flanges and an intermediate disk which is fitted internally with a stress relief electrode. Corona plates which also carry bleeder resistors complete the assembly.

Source supplies and controls were installed inside the Faraday cage in open racks supported on polyethelyene insulators,. This assembly gave a very compact system at a location where space was at a premium, whilst also allowing easy access for maintenance. The minimum clearance between racks and the cage is about 330 mm.

Following problems with backstreaming oil vapours from turbopumps on the RFQ test stand, virtually oil-free magnetic bearing turbopump systems were adopted to pump the high hydrogen load.

2 HIGH VOLTAGE SYSTEM

For the operational injector a modified standard commercial high voltage supply was chosen. The supply was specified for 120 kV, 1.2 mA with a current limiting mode and modified for interlock and control purposes. High voltage was led into the Faraday cage via a length of RG218 cable.

Figure 1 shows the layout of the high voltage system which can probably be described as fairly conventional. During off-line tests of the RFQ, a 100 nF capacitor was used as an energy reservoir to maintain the voltage during the beam pulse. As this did not give rise to problems, it was adopted for its simplicity for the operational machine. A single point earth very similar to that used on the test stand was also installed. It soon became obvious that the selected earth point had been badly chosen as HT flashovers often resulted in trips of the vacuum pump electronics (and other power supplies).

A new star point was found which resulted in a complete elimination of the problems with the vacuum pump controllers although there are still occasional problems with power supplies latching up.

Flashovers are detected and cause the HT reference to be automatically reduced to a low value. A programmed ramping of the reference then takes place bringing the voltage back to normal after about one minute. During this time the source is inhibited until the HT has reached about 95% of the nominal. Depending on the weather the typical flashover rate varies from zero to about five per week. An additional interlock is provided to protect the system from the consequences of bursts of flashovers.

The control interface between ground and the source racks in this system has always been via fibre optic interfaces. Originally, it was based on a Camac serial loop. Now, in order to economise rack space, to reduce maintenance costs and to prepare for the obsolescence of certain Camac modules, an industrial based CAN bus controller interfaced to the ground level VME is in use [3]. Present experience has shown this to be rather resistant to the consequences of HT flashovers.

3 BEAM LOADING COMPENSATION

The original C-W set had stringent requirements for voltage stability. Fortunately, the RFQ is much more tolerant in its requirements for injection energy stability. With the chosen power supply, passive energy storage with a 100nF capacitor could maintain the voltage for the 120 μs beam to within 0.5%. However, with the desire to reduce the stored energy of the system, a simple active compensation scheme was developed.

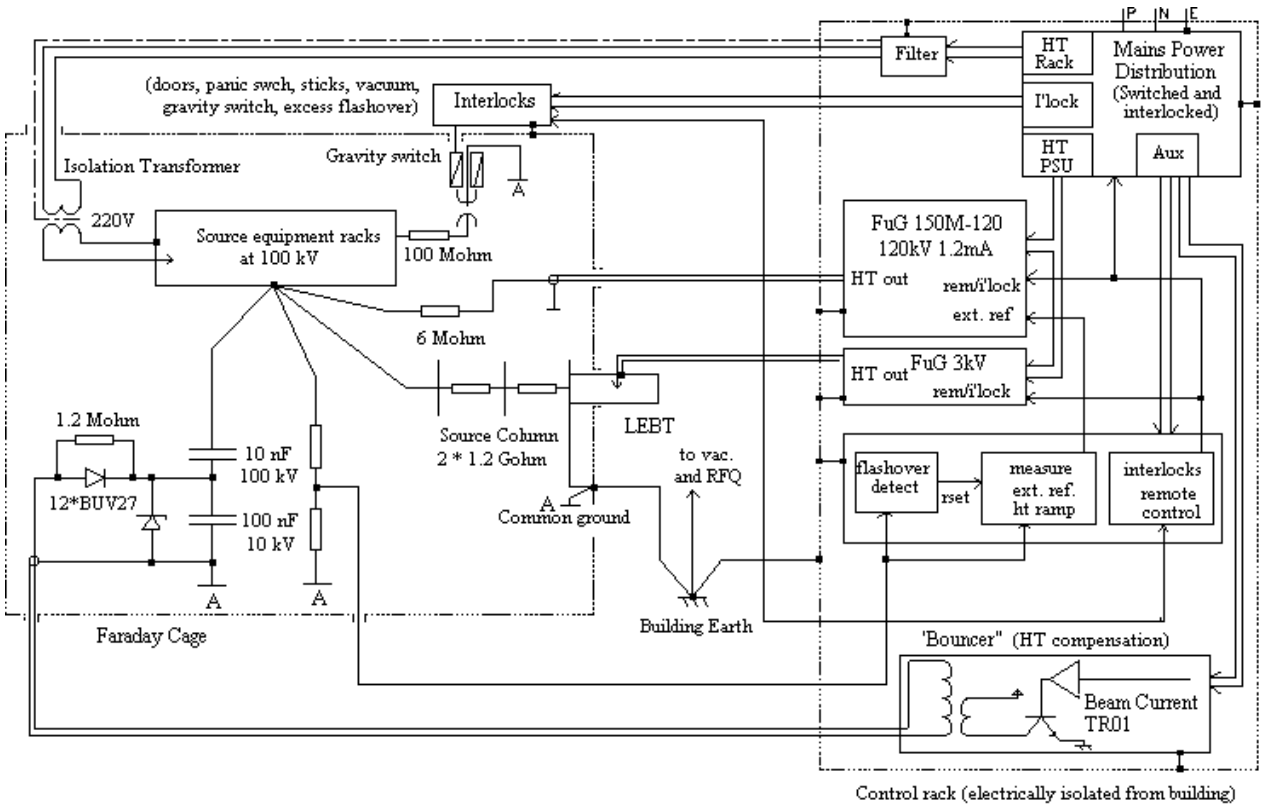

Figure 1: Schematic layout of the High Voltage system

If capacitor (C2) in Fig.2 is charged at constant current, the voltage at its high terminal increases linearly. It is then only necessary to arrange that the increase in voltage compensates the fall due to beam loading on the system capacitance. For a beam of constant intensity and length, a square pulse synchronous with the beam would be suitable to charge the capacitor. Unfortunately, at CERN pulse to pulse modulation of the beam length is used to provide only the number of protons that are actually demanded by the user. This results in the proton pulse length varying from 20 to 150 μs.

A beam transformer downstream of the source provides a quasi square wave signal which reflects both the intensity and length of the beam pulse. This signal is amplified in a transistorised power amplifier which drives a 100:1 pulse transformer. The output pulse of the transformer charges capacitor C2. Typically, the primary current is of the order of 300 A. Figure 3 shows the HT with and without beam load compensation for a source current pulse of 300 mA (trace 2), with a useable length of 92 μs. Figure 4 shows laboratory measurements on the system for a simulated beam of 300 mA and the linear rise of the voltage at C2 can be clearly seen for a constant charging current (traces 3 and 2).

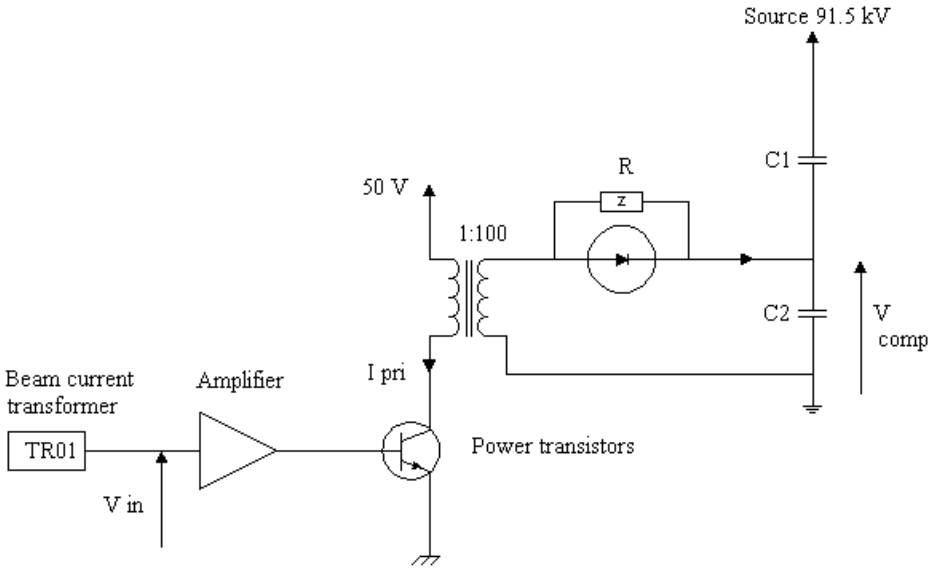

Figure 2: Block diagram of compensation scheme

The transistorised power amplifier consists of 240 BUV27 transistors in parallel made up into eight removable modules and is placed between the pulse transformer and

ground, the high side of the transformer being connected to the supply rail. A RG213 cable 6 m. long connects the secondary to the capacitive divider. After the passage of the beam, C2 is discharged through the resistor R in preparation for the next cycle. In the laboratory the compensation has run at up to 5 Hz but could probably run at a higher frequency.

Fine tuning of the compensation is achieved by trimming the gain of the preamplifier and the high voltage can be maintained to better than 0.1% during the passage of the beam (trace 1 Fig 3). Apart from amplification of the beam current signal no other treatment of this signal has proved necessary.

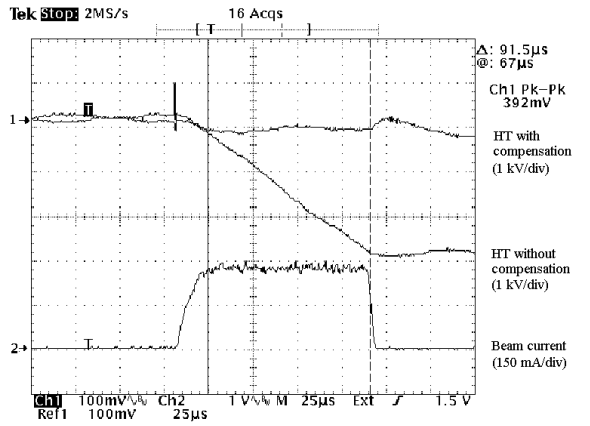

Figure 3: Comparison of high voltage stability with and without beam loading compensation.

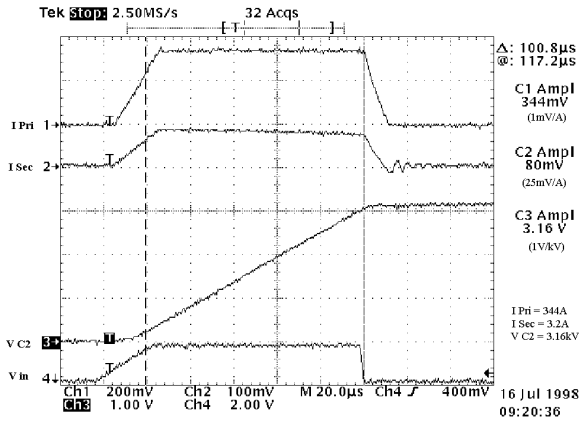

Figure 4: Voltage and current waveforms at key points in Fig.2 under simulated operation at 1 Hz.

4 RELIABILITY

Reliability of the injector is of prime importance, especially with the increasingly longer operational periods now becoming common at CERN. In 1998, the longest continuous period will be of 29 weeks. For the systems described here, the commercial power supplies have shown themselves to be particularly reliable and it has proved to be of great advantage to use a current limiting HT power supply. After a particularly severe flashover which caused some damage to the accelerating electrodes in the HT column, current limiting enabled the problem to be diagnosed quickly without repeated tripping of the high voltage.

Surprisingly, the transistorised drive amplifier for the beam loading compensation has not suffered any failure in its six years of operation. However, the main problems experienced to date concern the pulse transformers. Although specified for the required service in consultation with, and manufactured by, industry, they have suffered internal insulation failures. Investigations showed that the insulation was inadequate and badly designed. To overcome this problem, the transformers are being rewound "in house".

The high voltage system and the beam loading compensation now meet the requirements of simplicity and reliability. In the near future, as new modules pass flashover immunity tests, it is intended to replace the residual Camac and NIM based cards to Eurochassis standards thus eliminating obsolete, ageing and expensive equipment.

Abstract

The problem of gas loading on vacuum conditions in RF linac structures from traditional ion injectors based on duoplasmatron type source is well known. At the stage of starting high power linac trials and drills it often requires significant increase of pumping capacity to maintain the working vacuum level in resonators. The problem is mostly vital at development of multiple aperture linac structures. To simplify the problem new compact test injectors based on spark ion sources are discussed.

1 INTRODUCTION

Recently there has been a great deal of interest in studying of possible methods of remote non-destructive object composition testing by means of nuclear detection of targets irradiated by accelerated beams of light ions.

The approach known as pulsed fast neutron analysis (PFNA) is based on measuring of gamma ray spectra from remote target after its irradiation with extremely short neutron pulses produced by RF linac [1]. The obtained time and energy gamma spectra are used for material interrogation. The information is stored by means of time-of-flight analysis between the accelerator pulse and the arrival of γ-rays to *NaI* detectors located far enough from an examining object [2]. On the other hand, pretty low angular divergence of accelerated beam is required to transport it to remote target with minimal losses. The method of simultaneous acceleration of many short pulse ion beams in the same RF accelerator structure is expected to be the most promising for this purpose. Two approaches of multiple beam injection are under consideration. The first approach is based on the ion injector with multiple individual channels. The other way is based on generation of wide common ion beam with low angular divergence within ion source placed in the nearest close to multiple aperture RF structure with beam multiple channel collimating before the structure.

A compact injector of deuterium ions based on spark ion source is one of possible decision for the second approach. On the other hand, such kind of injectors may be used as test equipment for any RF structures trials and drills due to its feature to avoid the problem of gas loading on accelerator cavity.

2 MULTIPLE BEAM SYSTEMS

2.1 General comparison of single and multiple channel accelerator systems

It is well known requirements of simultaneous high intensity and small divergence of charged beams are in contradiction because of space charge loading, and only multiple beam accelerator systems are principally able to resolve the problem [3]. Let us compare properties of single and multiple channel systems with strong focusing.

If every the channel with aperture radius of a which is among multiple $(M\cdot N)$ beam system is able to accelerate maximum beam current of i_{Mm} then total current of the system is

$$I_M=(M\cdot N)\, i_{Mm},$$

And for traditional single channel linac with aperture radius of R and the same channel characteristics, maximum beam current is I_1 and it is easy to see that

$$I_M / I_1 = (a/R)^2 (M\cdot N). \qquad (1)$$

At analogous comparison of angular divergence α at the output of single and multiple beam linac systems their relationship may be estimate as

$$\alpha_1 / \alpha_M = R / a.$$

So taking into account (1) we have

$$\alpha_M = \alpha_1 [I_M / (M\cdot N \cdot I_1)]^{0,5}.$$

It is easy to see that at the same value of total current beam angular divergence at the output of multiple channel system is by factor of $(M\cdot N)^{0,5}$ times less than it is in a single channel system. It means that at given value of beam current its output angular divergence may be decreased by increasing of number of channels.

2.2 Multiple aperture RF accelerator system with space lattice focusing

Design features of multiple channel accelerator systems with alternating phase focusing (APF) as well as with some multiple channel RFQ modification [4] considered below are promised to be adequate decision for simultaneous acceleration of some hundred beams.

Let us consider the multiple beams RFQ system by using a new focusing element called "space lattice" (SL-focusing) [5]. The main idea is based on the following feature of RF accelerating fields. At the edges of drift tubes particles are exposed to transversal focusing or defocusing pushes from RF field. In particular, in drift tube linac a particle is pushed by defocusing RF field at the input and by focusing field at the output edges of drift tubes while it is roughly free from RF field action within both drift tubes and accelerating gaps. We considered a possibility of substantial amplification of focusing action from RF field by increasing a number of indicated boundary edges. It may be possible if some additional electrodes are placed within every accelerating gap.

By making *M* horizontal grooves from one flat side of the thin electrode plate to the middle of its thickness as well as *N* vertical grooves from the other side of this electrode again to its middle we get metal space lattice with *(M· N)* rectangular aperture holes with relatively thin walls in between (see fig.1).

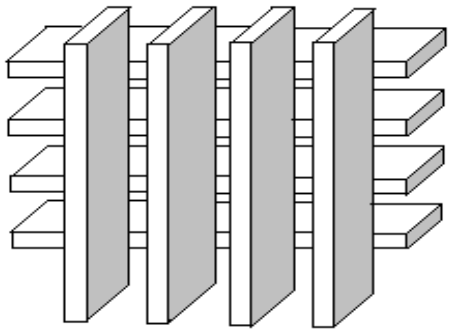

Fig.1.The fragment of Space Lattice electrode.

If several thin SLs are arranged along the common axis one after another at the equal distances between them within accelerating gaps of the multiple channel linac we have a system which can accelerate some hundred beams simultaneously. In case of circular apertures in thin electrodes focusing and defocusing forces at both edges of thin electrodes are almost mutually compensated while in SL every particle is pushed in vertical direction at the input and in horizontal direction at the output edges even at very thin electrode depth. If we arrange *n* SLs within an accelerating gap particles will be *n* times pushed by focusing strength in the vertical plane and *n* times pushed by defocusing strength in the horizontal plane. When SLs are arranged within every gap particles will be suffered some focusing action in one of transversal direction and defocusing action in other transversal direction. By turning SLs by an angle of 90^0 in every the following gap it is possible to create a sequence of sign-alternating strengths analogous to field strengths at space-homogeneous RFQ focusing. In fig.2 some possible realization of SL focusing electrodes with 324 aperture holes as well as their use in multiple channel accelerator structure is presented.

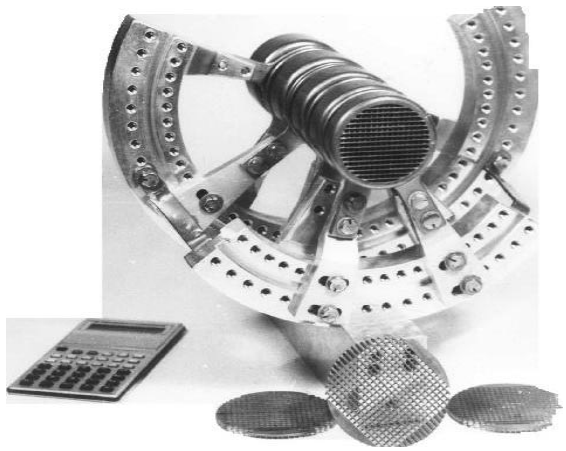

Fig.2. Space lattice electrodes and their possible arrangement in RF structure

3 SHORT PULSE TEST INJECTOR

The injector is designed for generation of very short pulses of ion beam as well as its preliminary acceleration in the range from 50 keV up to 150 keV [6]. The important feature of the injector is its small sizes due to possibility of placement both ion source and high voltage accelerator block within the same metal-ceramic package of *680 mm* long and *130 mm* in diameter. Such a configuration may produce protons, deuterons or heavy ions formed with pulses of nanosecond or microsecond ranges and followed with repetition rate up to some tens or hundred pps. On the other hand, such injector may be fixed at input flange of multiple channel RF accelerator structure at once due to the property of discharge initiation with no initial gas concentration (gas is stored in source electrodes as hydride of metal).

Vacuum accelerating tube of TNT-147 designed earlier in ARRIA for neutron generators is used as the main part of the injector. Ion generation is based on the property of desorption of deuterium occluded in metal cathode at spark charge, and its ionization in arc of spark discharge. Ion pulses are generated by formation of accelerating voltage of nanosecond range at microsecond pulse current of ion source. Ions are extracted from plasma bunches at electric field supplied between plasma gun anode and extracting electrode. Plasma gun is switching on at the moment of capacity discharge or inductive energy storage on the anode-cathode gap of the gun.

A spark-type ion source is based on the feature of some metals, such as *Ti, Zr, or Sc,* heated in the condition of hydrogen or its isotopes, to form hydride of metal as result of exothermic reaction. The process leads to saturation of a metal cathode with hydrogen. The saturated metal cathode in the form of washer is placed within the body of the ion source (fig.3).

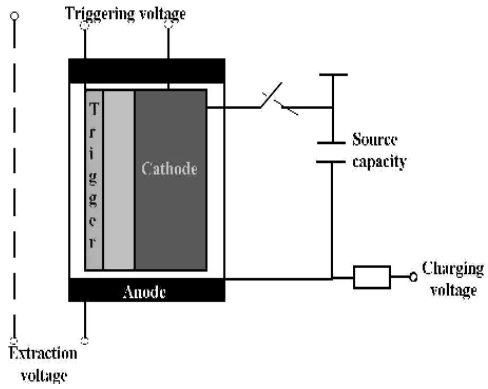

Fig.3. Short pulse spark ion source

The trigger electrode placed near the cathode supplies initial electrons to heat the cathode for gases desorption in the source volume. The electric arc is formed between cathode and anode electrodes. It is drifting to an open edge of plasma gun where ions of hydrogen are extracted and accelerated by high voltage potential. Pulse source is used as a source of trigger voltage. Pulse duration of extracted ion beam is in strict accordance with the duration of pulses of extraction which is able to be varied in rather wide time range from some nanoseconds to several tens of microseconds. The problem of electrical insulation is simplified in short pulse mode of source work. The unit of pulse formation is based on the scheme with electric capacity energy storage and pulse transformer. High voltage pulses are generated at the transformer's secondary and supplied to the gap between trigger electrode and anode.

The acceleration block of the injector includes spark ion source and trigger pulse former which contains high voltage transformer, accumulator capacitors and high voltage throttle. The elements of the acceleration unit are mounted within the same frame of metal ceramic tube. One of butt-ends of the tube is covered hermetically with the lid supplied with high voltage connectors, the other one serves to join injector with RF accelerator structure. The output flange of the accelerator structure is connected with the injector body by bellows for adjusting purpose.

Independent tests were carried out with proton and deuteron short pulse injectors. The cathode of the proton source was saturated with hydrogen. Pulse ion beam with output energy varied from *60 keV* to *120 keV* at pulse duration of about *1 μs* and repetition rate up to *30 pps* was formed.

We investigated regimes of pulse output current depending on ark trigger voltage at different values of anode voltage at pulse repetition rates of *1, 10,* and *30 pps.* The beam collimator with a single aperture diameter of *10 mm* was placed *100 mm* behind the injector with output aperture diameter of *60 mm*. At the distance of *80 mm* behind the collimator beam current has been measured by the system of 13 current pickups of *5 mm* in diameter every. The pickups were placed symmetric by the beam axis in three transversal layers - the central pickup and two peripheral layers of 6 pickups every. The distances from the beam axis to peripheral pickup layers are *16 mm* and *28 mm*.

The central part of the transversal beam distribution of *20 mm* in diameter contains about *60%* of total beam current while the tendency of both beam current and core diameter rising at injection voltage increase was also noted. The instability of pulse amplitude at this stage was observed rather high and sometimes exceeded *± 100%*.

The short pulse proton injector based on spark ion source was used for first trials of experimental deuteron APF linac structure with output energy of *4 MeV* at half level of RF gradients in accelerator gaps (*85 kV/cm)*. At that stage the main purpose was to calibrate all the technological units including RF level required for supply, level of optimal injection energy, etc. The *1 m* long *148.5 MHz* RF accelerator structure based on *H*-resonator with drift tubes was jointed to the injector output edge due to the injector feature of working at pretty high vacuum. The collimator with a single axis aperture hole of *10 mm* was arranged at the flange of vacuum tank *50 mm* before the first drift tube of the RF accelerator channel.

The tests of the structure have confirmed abilities of the injector to be prepared quickly for the working with high vacuum RF accelerator structure with injection current level of some tens *mA* and its easy of handling. On the other hand, the tests have pointed to the necessity of improving some injector parameters and its stability firstly.

Abstract

The injector for the DARHT second-axis will use an 8" thermionic dispenser cathode. Because the cathode is relatively large and requires a large amount of heat (5 kW) there are certain engineering issues that need to be addressed, before the DARHT injector reaches the final design stage. The Cathode Test Stand (CTS) will be used to address those concerns. The CTS is a new facility, presently under construction. The CTS will consist of a high-voltage pulse modulator, a high-vacuum diode test-chamber, and a short beam-transport section with diagnostics. This paper discusses the status of the project.

1 INTRODUCTION

The DARHT second-axis (DARHT-2) requires a 3.2 MV, 4 kA, 2 μsec injector [1]. The injector will use an 8" diameter thermionic dispenser cathode. Because such a cathode has requirements exceeding existing cathode assemblies, we are building a facility for measuring its most important engineering features. The cathode will be tested in situ as part of an operational electron-gun which has most of the design features envisioned for the DARHT-2 injector. The cathode requires 5 kW of heater power. We will measure: temperature uniformity over the cathode surface, differential thermal expansion between the cathode and focusing electrodes, and outgassing and vacuum properties. We will also test field-emission from the focusing electrodes up to an electric-field strength of 160 kV/cm. We will extract a 500 kV, 500 A beam using a PFN and a step-up transformer to generate a 1-μsec pulse. After a modest compression of the beam and a short transport section, we will measure the beam profile to assess electron-current emission-uniformity, paying particular attention to beam halo in preparation for further studies of emittance growth due to non-linear focusing forces.

2 GUN DESIGN

The electron-gun design for the CTS is very similar to that being designed for DARHT-2 by Lawrence Berkeley National Lab [2]. It is not identical because the electrical characteristics of the CTS (500 kV, 500 A) are more modest than DARHT-2 (3.2 MV, 4 kA). However, compared to the DARHT-2 design the CTS gun uses the same 8" thermionic cathode, has focusing electrodes with the same shape and is also a high perveance design (1.4 μP). The gun is designed using the computer code EGUN. The gun geometry and the electron-beam trajectory are shown in figure 1.

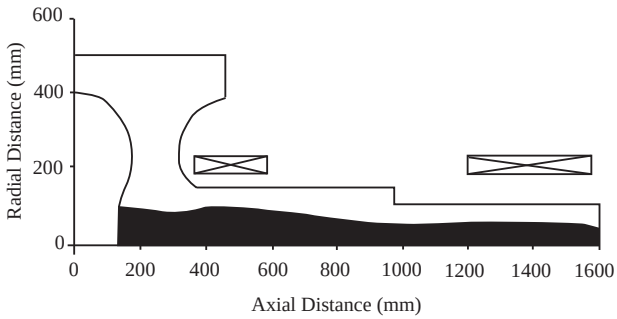

Figure 1: Electron gun design and beam envelope. Note axes are not scaled equally.

The injector uses two focusing solenoids to extract and transport the beam. Both solenoids are located down stream of the anode and have a peak magnetic field on axis of about 200 Gauss. The primary purpose of the magnetic optics is to transport the beam with a small amount of beam compression and negligible emittance growth. Under these circumstances a beam profile measurement at the end of the beam transport section can be used to determine electron-emission uniformity at the cathode.

The gun uses a M-type dispenser cathode, i.e., BaO impregnated into a tungsten matrix with a few thousand Angstrom Os/Ru coating sputtered on the surface to enhance emission and life. The cathode is heated with two counterwound filaments supplying about 5 kW of heater power. The focus electrode follows the standard Pierce diode design (67 degrees) and extends out to a large (stainless steel or molybdenum) radius shroud to minimize electric field stress.

3 EXPERIMENTAL SETUP

The configuration of the gun inside its vacuum chamber is shown in figure 2. After initial thermo-mechanical experiments, that don't require beam extraction, a beam transport line will be attached to the diode vacuum chamber. The cathode is supported by a 22" long ceramic insulator stack. Stainless steel rings are used to grade the

* Work supported by the US Department of Energy.

electrical stress along the stack. On the oil side, torlon rods under tension are used to maintain the insulator stack under compression and help support the cantilevered cathode assembly which weighs about 400 pounds. Radial and upstream heat shields surround the cathode structure to prevent heat loss and to maintain temperature uniformity. Water cooling is provided to the cathode support structure and shroud.

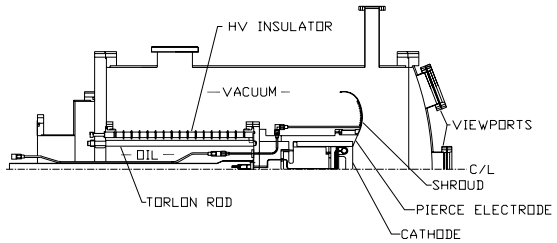

Figure 2: An assembly drawing of the gun and vacuum test chamber.

The vacuum chamber for the gun has 1 cryopump (4000 liters/sec) and 2 turbo pumps (500 liters/sec each). Because the cathode can be easily poisoned by contaminants (e.g. water, hydrocarbons) only metal seals are used and all components are to be baked for 10^{-9} Torr vacuum operation. There are several viewports on the vacuum chamber to be used for instrumentation. Ports are also available to insert quartz heating elements for in situ baking.

4 HIGH VOLTAGE MODULATOR

The HV modulator consists of a solid-state switching power supply, two 7-section PFNs wired in parallel, and a HV step-up (13:1) transformer. The modulator is presently being commissioned using a 1 kΩ dummy load. Each PFN has a characteristic impedance of about 11 Ω. An example of the modulator output and a simulation of the output are shown in figure 3.

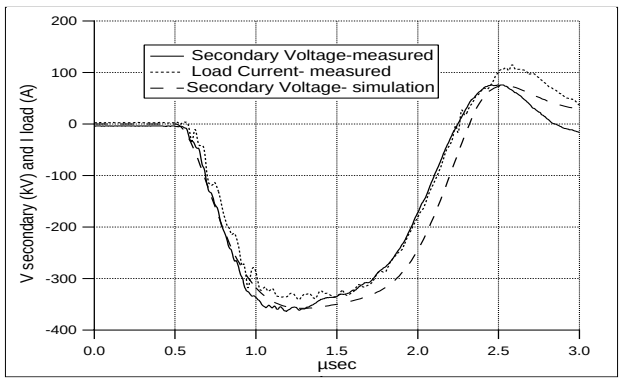

Figure 3: Modulator output waveforms compared with a circuit model simulation.

The modulator output voltage shown in figure 3 has unacceptable droop. We are in the process of replacing the PFN inductors with variable inductors. This will give us the ability to vary the waveform pulse shape and make it more constant. The modulator is capable of running at 10 Hz but we envision running the gun between 0.1 Hz and 1.0 Hz.

5 PLANNED EXPERIMENTS

The experiments to be performed on the CTS can be grouped into two categories, those without beam and those with beam. Experiments without beam will consist of measuring thermal, mechanical, and vacuum properties of the gun. Because of the high heat load (5 kW) some differential thermal expansion of components is expected. In particular, we will measure relative movement between the cathode, Pierce electrode, and shroud. EGUN simulations indicate that relative displacements of ~1mm have adverse effects on the beam quality. Pyrometers will be used to measure thermal uniformity on the cathode surface. The cathode is heated to 1100 degrees centigrade and a temperature uniformity of ±5 degrees is desired to maintain electron emission uniformity to a few percent over the 324 cm^2 cathode surface area. If we find that the temperature uniformity is greater than desired the 2 cathode filaments will be reconfigured to run off independent power supplies to gain more control of the heat deposition profile.

Another important experiment for the CTS regards field emission from the shroud. Field emission can cause breakdown and contamination of the cathode. The peak electric field at the shroud surface for the DARHT-2 injector is 160 kV/cm. The peak electric field during beam extraction for the CTS gun is only 39 kV/cm. Therefore to test for field emission from the shroud we plan to use a small grounded electrode placed close to the shroud to locally enhance the electric field. The experiment will be performed using a HV pulser with little energy storage. In this way we will achieve a high-electric field with negligible current emission from the cathode. This experiment will be performed with a hot cathode providing the same vacuum environment (dominated by the barium outgassing from the cathode) that is present when the gun is being pulsed normally.

After the first phase of experiments are complete a short beam line (~ 1m) will be installed to transport the beam to a beam profile diagnostic (see figure 1). Simulations show that with two solenoids (20 cm and 40 cm long) the beam can be transported with negligible emittance growth. By measuring current density at the end of the transport section with a beam profile diagnostic we will assess beam current-emission uniformity at the cathode surface.

6 SUMMARY

The CTS is a new facility under construction. It will be used to investigate critical engineering issues for the DARHT-2 electron gun. The modulator is built and operating. The gun is in the final design stage and fabrication of some parts has begun.

Abstract

The Spallation Neutron Source front end comprises a 35-70 mA volume H^- source, a multi-element electrostatic LEBT including chopping and steering, a 402.5 MHz RFQ with low output emittance and a 2.5 MeV MEBT also including chopping. The beam duty factor is 6%, with possible extension to 12%. This system, along with an LANL-supplied 1 GeV linac and a BNL-supplied storage ring, provides an average beam power of 1-2 MW to an ORNL and ANL-supplied neutron target and beam instruments facility. The current status of the front end design is described, along with results of several R&D projects leading to the final design.

1 INTRODUCTION

Over the last year the SNS design has undergone two DOE reviews and the project is expected to receive authorization for construction start. This paper reports on physics and engineering progress since the last report[1]. Hardware models have been built to test various subsystems, and some technical systems are now moving into prototype engineering design stages.

2 ION SOURCE

The design of the SNS prototype H^- ion source will be based on experiences gained with the SNS R&D ion source number 1, which is currently mounted on an ion source test stand at LBNL. A schematic of such an rf-driven (2 MHz) multicusp H^- ion source is shown in figure 1. A detailed design of this ion source has already been described elsewhere[2] .

Last year the ion source development was mainly concentrated on the extraction system[3]. Because of the high electron fraction in the beam extracted from a volume H^- ion source, an efficient electron removal scheme is essential for the 6% duty factor operation of the SNS H^- extraction system. We have chosen a novel design which deflects most electrons back to the ion source by a strong (1300 Gauss) magnetic field across the extraction hole as described in reference[4]. Only a small electron leakage current, which diffuses through the strong magnetic field, has to be dumped at a downstream electrode. To

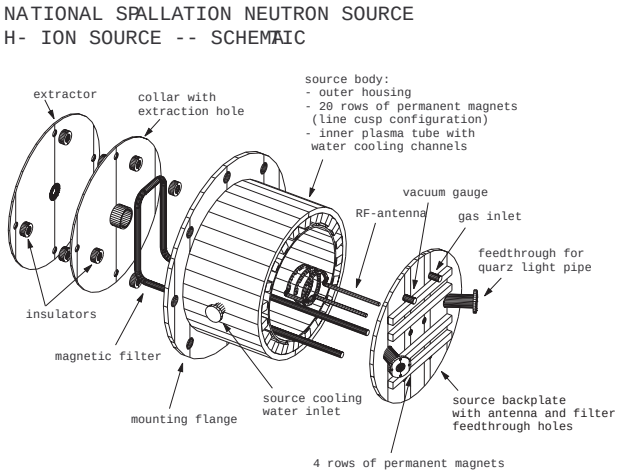

Figure 1: Ion Source Cross Section

further reduce this unavoidable power load, we have added an intermediate electrode between the plasma outlet and the extractor electrode as shown in figure 2. All electrons leaking out of the magnetic deflector will be caught on this intermediate electrode, which has only a 3kV potential difference to the ion source potential.

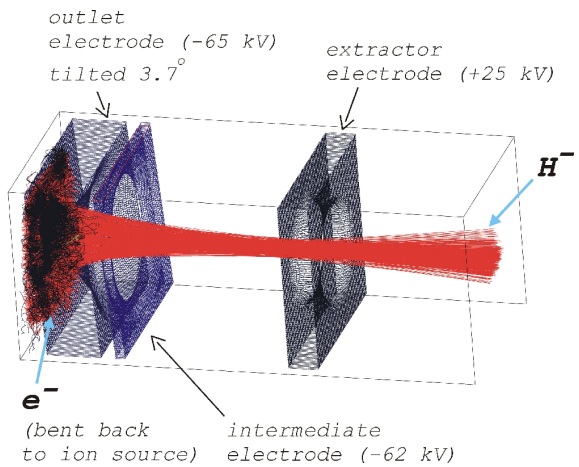

Figure 2: Ion Source Trajectories

The design of the magnetic field distribution across the extraction hole has been optimized with the 3D-ion-optics code KOBRA in combination with the 3D-magnet code TOSCA[5]. To compensate for the H^- ion beam deflection the outlet electrode must be tilted (see figure 2). It has been found that no transverse shift of the electrode is nec-

* This research is sponsored by the Lockheed Martin Energy Research Corporation under the U.S. Department of Energy, Contract No. DE-AC05-96OR22464, through the Lawrence Berkeley National Laboratory under Contract No. DE-AC03-76SF00098.

essary to inject a straight H^- ion beam into the LEBT. This feature eases the mechanical design and alignment of the SNS LEBT considerably.

3 LEBT

The Low Energy Beam Transport system has undergone some modification, described below. The all-electrostatic transport system provides a 65 keV beam to the RFQ entrance with a normalized emittance of less than 0.15π mm-mrad, with twiss parameters α = 1.6 and β = 6.5 cm.

Figure 3 shows a cross section of the LEBT electrode arrangement. The beam enters from the plasma generator off to the left, and is delivered to the RFQ through the tank endwall on the right.

The electrode geometry includes two pseudo-einzel lenses, allowing both α and β twiss parameters at the RFQ to be varied independently over a large range, and the last electrode, split into quadrants, allows beam angular steering by biasing the four segments, and beam chopping, by applying a $\pm$3 kV bipolar waveform to each segment, deflecting the beam in a stepped rotary pattern onto a four-segment beam stop. The length of the last focusing electrode has been extended to enhance the steering and chopping sensitivity. The electrically isolated four-segment beam stop, integrated into the RFQ endwall, will provide diagnostic signals of beam intensity and steering during the 35% of the time the beam is deflected away from the RFQ entrance by the LEBT chopper.

Tests on a prototype LEBT at LBNL show that the 3 kV bipolar chopper power supply rise/falltime is less than 40 nsec, and that the beam extinction time is 25-30 nsec.

The entire LEBT assembly is movable with respect to the RFQ for beam centering.

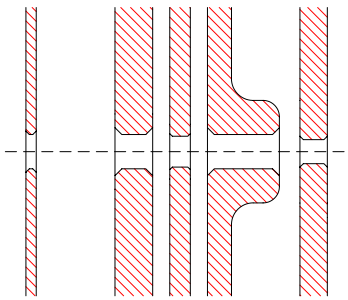

Figure 3: LEBT Cross Section

4 RFQ

The 3.7 meter-long RFQ accelerates 60 mA of H^- beam at greater than 95% transmission from 65 keV to 2.5 MeV. The r.f. duty factor is initially 6%, but the RFQ is capable of operating at 12% for a possible future upgrade of the facility to extend the average beam power to 4 MW. The RFQ comprises a single 402.5 MHz cavity, with pi-mode stabilizing loops[6] maintaining the quadrupole field symmetry in the presence of assembly errors. The one technical recommendation from the first DOE review committee was to increase the maximum current the RFQ could accommodate. This was done by increasing the peak field at the vanetips from 1.75 to 1.85 kilpatrick.

A r.f. cold model has been constructed and operated. It is full size in cross section and one-quarter length of the actual RFQ, with six pairs of pi-mode stabilizers, spaced 15.5 cm apart, as shown in figure 4. Perturbing one of the four quadrant frequencies by 1.53 MHz with plunger-type tuners causes a change in the quadrupole field balance by 2.7% worst case, with field levels in the remaining quadrants varying less. This substantial field stability will provide good field balance with normal mechanical assembly errors.

The pi-mode stabilizers move the quadrupole operating frequency down by 11 MHz and the two degenerate dipole modes up by 36 MHz from the non-stabilized cavity frequencies, with a resulting quadrupole-dipole separation of 35 MHz. No longitudinal stabilization is provided. The RFQ is five free-space wavelengths long, comparable to the JHF RFQ[6], which has no longitudinal stabilization and a measured field longitudinal field flatness of $\pm$1%.

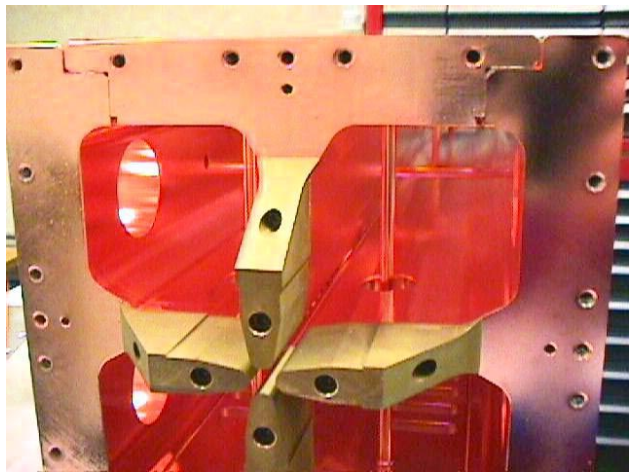

Figure 4: Cold Model End Detail, with Stabilizer

The RFQ mechanical design incorporates four separate vane quadrants which are brazed together to create the final cavity configuration. This design eliminates the need for demountable rf joints in regions of high rf wall currents. The vanes and cavity walls are made from OFE copper and they are backed by a brazed-on one inch thick piece of Glidcop AL-15©. Cooling water channels will be milled into the OFE prior to brazing on the Glidcop. Four of the 93 cm long completed modules will be joined using bolted joints with vacuum and rf seals. This method is acceptable since the longitudinal rf currents across the interfaces will be much lower than the azimuthal currents in each module. Rather than a flanged connection, the joint design will incorporate axial bolts inserted into recesses in the Glidcop

layer. Benefits of this type of joint include higher strength, more reliable seal loading and a lower profile. Canted coil springs will be used in the area between adjoining vane tips to ensure good electrical contact.

Vacuum ports will consist of an array of slots small enough to attenuate any rf leakage. The ports will be incorporated identically in all four quadrants to ensure rf symmetry. Nearby tuners will be used to compensate the locally depressed cutoff frequency near the pumping ports, leveling out local variations in the vane tip voltage distribution. The RFQ vacuum level will be maintained in the 10^{-7} Torr range.

The RFQ mechanical design and prototype RFQ models are covered further in two other papers at this conference[7] [8].

5 MEBT

The MEBT transports the 2.5 MeV H^- beam from the RFQ to the DTL, and accommodates a fast traveling-wave clean-up chopper, supplied by LANL[9]. Three rebuncher cavities and 18 quadrupoles transport the beam over the 3.6 meter length. Nonlinear space charge emittance blowup is reduced to less than 20% by the large number of closely-spaced quadrupoles, which adiabatically taper the transverse betatron period length up at the entrance, focus the beam for the traveling-wave chopper, and then adiabatically refocus the beam into the DTL.

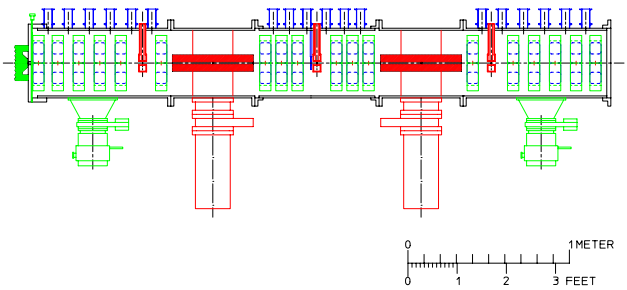

Figure 5: MEBT in Common Vacuum Chamber

The original MEBT physical configuration consisting of individual diagnostic boxes between the quadrupoles has been supplanted by a design where all components are contained inside a common vacuum chamber as shown in figure 5. Spool pieces between the beam line elements are used to maintain a low wall impedance, damping the excitation of wake fields in the vacuum chamber. The previous concept, which used a combination of EM and permanent magnet quadrupoles, has been replaced by a design incorporating only EM quadrupoles. The MEBT's high quadrupole filling factor necessitates minimizing the physical length of the magnets in order to maximize the inter-quad gaps for diagnostic devices. The associated fringe fields allow the length of an EM quadrupole to be up to one aperture radius shorter than an equivalent PM quad. To provide steering, six of the quadrupoles will be equipped with additional trim windings to create magnetic dipole fields of up to 0.03 T. All coils will be wound with solid conductor and the cores will be water-cooled.

The quadrupoles will be locally aligned to each other in groups of six on three separate strong-back structures. Mechanisms for mounting and aligning the individual strong-backs within the vacuum chamber will be provided. A distributed pumping system will be used to achieve a pressure of less than 5×10^{-8} Torr at the DTL entrance. The MEBT vacuum will be isolated from the RFQ and DTL by a pair of thin gate valves.

MEBT diagnostics will include two-slit emittance devices, Faraday cups, beam position monitors and a beam calorimeter. Additionally, toroidal beam transformers, capacitive phase probes and profile monitors will be used during routine operation of the neutron source since they are non-intercepting diagnostics.

Abstract

Ferroelectric ceramics of the PLZT type, i.e. lead zirconate titanate lanthanum doped, in form of thin disks have been tested as photocathodes. The disc of material, with the back surface only metallized and held in place by a metallic ring, was set in front of a solid anode. The applied accelerating field reached 20 kV/cm and the light pulse was 25 ps long, 532 nm wavelength and its energy arrived up to 6 mJ on an area of about 10 mm^2. The vacuum was very poor. The maximum output charge was 1 nC, but it was clearly limited by space charge. A theoretical explanation of the results is only hinted because the material surface structure is very complicated and various emission mechanism concur.

1 INTRODUCTION

The photoemission from ferroelectric material has become interesting after the experiments at CERN [1, 2]. The reasonably good emissivity at wavelength varying from green to UV, coupled to robustness makes this ferroelectric lead zirconate titanate lanthanum doped (referred as PLZT) ceramic a real subject of research for an efficient and robust photo-cathode for induction linac [3], next generation of accelerators [4], FEL, ultrashort x-ray sources.

The problem of the physical interpretation of the photoemission from these materials appeared soon very difficult. In reference [5] a new physical model has been proposed in order to account for the different experimental observations.

An experimental program has been set with the aim to investigate further the physics of the emission. The green light has been chosen because it seemed more suitable for that investigation.

The sketch of the experimental setup is shown in fig. 1.

The experiment has been carried out with PLZT having composition 8/65/35 and 4/95/5, where the numbers refer to lanthanum (in relation to lead), zirconium and titanium relative atom percentage and with lead titanate, PTO_3, sample. The ceramics 8/65/35 and PT are in ferroelectric phase at room temperature, while the 4/95/5 is in antiferroelectric phase, but it undergoes a transition from antiferro to ferroelectric phase under the action of an enough high electric field [6]. These materials have a high density of defects [7], whose activation energy is about 1 eV. The samples were not prepoled. The cathodes are disks of 16 mm diameter and 1 mm thickness, coated by a uniform metallic film at the back surface and by an external ring only at the front surface, see fig. 1 b).

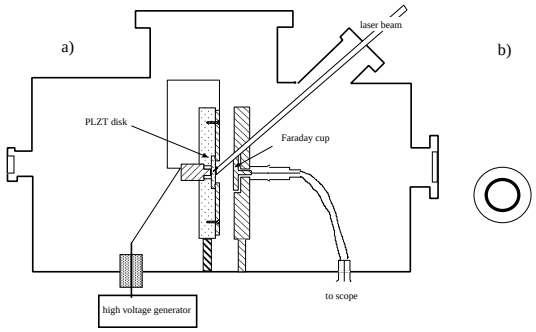

Figure 1: a) Sketch of the experimental apparatus used in the photoemission experiments; b) sketch of the cathode with the ring electrode at the front surface. The passively mode locked Nd-YAG laser provides some mJ of light at λ = 532 nm for a pulse length of 25 ps.

2 EXPERIMENTAL RESULTS

2.1 Experiments on PLZT 8/65/35 with bare front surface.

The results of the emission from a PLZT 8/65/35, fig. 1 b), are given in figures 2 and 3. The emission reached such a level that the saturation effect becomes evident. From the shape of the emitted charge versus the incident laser power, we can see that: there is a threshold and the yield in logarithmic scale increases linearly with an angular coefficient nearby 4. Extrapolating with an accelerating field high enough to avoid saturation effects, the emitted charge at 6 mJ of laser light would be 2 nC. The value of quantum efficiency results around 10^{-6}.

2.2 Experiments on PLZT 4/95/5.

We have investigated the emission from antiferroelectric PLZT 4/95/5 samples. The results are summarized in figures 4, 5 and 6.

The charge emitted increased from some picocoulombs to a couple of hundreds of picocoulombs when the applied field passed from 3.5 kV to 7 kV (equivalent to 20 kV/cm).

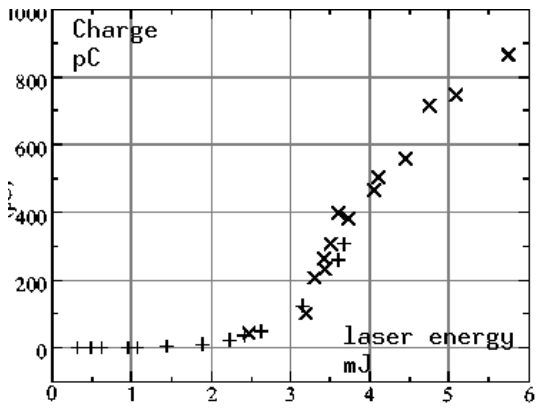

Figure 2: Emitted charge versus laser energy for a PLZT 8/65/35 without the front grid. Notice the clear bending of the curve due to the space charge effect.

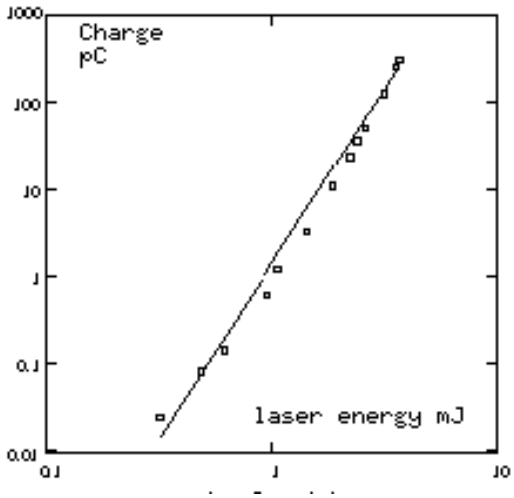

Figure 3: Emitted charge versus laser energy for a PLZT 8/65/35 without the front grid in log-log frame. The continuous line is a fit with $Q\alpha I^4$ scaling law.

In addition the log-log plot of emitted charge as function of laser power changed the slope from about 2 to the higher value around 3.

2.3 Experiments on PT.

This lead titanate material is a hard ferroelectric, good absorber of radiation in optical range. It emitted at much lower level as shown in fig. 7. We remark that the emission from this sample follows the two-photon absorption law [8], as the case of 4/95/5 sample at relatively low electric field in the diode gap.

We have, finally, tested the emission with two light pulses separated by 2 ns. The two emissions are substantially stable. The system seems able to provide pulse trains with nanosecond time separation.

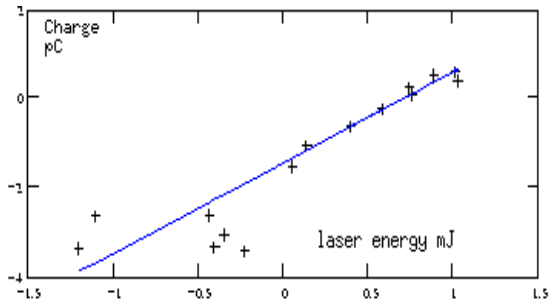

Figure 4: Emitted charge versus laser energy in logarithmic scale for a PLZT 4/95/5 sample when the applied voltage through the gap was 3.5 kV. The continuous line fits with $Q\alpha I^2$ scaling law.

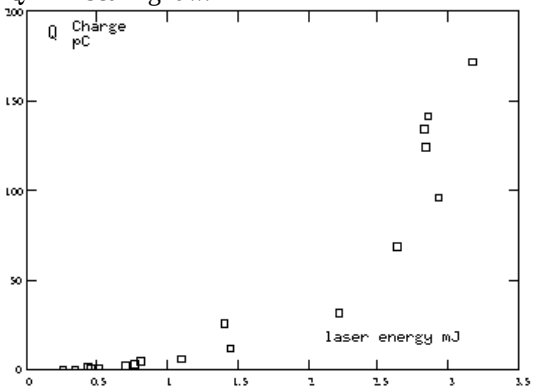

Figure 5: Emission versus laser energy for a PLZT 4/95/5 sample when the applied voltage was 7 kV.

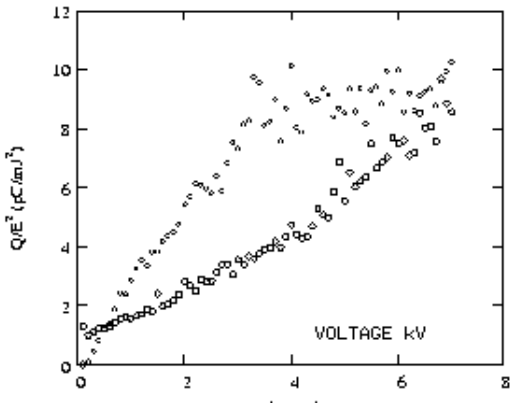

Figure 6: Emitted charge versus laser energy: the lower points are obtained at 7 kV of applied voltage, while the points of the upper curve are obtained in succession but after having reduced the voltage to 3.5 kV. The hysteretic behavior was not observed keeping constant the voltage.

3 DISCUSSION

The two main characteristics of the strong emission are: the almost negligible emission up to a laser intensity of about 1 GW/cm^2 (i.e. 2 mJ) and the high non-linearity starting from that point. In addition to this, the other notable fact is the change of the operational regime for the PLZT 4/95/5

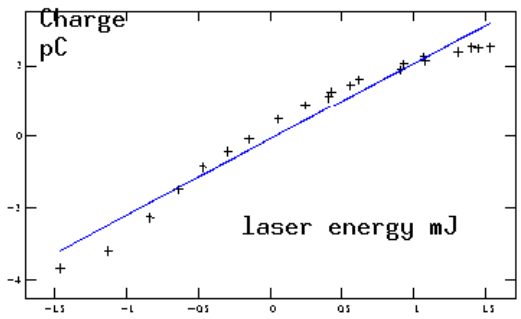

Figure 7: Charge versus laser energy in log-log scale for PT. The continuous line fits with $Q \alpha I^2$ scaling law.

sample when it is immersed in a relatively high electric field. The PT sample has stably two-photon emission.

The generalized Fowler-Dubrige theory [8] cannot explain these results. An average potential barrier higher than 4 eV is estimated in these materials for the electrons of the defect traps. The electron affinity E_a is not well defined because the surface state is un-defined: is like a patchwork of pieces with different physical characteristics, which range from insulating to metallic [9, 10, 11]. That value of the potential barrier is a fairly crude approximation.

Furthermore, our disk is immersed in the electric field applied through the diode gap, hence a counter field is created by the induced polarization. When the crystal is polarized, there is a band bending at the surfaces with a potential well for electrons at the positive side of the polarization, while there is a barrier at the opposite side [12].

The emission at 2.3 eV and its non-linearity with a power equal or greater than 4 would envision the anomalous heating regime [13], cooperating with the Auger effect [5].

More generally, we should have the concurrence of different contributions: one and two-photon emission, thermally assisted and Auger emission.

The increase of the emission of 4/95/5 sample as a function of the applied field, together with the hysteretic behavior of fig. 6 tells that the polarization is very important: when the polarization builds up in the sample, the emission steps up, then the sample remains polarized when the electric field is reduced because of the hysteresis loop. The experiment with PT material says that the polarization by itself is not sufficient for obtaining strong emission, but a strong doping, that is a large number of defects, must be also present.

Assuming that the electron pulse length is strictly correlated to the light pulse length, that is $\approx 25ps$, since the illuminated area is about 10 mm^2, the current density would be higher than 1 kA/cm^2. The laser power is well below the damage threshold.

4 CONCLUSIONS

A new very efficient configuration for ferroelectric photocathodes has been investigated. We got 1nC level of emission only because the charge was limited by space charge effect. Since the damage threshold of a ceramic is relatively high, a large amount of extracted charge can be foreseen.

The emission has shown to be very sensitive to the sample polarization. This fact allows to foresee a large enhancement of the quantum efficiency just increasing the polarization. This polarization increasing occurs naturally with the high electric field that are customary applied in electron guns.

The characteristics of these cathodes, are: a)strong robustness, they work in any kind of vacuum showing a long life; b) they do not require any particular processing; c)they can be operated with green light. In the near future the extracted electron beam will be characterized in terms of time structure. If the electron pulse duration is strictly related to the laser pulse duration, these cathodes promise to deliver current densities larger than 1 KA/cm^2 and to be valid competitors of both metallic and alkali cathodes.

FIELDS INDUCED BY CHOPPED BEAMS IN THE TANK CAVITY

Abstract

In order to accelerate high-intensity beams at the 12-GeV proton synchrotron complex at KEK, the 40-MeV proton linac has been successfully operated as an injector. The 40-MeV proton linac consists of two tanks. Recently, an acceleration of chopped beams has been tried to obtain good transmission from the Booster to the 12-GeV main ring. We thus measured the fields induced by chopped beams in the second tank, where the accelerating field is stabilized by post-couplers. The effects of the induced field on the longitudinal motions have also been observed. In this report, the measured results are described.

1 INTRODUCTION

The KEK 40-MeV Proton Linac has worked very well to supply beams to the 500-MeV Booster Synchrotron since the upgrade from the accelerating energy of 20-MeV to 40-MeV. Recently, an increase in the beam intensity of the 12-GeV Proton Synchrotron is required for experiments about neutrino oscillation. It is thus very important to accelerate beams with good quality and high intensity. Therefore, at first, we arranged a beam-monitor system and then improved the control system, the RF-source for a prebuncher and the RF-source for a debuncher system [1]. The effects of the tuning procedure of the linac on the transversal motions have been studied [2]. Otherwise, a beam-chopping system [3] has been developed and the acceleration of chopped beams has been attempted in order to control the bunch shape in the Booster.

At KEK, a 200-MeV proton linac for the Japanese Hadron Facility (JHF) has been designed [4]. The main features of the linac are a high peak current, a high average current, a high duty factor and a high performance for beam-loss problems. Therefore, an RF-source with high specifications must be fabricated, where we must guarantee that the accelerating field is stabilized within about ±1% in amplitude and within about ±1° in phase. In this linac, also, the acceleration of chopped beams with a micro structure and a long-pulse high intensity is required to paint the linac beams onto the longitudinal phase space in the next accelerator.

We think that in the near future chopped beams with a high peak current can be accelerated in a proton linac. We thus measured the fields induced by chopped beams and those effects on the longitudinal motions. In this report we describe the results measured with chopped beams produced by a beam-chopping system.

2 INDUCED FIELDS

Nominal beams accelerated by the proton linac have only the frequency components of (driving frequency) × n and a small fraction due to the phase spread. However, chopped beams have many frequency components, like (driving frequency) × n ± (chopping frequency) × m and the fraction. Figure 1 shows the frequency components of chopped beams accelerated in the first tank at KEK.

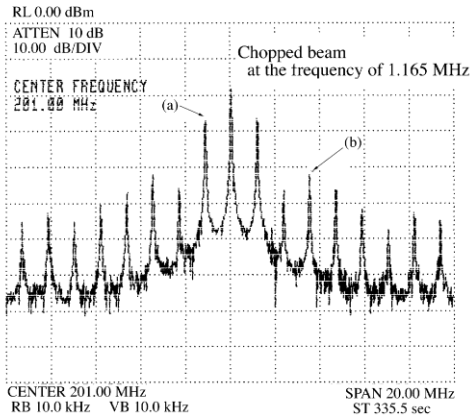

Fig. 1 Frequency components of chopped beams. Chopped beams were produced by using a beam-chopping system developed at KEK. An average beam intensity was about 8 mA. The post-1 and TM012-modes were excited by the frequency components of (a) and (b), respectively.

Furthermore, the proton linac comprises many tanks, each of which also has many resonance modes, like the TM and TE modes, and which must accelerate long-pulse high intensity beams with good quality. Therefore, when such beams pass through a tank and the beam-frequency component is near to a resonance mode in the tank, the mode would be strongly excited by the beams.

In general, such a field would be given by [5]

$$E_{bl}=\alpha_l I_l\{\exp(-j\Omega_l t)-\exp(-\omega_l t/2Q_l)\} \times \exp\{j(\omega_l t+\phi_b)\}\cos(\pi z/L). \quad (1)$$

where α_l = coefficient which is dependent upon parameters regarding to the l-mode,

I_l = beam-frequency component of beam bunches,

ω_l = l-mode frequency,

Ω_l = (TM010 mode frequency) - (l-mode frequency),

Q_l = total Q for the l-mode,

ϕ_b = accelerating phase angle,

L = tank length = 12.84 m.

Thus, the total field in the tank is given by the following superposition,

$$E = E_0 \exp(j\omega t) + \Sigma E_{bl}$$
$$= E_0 \exp(j\omega t)\{X + jY\}. \quad (2)$$

Therefore, the phase shift relative to the driving field is Y/X and wiggles with a frequency of ω-ω_l, which would correspond to the chopping frequency. We can then estimate a phase shift of about 4°, where the ratio of the induced field to the driving field is assumed to be about -40 dB. A variation of the phase shift due to the induced field is larger than a phase stability of about ±1° required for stable operation of the JHF proton linac. At the KEK proton linac, the driving frequency is 201.07 MHz and the chopping frequency is about 2.2 MHz, which is near to a post-2 mode in the second tank.

3 MEASUREMENTS

3.1 Fields Induced by Chopped Beams at KEK

The second tank has 17 rf-loop monitors for checking the field distribution of the accelerating modes. Thus, the TM01n-like mode has only been observed by using those loop monitors. At first, we measured fields induced by chopped beams in the second tank as variations of the chopping frequencies. Figure 2 shows the relation between the chopping frequency and the induced field. The measured frequencies of all the modes are consistent with the frequencies given in Reference [6]. All of the modes were determined by measuring the field distributions along the second tank. The strength of the induced field depends upon the frequency components of the beam bunches injected to the second tank and the operational phase between the first tank and the second one. We measured the ratios between the strength of the induced field and the frequency components, as shown in Figure 3. The measured results show that the higher post-modes would be not strongly excited by the beam-frequency component.

3.2 Effects of the induced field on the longitudinal motion

Though an average intensity of the chopped beams was about 8 mA, the ratio of the field strength of the post-1 mode to the main field strength (201.07 MHz) was about -43 dB, as can be seen in Fig. 2. This ratio is comparable to the ratio of the field induced by the nominal beam with an intensity of about 130 mA [5]. We thus think that the post-1 mode excitation might affect the longitudinal motion of the beams. Therefore, we measured an acceptable phase area to the second tank at beam positions (1) and (2) and on conditions whether the mode has been excited or not, as shown in Figures 4a and b.

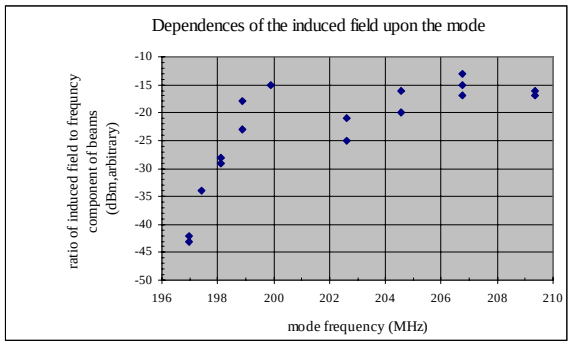

Fig. 3 Ratios of the induced field to the frequency component of bunched beams injected into the second tank. Higher modes of the post-type modes are weakly excited. However, the TM01n modes are almost equally excited.

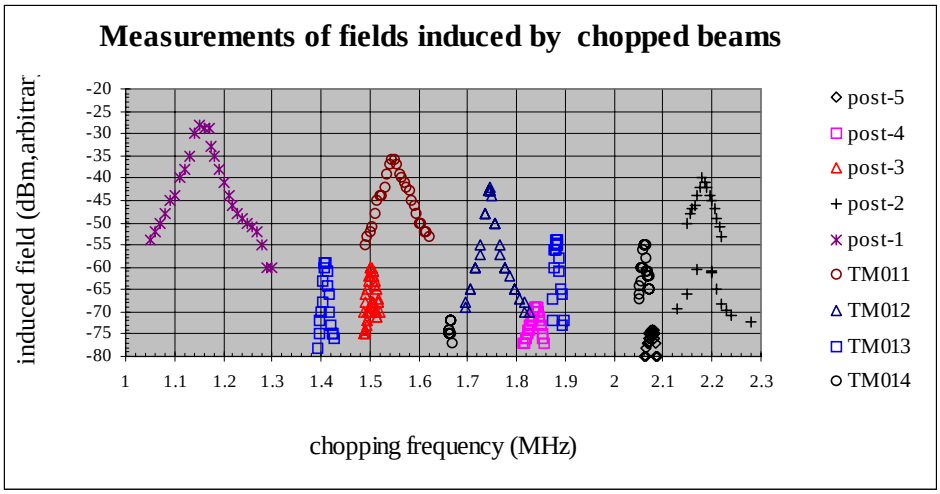

Fig. 2 Relation between the chopping frequency and the induced field. We measured the field distributions using 17 rf-monitors installed along the second tank, and then determined all modes of the measured fields. In our case, the post-2 mode is excited because the rf-frequency in Booster is about 2.2 MHz.

The measured results are shown in Figures 5, 6 and 7. Fig. 5 shows that the field levels of the post-1 mode are dependent on the operational phase between two tanks. We could observe some differences in those dependence between the post-1, post-2 and TM-modes.

Fig. 6 shows the energies accelerated in the second tank under conditions of different excitation levels of the post-1 mode. We thus conclude that the average energy would be independent of the induced field levels.

We can see variations of the acceptable phase areas in Fig. 7, which were measured at different beam positions and under different conditions of excitation levels of the post-1 mode. We can now conclude that the field induced by chopped beams in the tank might disturb the longitudinal motion of beams, and then narrow the acceptable phase area. Hence, it would be very important to study the relations between the resonance mode of the tank cavity and the chopping frequency. Next time, we will study the induced fields, like the TE-modes and their effects.

DESIGN AND DEVELOPMENT OF THE LEDA SLOW WIRE SCANNER PROFILE MEASUREMENT*

J. F. O'Hara, ALLIEDSIGNAL FM&T**; J. F. Power, LANL;
J. Ledford, LANL, J. D. Gilpatrick, LANL; J. Sage, General Atomics, M. Stettler, LANL

Abstract

The Low Energy Demonstration Accelerator (LEDA) [1, 2] is being developed at Los Alamos National Laboratory as part of the Accelerator Production of Tritium (APT) project. One of the diagnostics being developed to commission LEDA [3] is a slow wire scanner beam profile measurement. Initial profile measurements will be made at 6.7 MeV beam energy and 100 mA beam current. The wire scanner is an interceptive device that will move two silicon carbide coated graphite mono-filament fibers (wires) through the beam, in order to obtain the profile. Some of the design considerations discussed are; Mechanical design, wire temperature analysis, secondary electron detection, signal processing, and system control.

1 SCANNER MECHANICAL DESIGN

Fig. 1 shows the LEDA Slow Wire Scanner. The wire scanner will be mounted at 45° angle to the beam line in the diagnostic pump port of the LEDA High Energy Beam Transport (HEBT) [4]. The sensing wires are 100 μm silicon carbide fibers mounted on an aluminum fork. This material was selected based on the successful use of silicon carbide at LANSCE (Los Alamos Neutron Science Center) [5]. In order to prevent the x and y scanning wires from being in the beam at the same time the wires are mounted in a "V" design. Two biasing wires surround each signal wire. The biasing wires are also silicon carbide and will have a high voltage on them. The biasing wires prevent the secondary electrons from back streaming on to the signal detection wires and also will optimize the Secondary Electron Coefficient (SEC) of the wires. This configuration called for approximately 370 mm of travel to get both signal fibers fully through the beam scanning area. To clear the fork back out of the scanning area requires an additional 90 mm of travel.

1.1 Drive System

A fractional horsepower stepper motor moves the scanner through the beam. Coupled to the stepper motor is a modified Huntington Labs linear motion feed through. The stepper motor drives a ball screw that converts rotary to linear motion.

*Work supported by the US Dept. of Energy.
**Operated for the US Dept of Energy under Contract No. DE-ACO4-76-DP00613.

There are two separate position feedback systems, a rotary potentiometer and a linear optical encoder. Preliminary system testing shows the rotary potentiometer has an uncertainty of 0.17 mm and the linear optical encoder has an uncertainty of 0.013 mm.

1.2 Vacuum Considerations

The drive system lies outside the vacuum boundary of the beam line. A flexible welded bellows seals the actuator to atmosphere. The actuator mounts to the beam line with the use of metal sealed flange connections. Inside the vacuum chamber the actuator bolts to the fork that is in turn connected to a recirculating ball linear bearing. The linear bearing moves on a precision guide rail. The linear bearing guide rail system stabilizes the wire configuration during data acquisition.

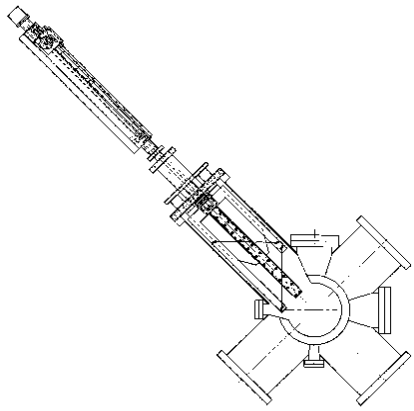

Figure 1. LEDA Slow Wire Scanner

2 WIRE TEMPERATURE ANALYSIS

The sensing wires will intercept the beam as they move through it. The protons that move through the wire will interact with the electrons in the wire material atoms. The electron will sense an attractive force due to the oppositely charged proton. This force can cause the electron to move to a higher lying shell (excitation) or if it is large enough it can actually remove the electron (ionization) [6]. The energy lost to the wire material comes at the expense of the proton, and this energy will cause a temperature increase in the wire material. The problem with this measurement technique is that if the energy deposited in the wire becomes too great it can cause the destruction of the wire. In order to predict the operating parameters that the wire is capable of surviving it was necessary to do a thermal analysis of the sensing wires.

2.1 Governing Equations

The analysis began by performing an energy balance on a control volume around the wire [7] and arriving at the following governing equation:

$$0 + \rho \frac{dE}{dx} I_{peak} V - \varepsilon\sigma\left(T^4 - T_{surr}{}^4\right)A_s = \rho V c_p \frac{dT}{dt}$$

Where,

ρ - wire material density (gm/cm^3).
dE/dx - stopping power (MeV-cm^2/g).
I_{peak} - peak current of the beam (μA/cm^2).
V - the volume of the wire under consideration (cm^3).
ε - emissivity of the wire material.
σ - Stephan-Boltzman coefficient (W/(cm^2-K^4)).
T - temperature of the wire (K).
T_{surr} - temperature of the surroundings (K).
A_s - surface area of the wire (cm^2).
c_p - specific heat capacity of the wire material (J/(g-K).
dT/dt - time rate of change of temperature (K/s).

The first term represents the energy entering the control volume that, in this case, is zero. The second term represents the energy generated inside the control volume, which is due to the stopping power [8] of the wire material and to the beam current. The third term represents the energy out, or the radiant cooling of the wire. The term on the right hand side represents the energy stored inside the control volume.

2.2 Numerical Analysis

A numerical integration technique is used to determine the time rate of change of temperature (dT/dt). Early on in the development of the scanner it became clear that no material would be able to withstand the intense CW beam conditions. It was therefore necessary to determine what pulsed mode operating parameters the wire material could tolerate. Fig. 2 shows a typical plot of the temperature rise in a 100 μm silicon carbide wire at a 500 μs beam macro pulse length and a 1 Hz beam repetition rate.

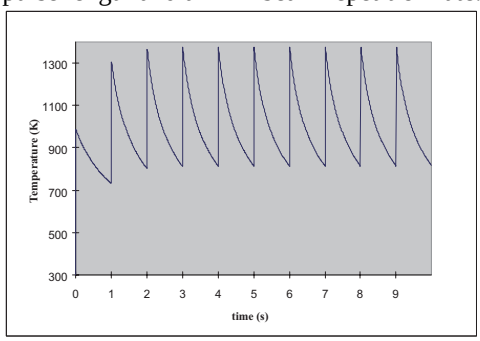

Figure 2. Temperature rise in SiC Wire

A series of analyses were done at various pulse lengths and repetition rates in order to determine the safe operating conditions of the wire. Fig. 3 shows the safe wire operating conditions based on a 500 ms beam pulse length at different repetition rates. The primary requirement was to keep the wire temperature below 1400 K, based on manufacture supplied data (Textron Systems, Wilmington, MA).

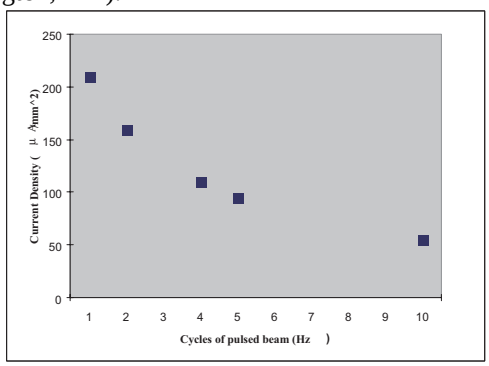

Figure 3. Scanner operating parameters for 500 μs beam pulse length.

2.3 Finite Element Analysis

A finite element analysis (FEA) was also done on the wire. Included in the FEA was the effect of the thermal conductivity of the material. Fig. 4 shows the results of an FEA model of a SiC fiber exposed to a 500 μs beam pulse and the conduction effects as the heat is being transferred along the wire axis.

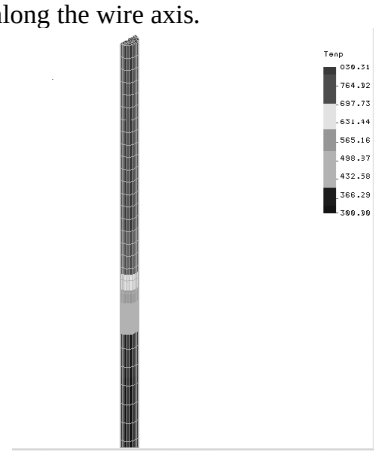

Figure 4. FEA model showing conduction effects

3 SECONDARY ELECTRON DETECTION

The signal for this measurement is taken directly from the sensing wires. The signal will be the sum of the protons stopped in the wire and the secondary electrons leaving the wire surface.

3.1 Secondary Electron Yield

Protons passing through the wire surfaces generate secondary electrons, both as they enter and as they exit. Using Sternglass's theory [9] the amount of secondary electrons generated can be stated as follows:

$$Y = \frac{Pd}{\varepsilon}\frac{dE}{dx}.$$

Where,

Y = electron yield.
P = probability that electron will escape (0.5).
d = average depth from which the electron escapes (nm).

e = average kinetic energy lost by an ion per ionization in material (MeV).
dE/dx = stopping power (MeV-cm^2/g).
The anticipated secondary electron yield for the LEDA wires is: Y= 0.012, which corresponds to a 16 mA signal at the distribution peak with 100 mA beam current.

3.2 Signal Processing

The current or charge measurement electronics will be packaged in VXI format. An onboard Digital Signal Processor (DSP) will enhance measurement and data analysis features. An on-line calibration and verification system will also be included.

3.3 Secondary Electron Coefficient, Ψ, Calculation

One of the features being incorporated into the scanner control system will be the ability to do an on-line calculation of the SEC, Ψ. This is done by measuring a beam profile, normalizing the average beam current present during each point in the scan, as measured by the ac Beam Current Monitor system. The average SEC is calculated as the measured wire current divided by the theoretical current intercepted by the wire, assuming a Gaussian distribution.

4 SYSTEM CONTROL

The wire scanner will be controlled by the Experimental & Physics Industrial Control System (EPICS) [10, 11]. Motion control sequences are written in State Notation Language, the EPICS implementation of a finite state machine. There will be three main screens.

4.1 Calibration Screen

This screen will be used to perform the on-line system verification. The operator will have the capability to check the condition of the sensing wires and verify the voltage on the biasing wires. The operator will also be able to verify the scanner position accuracy by running the scanner, acquiring position information and comparing this information against past performance.

4.2 Status and Scan Execution Screen

This screen will provide the operator information about the scanner and other accelerator functions. There will be links to the Run Permit system, information on beam pulse width, beam repetition rate, and the measured beam current. The operator will select from five types of scans.

Fast scan: This scan is intended to provide a quick, coarse resolution profile.

Slow scan: This scan is intended to provide a high resolution profile.

Find peak scan: This scan is a combination of the fast and slow scans.

Go to position and stay: The scanner will move to the operator-defined position and remain there.

User-defined scan: The operator has the ability to define the scan range (for both x and y axes) as well as the desired bin size (distance between data points).

4.3 Data Analysis Screen

This screen is where the profiles will be displayed. There will be two plots, one for each axis profile. Interactive Data Language (IDL) will be used for data reduction. IDL is a commercial software package used for analysis and display of scientific data. The operator will have the ability to display calculated moments of the raw data and the parameters determined from a Gaussian fit.

5 SUMMARY

Wire Scanner system testing and development are continuing. The scanner is scheduled for use this fall during The LEDA commissioning process.

6 ACKNOWLEDGEMENTS

The LEDA Slow Wire Scanner design was based heavily on scanners currently in use at LANSCE. The LANSCE-2 group was responsible for the design of these scanners. We gratefully acknowledge their generosity and assistance.

IMPROVEMENTS ON THE ACCURACY OF BEAM BUGS

Yu (Judy) J. Chen and T.J. Fessenden
Lawrence Livermore National Laboratory, Livermore, CA 94550

Abstract

At LLNL resistive wall monitors are used to measure the current and position of intense electron beams in electron induction linacs and beam transport lines. These, known locally as "beam bugs", have been used throughout linear induction accelerators as essential diagnostics of beam current and location. Recently, the development of a fast beam kicker has required improvement in the accuracy of measuring the position of beams. By picking off signals at more than the usual four positions around the monitor, beam position measurement error can be greatly reduced. A second significant source of error is the mechanical variation of the resistor around the bug. In addition, in-situ bugs used on ETA-II show a droop in signal due to a fast redistribution time constant of the signals. This paper presents the analysis and experimental test of the beam bugs used for beam current and position measurements in and after the fast kicker. It concludes with an outline of present and future changes that can be made to improve the accuracy of these beam bugs.

1 DESCRIPTION

Perhaps the most important diagnostic developed for electron induction accelerators is the device that monitors the beam current and position in the accelerator and associated beam transport lines. This type of monitor [1] was first developed for use on the LBL ERA accelerator about 1970. It was rapidly adapted [2] for use on the Astron Accelerator [3] and has been used on all LLNL induction accelerators since. These instruments, commonly called "beam bugs", are capable of measuring kiloampere beam currents and beam position with rise times of less than 0.2 ns and relative position resolutions less than 100 μm. Signals are generated by placing a resistor in series with the inner wall of the beam transport lines and detecting the currents induced in the wall by the passage of the beam. The resistors are made of 0.2 mil nichrome foil (5.4 μm) that is spot welded across an insulated break in the beam tube wall to form a band that encircles the inside of the beam pipe. The diameter of the band equals the inner diameter of the beam pipe so that the beam sees no abrupt steps or extraneous capacitance during its passage through the bug. A small overlap is formed as the band wraps around the inside diameter of the pipe.

Figure 1 shows the design [4] of the beam bug used with the ATA accelerator [5]. The ETA-II bugs are only slightly different. The resistance of the resistor foil was approximately 20m• with a resulting sensitivity of the instrument of 1 kA/V. Also shown are measurements of the response of the bug to a 10 amp fast rising current

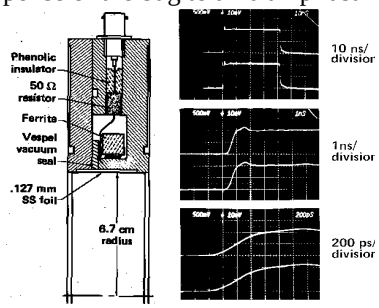

Fig. 1. Drawing of an ATA beam bug. ETA-II bugs use 5.4 μm nichrome foil and have no 50 Ohm resistor in series with the outputs. Also shown is the response of the bug (lower trace) to a 10 Amp pulse (upper trace) along the bug axis from a mercury pulser.

flowing around the resistor. Because of the very low foil resistance, the *L/R* time for the current to decay is very much longer than the beam pulse. Eight pickoffs around the circumference of the bug are used to develop the current and position signals. Two of the pickups encircle the ferrite in a direction opposite to that of the other six thus producing a negative signal. The current signal is formed by adding four positive signals from cardinal points around the bug. The *x* and *y* position signals are formed adding positive and negative signals from opposite sides of the bug. Additional information on beam bugs and other diagnostics for high current linacs can be found in [6] and [7].

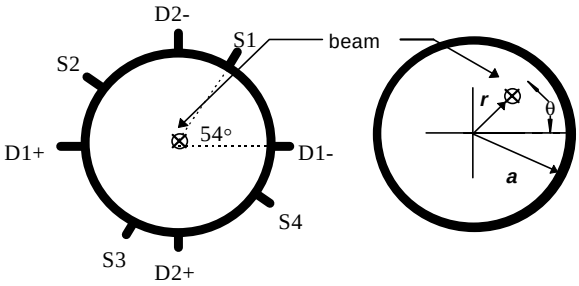
2 ANALYSIS

Consider a beam moving within a conducting pipe as sketched in Fig 2. It is possible to show (by the method of images for example) that a current *I* flowing within a pipe of radius *a* at a distance *r* off axis causes a surface current to flow on the inner pipe wall.

Consider interrupting the beam pipe with a resistive band or ring placed at the inner circumference of the pipe with total resistance R. The surface current passing through the resistor that initially or for a short time develops a voltage around the pipe *V(•)* given by [7].

$$V(\theta) = IR\frac{\rho^2 - 1}{1 + \rho^2 - 2\rho\cos\theta}. \qquad (1)$$

where • = *r/a* is the normalized beam displacement. The angle • is defined by Fig. 2b. For most of the ETA-II accelerator and transport the beam current signal comes from adding the voltages of the four sum ports, S1 to S4. It is fed through a resistive summing circuit in which care



(a) (b)

Fig. 2. (a) ETA-II's beam bug port configuration and (b) Sketch of a beam off-axis in a conducting pipe

is taken to avoid reflections in the cabling. Therefore,

$$V_I = [V(54^o) + V(144^o) + V(234^o) + V(324^o)] \quad (2)$$

Similarly, the position signals are obtained with

$$\begin{aligned} V_x &= V(0) - V(180^\circ) \\ V_y &= V(90^\circ) - V(270^\circ) \end{aligned} \quad (3)$$

Combining (1)-(3) and taking the limit of small beam displacement (• << 1), we obtain

$$V_I = 4IR \quad (4)$$

and

$$V_x = 4IR\rho\cos\theta \quad (5)$$

or

$$\frac{x}{a} = \rho_x = \frac{V_x}{V_I}; \qquad \frac{y}{a} = \rho_y = \frac{V_y}{V_I} \quad (6)$$

3 IMPROVED CURRENT AND POSITION FUNCTIONS

The determination of beam current and position can be improved by using all eight pickoffs to determine beam current and position which already exists on ETA-II's beam bugs (see Fig. 2a). Define the beam x and y-position relations as:

$$\begin{aligned} V_x &= V(0) - V(180) + [V(54) - V(234)]\cos(54) \\ &\quad - [V(144) - V(324)]\sin(54) \\ V_y &= V(90) - V(270) + [V(54) - V(234)]\sin(54) + \\ &\quad [V(144) - V(324)]\cos(54) \end{aligned} \quad (7)$$

and the relation for the beam current is given by

$$\begin{aligned} V_I &= V(0) + V(54) + V(90) + V(144) + \\ &\quad V(180) + V(234) + V(270) + V(324) \end{aligned} \quad (8)$$

The relationships for *x* and *y* are the same as (6).

Let us consider in detail the error in the position signal resulting from the assumption of small beam displacement •. Fig. 3 shows plots of the error in measured beam position by the bug as a function of the normalized beam displacement • for the case of two and six pickoffs as defined above. These curves were obtained from Eq. (3) and (7). Each pair of curves show the values to be expected for the case of the beam displacement angle toward a pickoff point and for the case of the beam displacement angle half-way between two pickoff points. For an arbitrary displacement these curves bound the measurements to be expected. At a normalized displacement of •• = 1/2, the position error ranges from -37% to 48% for the case of two pickoffs and -7% to 3% for six pickoffs, a drastic improvement.

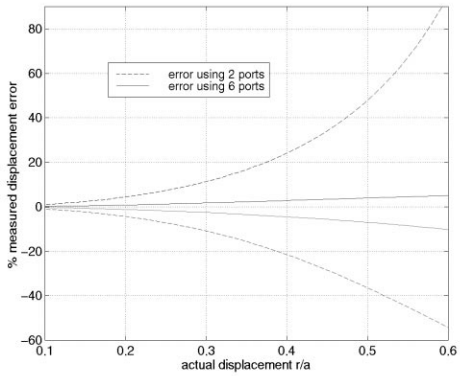


Fig. 3. Plots of the measured error as a function of the normalized beam displacement from axis for two and six pickoffs as defined above. For arbitrary angle, the point will be bounded by the two curves.

4 MECHANICAL ERRORS

Beam bugs are tested and calibrated using a mercury pulser and a test fixture. The fixture consists of two coaxial cylinders; the larger has an inside diameter equal to that of a beam bug that is attached in its center. The second simulates the beam and threads the assembly. It is smaller in diameter by a ratio of 2.3 to achieve a 50 Ohm impedance. The two cylinders are attached with tapers to a coax line that is driven by a mercury pulser. The pulser generates current pulses with a rise time of 0.2 ns that are typically 200 ns long. The oscillograms presented in Fig. 1 were obtained from such a fixture.

Measurements of the eight output signals from the beam bug show random amplitude variations of approximately ± 2%. For the ETA-II bugs this implies an uncertainty in beam position of ±1.4 mm. These errors result from variations in the resistance of the foil around the circumference of the bug. These variations arise principally from two causes. Measurements revealed that the thickness of the 5.4 μm foils randomly vary by about 2%, and variations in the spot welds that attach the foil also contribute to the error. This latter effect is evident in Fig. 4. The foil on Beam Bug 26 was re-welded with extreme care. This reduced the variation between pickoffs by about a factor of two.

5 SIGNAL DROOP

The beam bugs are fabricated of metal and essentially shorted by the housing as shown in Fig. 1. The inductor provides time isolation for the monopole current signal for times long compared with the beam pulse. This time is determined by the *L/R* time constant developed by the ferrite inductor and foil resistor. For ETA-II parameters this time is typically hundreds of microseconds. Thus the

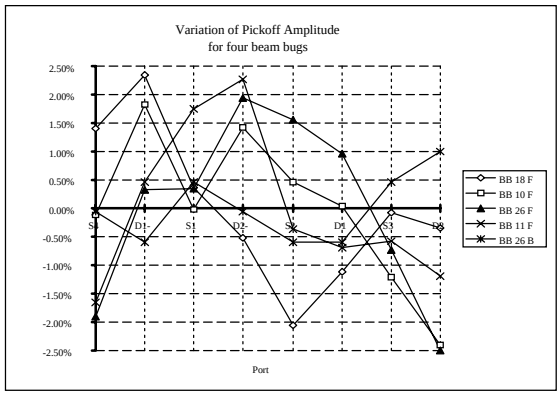

Fig. 4. Variations between electrical signals at the eight ports of four ETA-II beam bugs. The foil on Beam Bug 26 was re-attached with extreme care.

current signal will droop by less than 0.1% in the time of the 70 ns ETA-II pulse. The position signal is generated by an off-axis beam which produces a dipole excitation of the bug. The dipole component of the excitation does not link the ferrite inductor. As a consequence the droop of the position signal is much faster.

The center cylinder of the calibration fixture can be moved with respect to the outer cylinder so as to simulate an off-axis beam. Fig. 5 shows bug signals developed at opposite sides of a one centimeter offset of this center cylinder. Adding these signals together produces a signal that is proportional to the offset of the center conductor. For the parameters shown here the decay time constant is approximately 200 ns. Thus, in the 70 ns of the ETA-II pulse, the position signal droops by approximately 30%. For centering the beam this droop is of little consequence. However, for determining the position of an off-axis beam this droop must be compensated by either processing the position signal or partially integrating the signal.

The present droop compensation scheme on ETA-II is to correct it in software, thus preserving signal strength. A simple yet accurate approach is to calculate the amount of droop by finding the value the signal immediately reset to (and it is usually non-zero) and add a ramp to the signal with that amplitude. In addition, RC circuits have been built to boost the RC time constant. The advantage of using hardware compensation is speed of data processing but signal strength is compromised. These circuits have not been used yet.

6 CONCLUSION

A wealth of extremely detailed characterization on two generations of beam bugs (ATA and ETA-II) has pointed to a number of improvements that can be made on the accuracy of these diagnostics. It has been known that increasing the number of pickoff points increases off-axis accuracy. However, one must be careful about implementing this idea. The increased number of pickoffs also increases the inherent error in port to port variations as shown in Fig. 4. To combat this source of error, one should document port amplitude variation for each port on each beam bug. This can be stored in a look-up table and compensated in software. This necessitates individual measurement of each pickoff and summing and differencing is processed in software, not hardware as has been traditionally done. This also increases on-axis precision as long as bit noise is not a major source of error (if one goes to 16-bit data acquisition).

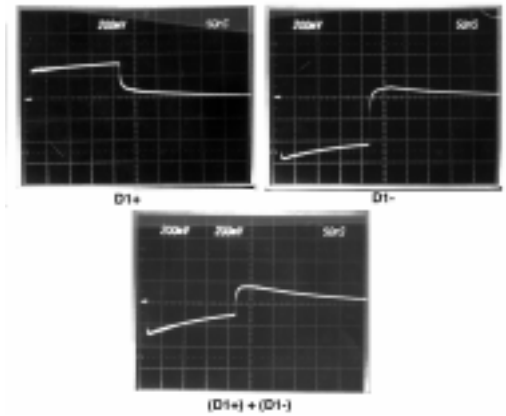

Fig 5. Oscillograms showing bug signals generated from a 1 cm offset of the center conductor of the test fixture.

The dipole *L/R* droop on ETA-II beam bugs has been corrected in software. In addition, a real-time display of processed I, X, and Y values has been implemented. In the long term, beam bugs around the fast kicker (which require a high level of precision) will have it's pickoffs individually routed to the control room.

A COAXIAL CABLE BEAM LOSS MONITOR ION CHAMBER SYSTEM FOR HIGH POWER MULTI-BUNCH BEAMS*

M. C. Ross and D. McCormick
Stanford Linear Accelerator Center, Stanford University, Stanford, CA 94309

Abstract

Gas filled coaxial cable beam loss monitors are a proven diagnostic in short pulse linacs and transport lines. At the SLAC linear collider (SLC), where the bunch length (σ_z) is ~ 1 mm, monitor cables with lengths ranging from 100 m to 3 km are used to locate beam losses of 5 x10^8 particles (1.5% of the nominal intensity) with a resolution of +/- 1 m. The monitor is effective because of the simplicity of its installation and signal interpretation. Future linear colliders (LC) will use beams made up of trains of many closely spaced bunches and will therefore require more careful signal processing in order to locate losses. Typical collider operation will involve the use of pilot pulses, made up of only one bunch, to test subsystem performance prior to full power operation. A simple signal processor will be able to locate losses by comparing the evolution of the loss monitor signal as the number of bunches is increased. The monitor must have 10 times greater sensitivity than the SLC monitors in order to provide a prediction of the expected beam loss at full power using only the signal from the pilot pulse. This paper describes the proposed linear collider loss monitor system.

1 INTRODUCTION

Future LC differ from the SLC in that they will use multi-bunch, very high power beams. The machine protection system (MPS) role is therefore more critical than in older, lower power machines [1] and the consequences of its failure are more severe.

The MPS for LC consists of two primary sensors: a device controller monitor and an errant beam detector (EBD). The purpose of the device controller monitor is to query the state of all appropriate devices before allowing the system to produce beam pulses. The monitor can be as simple as an analog comparison of magnet currents and will be queried and tested before each pulse. The EBD is typically comprised of loss monitors, such as gas filled ion chambers, current monitor toroid comparators and solid state radiation detectors as well as simpler devices such as thermal sensors. In an ideal system, the device controllers would be adequate to ensure that the machine is not in danger of damage from simple failures.

Some failures, such as instabilities in upstream systems, will not be identified by the device controllers. In this case, it may not be possible to recover stable operation without a diagnostic process that includes the generation of a sequence of beam pulses that may then be analyzed in order to determine the underlying cause of the fault. An essential aspect of the EBD system operation is to allow the generation of the diagnostic pulses and eventually to allow the recovery of full power operation.

2 MACHINE PROTECTION SYSTEM

The linear collider MPS will control both the termination of operation in the case of a device controller signal or an EBD signal and the restoration of full power operation. The system must at the same time protect the accelerator structure from possible single pulse induced failure (SPIF), i.e. failure that results from a single errant pulse without any warning. SPIF is a concern in future LC because the charge density, and therefore the power density, is high enough to cause substantial material damage.

Restoration of full power operation proceeds in 5 stages as outlined in table 2; 1) generation of a low repetition rate benign, low intensity, high emittance single bunch pulse which cannot cause SPIF, 2) generation of the same pulse at high repetition rate, 3) at full repetition rate, increase the single bunch intensity, 4) reduce the emittance to the nominal value, and finally, 5) raise the number of bunches (n_b) to the nominal.

The purpose of the coaxial cable loss monitor (CCLM) system is to aid in predicting what the beam loss profiles will be in order to allow the steps listed above to proceed. We will focus only on the last step, increasing n_b, since it involves the highest power beams. Collider systems are designed such that the difference between the trajectory and phase space volume of a single bunch and the projected volume of the entire train is small. However, following a system failure or an interruption, this cannot be guaranteed, so the response of the loss monitor must be checked and evaluated as full power operation is restored.

Typical Next Linear Collider (NLC) parameters are listed in table 1. Table 2 shows a typical full power recovery sequence from a 'benign' pilot beam at low repetition rate to full power operation.

* Work supported by the Department of Energy, contract DE-AC03-76SF00515

Table 1: NLC beam parameters [2]

Bunch intensity (I_b)	1 x 10^{10} e+/e-
Number of bunches (n_b)	90
Bunch spacing (τ_b)	2.8 ns (total Δz=77m)
$\gamma\varepsilon_x$(horizontal invariant emittance)	100 x 10^{-8} m-rad
$\gamma\varepsilon_y$	10 x 10^{-8} m-rad
Energy	500 GeV
Repetition rate	120 Hz
Typ. linac beam size (σ_x)	10 μm
σ_y	1 μm

Table 2: Five step full power operation start sequence for NLC. Note that beam power increases by 10^5. The multi-step sequence is required in order to use the benign pilot beam as a diagnostic and smoothly make the transition to full power operation.

Step	Parameters n_b, I_b, typ. $\sigma_{x,y}$	Charge density (C/m^2)	Average beam power
Pilot beam	1, 1 x 10^9, 30μm(1Hz)	.04	80
Full rate	120 Hz	.04	10KW
Nominal I	1, 1 x 10^{10}, 30μm	.3	100KW
Nominal ε and I	1, 1 x 10^{10}, 3μm	23	100 KW
Nominal	90, 1 x 10^{10}, 3μm	2100	8MW

The rate at which the sequence proceeds depends on the characteristic stabilization times of systems used to control the beam parameters such as the emittance controller and beam energy loading compensation. Typically, the transition between steps may require 10 or more machine pulses or sub-steps so that, for example, n_b might follow a 1,5,10,20,40,60,80,90 progression.

Table 3: Loss monitor sensitivity requirements and test results using SLC beam (see figure 3).

Trip threshold energy(V_{thres})	2 J (corresponds to 240W at full rate)
Required sensitivity	250 mV/J (5mV/(V_{thres}/n_b))
Nominal SLC system sensitivity [3]	60 mV/J
Fast gas –Ar CF_4	150 mV/J – test result
Ar CF_4, larger cable, HV gradient doubled	450 mV/J – test result

The threshold used in the MPS is determined using an estimate of the average power that can cause damage in a given mechanical subsystem (typically a few hundred watts). Operation with CCLM signals greater than the threshold voltage is not permitted. Since the nominal pulse rate is 120 Hz, the threshold against which each pulse will be compared is about 2 J (V_{thres}). An electronic sensitivity of 5mV/(V_{thres}/n_b) is required so that an estimate the losses at full n_b is possible. Table 3 summarizes the threshold and CCLM sensitivity requirements.

3 LOSS MONITOR SYSTEM

Gas-filled coaxial cable loss monitors have been used at SLC and other accelerators for the last few decades [3, 4, 5]. They offer excellent position resolution (1m) and good sensitivity for short bunches. As the gas in the cable is ionized, a signal propagates in both directions along the cable. In the direction opposite that of the beam, the signal carries position dependent loss information. For multi-bunch trains, the signal from losses of a small portion of each bunch in the entire train at a single location and that from a few bunches at more than one location can be similar. One way to resolve the ambiguity is by monitoring the evolution of the signal during the n_b progression. Figure 1 shows the expected waveform from a single point loss and illustrates how the signal evolves through the power up sequence.

The complete MPS will also rely on discrete loss monitor EBDs. These devices indicate the local energy deposition less ambiguously but do not have the comprehensive geometric coverage of a CCLM.

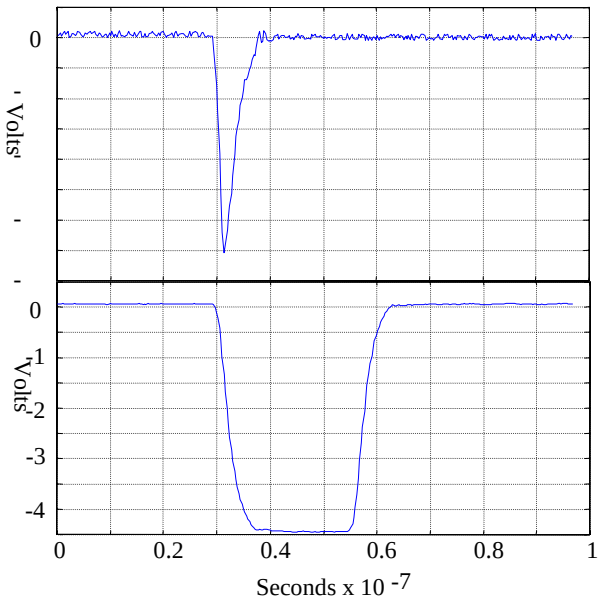

Figure 1: Simulation showing the expected CCLM performance as n_b is increased from 1 (top half of figure) to 90 (bottom half). The top half of the figure was recorded during SLC operation and illustrates a beam loss of 0.2J.

The loss monitor MPS signal processing schematic is illustrated in figure 2. Because the bunch train is long compared to the rise and fall time of signals in the cable, a simple V_{thres} comparator does not provide an accurate estimate of the local power deposition and an integrator with a time constant of $n_b\tau_b$ must be used.

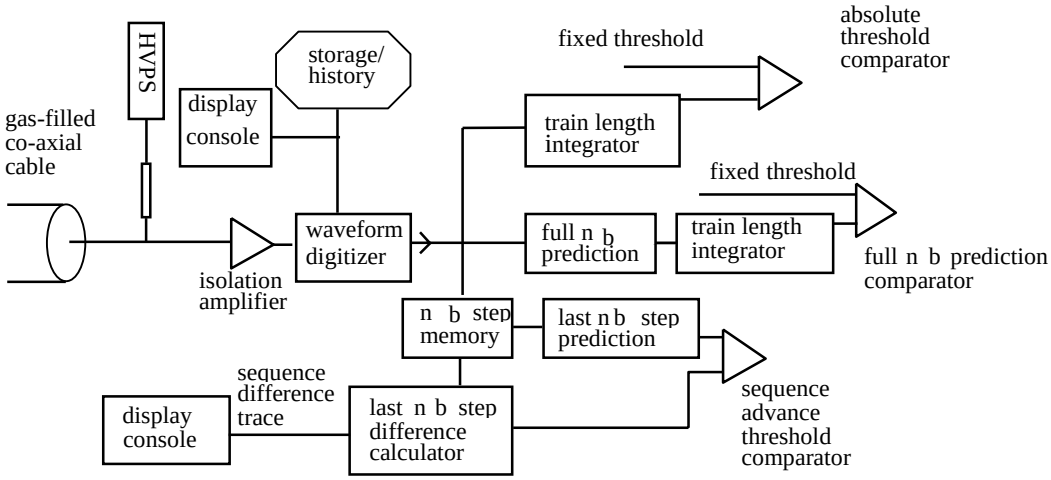

Figure 2: Signal processing schematic for CCLM MPS. The loss monitor signal emerges from the cable at the left side of the figure, is separated from the DC HV, and is amplified and digitized on each 120/s pulse. The signal is then processed and checked using the 3 comparators shown at right. If any threshold is exceeded, the sequence is terminated and a diagnostic process begins.

The electronics will use three comparators: 1) a local power threshold (V_{thres}), 2) anticipated V_{thres} for full n_b, and 3) a comparison of the observed vs. expected difference between the latest steps in the n_b sequence. It will analyze the signal evolution and abort the sequence, if necessary, before actually producing the pulse that exceeds the threshold.

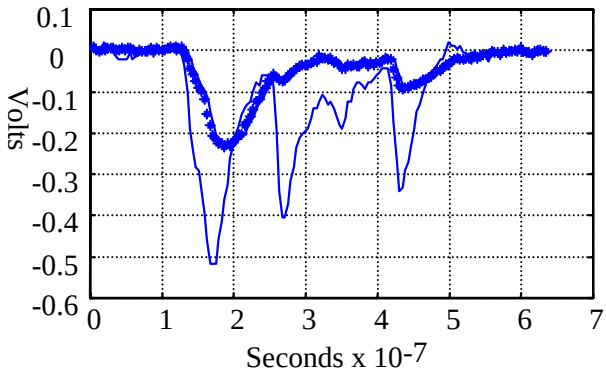

Figure 3: Loss monitor signals, (recorded during 1.2 GeV SLC beam operation), showing the difference between the Ar/CO_2 (95/5%) gas mixture (*) and the Ar/CF_4 (90/10%) gas mixture (-)[6]. The figure shows CCLM signals from a beam loss of about 4 x 10^9 particles distributed over three locations (0.8J total). The CCLM was mounted 0.3 m from the beamline.

Figure 3 illustrates results of tests aimed at increasing the sensitivity of the CCLM. As indicated in Table 3, the cable gas volume and the high voltage gradient were increased and a 2 x higher drift velocity gas was used. The combination of the three improvements provided adequate sensitivity.

4 CONCLUSION

The purpose of the pilot project is to develop a system for use of CCLM and determine its role in the LC MPS. While the CCLM does not replace discrete loss monitors, it has several advantages and will be used at future LC.

TIME RESOLVED, 2-D HARD X-RAY IMAGING OF RELATIVISTIC ELECTRON-BEAM TARGET INTERACTIONS ON ETA-II*

C. E. Crist, SNL; S. Sampayan, LLNL; M. Krogh, AlliedSignal FM&T; G. Westenskow, G. Caporaso, T. Houck, J. Weir, D. Trimble, LLNL,

Abstract

Advanced radiographic applications require a constant source size less than 1 mm. To study the time history of a relativistic electron beam as it interacts with a bremsstrahlung converter, one of the diagnostics we use is a multi-frame time-resolved hard x-ray camera. We are performing experiments on the ETA-II accelerator at Lawrence Livermore National Laboratory to investigate details of the electron beam/converter interactions. The camera we are using contains 6 time-resolved images, each image is a 5 ns frame. By starting each successive frame 10 ns after the previous frame, we create a 6-frame movie from the hard x-rays produced from the interaction of the 50-ns electron beam pulse.

1 INTRODUCTION

Of the variety of diagnostic tools available to an experimenter, an image or picture representing salient features under investigation is a significant tool. At ETA-II, one of the diagnostics that provides reliable data is a 6-frame x-ray camera. This instrument, created at Sandia National Laboratories in 1985 by Dr. William A. Stygar, provides six time-resolved images and one time-integrated image of the hard x-rays produced by relativistic electron beam as it interacts with a bremsstrahlung converter.

2 THE CAMERA

To operate in a high, x-ray noise environment, the camera, (fig 1) consists of a 26-inch diameter, 32-inch long, lead filled housing with an opening of 12 ½-inches (fig 2).

Figure 1

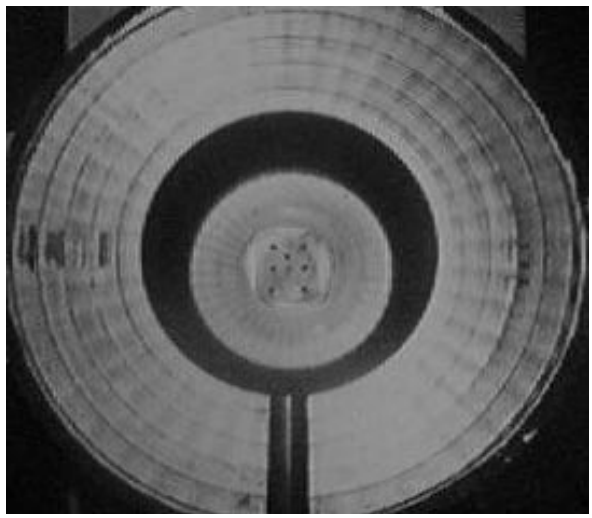

Figure 2

The reasons for the extensive lead shield is to minimize the signal from sever scattered x-ray noise. Inside the camera housing are the camera's six micro-channel plate (MCP) intensifier tubes and film holders. (fig 3)

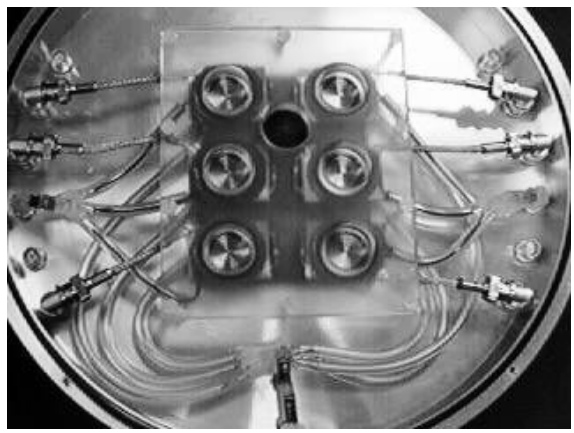

Figure 3

This housing provides a minimum of nine inches of lead shielding in front, seven inches of shielding on the sides and three inches of shielding aft, between the x-ray source and micro-channel plate MCP tubes. For imaging the x-ray spot, we are using tapered tungsten pinholes that are ~ 6 inches long with a final aperture of

.015 inch diameter. This provides us with an image resolution of ~ .3 mm with an on axis signal x-ray to scattered x-ray of over 1×10^{6} and off axis of over 1×10^{3} (fig 4).

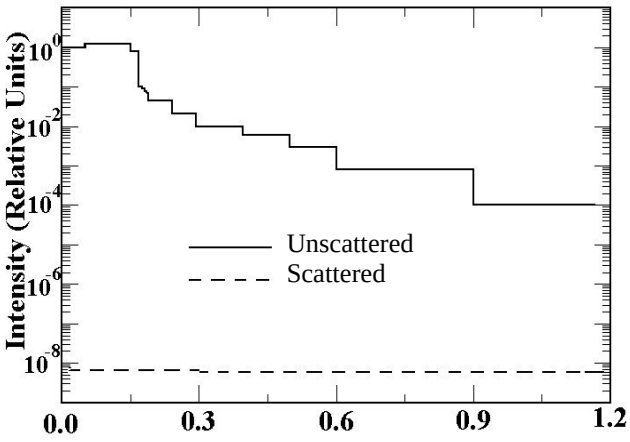

Figure 4

3 DRIVE ELECTRONICS

To control the timing of the individual MCP tubes in the camera, we use high-speed avalanche pulsers assembled at LLNL by Stephen Fulkerson [1]. The pulsers provide the 1-kV signal across the MCPs that in turns controls the precise gain or gating of the camera. For the experiments on ETA-II, the pulsers provide a signal for 5-ns, with each successive pulse arriving 10-ns later. This creates a 6-frame movie with an integration time or frame time of 5-ns with an inter-frame time of 5-ns (fig 5).

Figure 5

For monitoring the individual MCP sequencing, a sample from each pulser is summed via a resistive network. This signal is then combined to a signal from a beam current monitor which is located ~2.5 m upstream of the bremsstrahlung converter. All signals are then combined via the summing function of a Tektronix 7104 oscilloscope and recorded on film. The film is later scanned via the flatbed scanner and archived for later processing (fig 6).

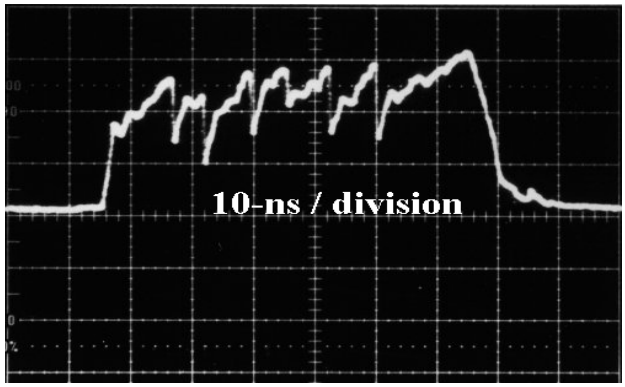

Figure 6

4 DATA RECORDING

Recently, we are using Polaroid Type 52 and Type 57 file for our data recording. While this is not the optimum recording medium, this camera/film combination provides a relatively convenient recording format. After developing the film, we utilize a standard flatbed scanner with an optical resolution of 1200 dots per inch (dpi). The film is scanned as an eight-bit gray scale image at 1200 dpi. The result 22-Mb image is then stored in a Joint Photo. Expert Group (JPEG) format image file. The files are then available for image processing and data reduction

5 RESULTS

For the applications at ETA-II, we are presently measuring beam profiles with feature sizes from ~ .5-mm to 2.0-mm. This combination of optics, shielding, film, and digitalization, provides us with a reasonable representation of the x-ray spot behavior as a function of time. As a result of utilizing this diagnostic we have performed several critical experiments in support of DARHT and AHF programs [2,3]. An example of the raw data provided by this system, clearly demonstrates some of the unique advantages of this instrument (fig 7 & fig 8).

Figure 8

6 FUTURE PLANS

Future activities include installing an array of video type cameras with a resolution in excess of 30 lp/mm. The cameras, CID Technologies Corporation's model TN 2250, create an image using a 512 element by 512 element Charge Injection Device (CID) sensor. The individual square pixels are 15-μm by 15-μm on a side. The input of the CID arrays are coupled to the output of the micro-channel plate intensifiers by means of fiber-optic tapers. This provides a convenient means of matching the 18-mm diameter MCP to the camera's ~0.3-inch x 0.3-inch CID array. With video frame-grabbers, from Imaging Technologies, containing eight-bit flash A/D converters, direct digitization and computer storage of the images is possible. This configuration should allow us to acquire, store, and pre-analyze the spatial and temporal history of the beam at a rate consistent with the accelerator operation.

ABSOLUTE BEAM POSITION MONITORING USING HOM-DAMPER SIGNALS *

C. Peschke, G. Schreiber, P. Hülsmann, H. Klein
Institut für Angewandte Physik, Universität Frankfurt/Main, Germany

Abstract

To preserve the required beam quality in an e^+/e^--collider it is necessary to have a very precise beam position control at each accelerating cavity. An elegant method to avoid additional length and beam disturbance is the usage of signals from existing HOM-dampers. The magnitude of the displacement is derived from the amplitude of a dipole mode whereas the sign follows from the phase comparison of a dipole and a monopole HOM. To check the performance of the system, a measurement setup has been built with an antenna which can be moved with micrometer resolution to simulate the beam. Furthermore we have developed a signal processing to determine the absolute beam displacement. Measurements on the HOM-damper cell can be done in the frequency domain using a network analyser. Final measurements with the nonlinear time dependent signal processing circuit has to be done with very short electric pulses simulating electron bunches. Thus, we have designed a sub nanosecond pulse generator using a clipping line and the step recovery effect of a diode. The measurement can be done with a resolution of about 10 micrometers. Measurements and numerical calculations concerning the monitor design and the pulse generator are presented.

1 INTRODUCTION

To explain the principle of operation, we take a look to the modes of a single pillbox resonator. On the one hand, the monopole modes have a nearly constant longitudinal electrical field near the axis. Therefore their excitation by a bunch of charged particles does not depend on the displacement. The amplitude after a passing of a bunch is proportional to the charge of the bunch, the starting phase is independent of the displacement. On the other hand, the dipole modes have no longitudinal electrical field on the axis. Off-axis the field rises with the first Bessel function. Near the axis, the amplitude after a passing of a bunch is proportional to the magnitude of displacement and the charge, the starting phase ($0^\circ/180^\circ$) depends on the sign of the displacement.

So we can use the complex amplitude of a dipole mode to measure the absolute beam position in one azimuthal direction. A higher monopole mode serves as a phase reference to detect sign of bunch displacement. The accelerating mode is not useful for this purpose since amplitude is dominated by the klystrons.

One possibility for the choice of a suitable monopole mode is the TM_{011} pillbox mode. Due to the fact of different frequencies of the TM_{011} and TM_{110} mode phase comparison of both modes is very difficult. This method was described in a preceding paper [1].

To simplify the method it is desirable to have the same frequency for both modes. This would simplify the synchronisation with the bunch and reduces the number of intermediate frequency stages which leads to a considerable reduction of costs. Thus one needs an additional monopole-like mode with the frequency of the TM_{110} dipole mode. This is ensured by the presence of reflections in waveguide corners of the HOM-damping system attached (see for example the SBLC [2] HOM-damping system).

One suitable mode was found by a MAFIA-simulation (eigenmode solver) of the coupler cell closed by electrical boundaries within the iris and waveguide flanges. The mode on the left hand side of Figure 1 is the desired monopole mode with electrical field on axis. On the right hand side one sees the dipole pillbox mode geometry changed by the damping system attached. Due to the strong damping effect on both modes, the resonance curves are widely overlapped. Thus one can choose a frequency near both resonances. To proof the existence of the monopole mode and their coupling to the beam a MAFIA time domain simulations have been done.

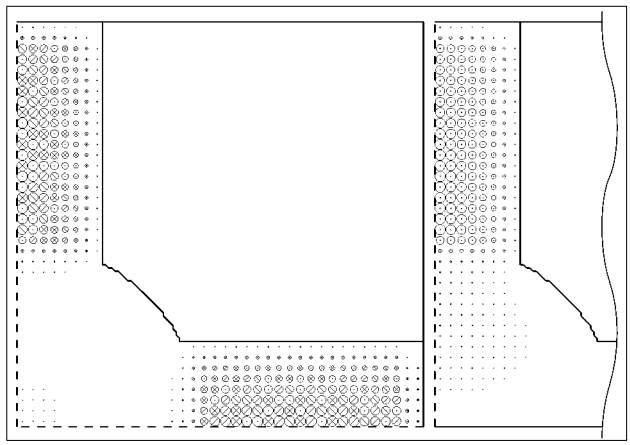

Figure 1: MAFIA[3]-simulation of the coupler cell: monopole-like waveguide mode at 4.1682 GHz and dipole mode at 4.1115 GHz.

2 FREQUENCY DOMAIN MEASUREMENTS

For the measurements the beam was simulated by a movable antenna nearby the axis. Therefore a positioning system has been build with a mechanical resolution of 1.23 micrometers. As long as all components of the signal processing electronics are linear and time invariant, the measurements can be done in frequency domain. During the measurements the RF-source was connected to the movable antenna. The signals of the modes were detected by two pick-up antennas mounted in the waveguides of the damping system. The separation of monopole and dipole signals were done by a 180˚ ring hybrid which delivers the sum and the difference of the signals. Figure 2 shows mag-

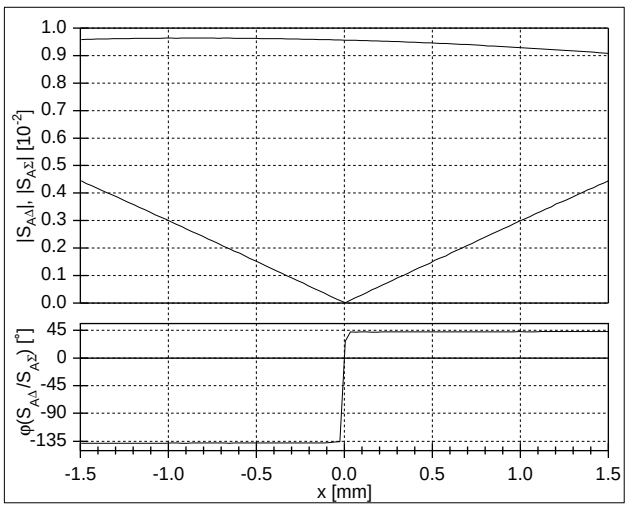

Figure 2: Transmission from antenna to Σ- and Δ-Port at 4.198 GHz in dependence of the displacement.

nitude and phase of the transmission from the movable antenna (A-Port) to the Σ- (monopole signal) and the Δ-Port (dipole signal) of the hybrid depending on the position of the input antenna. As expected, the dipole signal rises linearly with the magnitude of displacement and the phase between monopole and dipole signal jumps by 180˚ at zero displacement. Furthermore the result shows a much stronger coupling to the monopole than the dipole mode. Even at positions far off axis (1.5 mm) the monopole transmission is two times the dipole transmission. Thus it is clearly shown that the 180˚ ring hybrid is necessary.

Figure 3 shows the ratio of dipole to monopole transmission in magnitude and phase with the maximum resolution of the positioning system. This measurement was performed at optimum frequency of 4.197 GHz. We found a phase jump within 1.23 micrometers on axis. Apart from the optimum frequency the minimum is flatter and is further away from zero. Due to the fact of mechanical tolerances of the damping system, the electrical axes of the monopole and the dipole modes are different (Figure 2). Thus the electrical field of the monopole mode is not constant near the axis of the dipole mode. Together with the

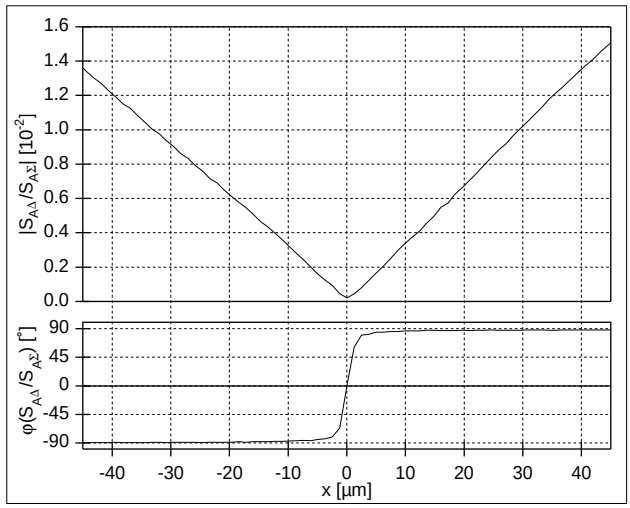

Figure 3: Transmission ratio at 4.197 GHz in dependence of the displacement.

limited isolation of the hybrid the signal is not symmetric, which causes a relative inaccuracy of 6 % of the beam displacement.

Further measurements with the nonlinear time dependent signal processing circuit have to be done with very short electric pulses simulating electron bunches.

3 BEAM SIMULATIONS BY SHORT PULSES

The requirements to produce a short pulse are small transition time and small pulsewidth. A 10 MHz oscillator pulse is shaped by a clipping line and the transition time is shortened by a step recovery diode. The pulse generator is realized on a single microstrip line printed circuit board completely. The schematic configuration is shown in Figure 4.

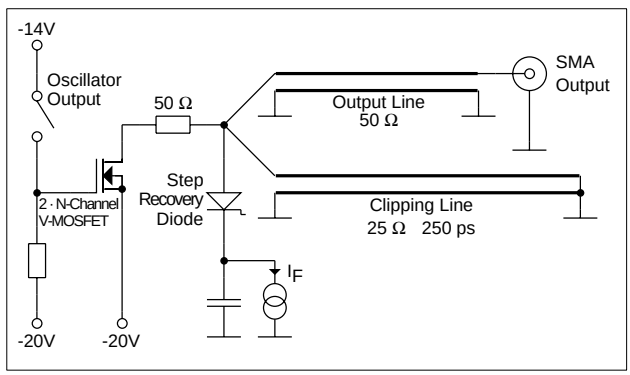

Figure 4: Schematic of a fast pulse generator (simplified).

The step recovery diode can be described as fast switch reducing the fall time of the oscillator pulse. A forward bias I_F stores charge and the negative oscillator pulse, powered by two V-MOSFETs, causes a reverse bias I_R which depletes this charge, and when fully depleted the step recovery diode ceases to conduct current. The action of turning

off takes place within 100ps or less depending on forward and reverse bias and the specific carrier life time of the diode.

The clipping line changes the falling edge into a pulse, and pulse length is given by two times the delay of the clipping line which has to be longer than two times the rise time of negative edge. Otherwise the resulting pulse height decreases. To avoid multiple reflections the entrance of the clipping line, seen from the short end, should be matched. But due to presence of the diode capacity and parasitic inductances of the MOSFETs perfect matching is impossible. The effect of multiple reflections on the resulting pulse can be seen in Figure 5, after the desired negative pulse,

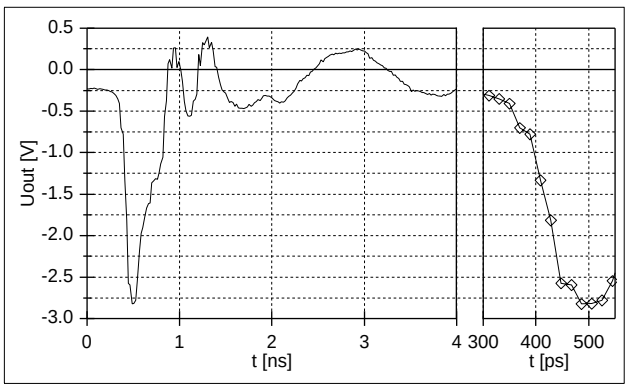

Figure 5: Measured output signal of the pulse generator in Figure 4.

which ends around 800 ps, the signal is oscillating around zero.

One possibility to get rid of the undesired multiple reflections caused by the mismatch of the clipping line is to connect the diode directly to the common drain of the MOSFETs. The disadvantages are now the parasitic inductances and capacities of the MOSFETs which influence the pulse stronger than before. On the other hand due to the inductances the pulse height is increased. Additionally length and impedance of the clipping line were optimized to achieve a more proper pulse. This is ensured by destructive interferences eliminating the parasitic oscillations. Furthermore leading parasitic oscillations can be minimized using a second line with an open end. All these precautions were verified numerically with the program SPICE [4] and are not yet realized experimentally. The configuration is shown in Figure 6 and the results are presented in Figure 7.

4 CONCLUSION

The resolution of the HOM-damper beam position monitor is limited by strongly excited monopole modes. It has been shown that a resolution of 10 µm seems possible. The relative inaccuracy caused by the axes offset of the monopole mode, which is in the order of 6 %, can be decreased by the construction of a new HOM-damping system which can be machined more precisely. Furthermore an inaccuracy due

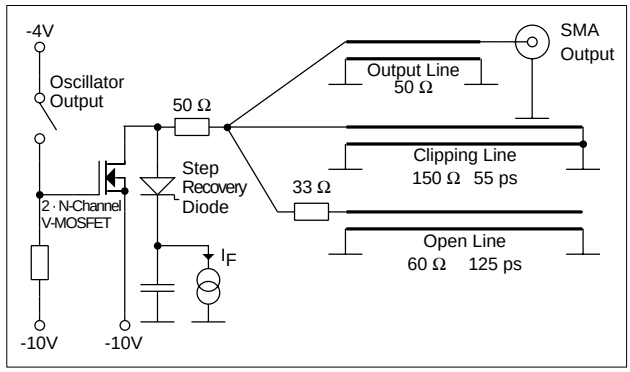

Figure 6: Schematic of a optimized pulse generator (simplified).

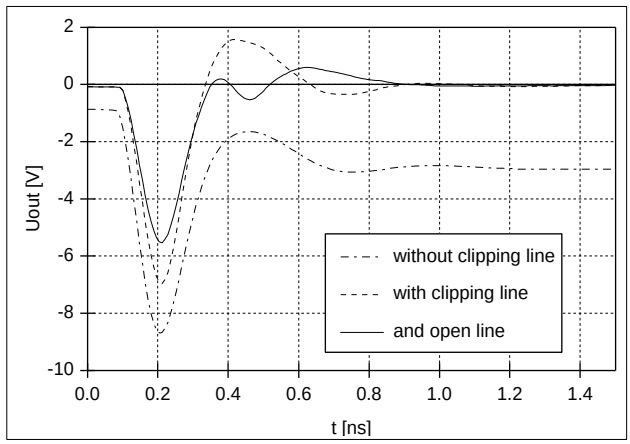

Figure 7: Calculated output signals of the pulse generator in Figure 6.

to the evanescent accelerating mode in the HOM-damping waveguides is expected. But this influence depends strongly on the signal processing electronics and has not yet been proven. For measurements with the pulse generator the new proposed setup (Figure 6) will be built and tested.

This concept of a beam position monitor can be applied to any high energy cavity type linac with symmetric HOM-damping system. Due to the synchronisation with a higher monopole mode, external synchronisation to the timing system of the linac is not necessary. Thus beam position monitoring is also possible in non accelerating cavities.

DESIGN OF THE RF PHASE REFERENCE SYSTEM AND TIMING CONTROL FOR THE TESLA LINEAR COLLIDER

A. Gamp, M. Liepe, T. Plawski, K. Rehlich, S.N. Simrock, DESY
Notkestr. 85, D-22603 Hamburg, Germany

Abstract

The frequency distribution system for the TESLA linear collider must deliver a highly phase stable rf signal to the 616 rf stations over a length of 33 km. At the operating frequency of 1300 MHz a short term and long term stability of the order of 1 degree with respect to the accelerated beam is required. Our solution involves three coherent oscillators, a 9 MHz low loss coaxial cable distribution, 1.3 GHz fiber optics, and continuous calibrations based on beam phase measurements. This system is transparent to beam operation and will continually monitor and correct slow phase drifts.

1 INTRODUCTION

The overall layout of the TESLA linac [1] is sketched in Figure 1. The main elements are two linacs with a length of 2×12 km, the damping rings which make use of the linac tunnel, the source for electrons (laser driven rf photocathode gun), the source for the positrons which is based on the concept of high-energy photon conversion into e^+e^-, and a 3 km region for the beam delivery system in between the two linacs. The photon are generated by the spent high-energy electron beam passing a wiggler. The acceleration system in each linac consists of 9856 superconducting cavities which are powered by 308 klystrons (32 cavities per 10 MW klystron)

The various rf system that must be phase synchronized with picosecond stability over the full accelerator length are:

- the 616 rf systems operating at 1300 MHz in the two superconducting linacs.
- The 433 MHz rf systems for the damping rings
- the 1300 MHz rf system providing power to the photocathode rf gun of the electron source and the associated laser for illumination of the photocathode.

The timing system must guarantee that the bunches which are spaced by 337 ns (3 MHz repetition rate) arrive at the same time at the interaction region.

2 RF DISTRIBUTION STABILITY REQUIREMENTS

The phase stability requirements for the accelerating field in the linac cavities are dictated by the low beam energy spread requirement of $\sigma_E/E < 7\times10^{-4}$ and the timing requirements for the bunch arrival at the interaction point. Assuming that a third of the energy spread contribution originates from phase fluctuations of the accelerating field a correlated phase error of only σ_ϕ =0.4° at 1300 MHz corresponding to a timing error of 0.8 picoseconds can be tolerated.

The phase stability of the 433 MHz rf systems of the damping rings determines that arrival time of the bunches at the interaction point. The interaction position error should not exceed one bunchlength (1 mm) resulting in the same timing stability requirements as dictated by the low energy spread.

In addition to the rf phase reference system a timing system with event coding capability is required to allow for real time synchronization of the various rf and other subsystems. The electron and positron bunches must be accelerated in selected rf buckets (every 438^{th} bucket, this number is given by the ratio of bunch spacing and the period of one rf cycle) to guarantee that the collision takes place in the center of the detector. A misplacement by 1 bucket would result in a collision position error of 23 cm (λ=c/f=23 cm). Therefore the timing system for the rf gun must guarantee a trigger signal stability of better than 770 ps. The timing system clock will also be synchronized to the master oscillator and can therefore provide phase stable timing for the digital feedback and rf system monitors.

3 DESIGN CHOICES AND ISSUES

The four basic choices for a phase stable reference system are:

- coaxial distribution system
- fiber optic distribution system
- coherent oscillators
- beam pickup

All systems with the exception of the beam pickup require a beam based calibration scheme since calibrations by measurement of the electrical length of the subsystems is not sufficiently accurate. It is desirable to use a fast coarse calibration scheme for initial start-up of the accelerator and a slow and precise calibrations scheme which is active during accelerator operation and which is transparent to the beam experiments.

The rf distribution system for the TESLA linear collider has been designed as a combination of all of the above options to utilize the advantages of each of the systems thereby maximizing performance and providing some level of redundancy.

The design employs a coaxial distribution system in the linacs. It provides a phase stable 9 MHz signal to all of the 616 rf stations in the linacs and the 433 MHz systems in the damping rings. The signals are locally multiplied by 144 or 36 respectively. Coherent oscillators operating at 9 MHz are located at the beginning of each linac close to the 433 MHz rf systems (also close to rf gun for electrons and auxiliary positron source) and in the experimental hall

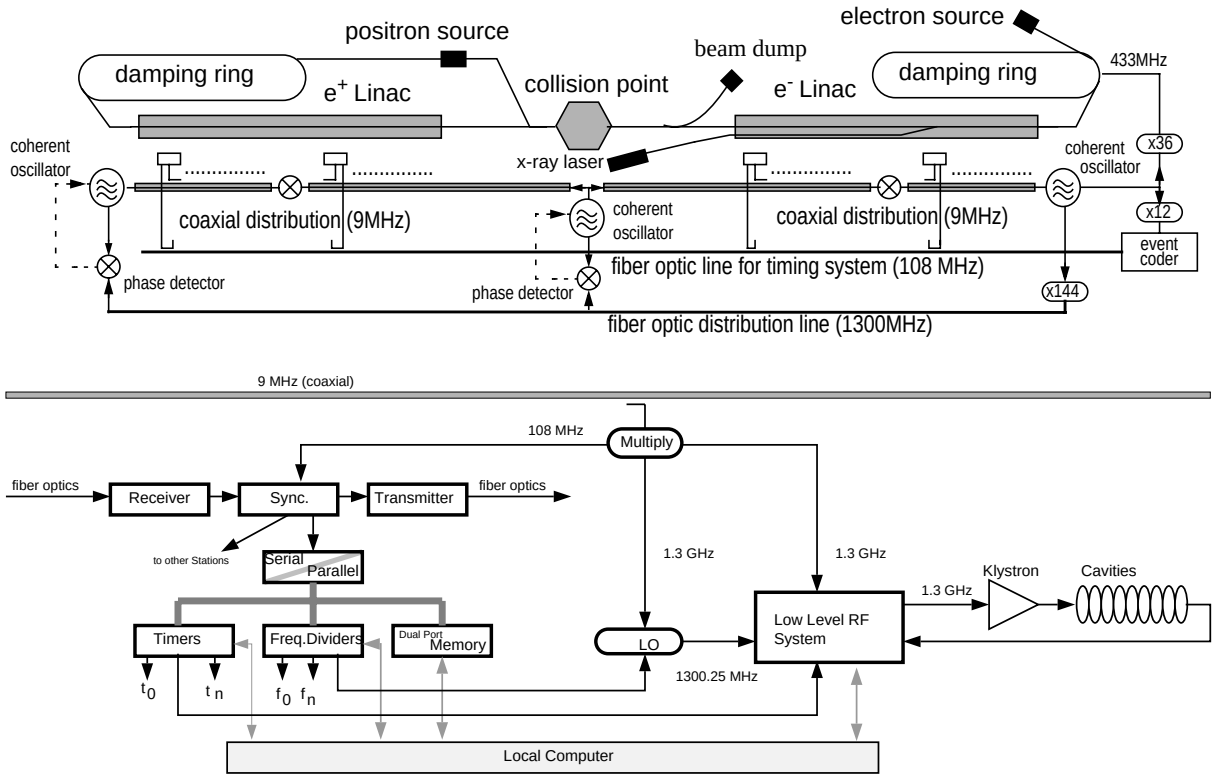

Figure 1 : Overall layout of the TESLA Linac. The phase reference system and timing control distribution are shown.

between the linacs. The three oscillators are synchronized by a optical fiber system. Each of the oscillators provides the reference signal for half of the linac closest to it. All systems are measured against each other and calibrated with reference to the beam utilizing the beam induced transients.

3.1 Coaxial Distribution System

The distribution of rf signals by coaxial cables or waveguides appears to be the most obvious solution since the rf signal can be transported directly to its destination. For the distribution to many rf stations directional couplers are recommended for good isolation between the tap points. This scheme allows for relatively high power levels of up to a few hundred watts at the input of the distribution line and can provide several milliwatts to several watts of rf power to each station. The main parameters that need to be considered for a coaxial distribution system are:

- frequency to be distributed
- distance between signal source and destination
- numbers of destinations to which the signal must be supplied
- power level of signal required at destinations
- power level available at signal source
- attenuation of coaxial cable
- power handling capability of the cable and the directional couplers
- thermal stability (phase stability of cable)
- number of amplifier needed within the distribution system
- sensitivity to microphonics

In the case of TESLA it is advisable to distribute a lower frequency and to convert the frequency locally to the operating frequency by use of multipliers. This method reduces the rf losses in the distribution system significantly. The lower frequency limit is given by the efficiency, noise characteristics, and phase stability of the local frequency multipliers.

For the TESLA accelerator the operating frequency is 1300 MHz but the coaxial frequency distribution along the linac is operated at 9.0278 (= 1300/144) MHz. The signal sources - H^--masers controlled low noise oscillator operating at 9 MHz and boosted by 200 W amplifiers - are located at the beginning of each linac and in the experimental hall between the linacs. For the coaxial distribution system a 1 5/8" (type LDF-50A1-5/8-inch Heliax) cable has been chosen because of its low insertion loss of 0.2 dB/100 m, the excellent phase stability (10 ppm/deg. C) and power handling (42 kW) capability. With a group velocity of 0.88c this results in a phase sensitivity of 177 deg./°C/10 km. The actual sensitivity may deviate from this number since the cable cannot expand freely due to its own mass.

The directional couplers (type HDC1460 from HD Communications) exhibit an insertion loss of 0.15 dB /

coupler. The distribution scheme for the linac is shown in Figure 1. Input power for each of the 7 km long sections is 200 W. The number of couplers has been reduced to 50 with a spacing of 120 m. A three way power splitters feeds a subnet consisting of LDF 1/2" cable to the two adjacent stations. The 9 MHz signals are then locally multiplied by 144 in the linacs and 36 at the damping ring rf systems.

3.2 Fiber Optic Distribution

Over the past years, fiber optic distribution links have replaced coaxial cable distribution for phase reference systems [2]. Optical fibers are the preferred medium for distribution because of their low attenuation, immunity to EMI/RFI, and temperature stability.

The thermal coefficient of delay for a typical optical fiber is of the order of 7 ppm/°C and therefore comparable to that of phase stabilized coaxial cables. A LCD coated optical fiber from Sumitomo [3] which has been specifically designed for high thermal stability provides a stability of better than 0.4 ppm/°C at an operating temperature close to 0°C. At a more realistic operating temperature of 30°C the coefficient increases to 1 ppm/°C. The group velocity in this fiber is 0.66c resulting in a phase sensitivity of 23.6 deg./°C/10 km.

The phase noise characteristics of a fiber optic distribution system suffers from the low signal levels retrieved at the individual receivers. The minimum phase noise level at 1300 MHz is expected to be around -100 dBc (> 10 kHz) [2] corresponding to an rms phase error of 0.57 deg. or 1.2 ps timing jitter which is marginal for our application.

3.3 Coherent Oscillators

The timing stability requirements between two remote locations such as the rf stations for the damping rings which are separated by a distance of 32 km could be fullfilled with two absolutely coherent oscillators. Present technology utilizing a H^- Maser allows for a frequency stability of $2x10^{-13}$/s corresponding to a phase stability of about 0.1 deg./s (or 0.2 ps/s) thereby exceeding the requirements for intrapulse and pulse-to-pulse stability. Even oven stabilized crystal oscillators can achieve a stability of the order of 2×10^{-12}/s which might be sufficient.

The coherent oscillators will be synchronized with the fiber optic distribution system with a time constant of 10 - 100 s to ensure long term stability.

3.4 Beam Based Phase Calibration

The ultimate reference for the rf systems in the linacs, the damping rings, and the timing of the bunches at the collission point will be the beam itself. It is therefore foreseen to synchronize all rf systems with respect to the beam. To achieve a measurement accuracy of better than 0.5 deg. or 1 ps, the transient beam loading based algorithm must average over several hundred measurements resulting in a measurement time of up to 100 seconds. Therefore the beam based phase correction can take place at a time scale of 100-1000 s.

4 TIMING CONTROL

The timing system provides various triggers and fixed frequency signals as well as machine parameters in a dual-port memory. A central timing signal source is synchronized with the master oscillator. This signal source generates encoded telegrams and sends them via a fiber optic distribution system to all devices along the linac and the damping rings. Repeaters every 120 meter receive the signals, resynchronize them with the 9 MHz, distribute the data to the local equipment and retransmit the signals to the next stations. The received serial telegrams have to be encoded and converted into parallel data streams. This data stream contains events and data words from the master station. Since the telegrams are synchronized with the main oscillator fixed frequencies with low phase errors can be derived from the telegrams also. The data stream is used to filter events in a timer unit and data words in the dual port memory. Programmable timers are triggered by these events to generate the start pulses for the klystrons or digital signal processors for instance. A timer unit provides several independent output channels. Some machine parameters that change from macro pulse to macro pulse need to be delivered in time to run all digital feedback loops in parallel. The data words from the telegrams are stored in a dual port memory. This information is readable from the local connected computers or signal processors.

5 CONCLUSION

The design of a rf phase reference and timing system for the TESLA linear collider is a challenging task due to the tight timing stability requirements of about 1 picosecond over a distance of more than 30 km. It should be possible to meet these requirements if a combination of coaxial distribution, optical fiber distribution, coherent oscillators and beam based calibration is used. It is planned evaluate the performance of such a scheme at the TESLA Test Facility.

FREQUENCY SOURCE FOR THE ISAC RFQ

K. Fong, S. Fang and M. Laverty
TRIUMF, 4004 Wesbrook Mall, Vancouver, B.C., Canada

Abstract

The ISAC RFQ cavity nominally operates at a frequency of 35 MHz. It can operate in either self-excited or driven mode. In the self-excited mode, the RFQ cavity itself is one of the frequency-determining elements. In the driven mode, the frequency is slaved to an external stabilized, digitally synthesized frequency source. In order to achieve glitchless transitions between the two modes, the RFQ frequency source is buffered by a phase-locked loop. When operating in the driven mode, RF switches in the loop configure the loop to lock to the external direct digital synthesizer. Reconfiguration of the RF switches in the self-excited mode turns the phase-locked loop into an oscillator whose frequency is determined by the phase shift of the RFQ cavity. The overdamping characteristic of the phase-locked loop prevents sudden transitions in either frequency or phase during switching between operating modes.

1 INTRODUCTION

The ISAC RFQ accelerator is a high Q, 4-rod RFQ with a peak potential between the electrodes of 74 kV. When operating under the fixed frequency mode, a stabilized direct digital synthesizer, whose frequency can be controlled remotely, drives the RFQ. During the powering and warming up phase, before the RFQ cavity reaches its operating temperature, the preferable mode is the self-excited mode, where the rf frequency is slaved to the resonance frequency of the RFQ cavity. The rf control system must be able to switch between these two modes under full power. Since the DDS frequency and the self-excited frequency are often different in frequency as well as in phase, this switching must be performed in such a way that will result in a gradual phase transition to prevent overloading the final RF power amplifier. A rf switch is used to provide the frequency switching, while a phase-lock loop is used to buffer the resultant switching transition. The phase-lock loop is designed with a large overdamp factor to enable the RFQ rf system to switch from one mode to another without generating large phase excursion.

2 DIRECT DIGITAL SYNTHESIZER

For operation of the RFQ in the driven mode, a frequency source whose output frequency ranges from 35.654517MHz to 35.851119MHz is needed. A digital direct synthesizer (DDS) is used to provide a very stable source with fine resolution, and is able to change frequency without generating phase jumps. As shown in Figure 1, a DDS is used as the core of this frequency source.

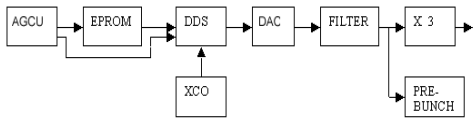

Figure 1: Block diagram of DDS

The phase data, which is stored in the EPROM shown in Figure 1, and the clock frequency are directly related to the output frequency by the equation (1).

$$f_o = \frac{f_c x(-\,phase)}{2^{32}} \qquad (1)$$

where f_c is clock frequency generated by an 80 MHz crystal oscillator (XCO), *-phase* is the phase data. The DDS input phase resolution is 32 bit, but the phase bus between the DDS and the EPROM is only 8 bit. Therefore, it is necessary to transfer the phase data four times from the EPROM to the DDS to obtain a new frequency. This control logic is performed by the Address Generator Control Unit(AGCU).

The DDS output frequency is the third sub-harmonics of the RFQ frequency (i.e. 11.884839MHz to 11.950373MHz). The DAC is used to convert the frequency digital data to analog voltages. A 3-pole Butterworth bandpass filter removes any spurious frequency components and splits the signal into two paths: one is used as the frequency source for a buncher placed upstream the RFQ and another requires tripling the frequency in order to obtain the desired frequency for the RFQ. The design frequency resolution is 6Hz and its stability is better than 1ppm.

3 PHASE-LOCK LOOP

The RFQ can be operated either under the driven mode, in which the DDS is used as the master frequency source, or in the self-excited mode, in which the signal from the RFQ cavity is used to determine the excitation frequency. An internally terminated high-isolation rf switch is used to select between the two frequency references. A phase-lock loop (PLL), with its versatility in frequency control, acquisition times, and step response, is used as a buffer

after this mode selection switch. A low phase drift limiting amplifier with 30-dB dynamic range is placed between the switch and the PLL to eliminate the amplitude dependency of the circuitry. The performance requirements of this RFQ PLL are different from that of an ordinary frequency synthesizer. In particular, it is designed to have a slow step response in order to satisfy the following two requirements.

1. The ability to switch from self-excited to driven operations under full power without phase jumps.
2. The ability of the entire system to recover from sparking in a rf cavity.

A spark can collapse the rf field in the cavity. Sometimes within several microseconds the RFQ voltage may recover after the spark has dissipated. The inclusion of the PLL circuitry is designed to be highly overdamped such that its VCO frequency does not react to the disturbance during this time interval. The power amplifier keeps energizing the cavity with rf power at the last resonance frequency allowing the cavity field to recover. The transfer function of the PLL is given by

$$\frac{\theta_o}{\theta_i} = \frac{G}{1+GH} \tag{2}$$

with

$$G = \frac{K_v K_p F}{s} \tag{3}$$

and

$$H = 1.$$

In equation (2), θ_i is the phase at the input of the PLL, and θ_o is the phase at the output of the PLL. In equation (3), K_V is the VCO sensitivity, K_p is the phase-detector gain constant, and F is the transfer function of the filter. Together they determine the response characteristics of the PLL. A unity gain bandwidth in the order of kHz and a phase margin of more than 45^o provides enough damping for spark recovery. Using a type 2, second-order PLL, zero frequency error at dc is guaranteed. The schematic of the PLL filter is shown in Figure 2.

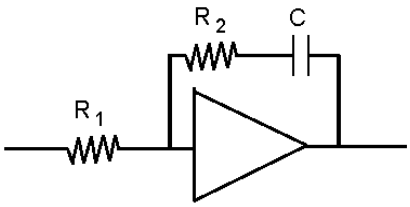

Figure 2: Schematic of PLL integrator/filter

In equation (3), the filter transfer function, F, is given by

$$F = -\frac{1+sT_2}{sT_1} \tag{4}$$

where $T_1 = R_1 C$ and $T_2 = R_2 C$. Figure 3 shows the output spectrum of the PLL. The x-axis shows the frequency at 5 kHz/div. The y-axis shows the power at 10 dB/div. This spectrum displays typical noise distribution of PLL output. The background noise is -70 dBc, while the oscillator noise with a bandwidth of 20 kHz is –55 dBc.

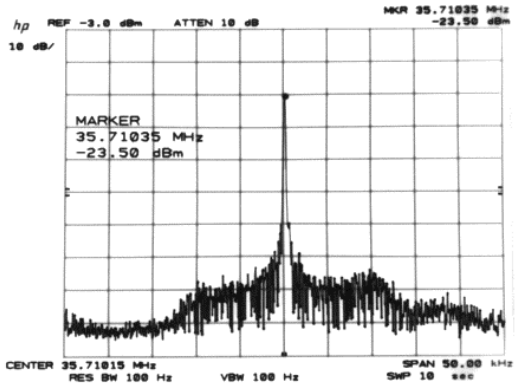

Figure 3: Output spectrum of PLL

4 SELF-EXCITED OSCILLATION

In the self-excited mode, the RFQ cavity determines the rf frequency. This is achieved by feeding the signal voltage at the RFQ cavity back into the input of the PLL. Thus θ_i is given by

$$\theta_i = \theta_o + \Delta\theta_m + \Delta\theta_l + \theta_c \tag{5}$$

where $\Delta\theta_m$ is the phase shift from the VCO to the output of the vector modulator. $\Delta\theta_m$ is the sum of the phase delay due to the VCO to the modulator and the phase shift of the vector modulator. $\Delta\theta_l$ is the phase shift due to the transport lag of the feedback loop. θ_c is the phase shift caused by the RFQ cavity. When the excitation frequency ω is close to the resonance frequency ω_o of the cavity,

$$\theta_c = -\frac{2(\omega - \omega_o)}{\omega_o} Q \tag{6}$$

Q is the quality factor of the cavity. These phase shifts must be adjusted to satisfy several constraints. In order to reduce crosstalks between channels in I/Q feedback loops, it is necessary to set the phase shift from the vector modulator to the vector demodulator to be integer multiples of 360^o (i.e. $\Delta\theta_l + \theta_c \cong 0.$). For proper operation of the self-excited mode, the phase shift from the output of the VCO to its input should also be integer multiples of 360^o. As a result, $\Delta\theta_m + \Delta\theta_l = 0$. This also implies that for the Q channel, the regulation is disabled and the open loop drive is set to zero. The overall phase relationship is illustrated in Figure 4.

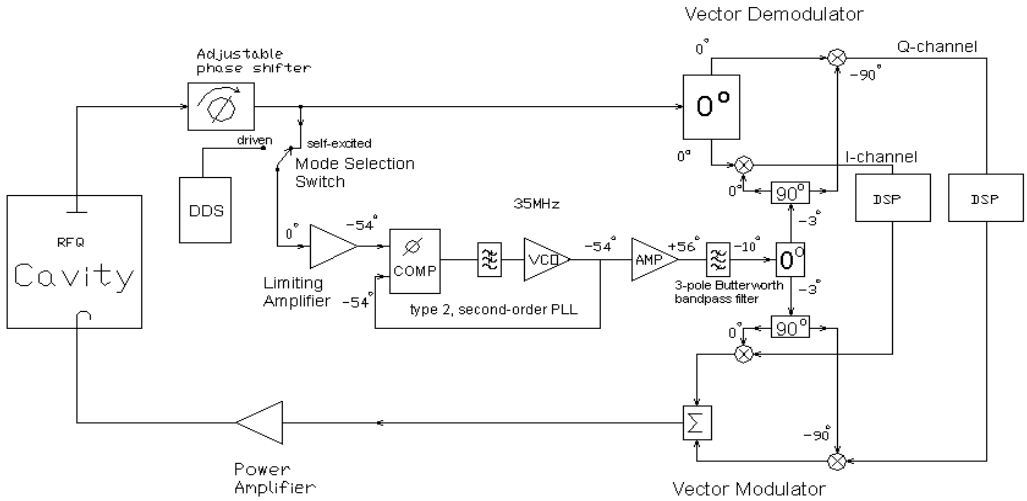

Figure 4: Phase relationship for proper operation of self-excited oscillation

When the above conditions are satisfied, the PLL will oscillate at

$$\omega = \frac{1+sT_2}{1+s\left(\frac{T_1\omega_o}{2K_pK_vQ}+T_2\right)}\omega_o \qquad (7)$$

The PLL in the ISAC RFQ has the following parameter values:

$$T_1 = 330\mu s$$
$$T_2 = 50\mu s$$
$$K_p = 0.16V/rad$$
$$K_v = 500\times10^3\ rad/s/V$$
$$\omega_o = 35.75\times10^6\cdot 2\pi\ rad/s$$

With these parameter values, Equation 7 then reduces to

$$\omega = \frac{1+\frac{s}{3\times10^3}}{1+\frac{s}{9\times10^3}}\omega_o \qquad (8)$$

where ω_o, the resonance frequency of the cavity, is the only varying factor. Since the variation in ω_o is due to thermal expansion, it varies slowly and thus,

$$\omega \cong \omega_o$$

Thus, the PLL tracks the resonance frequency of the RFQ cavity.

All the above mentioned circuitries (i.e. the PLL, the mode selection switch, the limiting amplifier, the vector modulator and the vector demodulator) are placed into a single C-size VXI module. In operation, the low pass filter at the PLL output is adjusted to give the desired phase shift as shown in Figure 4. Final phase adjustment is carried out using the variable phase shifter after the cavity. During self-excited mode operation, the Q-channel is disabled and the phase shifter is adjusted for minimum VSWR.

5 SUMMARY

The mixing of digital and analog technology in the frequency source for the RFQ allows for both performance and flexibility. A direct digital synthesizer is able to generate a highly stable and programmable frequency source. An overdamped phase-lock loop allows the rf power amplifier to switch from a self-excited mode to a driven mode without sudden phase jumps. To date, the system has been running in close-loop operation with the ISAC RFQ cavity. Stable operation has been achieved with both self-excited and driven modes. Switching between the two modes has been demonstrated at different power levels including full power without tripping the rf power amplifier. Spark recoveries at both modes are also observed to be similar. The rf system is able to recover from short duration sparks. In the driven mode, the digital direct synthesizer (DDS) as a frequency source is capable of reaching high stability, high resolution and is proving to be easily controlled.

A DEVELOPMENT AND INTEGRATION ANALYSIS OF COMMERCIAL AND IN-HOUSE CONTROL SUBSYSTEMS

D. M. Moore (WSRC), L. R. Dalesio (LANL)
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

The acquisition and integration of commercial automation and control subsystems in physics research is becoming more common. It is presumed these systems present lower risk and less cost. This paper studies four subsystems used in the Accelerator Production of Tritium (APT) Low Energy Demonstration Accelerator (LEDA) at the Los Alamos National Laboratory (LANL). The radio frequency quadrupole (RFQ) resonance-control cooling subsystem (RCCS), the high-power RF subystem and the RFQ vacuum subsystem were outsourced; the low-level RF (LLRF) subsystem was developed in-house. Based on our experience a careful evaluation of the costs and risks in acquisition, implementation, integration, and maintenance associated with these approaches is given.

1 INTRODUCTION

There were several reasons the control systems for major subsystems were outsourced for the LEDA project. A major reason was that delivery of the subsystem control system along with the subsystem allowed complete testing at the supplier's location before shipment. From our experience with several subsystems, we will analyze aspects of these implementations and provide strategies for successful acquisition of future subsystems.

2 SUBSYSTEM OVERVIEWS

Provided below is a summary of each subsystem included in this study. Brief descriptions of the computer system hardware, software, and external interfaces are presented. These subsystems have been, or are being, integrated into the integrated control system for LEDA, which is based on the Experimental and Physics Industrial Control System (EPICS). [1]

2.1 RFQ Resonance-Control Cooling Subsystem

The RCCS is a water cooling system used to maintain the RFQ's temperature, thereby controlling the resonant frequency of the accelerating cavity. Provided by Allied Signal, the RCCS includes an EPICS input/output controller (IOC) connected to devices like flow meters, thermocouples, valves, variable-speed pumps, etc.

2.2 High-Power RF Subsystem

The high-power RF subsystem control system is comprised of two PLCs used to control each klystron. An Allen-Bradley PLC-5/40 interfaces to the klystron control electronics (called the "transmitter"), and an Allen-Bradley SLC 5/03 interfaces to the high-voltage dc power supply. The transmitter provides magnet power, ac filament power, and crowbar triggering for the klystron, and the power supply provides the cathode voltage for the 1.2 MW continuous wave klystron amplifiers. Both PLCs were provided and programmed by the vendors as part of the purchase specifications for the equipment – Continental Electronics Corp. supplied the transmitter, and Maxwell Technologies supplied the power supply.

2.3 RFQ Vacuum Subsystem

The RFQ vacuum subsystem is used to achieve high vacuum. This subsystem was contracted to Lawrence Livermore National Laboratory (LLNL), and consists of five cryo pumps, two scroll pumps, and one turbo pump. Control is implemented using a Modicon PLC for equipment interlocks, Granville Philips ion-gauge controllers, and a Labview system for operator display and automatic shutdown.

2.4 LLRF Subsystem

The low-level RF subsystem is comprised of 5 VXI boards used to control the cavity field and resonance and to provide high-power RF protection and RF reference frequency generation and distribution. The clock distribution module provides the master timing signals to the other modules. The field control module provides feedback/feedforward I/Q control based on beam and field I/Q inputs. The amplifier control module compensates for individual klystron phase differences to 10 kHz. The resonance control module controls cavity resonance and allows for frequency agility during cavity warm-up. The high-power RF module protects the klystrons, windows, loads, and the accelerator from excessive reflected power.

The VXI boards were developed and programmed by the LANL RF group, and the external interface is via the slot zero controller mounted in the VXI chassis.

3 EVALUATION OF COST AND RISKS

All four subsystems described above are, or will be, integrated into the LEDA instrumentation and control system. This integrated system is implemented in EPICS, a control system tailored for accelerator and research applications. Whether the subsystems were outsourced or developed in-house had a definitive impact on the cost

and risks involved in acquisition, implementation, integration, and maintenance. Each of these areas is discussed below.

3.1 Acquisition

The acquisition cost for outsourced subsystems is difficult to quantify, particularly when the control systems portion is not identified as a separate, billable expense. However, a general estimate on the materials and effort involved is possible.

In the case of the RCCS, it was developed using hardware specified by the LANL Accelerator Controls and Automation group, which has primary responsibility for the integrated LEDA control system. When compared to a typical EPICS system design as developed by the Controls group, the only extra component added by the supplier is the learning curve required to become productive with the EPICS toolkit. This has been estimated at 3 man-months effort for this supplier.

In the case of the high-power RF subsystem, the materials include the two PLCs and their associated input/output modules, sensors, and cabling. Approximate costs of these are on the order of $25K. The effort includes the PLC programming, installation and testing by the vendor's control system engineer, as well any support provided by LEDA personnel involved in factory and site acceptance testing. This has been estimated at 12 man-months for the system.

In the case of the RFQ vacuum subsystem, it was developed using Labview due to LLNL's familiarity with that software, and the steep learning curve for EPICS. Interlocks were programmed into the PLC's ladder logic, and the automatic shutdown sequence was implemented in Labview. This Labview system is being replaced with an EPICS implementation for LEDA. The effort to support requirements definition and equipment testing has been estimated at 9 man-months.

In the case of the LLRF subsystem, the acquisition cost and risks are nonexistent. They are instead reflected in the implementation section.

3.2 Implementation

The RCCS took approximately 10 man-months to implement. Collecting requirements took 4 months, developing device drivers took 5 months, and testing took 1 month. Had the subsystem been implemented in-house by the LANL Controls group, it is estimated that 4 man-months could have been eliminated. However, this would have impacted the schedules of other subsystems due to resource limitations. Also, problems were encountered during device driver development and integration with the RCCS that required additional implementation time.

Since the high-power RF subsystem used two different models of PLCs, implementing the EPICS interface proved somewhat difficult. The PLC-5 communicates to other PLCs via Allen-Bradley's DataHighway Plus or DF1 protocols, while the SLC communicates via DH-485 or DF1. Since DF1 is the common protocol, an EPICS device driver was written to allow communication between a PC IOC and the PLCs. Coding and testing of this driver took approximately 4 man-months, and development of a fault logger similar to the vendor's implementation took approximately 2 man-months. There will be three klystrons connected to the LEDA RFQ. A commercial, off-the-shelf (COTS) hardware board was ordered for each klystron's PC IOC, at a cost of $750 each, to communicate with the transmitter PLC via DataHighway Plus. Communication with the power supply PLC is via the PC's serial port. Interfaces to the integrated control system were allowed for, but integration details were not initially designed. Had the LANL Controls group implemented the klystron controls, a large portion of the PLCs ladder logic would have instead been implemented in the EPICS IOC to reduce maintenance costs.

The RFQ vacuum subsystem was implemented in 4 man-months, which was spent developing the Labview display, automatic pumpdown sequence, and Modicon PLC program. Device drivers for the GPIB communications protocol were already supported in EPICS, but the Modicon PLC interface driver had to be created.

In the case of the LLRF subsystem, control system materials include only the slot zero controller and associated software licenses. Costs of these are on the order of $10K. The effort includes the software installation and configuration, ethernet wiring, and device driver development for each VXI module. This is estimated at about 11 man-months.

3.3 Integration

The RCCS was easily integrated into the LEDA control system, since it was designed as an EPICS application. Integration costs included implementing the database, sequences, and displays, and is estimated at 9 man-months.

For the high-power RF subsystem, EPICS database and operator screen development took 12 man-months for the first klystron. A considerable amount of time was spent analyzing the data available in the two PLCs and determining how best to duplicate this information for the other klystrons to be added to the network. Subsequent klystrons will be added rather easily due to the repetitive nature of the design, and this is estimated to take 0.5 man-months per additional klystron.

The RFQ vacuum subsystem was integrated into the LEDA control system by porting the Labview application to EPICS, and took 2 man-months. This includes reviewing the requirements, using the ladder logic and Labview programs as a foundation. Integrating a GPIB

device took 2 days, and overall system testing by LLNL and LANL is expected to require another man-month.

Integrating the LLRF subsystem is ongoing. EPICS device drivers are being written for each VXI module as they are delivered, and engineering databases and screens are being developed for testing and commissioning purposes. This effort was included in the implementation section. Further integration with the high-power RF subsystem databases and screens will take another 3 man-months, after obtaining all operational requirements.

3.4 Maintenance

Maintenance costs for these subsystems are affected by formality of the vendor relationships and the familiarity the LANL Controls group has with the overall system design. For instance, maintenance of the RFQ vacuum subsystem is not expected to take any extra time, since the ladder logic is the only component remaining from the original system design, and familiarization with that software was required to implement the porting into EPICS. Also, the LANL Controls group will now have maintenance responsibility for that software. However, high-power RF subsystem maintenance is complicated by the fact that all ladder logic changes will remain the responsibility of the vendors. This is likely to result in longer response times for software revisions, which could impact LEDA operations since some control algorithms and sequences are implemented in the PLC and not in the EPICS IOCs. Maintenance concerns are minimized for the RCCS and the LLRF subsystem since these are strictly EPICS implementations, and are only limited by the resources available to the LANL Controls group to perform these tasks.

4 SUMMARY

The effort involved in implementing a control system with subsystems developed by both outside suppliers and in-house personnel is affected by many factors. Included in these are the overall complexity of the subsystem, the amount of software to be developed while integrating new modules, and the amount of communication between subsystem developers and the integrated controls group. Table 1 lists efforts in man-months for the acquisition, implementation, and integration of the four subsystems discussed above.

Phase	RCCS	HPRF	RFQ Vacuum	LLRF
Acquisition	3	12	9	0
Implementation	10	6	4	11
Integration	9	13	3	3

Table 1. Effort (man-months) for Each Subsystem

5 CONCLUSIONS AND RECOMMENDATIONS

Although the LEDA control system is not yet fully operational, the following conclusions can be drawn from the experience gained to date in this effort:

- The amount of involvement in subsystem design and implementation by the LANL Controls group is inversely proportional to the effort to integrate each subsystem in the LEDA control system.
- Surprisingly the largest amount of time spent developing and integrating these subsystems into the LEDA control system has been in collecting requirements.
- When there are repeating elements in the control system, as is the case with the klystron PLCs, time spent replicating added elements is greatly reduced by carefully evaluating and planning the initial design.

The following recommendations can be made to improve future developments, both in outsourcing and in developing in-house:

- Ensure the personnel responsible for the integrated control system are involved in establishing subsystem requirements.
- Ensure the personnel responsible for the integrated control system are involved in periodic reviews of subsystem implementation.
- Reduce the role of PLCs in the design to that of equipment protection interlocking, and implement all sequencing and control algorithms in the EPICS IOCs. This will reduce complexity of the PLC design, and improve the flexibility of the integrated control system.
- When outsourcing, include in the purchase requisitions a minimum response time to software and hardware change requests, and add a minimum time period where there are no fees for these changes.
- When developing custom hardware in-house, the schedule must include time to integrate and test these components into the overall control system.

PERFORMANCE OF THE KLYSTRON MODULATORS AT THE S-BAND TEST FACILITY AT DESY

S. Choroba, J. Hameister, M. Kuhn
Deutsches Elektronen-Synchrotron, DESY, 22603 Hamburg, Germany

Abstract

The klystrons at the S-band test facility at DESY require high voltage pulses of 550kV at a flat top pulse duration of 3μs, at a current of 700A and a repetition frequency of 50Hz. Two HV pulse modulators with a nominal power of 375MW were built. The design and results of the commissioning of the first system were described in [1]. The second system came into operation and was operated at an output power up to 475MW (610kV, 780A). In addition it was modified to investigate capacitor charging power supplies, which might be used in a linear collider tunnel. This type of power supply promises a better efficiency than the conventional resonant charging method and also saves space in the linear collider tunnel. This paper describes the operation experience with the HV modulators at the test facility especially with the second system. It reports the modifications, which were required to operate the modulator with the new type of HV power supply and presents results of the operation.

1 INTRODUCTION

The S-band test facility at DESY is a 400MeV electron linac, which serves for the development and evaluation of components which might be used for an S-band linear collider. Two pulse klystrons operating at 2.998GHz with a nominal output power of 150MW are installed at the test facility. The pulse duration is 3μs and the repetition rate 50Hz. In order to generate the microwave power of 150MW a klystron cathode voltage up to 550kV and a current up to 700A are required. The high voltage pulses of 3μs flat top pulse duration are produced by line type modulators. Although the resonance charging method, used in both modulators, is a well established and reliable technique to charge the capacitors of pulse forming networks, a new type of capacitor charging power supply, which is now available from different manufacturers, was installed at the second modulator. It can be used alternately with the existing resonance charging system. Constant current capacitor charging power supplies have a high efficiency and a compact size. Both are properties, which are especially desirable for modulators, which need to be installed in a linear collider tunnel, but of course are also of interest for other linear accelerators. The first modulator is in operation since three years and the second since one year. In the following we present a short overview of the modulator system and report on our operation experience so far. After that we describe the modifications required to install the new charging power supply and present results of the measurements performed on the system.

2 LINE TYPE MODULATOR LAYOUT

Table 1 shows the parameters of the modulator and figure 1 shows the basic circuit diagram.

Table 1: Modulator parameters

Pulse Voltage	550 kV
Pulse Current	700 A
Flat Top Pulse Duration	3 μs
Repetition Rate	50 Hz
Equivalent Square Wave Duration	4.8 μs
Rise Time 10 - 90 %	700 ns
PFN	four lines parallel, each line ten sections
PFN Impedance	1.34 Ω
Total Capacitance	1.8 μF
Capacitor Capacitance	45 nF
Coil Inductance	1.3 μH
Charging Voltage	50 kV max.
Peak Current (primary side)	16 kA
Pulse Transformer Ratio	1 : 23

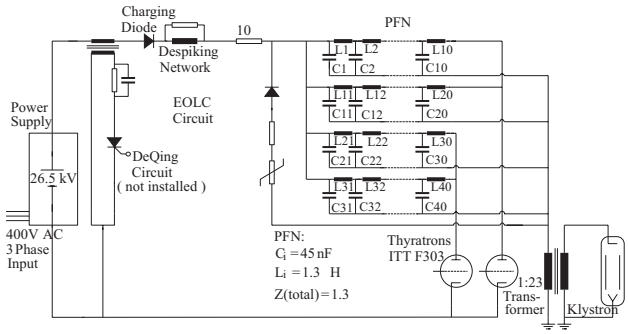

Figure 1: Basic circuit diagram

The pulse forming network is formed by four parallel lines of ten sections. They are discharged by two thyratrons, ITT F303, via the pulse transformer into the klystron. There is a slight positive mismatch between the pulse forming network and the klystron. The capacitors of the lines are charged by a resonant charging system consisting of a DC power supply (26.5kV, 5A), a charging choke of 16H and a charging diode capable to withstand

80kV. The PFN can be charged up to 50kV by a sinus half wave current of 17ms duration. This allows to operate the modulator at a repetition rate up to 50Hz. The DeQing system shown in the figure 1 was not installed, because the DC power supply has good regulation properties, which already allow a pulse to pulse variation smaller than 0.5%. Figure 2 shows typical waveforms at more than 500kV.

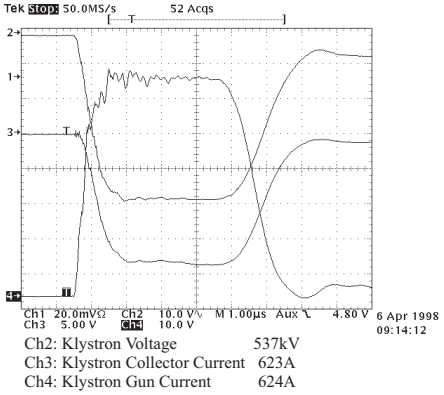

Figure 2: Typical waveforms

More detailed information can be found in [1].

3 OPERATION EXPERIENCE

At the beginning of operation electromagnetic noise generated by the modulators was a major concern. It entered the interlock system or other components and could lead to interruptions of the modulator operation. In the worst case it could even muddle up the thyratron driver trigger logic and damage components in the driver, especially the drivers thyristor switches. Since the source of noise could not be eliminated, we installed RC filters in the drivers and also in other components, which were affected by the noise. This solved our problem and allowed to operate without interruptions.

It is necessary to control the thyratrons reservoir voltage carefully. Otherwise the situation can occur, that instead of firing both thyratrons simultaneously, the thyratrons fire at different times or in the worst case one thyratron fails to fire. This does not harm the klystron, but leads to large thyratron grid spikes and can damage the thyristor switches in the driver circuits.

Besides these we had no major problems.

The klystron output power of 150MW could be reached with a cathode voltage of 550kV. With a PFN charging voltage of 50kV even 610kV could be achieved at the klystron. At this voltage an output power of 213MW could be extracted from the klystron. Since the klystron was developed for an RF power of 150MW at 3µs pulse duration and a repetition rate of 50Hz, we reduced the RF and HV pulse duration to 1µs and the repetition rate to 12.5Hz. The reduction in pulse width was accomplished by removing five capacitors per PFN line. At a flat top pulse duration of 1µs a maximum voltage of 610kV at 780A, which corresponds to a power of 475MW, was achieved and could be handled without problems. Longer pulses might be even possible but have the risk of damaging the klystron or the modulator. Since we need the klystron to operate the test facility linac, we refrained from running at longer pulse width at this power level.

4 MODIFICATION

The second modulator was modified in order to investigate the properties of a constant current capacitor charging power supply. This type of power supply might be able to replace the resonant charging method. It charges a pulse forming line with a constant current to the desired voltage without the use of a charging choke. Maxwell (San Diego, USA) offers power supply modules up to a voltage of 50kV and a power rating of 10kJ/s. Modules can be connected in parallel to build one power supply with more output power. In a first stage we installed three modules, which are sufficient to operate the modulator at maximum peak power, but at a reduced repetition rate of 12.5Hz instead of 50Hz. In a later stage the new power supply could be upgraded to full average power by installing up to twelve modules in parallel. In the meantime the existing resonance charging system must be used, if operation at 50Hz repetition rate is required. Therefore all modifications of the existing modulator needed to be done in a way, which allows to switch easily between the two charging methods.

A freewheeling diode and two series resistors must be installed between the pulse forming network and the constant current charging power supply output. This is necessary, because the charging power supply must be protected from negative voltage at its output. In this case a current could flow through the power supply rectifier diodes, which might exceed their capabilities. Negative voltage at the power supply output arise during fault conditions like klystron arcing or PFN breakdown and even also during normal operation conditions. The EOLC diode is not sufficient to protect the power supply, because it does not connect the power supply output and ground. We therefore installed a another diode at the thyratron side of the PFN. Figure 3 shows the diagram of the modified circuit.

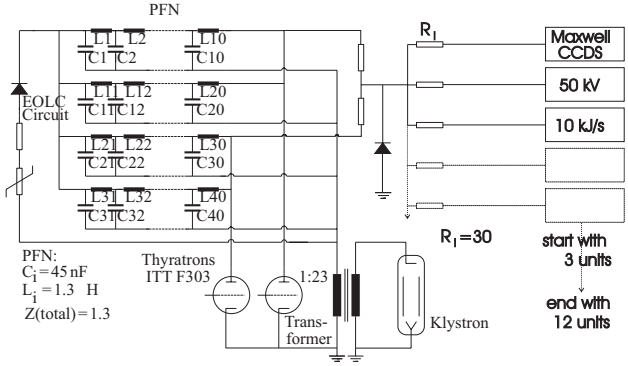

Figure 3: Diagram of the modified circuit

The protecting diode is made of 25 high voltage diodes in series (4kV each), each with a varistor in parallel. Two 30Ω series charging resistors serve for the decoupling of the two thyratrons. This allows switching of both thyratrons at the same time. Each of the power supply modules has a separate output cable, which is terminated by a another series resistors. We did not combine the output of modules directly after the output and did not use just one cable and resistor instead of many, because this would have made it more difficult to install or remove modules for test purposes. For a set up, which does not require this flexibility, a connection with just one cable could of course be made. The protecting diode and the resistors were installed in the PFN cabinet.

The compact size of this new type of power supply makes it attractive if space availability is an important aspect, e.g. in the case of a linear collider tunnel. The size of each of the modules in use is 220mm high, 508mm long and 19 inch wide. All modules, which would be sufficient for a modulator operation at full average power, would fit in two 19 inch racks. This reduces the space required by the existing DC power supply and the charging unit by about a factor of ten.

Another motivation to test the new type of power supply results from the efficiency demands of a linear collider. The existing resonance charging method has an efficiency of 88% for the charging path from the mains to the PFN, partly caused by the DC power supply efficiency and partly caused by ohmic and eddy current losses due to the charging choke. We measured the efficiency of the power supply at various output voltage settings. At the maximum voltage of 50kV it reaches 93%. Even if one includes the losses in the series charging resistors, the efficiency for the charging path from the mains to the PFN is still 91.5%.

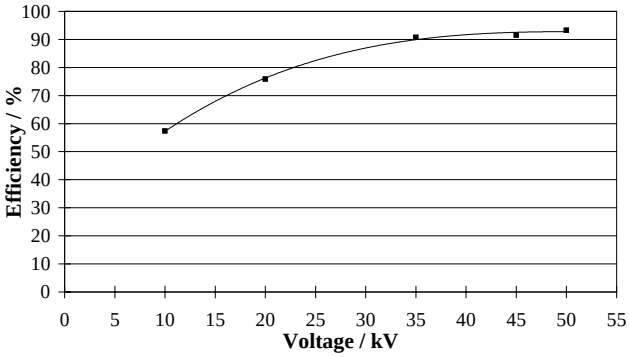

Figure 4: Charging power supply efficiency versus PFN voltage

The pulse to pulse variation was measured in the same way as for the resonance charging method by superposing 1500 klystron voltage pulses. The variation did not change significantly. and is still smaller than 0.5%.

An important aspect for a linear collider is the impact of the modulator power supplies on the line. Therefore we measured the voltage and the current of each of the input phases and calculated the input power of each phase. Figure 5 shows the linear ramp of the PFN voltage and the power extracted from the three phases of the mains. It is basically a picture one would expect from a three phase double way rectifier, which has do provide a linear increasing output power. This process is repeated with the modulators repetition rate. The power consumption from the mains is not constant and in case of a large number of modulators would probably disturb the mains. Further development to limit this effect is required.

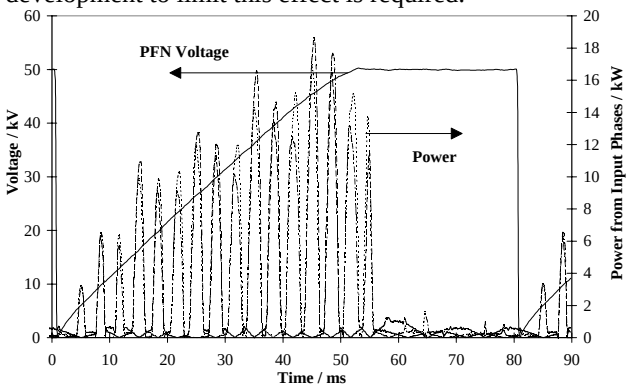

Figure 5: Charging voltage and power extracted from the three phases of the mains during one charging cycle

More detailed information about the modification of the second modulator can be found in [2].

5 CONCLUSION

The high voltage pulse modulators at the S-band test facility are in operation at nominal conditions of 550kV at 3μs pulse duration and a repetition rate of 50Hz. The second system can be even operated at a higher power level up to 475MW (610kV, 780A) at 1μs pulse duration and 12.5Hz repetition rate. The operation of the modulators is reliable, but the thyratron reservoir voltage setting needs careful control and adjustment. A new type of charging power supply was installed at the second system. It has a high efficiency and is of compact size, which makes it attractive for linear collider applications. Its reaction to the mains was investigated, but further work is necessary to limit disturbing effects to the mains.

ADVANCED BUCK CONVERTER POWER SUPPLY "ABCPS" FOR APT *

R. Street, T. Overett, E. Bowles
General Atomics, San Diego, California 92186-5608 USA

Abstract

To meet the Nation's needs for Tritium one proposal is to use a high-power proton Linac, The Accelerator for the Production of Tritium or APT project **. The 1700 million electron volt (MeV) proton beam accelerator will be powered by radio frequency (RF) klystrons. A direct current (DC) power supply is required for each of the approximately two hundred and fifty 1-megawatt (MW) continuous wave klystrons in the RF power system. The requirements are that the power supply meet output performance specifications, provide fault protection for the klystron, have high efficiency, high reliability, good maintainability, and be readily manufacturable. As the power supplies are one of the largest cost elements in the accelerator, a technology review was made to determine the most economical approach to satisfy the requirements. A switch-mode power supply employing a buck-regulator was identified as being potentially the lowest cost approach. As the switch represents a certain development risk, a small-scale prototype has been constructed for evaluation, and has resulted in the decision to fabricate a full-scale prototype power supply. The prototype design and performance test information will be made available to potential suppliers. A description of the concept follows.

1 INTRODUCTION

The proposed APT plant will use proven accelerator based technology. The 1700 MeV proton accelerator will utilize three standard 350 megahertz (MHz) klystron RF sources to drive the RF Quadrupole. There will be two hundred and forty one 700 MHz klystron RF sources to power the normal temperature low-energy linac and the super-conducting radio frequency cavities in the high energy linac to create the high-energy proton beam.

2 APT RF POWER SYSTEM

The APT plant requires one high voltage power supply (HVPS) for each of the 244-klystron RF power sources. Three HVPS provide 2 MW DC to 1.2 MW (RF) klystrons and the rest supply 1.6 MW DC to 1 MW (RF) klystrons. Two-MW DC power supplies rated for 95 Kilovolts (kV) @ 21 Amperes (A) DC are planned throughout for commonality.

*Work supported by DOE under contract DE-AC04-96al89607.

** George P. Lawrence's invited talk at this conference.

In addition to meeting specification requirements in section 4, the HVPS must also provide fault protection for the klystron, have high efficiency, high reliability, good maintainability, and be readily manufacturable. As the HVPS are one of the largest cost elements in the accelerator, a technology review was made to determine the most economical approach to satisfy the requirements. The results of that review indicated a switch-mode power supply employing a buck-regulator was potentially the lowest cost approach to satisfy all plant requirements.

The buck-regulator topology is potentially the most economical because the high voltage rectifier bridge and the high voltage step-up rectifier transformer are removed from the power supply. All other topologies, including the resonant power supply utilize expensive magnetic components, which increase their costs and complicate their manufacturability.

To accomplish this, the 230-kV high voltage, utility distribution transformers would become the rectifier transformers. The transformer secondary voltage is rectified to provide twelve pulse DC power to the system. This also simplifies and reduces the cost of the utility distribution system for APT because the usual branch circuits and components used to step-down the utility voltage to a workable medium voltage are not required.

The utility source 230-kV, 677 megavolt-ampere (MVA) line feeds four substations. Each of four substations (Fig. 1) will contain two, 60 MVA isolation transformers for a total substation capacity of 120 MVA. This allows each substation to feed twenty five percent of the HVPSs. For redundancy, two high voltage rectifier bridges would be connected to the secondary of each distribution transformer. There would be a total of eight rectifier-transformers and sixteen rectifier bridges. Interphase transformers tie the rectifier outputs from the phase-shifted transformers to make twelve pulse ripple. The transformer secondary is eighty-two kV rms. It is then rectified to 115 kV DC. Each rectifier bridge will be sized to support twice the usual number of HVPSs, in case one rectifier is out of service. Each of the four DC transmission grids would feed a minimum of sixty-one power supplies. Only three HVPSs will actually operate at 21 A. The remaining HVPSs will operate at 17 A. Fig. 1 shows a typical distribution substation pair of rectifier transformers including the DC rectifiers dedicated to the RF power system.

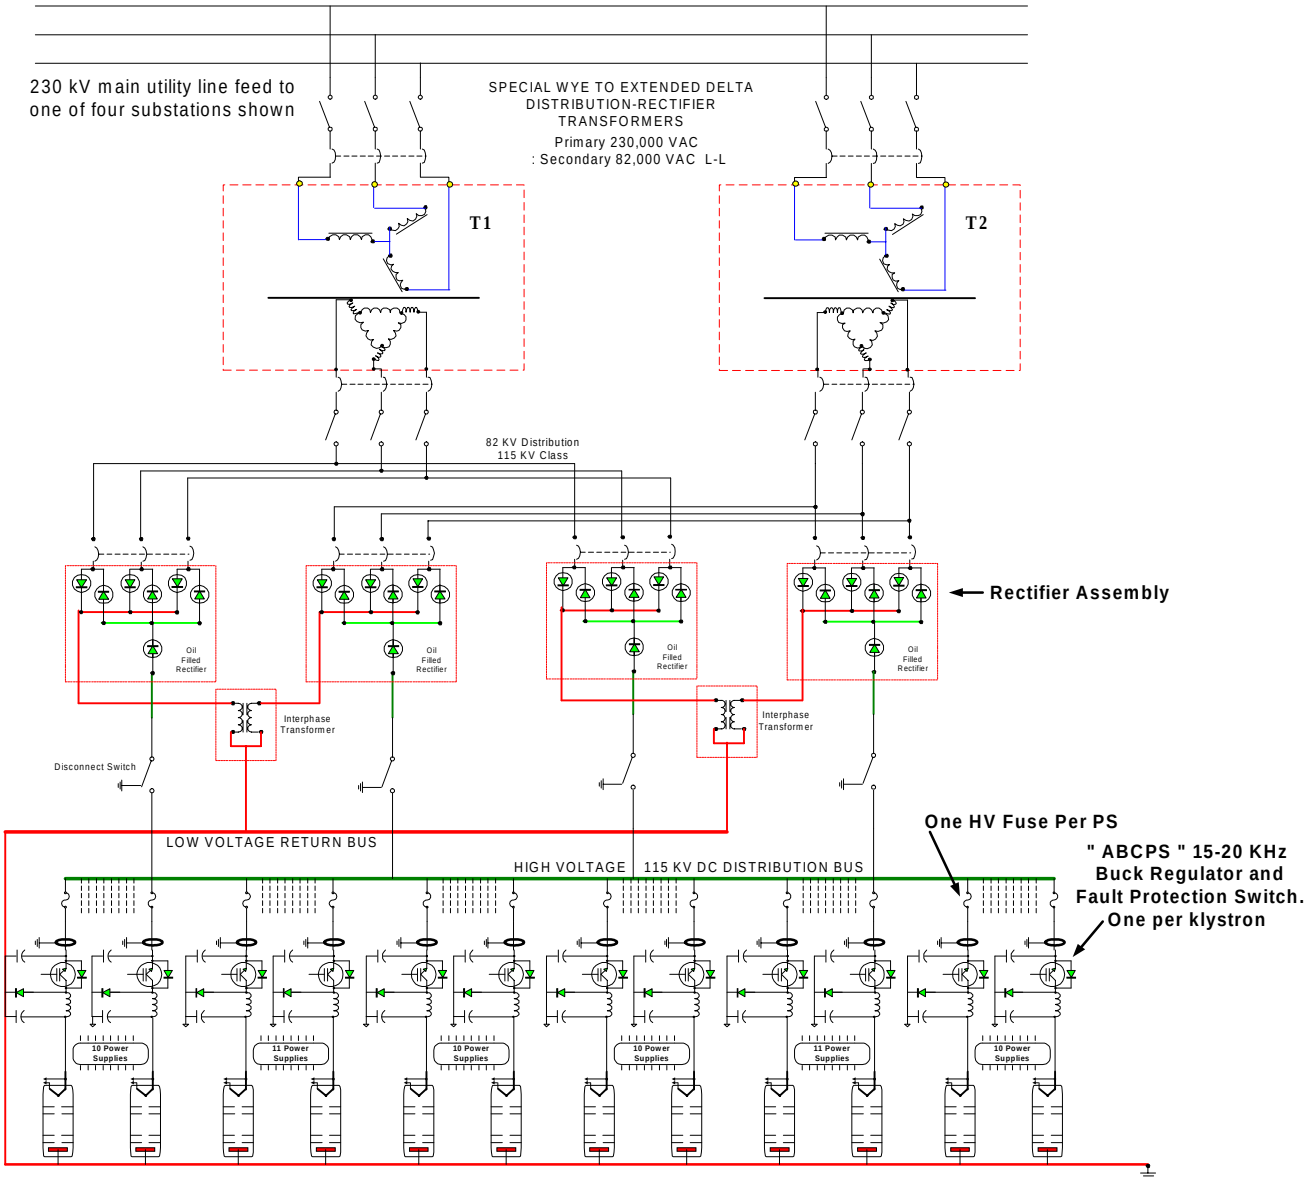

Figure 1: "ABCPS" DC Distribution System for APT

3 ABCPS

The Advance Buck Converter Power Supply, (ABCPS) is connected directly to the DC distribution bus. The topology of this converter is a DC to DC buck chopper which regulates the applied voltage to one klystron. A circuit schematic of a single ABCPS is shown in Fig. 2. The raw HVDC input is switched at approximately 20 kilohertz by a HV IGBT switch and charges the output capacitor through a switching inductor. A freewheeling diode transfers the inductor energy into the output capacitor during the IGBT switch off time. The circuit operates in the discontinuous current mode.

Additional output filter sections reduce output ripple voltage and also provide instantaneous fault energy limiting to the klystron. During operation, when the klystron may arc internally, the IGBT switch will interrupt the high voltage power supply output current in one microsecond or less. To prevent damage to the klystron, less than 40 joules will be deposited during an internal plasma arc. Individual primary high voltage fast acting fuses will be used for back-up power supply and klystron load protection.

The high voltage IGBT switch assembly is designed for ease of maintenance. The IGBTs, heat sinks, and gate drive circuits are mounted on plug-in circuit cards. Fiber optic signal isolation is utilized throughout the HVPS. The entire switch assembly can be bench manufactured and does not require special manufacturing or heavy assembly equipment. In addition no large magnetic cores

are needed. All the HVPS inductors are single layer wound air-core coils. The majority of the HVPS components are standard off the shelf types. This manufacturing approach reduces cost and procurement lead-time.

The most critical circuitry in this ABCPS is the high voltage solid-state switch. This switch is a string of paired IGBTs connected in series to hold off the 115-kV DC input. References [1] through [6]. The IGBTs are paired to provide redundancy. Uniform voltage sharing across each device is critical under all operating conditions. Each IGBT will have an independent gate control circuit. Once the fault is detected, the IGBT switch can operate in less than one microsecond to protect the klystron and provide fast voltage regulation and control.

4 HVPS OUTPUT CHARACTERISTICS

Output DC voltage: Continuously variable- 4 to - 95 kV
Output DC polarity: Negative with respect to ground
Output voltage set-point accuracy: +/- 400V
Output voltage rate of increase: 10 kV / second max.
Output current rate of increase: 200A / second max.
Regulation range: 10 – 95 kV
Regulation requirements (line & load): +/- 400 V max.
Ripple @ any 60 Hz harmonic: 800 V pk to pk max.
Total ripple (all causes): 1100 V peak to peak max.
Voltage stability: +/- 0.4% max.
Output DC current: 0 - 21 A
Load fault protection: 40 Joules max.

STATUS OF THE 36 MHZ RF-SYSTEM FOR THE HIGH-CURRENT-INJECTOR AT GSI

W. Vinzenz, W. Gutowski, G. Hutter, GSI, Planckstr. 1, D-64291 Darmstadt, Germany
B. Rossa, Thomcast AG, Bahnhofstr. 10, CH-5300 Turgi, Switzerland

Abstract

Within the beam intensity upgrade program at GSI some significant changes of the rf equipment will take place. The replacement of the four Wideröe tanks means at the same time the elimination of the 27 MHz operating frequency at GSI. To supply the new 36 MHz structures, rf amplifiers with a peak power of about 2 MW are needed. These stages will be designed and built up in house. 200 kW amplifier stages were specified, ordered and delivered. They act as driver stages for the 2 MW final stages and as final stages for feeding smaller cavities, respectively. The frequency change, as well as the future operation with beam load implies the replacement of more than 60 % of the present UNILAC low level distribution and control.

1 INTRODUCTION

In 1999 the 1.4 MeV/u prestripper section will be replaced by the High Current Injector HSI with an accepted mass over charge ratio for heavy ions up to 65 and with beam currents up to 0.25 A/q (mA) [1]. A 36 MHz RFQ and two IH drift tube tanks will replace the four tank Wideröe section. Each of the three new cavities will be fed by 2 MW final amplifier stages designed at GSI (see fig.1). The duty factor is up to 2% at maximum rf level, the specified rf power fraction into the beam is ranging up to 40%. Though the RFQ will need only up to 500 kW input power it was decided to have three identical amplifier chains. Beam dynamical aspects, as well as the dimensions of the cavities caused the choice of the new frequency 36 MHz. Because of the future UNILAC time share operation with two 1.4 MeV/u – Injectors and with up to three ion sources running in parallel, it was necessary to change the master frequency from 27 MHz to 108 MHz, the Poststripper LINAC frequency. The new 36 MHz system includes the following structures : RFQ, Superlense, IH 1, IH 2, a rebuncher at the 1.4 MeV/u gas stripper section and a debuncher at the 11.4 MeV/u transfer line to the synchrotron SIS. The operating modes of the 36 MHz Injector LINAC are :

a) up to 20 Hz repetition rate with 1 ms flat top at maximum power and full beamload;
b) up to 50 Hz repetition rate with 6 ms flat top at 40% of maximum power without appreciable beamload;
c) replacement of single pulses out of the pulse train in case b) with short high current pulses like in case a) resulting in a mixed mode operation.

Additionally, a small rebuncher structure focusing to the input of the Alvarez 1 tank will be driven by an existing 200 kW amplifier [2], which has been modified from 27 to 36 MHz.

2 AMPLIFIERS 200 KW

The required driving power for the 2 MW stages, as mentioned before, is calculated to be up to 200 kW. Further two 36 MHz final stages in the power range from 120 kW to 150 kW are needed to supply the Superlense and a debuncher cavity in the injection line to the synchrotron SIS (see fig.1). Therefore it was decided to procure five identical stages. Within a call for tenders rf amplifiers including all these features have been specified. Details about the design philosophy can be found in Ref.[3].
The major design part as well as the construction was performed by Thomcast AG (Turgi, Switzerland) after the order was placed (see Fig. 3). These stages use a class A/B solid state amplifier with a maximum peak output power of about 2 kW as driver . For the layout of the following tube stages the current use of the Siemens tetrode RS1084CJ at GSI and the working mode of the 2 MW final stages have been taken into account. The 200 kW stage works in a grounded cathode circuit in a class A/B mode (quiescent current at 2 Amp). To reduce power dissipation between the rf pulses the operating point will be switched to class C during the intervals. The anode circuit is a capacitively shortened $\lambda/4$ resonator in strip line design, tuneable by a vacuum capacitor at the tube side. The input (grid) circuit is a tuneable Π-network loaded with a capacitivly coupled 50 Ω.
The stages are designed as an 'all including' system. It means that all electronic components are installed inside the rack system, including the power supplies for plate, grids and heater of the 200 kW stage. In three amplifiers the grid supplies for the 2 MW final stages are included. In addition the amplitude and phase control units, the analogue value measuring and tube protection units, the free programmable control (SPS), the computer interface and also the automatic tank tuning system are housed in these cabinets. The timing information for rf pulse width, pulse space and sampling time, transmitted via a GSI two-wire-bus, is decoded in a special timing interface. The identification of a high current pulse is also done within this system [4].
With regard to the pulsed beam operation of the UNILAC (max. 16 virtual accelerators and low duty factor in the

high current mode) the analogue measurement unit had to be sampled. This allows to gate the measured values with the according beam pulse. For acceptable beam operation at unstable beam intensities, the frequency response of the amplitude and phase control loops had to be improved. For that reason a redesign of the existing control units of the Alvarez rf-transmitters was performed. Now the bandwidth of the amplitude control is set to f_{cutoff} = 500 kHz while the accuracy is up to ± 0.1%. The phase control unit attains a bandwidth of 1 MHz and an accuracy of ± 0.1 degree.

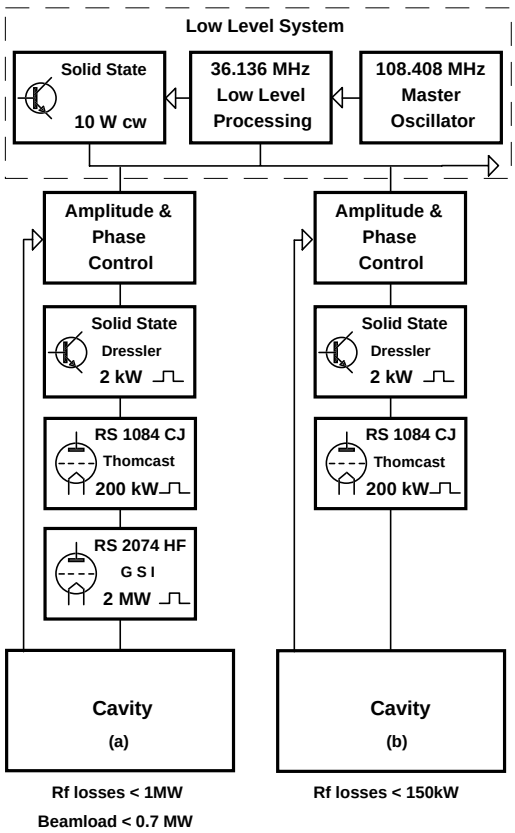

Fig. 1: Amplifier Chains of the New High Current Injector: (a) RFQ, IH1-DTL and IH2-DTL, (b) Superlense and Buncher

The delivery of the five stages to GSI started in December 97 and had been finished in July 98. Individual acceptance tests, including laboratory measurements, as well as electrical parameter tests (rf test with dummy load) and measurements of unwanted radiation leaks have been accomplished at the manufacturer. The observance of the very tight EN (European Harmonised) standards for electromagnetic compatibility and the IEC/VDE directives required an extension of the development time. Nevertheless this part of the project is terminated successfully with a delay of only three months. For tests of the RFQ tank and one 200 kW rf stage on resonant load, two of ten RFQ modules have been assembled to built a test cavity. They were powered by pulses of 90 - 100 kW peak at 1 ms / 20 Hz rep. rate and also by 20 kW at 6 ms / 50 Hz rep. rate. The results of the above mentioned RFQ tests showing excellent performance of the transmitter at 150 % of the nominal power level for the RFQ modules. Starting this test operation a parasitic oscillation at 190 MHz was observed at the plate circuit by switching the operating point to class A/B mode**.** This spurious mode could be eliminated by placing a frequency dependent attenuation circuit inside the anode circuit. An earlier detected oscillation at 280 MHz had already been eliminated at the manufacturer. At tests with the 2nd to the 5th stage at Thomcast AG by a pulsed grid voltage (-350 volts to 0 volts) with a resulting plate current up to 20 ampere, no parasitic effects could be seen. Tests were done with 50 Ω load, open and shortened amplifier output.

3 LOW LEVEL RF SYSTEM

The planned UNILAC upgrading requires also extended modifications within the low level rf equipment, including the master oscillator system and the low level rf distribution. The present system is driven by an oscillator frequency at 27 MHz. The frequency for the Poststripper section (108 MHz) is generated by quadruplicating the master oscillator frequency. This system will be replaced by a new 108 MHz master oscillator and a phase locked loop (PLL) synchronised slave oscillator at 36 MHz. Both low level systems are separately amplitude and phase controlled and can be supplied by different phase set values from the operating software. Thereby both 1.4 MeV/u UNILAC injector LINACs can be shifted in pulsed mode against the 11.4 MeV/u Poststripper LINAC. This feature is very important because the injectors can be operated in time share operation with different ions [5]. All input and output levels are normalised to +24 dBm (250 mW). Components like detectors, phase shifters, filters, oscillators, frequency dividers and amplifiers are designed and made in-house. Figure 2 shows the block diagram of the low level set-up and the rf-distribution.

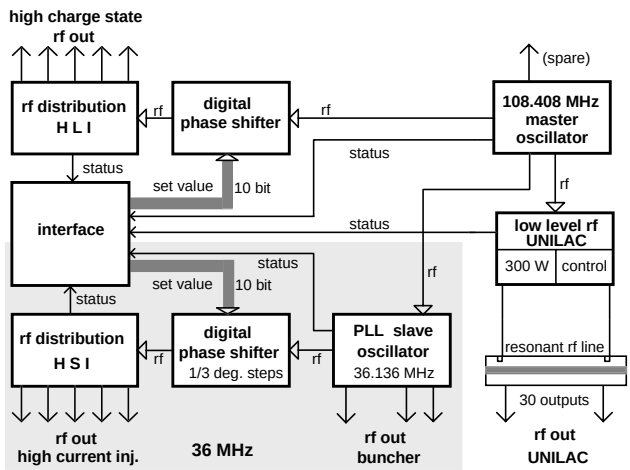

Fig. 2: Upgraded Low Level System

4 AMPLIFIERS 2 MW

The Siemens tube RS 2074 HF of the 2 MW final stages is the same tube as used at the final stages of the Poststripper LINAC (Alvarez 1 to 4). All the necessary calculations (partly performed with the Supercompact$^{\rightarrow}$ code) have been done for a 50 Ω load at the output of the amplifier. They were confirmed by cold measurements with a 1:1 model of the anode circuit using a dummy tube. The input circuit showed a good tunability. For a power range of 1:10 the load of different cathode currents at different power levels was simulated by variable resistors for this measurement. At present a prototype is under construction. The amplifier will be tested with rf on a dummy load early in autumn 1998. The construction of the three transmitters for the new injector should start by the end of this year. Commissioning of the RFQ and IH-Linacs with beam is scheduled for April to July 1999. A detailed report of the amplifier layout and the first results will be given elsewhere.

KLYSTRON RF STABILIZATION USING FEEDFORWARD CIRCUIT

H. Hayano, M. Akemoto, T. Naito, S. Takeda, KEK, Tsukuba, Ibaraki, Japan
D. Aizawa, M. Higuchi, T. Sakamoto, Tohoku-Gakuin University, Tagajo, Miyagi, Japan

Abstract

Klystron rf stability in the linac of ATF, Accelerator Test Facility at KEK, is important to make beam injection into the damping ring stable. The current pulse-to-pulse fluctuation of the output rf is 0.4% peak-to-peak in the amplitude and 1.5degree in the phase. The linac beam energy is correlated with rf amplitude fluctuation directly. In order to make more stable beam injection, storage and extraction in the damping ring, pulse-to-pulse jitter of injected beam energy should be reduced to half of it. By the analysis of rf fluctuation, the amplitude and the phase jitter are correlated with a charging voltage of the modulator. The charged voltage of the modulator is also correlated with the slope of charging rise cycle. The peak of the charging waveform slope which is a few ms in advance of a deQ trigger control gives a possibility of a feedforward to stabilize the charged voltage. We developed a new deQ circuit with a feedforward function which reduces a charged voltage fluctuation into about a half of it. The rf fluctuation of the klystron and the feedforward circuit test are described.

1 INTRODUCTION

ATF[1] is a test-stand of key components to realize a linear collider such as multi-bunch beam generation, high gradient acceleration, low emittance beam generation and its instrumentation development. ATF consists of 1.54GeV S-band Linac[2], damping ring[3] and extraction beam line[4]. The main purpose of the damping ring is to develop an extremely low emittance beam($1x10^{-11}$ m for vertical). After the commissioning on end of January 1997, single bunch operation and development were performed continuously. The emittance performance was confirmed as $1.3x10^{-9}$ m for horizontal $3.6x10^{-11}$ m for vertical with 1.29GeV energy and maximum $1x10^{10}$ electrons of single bunch storage. It is comparable with the design value within a few factor difference. One of the problem to be solved in ATF operation is extracted beam intensity fluctuation of pulse-to-pulse. The required specification for the intensity fluctuation in the linear collider is less than 1%, however, ATF beam is fluctuating more than 10%. This is coming from the injection efficiency fluctuation which is caused by the energy jitter and the wide energy spread expanded into whole damping ring acceptance of 1% full width. The energy spread will be reduced to half of it by the bunching section upgrade in this summer. The energy jitter of pulse-to-pulse has been studied by measuring correlation with various possible sources. The results of the correlation measurements showed that the most strong source was rf amplitude jitter of the klystron output. It is directly connected with driving pulse voltage jitter supplied by a klystron modulator. In order to reduce the energy jitter pulse-to-pulse, a stabilization of the klystron modulator output is essential. This paper describes a new deQ circuit with feedforward compensation to stabilize the output pulse amplitude of the existing modulator for the pulse klystron.

2 ATF KLYSTRON MODULATOR PERFORMANCE

In the ATF linac, 9 klystrons are in operation with 25Hz repetition. The first klystron which is used for the bunching section is operated with 70MW 1μs rf pulse output. The rest of them which are used for 8 regular accelerating unit are operated around 56MW 4.5μs rf pulse output with rf pulse compression. The average accelerating gradient is 25.6MV/m which gives 1.3GeV beam energy at the end of linac. There are two type of klystron modulators; one is a conventional resonant charging type from AC 200V. The other is a common DC power supply type with resonant charging. In both case, a deQ circuit stabilize the charged voltage less than 0.2% peak-to-peak. The charged voltage of the PFN capacitor is around 43kV in the operation. The following pulse trans makes about 340kV 7.5μs HV pulse which is applied to the klystron. The operational parameter of the modulator and klystron are summarized in Table.1. Also, the simplified diagram of the modulator is shown in Fig. 1.

Klystron	Toshiba E3712
frequency	2856MHz
output rf power	56MW, 4.5μs
cathode voltage	340kV, 7.5μs
Modulator	
PFN & pulse trans	12stage, 2 para., 3.0Ω, 1:16
PFN charged voltage	43kV with deQ
repetition	25Hz
pulse flatness	<1%p.p.
pulse amplitude jitter	<0.2%p.p.

Table.1 operation parameter of ATF klystron modulator

Since the AC line stability is not good by a conflict with the other accelerator operation and other power supply operation, there is a few % voltage fluctuation in the input AC line. By using a deQ circuit for PFN

charging and an AC line synchronized thyratron trigger, the PFN charged voltage is well regulated less than 0.2% peak-to-peak which is the design value of the modulator. In this condition, the correlation measurement between PFN charged voltage and the klystron output rf has been done using digital oscilloscope with offset function and vertical axis expansion. The results of this correlation are shown in Fig. 2. The amplitude and the phase of klystron output rf are well correlated with the PFN charged voltage.

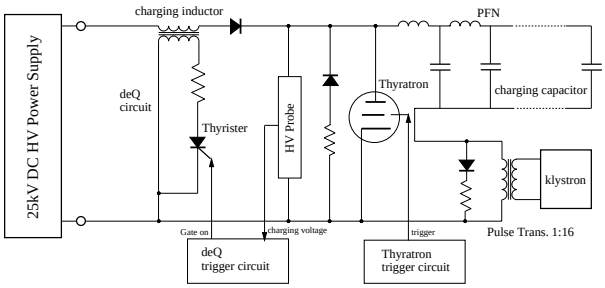

Figure 1: The simplified diagram of the modulator

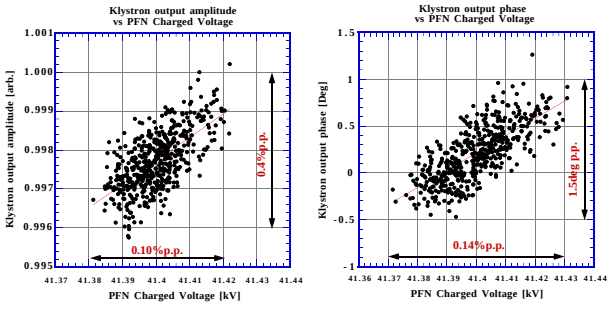

Figure 2: correlation plot between an amplitude and a phase of klystron output rf and PFN charged voltage

3 FEEDFORWARD FUNCTION FOR DEQING STABILIZATION

The deQ circuit of the ATF modulator consists of charging inductor which is a part of resonant charging circuit, its secondary winding circuit including a thyrister and a resister, PFN voltage monitor and thyrister trigger circuit, as shown in Fig. 1. The thyrister trigger circuit outputs 20V trigger pulse to make it on-state when the PFN voltage reached the set reference voltage. The charging current into the PFN capacitor is cut by this close action of the inductor secondary circuit. In this way, the charged voltage is stabilized.

Since there is a small time delay from the deQ trigger timing to charged voltage equilibrium, a small change of charging voltage slope at the reference voltage will make small overshoot or undershoot for the equilibrium. In this case, a change of the charging voltage slope is correspond to an amplitude fluctuation of the AC line which is slow compared to 25Hz. The correlation plot between a charging voltage slope and charged voltage equilibrium shows a good correlation relation as shown in Fig.3. The charging slope is detected by differentiating the charging voltage electrically.

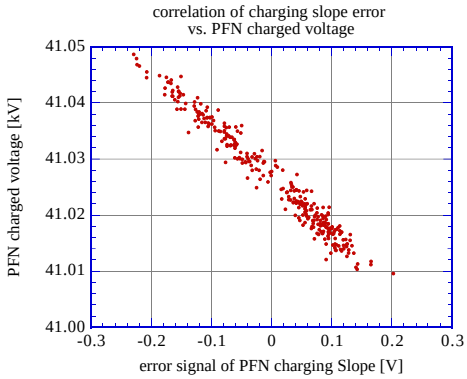

Figure 3: correlation plot between a charging voltage slope and charged voltage equilibrium

The maximum of the charging voltage slope is about 5ms in advance to the deQ trigger timing in case of the ATF modulator. Therefore, there is a possibility of feedforward from the slope information to the timing of deQ trigger in order to compensate overshoot and undershoot charging. A 5ms time duration is enough long for determination of the feedforward amount by a digital calculation or an analog circuit.

4 FEEDFORWARD TEST CIRCUIT

Using this slope detection, a feedforward test circuit was designed and built by the analog circuitry. The conversion function from the slope change to the delay of the deQ trigger was assumed to a linear for the circuitry simplicity. The charging slope detection circuit, the slope error signal generation, the amplifier for feedforward gain adjustment and deQ trigger delay circuit were added to the existing deQ circuit. The block diagram of the circuitry is shown in Fig. 4. The slope detection is done by a sample/hold at the peak signal of the differentiated charging waveform. A comparator outputs an error signal voltage from the reference which is coming from the deQ

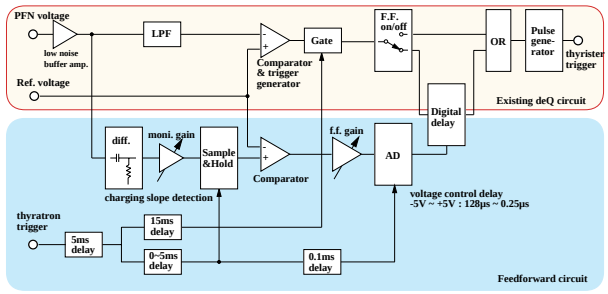

Figure 4: The block diagram of the feedforward circuitry

reference voltage. The error signal level is adjusted by the following amplifier and converted into a digital signal. The digital error data is converted to a time delay which is used for a deQ trigger delay. The amount of the delay is 0.25 to 128μs for +5 to -5V error voltage. By adding this delay circuit, the deQ trigger has an offset delay of about

60μs for the nominal control compared to the case of without feedforward.

5 RESULTS OF FEEDFORWARD TEST

The test of the feedforward circuit has been done using one of the ATF modulator which is the first modulator used for the bunching section. The charged voltage was 41kV which generated 328kV of the klystron cathode voltage and 49MW 1μs rf pulse. The measurement of the charged voltage and the klystron output rf has been done using the digital oscilloscope(Tektronics TDS684B) with offset function and vertical axis expansion into its maximum. The bit resolution is about 2 order small compared with the measured fluctuation width. In order to remove high frequency noise coming from a thermal noise and a thyratron noise, 20 sequential sampling points were averaged. The acquisition bandwidth of 20MHz was used only for the charged voltage measurement.

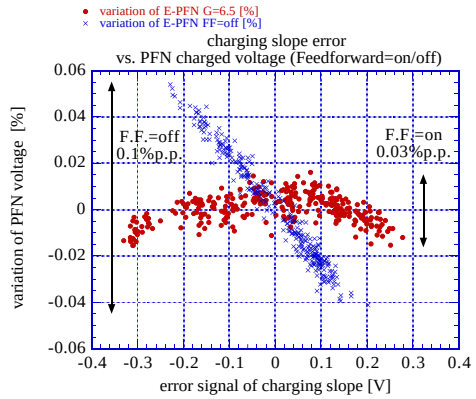

Figure 5: correlation between a charging voltage slope and charged voltage equilibrium with feedforward on/off

After the adjustment of the feedforward gain, the PFN charged voltage fluctuation was measured together with the error signal of the charging slope. The read-out time from the oscilloscope into PC was around 3 seconds for one correlation. The total number of the data points is 300 for each plot which is correspond to about 15 minutes duration. The plot shown in Fig.5 includes the correlation of the PFN charged voltage with feedforward and without feedforward. It shows the fluctuation is reduced from 0.1% to 0.03% peak-to-peak by the feedforward. As for the output rf stability shown in Fig. 6, the effect on the output rf is about factor 2 reduction, that is, from 0.3% to 0.13% peak-to-peak in amplitude and from 0.8degree to 0.5degree peak-to-peak in phase. A residual fluctuation in phase still remains. It seems that it may come from a noise conflict for the phase measurement and from the phase noise of the drive input rf of the klystron.

6 CONCLUSION

In order to reduce the energy jitter pulse-to-pulse, the stabilization of klystron modulator output has been tested by using new deQ circuit with feedforward compensation. The achieved performance on the PFN charged voltage stability was 0.03% peak-to-peak which was about factor 3 reduction from the existing deQ circuit. The rf stability of the klystron outputs were 0.13% peak-to-peak in amplitude and 0.5degree peak-to-peak in phase which were about factor 2 reduction. This method will provide easy modification of an existing deQ circuit and more than factor 2 reduction for an rf amplitude fluctuation.

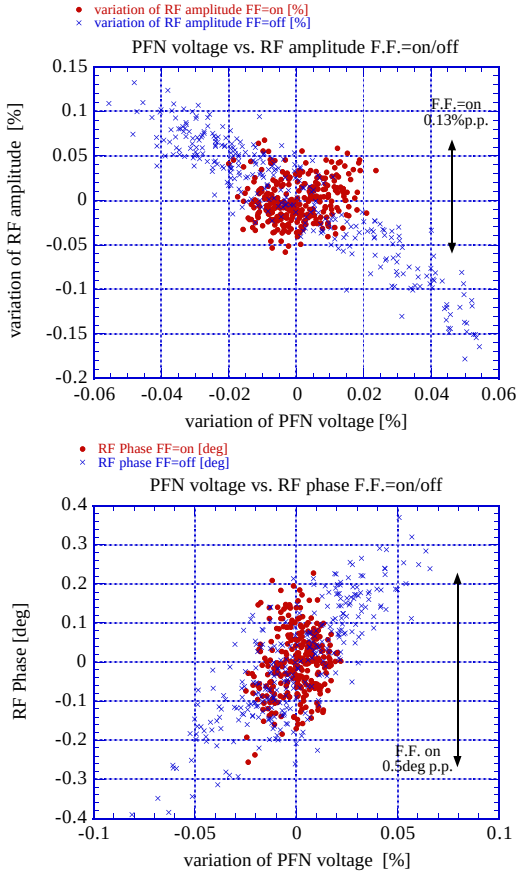

Figure 6: correlation between a charging voltage slope and klystron output rf with feedforward on/off

7 ACKNOWLEDGMENT

The authors would like to acknowledge Prof. H. Sugawara, director of KEK organization, for the support under the program of cooperation & development research. We also thank to all the member of the ATF group for their cooperation and useful discussion.

Abstract

An upgrade of the klystron modulator for the KEKB injector linac was completed before March, 1997. In this linac, SLED (SLAC Energy doubler) along with an upgraded klystron (which has an rf output power of 46 or 50 MW) is utilized to accelerate electron and positron beams up to 8 and 3.5 GeV, respectively. It is desirable to increase the pulse flat top of the modulator output pulse voltage for SLED operation. An improvement of the output waveshape had been carried out and a flat-top width of about 4μs was finally obtained. In addition, the time jitter of the modulator output pulse voltage was reduced to about 8ns by modifying the driver circuit for a thyratron.

1 INTRODUCTION

The upgraded modulators in the KEKB injector linac are capable of producing pulses with a 110 MW peak power and a 5.6μs pulse duration (calculated as one without a pulse transformer) for the upgraded klystron. SLED along with this klystron is utilized in order to obtain an energy gain of 160 MeV per one acceleration unit. At the initial stage of SLED operation, it became clear that there were some problems concerning the waveshape and the time jitter of the modulator output pulse voltage.

In order to obtain the aimed energy gain, it became important for the flat-top width of the klystron rf output to be increased as much as possible. A basic concept of the modulator upgrade was doubling the total capacitance of the PFN (pulse-forming network). The size of the PFN housing was therefore enlarged and the inductance of the wiring in the PFN output circuit was increased. The upgraded klystron causes the distributed capacitance of the pulse transformer to be increased, since its step-up ratio must have been increased compared to that in the old modulator [1]. These two factors deteriorated the pulse flat-top width of the output pulse voltage, i.e. the klystron rf output.

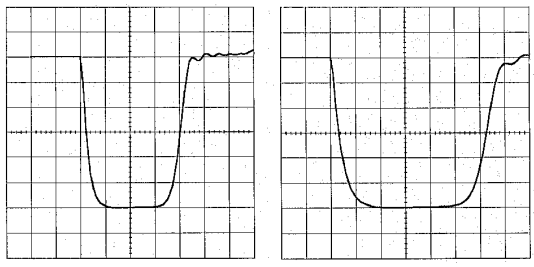
A reduction in the time jitter of the output pulse voltage is also important in order to obtain a stable beam energy. Since the time jitter of the modulator output pulse voltage is strongly dependent on a thyratron operation, improvements to the driver circuit for the thyratron were intensively performed. This paper describes the improvements mentioned above.

2 IMPROVEMENTS TO THE OUTPUT CIRCUIT

2.1 Improvement to the Waveshape of the Output Pulse Voltage

By considering the total number of acceleration units and available output power of the upgraded klystron, a SLED energy multiplication factor of 2.0 was selected as the design value. Taking into account the characteristics of the SLED cavity, a flat-top width of 4μs was reqired for the klystron rf output pulse [2].

Figure 1 shows the calculated output voltage waveshapes in the old (a) and upgraded (b) modulators using the circuit-simulation code “ISSPICE”. It can be seen from these figures that the increase in the flat-top width is less than that of the pulse duration due to the slower rise-and fall-time than those in the old modulator. It is therefore necessary to reduce the inductance of the wiring in the PFN output circuit.



(a) old (b) upgraded
horizontal scale: 1μs /div
Fig. 1 Output voltage waveshapes (calculated).

Figure 2 shows the arrangement and the wiring of the output circuit in the upgraded modulator. A copper pipe was being used as the wiring (a) between the thyratron anode and the high-voltage side of the PFN. The length of this wiring became longer than that in the old modulator and its inductance was increased. As for the wiring (b) between the thyratron cathode and the feeder, a copper plate perpendicular to low voltage side of the PFN was being used.

We carried out the following improvements to the output circuit in order to increase the flat-top width of the output voltage pulse (see fig.2):

(1) Another copper pipe was added to the wiring (a) in such a way that the two pipes are separated from each other as much as possible,

(2) The wiring (b) was made parallel to the low-voltage side of the PFN in order to reduce the area of the loop surrounded by the wiring,
(3) The capacitance of the added PFN capacitors was increased from 0.0146μF to 0.0155μF .

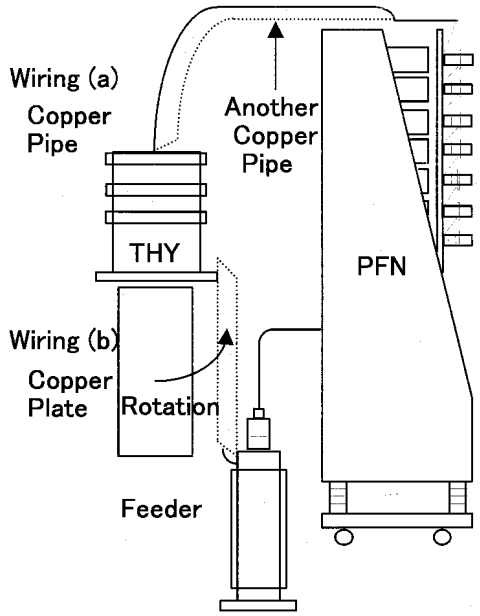


Fig. 2 Wiring of the output circuit.

Figure 3 shows the output-voltage waveshape of the modulator with the improved output circuit. It can be seen from this figure that the pulse duration is increased and the rise-time is being improved compared to fig.1(b). Figure 4 (a) shows an expanded trace of the flat-top of the waveshape. It can be seen that the flat-top width within 0.4% of peak pulse voltage is 3.8μs. Taking into account a recovery time of the oscilloscope, it is possible to say that the flat-top width of about 4μs was obtained. Figure 4 (b) shows an similar trace of the waveshape in the modulator without improvement to the wiring. It can be seen from this figure that the flat-top width increase of 0.4μs was obtained by carrying out the improvement to the wiring. An rf output pulse with the aimed flat-top width was obtained using this improved modulator.

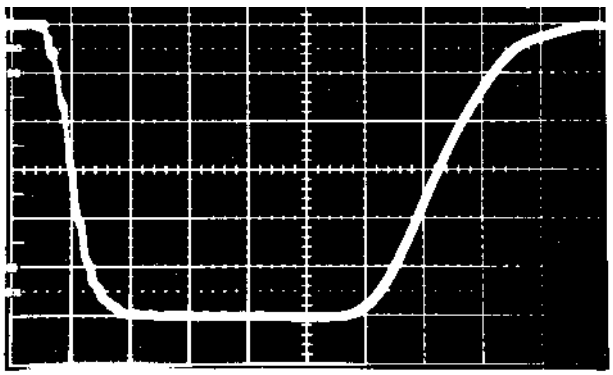

Fig. 3 Output voltage waveshape by the improved output circuit.
(horizontal scale: 1μs /div, peak voltage: 286kV).

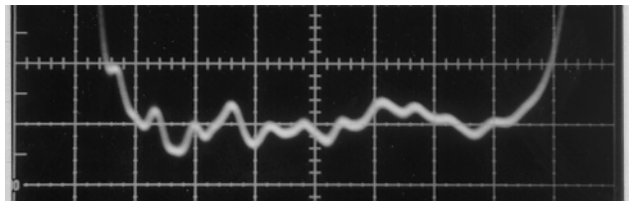

Fig. 4 (a) Expanded trace of the flat-top of an output-voltage waveshape (after improved). (horizontal scale: 0.5μs/div, vertical scale: 0.4% of peak pulse voltage/div).

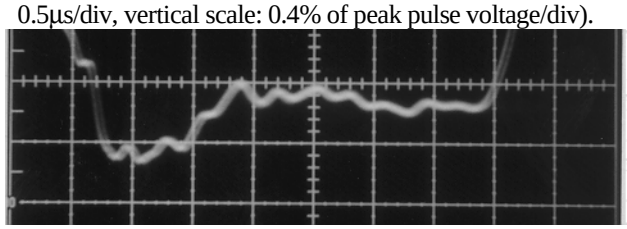

Fig. 4 (b) Expanded trace of the flat-top of an output voltage waveshape(before improved). (horizontal scale: 0.5μs /div, vertical scale: 0.4% of peak pulse voltage/div).

2.2 Improvement to the Thyratron Grid Driver

There are the following four factors which control the time jitter of the output pulse voltage: (1) the thyratron resorvoir voltage, (2) the output impedance of the thyratron grid driver, (3) the rise time of the pulse output voltage in the driver and (4) the input impedance of the thyratron input circuit. Figure 5 shows both the output circuit of the thyratron grid driver and the input circuit of the thyratron. The output impedance is derived from the impedance of the PFN and the step up ratio of the pulse transformer. In the old modulator, the output impedance of the thyratron driver was 100 Ω was equal to the value of the input impedance in the thyratron input circuit.

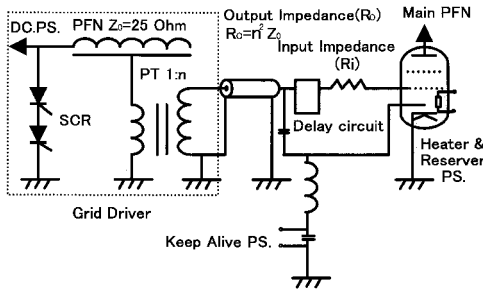

Fig. 5 Circuit between the driver and the thyratron.

Figure 6 shows the dependence of the time jitter in the output pulse voltage on the thyratron resorvoir voltage (jitter-resorvoir relation) measured under repetition rates of 25 and 50 pps in the old modulator. In this figure, it was impossible to measure the time jitter outside of both edges in each curve due to an unstable operation of the thyratron. It can be seen from this figure that the time jitter at each repetition rate and the difference between the values at two repetition rates increases when the resorvoir voltage decreases. This means that the thyratron driver of the old modulator has not fed sufficient power to the thyratron grid. It is also necessary to decrease the time jitter further for SLED operation .

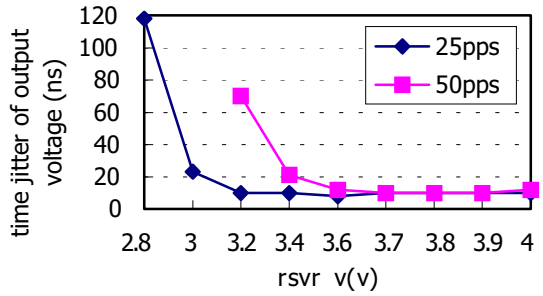

Fig.6 Jitter-resorvoir relations by an old driver.

In order to modify the old driver into one capable of feeding sufficient power to the thyratron grid, the jitter-resorvoir relation was investigated by changing the output impedance (Ro) of the thyratron driver and the input impedance (Ri) of the thyratron input circuit under repetition rate of 50 pps. Figure 7 shows the result of this investigation. The result obtained by changing the input impedance from 100 Ω to 22 Ω while maintaining the output impedance of the driver is almost same as that of the old driver. It is also known that the smaller is the output impedance, the smaller does the time jitter become. Though an output impedance of 28 Ω gives the smallest time jitter, such a modification costs too much, since it needs another PFN. Therefore, we adopted a driver with an output impedance of 56 Ω. Figure 8 shows the results of the jitter-resorvoir relations of this driver under both 25 and 50 pps operation. Since two jitter-resorvoir relations nearly coincide with each other, this driver feeds sufficient power to the thyratron grid.

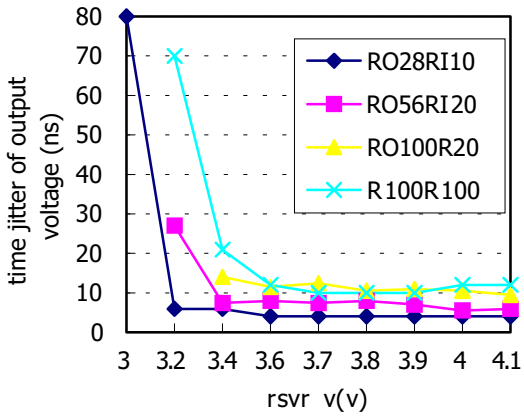

Fig. 7 Jitter-resorvoir relations investigated by changing the impedances (Ro, Ri).

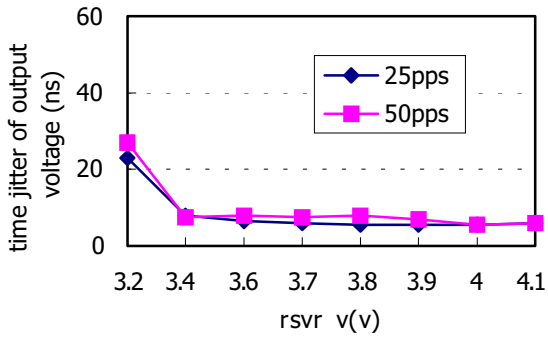

Fig. 8 Jitter-resorvoir relations by a new driver.

NEW HIGH POWER 200 MHZ RF SYSTEM FOR THE LANSCE DRIFT TUBE LINAC*

J. Lyles, C. Friedrichs, and M. Lynch, Los Alamos National Laboratory,
Los Alamos, New Mexico 87544 USA

Abstract

The Los Alamos Neutron Science Center (LANSCE) linac provides an 800 MeV direct H^+ proton beam, and injects H^- to the upgraded proton storage ring for charge accumulation for the Short Pulse Spallation Source. Accelerating these interlaced beams requires high average power from the 201.25 MHz drift tube linac (DTL) RF system. Three power amplifiers have operated at up to three Megawatts with 12% duty factor. The total number of electron power tubes in the RF amplifiers and their modulators has been reduced from fifty-two to twenty-four. The plant continues to utilize the original design of a tetrode driving a super power triode. Further increases in the linac duty factor are limited, in part, by the maximum dissipation ratings of the triodes. A description of the system modifications proposed to overcome these limitations includes new power amplifiers using low-level RF modulation for tank field control. The first high power Diacrode® is being delivered and a new amplifier cavity is being designed. With only nine power tubes, the new system will deliver both peak power and high duty factor, with lower mains power and cooling requirements. The remaining components needed for the new RF system will be discussed.

1 PRESENT HIGH POWER RF SYSTEM

The Los Alamos Neutron Science Center (LANSCE) linac provides high power proton beams for neutron science, Tritium target development for APT, nuclear physics, material science, isotope production, and weapons research. The number of simultaneous beam users places heavy demands on the RF powerplant, especially the 201.25 MHz final power amplifiers (FPA) driving four Alvarez DTL tanks for 0.75 to 100 MeV. Designed nearly 30 years ago, these amplifiers have operated at up to 3 Megawatts with duty factors of 12%. The large number of power tubes in the PA plate modulators, the age of the cooling and control subsystems, tube manufacturing problems, and operation near maximum PA tube ratings have all affected the system reliability.

For the past six years we have designed and installed system upgrades that have reduced the number of power tubes in the system from fifty-two to twenty-four [1,2]. A block diagram of the present RF system is shown in Figure 1. The maximum duty factor is rated at 12% where the plate dissipation of the final amplifier tube, a Burle Industries 7835 triode, is approximately 250 kW. The peak power from the final cavity amplifier for the largest DTL tank (tank 2) is slightly over 3 MW for some tunes. The triode FPA is unstable if operated with plate voltage but no RF drive. Consequently, the FPA is driven with constant RF drive from the IPA, using a Burle Industries 4616 tetrode. The plate voltage is simultaneously pulsed on and varied by the amplitude controller in order to adjust the saturated output and provide tank field control. This high voltage modulation technique requires four additional power tubes. The modulator has an internal voltage drop of about 10 kV when fully on, so the high voltage capacitor bank must be maintained above the level needed by the FPA by at least this amount. This causes an additional power dissipation of nearly 250 kW each, in three of the four plate modulators. The forth RF system drives DTL tank 1, which requires less than 500 kW of peak RF, relatively low power compared to the other units. In this report, this unit is not shown in the diagrams for simplicity.

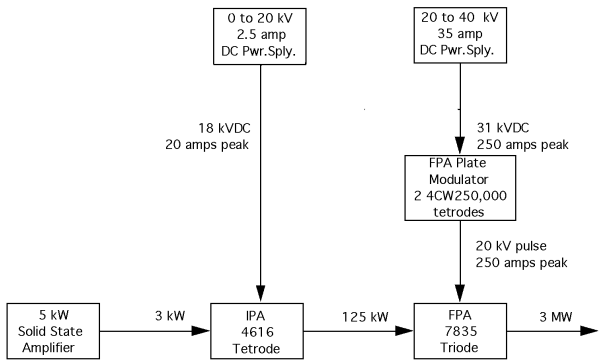

Figure 1. Present configuration - high power RF modules

The FPA triode has an output ceramic seal length of 7.62 cm. This requires that it be operated within a pressure vessel operating with 2.4 bar dry air at Los Alamos (2120 meters above sea level) to maintain voltage standoff. Because of the high average power, the pressurized air must be circulated through the cavity and cooled. The high-pressure turbine and pressurized heat exchanger require annual maintenance, and have contributed to system down time. Replacement of the FPA tube takes approximately 16 hours due to the enormous pressure vessel that must be removed first.

Higher beam current for new linac applications such as the proposed Long-Pulse Spallation Source [3] cannot be

* Work supported by the US Department of Energy

delivered simultaneously with other beams at high duty factor. Table 1 shows the RF power requirements for the present 18 mA and proposed 21 mA peak current needs. The RF pulse parameters are for up to 1350 microseconds width at 120 pulses per second repetition rate, resulting in up to 16.2% duty factor for the RF amplifiers. These requirements are within the fundamental capabilities of the 805 MHz RF System for the coupled-cavity linac that accelerates from 100 to 800 MeV; only the 201 MHz system needs this substantial upgrade.

Table 1. RF power requirements for DTL

RF Operating Levels						
Module	Energy	Tank Pwr.	21 mA Beam Pwr	8% margin	Peak Req'd	Ave. Req'd
	MeV	MW	MW	MW	MW	kW
1	4.64	0.37	0.10	0.04	0.51	82
2	35.94	2.57	0.75	0.27	3.59	582
3	31.39	2.10	0.66	0.22	2.98	483
4	27.28	2.23	0.57	0.22	3.03	491

2 POWER AMPLIFIER REPLACEMENT

We plan to install a new cavity amplifier, which will operate as a linear amplifier and eliminate the need for modulation of the high voltage. Output power control will be accomplished by varying the low-level RF drive to the preamplifier stage. This eliminates four more tubes in each system, leaving only two RF amplifier tubes per module (three in module 2), or nine for the entire DTL RF powerplant. In addition, the voltage overhead of the plate modulator will disappear, as the tube will operate with DC plate voltage and be pulsed into conduction with the control grid bias.

2.1 RF Power Tube Selection

Until very recently, there has been no reasonable alternative to the 7835 for the LANSCE 200 MHz DTL. Thomson Tubes Electroniques embarked on a program to develop a tube capable of delivering 3 MW peak, 600 kW average RF power, at 200 MHz. The tube was proposed for fusion heating as early as 1991 [4]. Employing double-ended RF geometry (as in the 7835 triode) can extend the frequency-power limits of gridded tubes. The TH628 Diacrode® is a double-ended tetrode, derived from the single-ended TH526 tetrode. The tube uses pyrolytic graphite grids, a thoriated-tungsten mesh cathode, and a multiphase-cooled anode rated to dissipate 1.8 MW. Pyrolytic graphite grids allow elevated grid operating temperatures without seconday electron emission. This allows for higher screen power dissipation, and higher output power without adverse effects. The first cathode-driven TH628 Diacrode® has recently passed acceptance tests at the factory, and is being delivered to LANSCE. No other modern tetrode has delivered this level of high power 200 MHz performance. Table 2 lists significant results from the tests.

Table 2. Thomson TH628 Test Results – June, 1998

Peak Power Output	3 MW peak
Average Power Output	600 kW
RF pulse duty cycle	20 %
DC-to-RF Efficiency	>60%
DC plate voltage	26 kV
Screen (G_2) Voltage	1.6 kV
Filament Power	18 VDC, 910 A.
RF Power Gain	>14 dB
Zero Drive Stability	No emissions 0 to 1 GHz
Coolant Flow	360 l/min deionized water

The planned configuration for DTL modules 3 and 4 is shown in figure 2. Two combined amplifiers may be required only for module 2, and this scheme is shown in figure 3. The upgraded system will employ circulators between the FPA and DTL. Air pressurization is not planned for these amplifier cavities, as the ceramic seal is longer on the TH628. Tube replacement time will be decreased from about 16 hours to 2 hours.

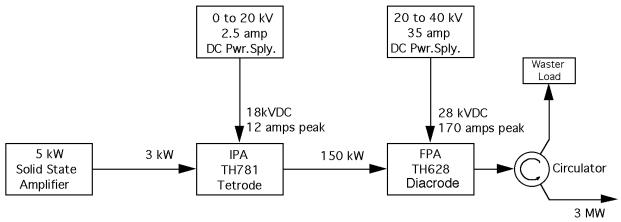

Figure 2. New configuration for RF modules 3 and 4

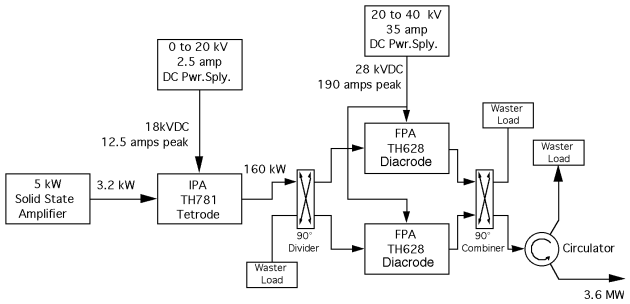

Figure 3. New configuration for RF module 2

2.2 Intermediate Power Amplifier

The existing 4616 tetrode intermediate power amplifier is capable of 150 kW peak power at our present duty factor. The statistical lifetime of these tubes has varied with variations in manufacturing, including component changes such as different filament alloys and sources of mica. As a grid-driven tetrode, the 4616 is capable of very high gain. Along with this high gain is a system sensitivity to variations in the screen emission and VHF resonances or back-cavity modes from the internal mica screen bypass capacitor assembly. We have a choice of continuing to utilize the existing amplifiers, or converting to a cavity amplifier using a Thomson TH781 tetrode, which has pyrolytic graphite grids, a thoriated-tungsten mesh cathode, and a multiphase-cooled anode rated to dissipate 250 kW. A nearly identical tetrode (TH681) is in

successful operation driving the CERN PS 40 MHz bunching cavity [5].

2.3 Power Supplies

The existing plate HV power supply/capacitor banks are adequate for the conversion, after the plate modulators are removed. The HV power supplies for DTL modules 2 through 4 are rated for 40 kV maximum, at 35 Amperes DC. With the existing capacitor banks, they were designed to drive the FPAs at 120 Hz, with 1200 uS pulses. The DC voltage will be reduced from the present charging level. The module 1 power supply will also be reused.

The 7835 triode requires 6900 Amperes of DC filament current. The original filament power supplies are very large. Removal of the present power supply will provide much floor space for the upgrade. The TH628 requires less than 1000 Amperes, supplied from a small power supply without water-cooled cables.

2.4 RF Output Components

The new FPA will be isolated from reflected power from the DTL by using a coaxial Y-junction circulator. Advanced Ferrite Technology has proposed a 35.5 cm coaxial device, which has less than 0.16 dB of insertion loss and 25 dB of isolation. This is especially important for the combined amplifiers for module 2, driving the high Q DTL. A water-cooled dummy load will be connected to the third port.

The power splitter and combiner for module 2 will be 3 dB hybrids, available from several manufacturers. Examples of the successful use of power combiners of this size are found at the MIT/Lincoln Labs ALTAIR radar in which two super-power triodes are combined at 160 MHz. At the CERN SPS, sixteen 35 kW tetrodes are successively combined at 200 MHz for 500 kW, and four 125 kW CW tetrodes are combined for 500 kW of total power [6]. A water-cooled dummy load (waster) will be required on the combiner, rated at one quarter of the overall power.

The full output power is to be transmitted to the DTL through the existing 35.5 cm diameter coaxial line. This line is theoretically capable of 40 MW peak and over 600 kW of average power at 200 MHz when pressurized with dry nitrogen, according to the manufacturer. The Brookhaven National Laboratory AGS Linac has used 30.5 cm line for up to 6 MW peak at low duty factor [7].

The present RF window seals the DTL vacuum while passing through the coaxial center conductor to connect to the drive loop. It is made of crosslinked polystyrene, or Rexolite®. Presently these windows are replaced about every 2 years of service, or when the following damage is noticed during inspection: Excess radiation darkening, evidence of streamer tracks, mechanical deformation, or evidence of sputtered metallization on the vacuum side. Further work is anticipated to improve the voltage standoff and lifetime of the windows for the higher peak and average powers proposed for LANSCE.

2.5 Cooling Plant

The cooling requirements will not add additional load to the plant, as the modulator heat load will be removed, and the waster loads on the circulators and combiner are only dissipating transient loads during tuning and unbalances. The water flow though each new FPA tube is 36% less than the present tubes, due to the more efficient multiphase cooling regime in the tubes.

3 CONCLUSION

The proposed upgrade to the LANSCE DTL RF powerplant is based on changing the FPA to a new type of tetrode, which has demonstrated excellent performance during testing. The other system changes will require RF, electrical, mechanical and thermal engineering, but nothing appears to be significantly challenging to prevent long term success. This project will be a significant improvement to the LANSCE linac RF system.

ACKNOWLEDGEMENTS

The authors wish to thank the LANSCE-5 RF team for their assistance in keeping the RF plant operating with high reliability and in their suggestions and assistance in all of the upgrades.

ACCELERATOR PRODUCTION OF TRITIUM 700 MHz AND 350 MHZ KLYSTRON TEST RESULTS

D. Rees, M. Lynch, P. Tallerico
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

The Accelerator Production of Tritium project (APT) utilizes a 1700 MeV, 100 mA proton Linac. The radio frequency (RF) power is provided by 244 continuous wave (CW) klystron amplifiers at 350 MHz and 700 MHz. All but three of the klystrons operate at a frequency of 700 MHz. The 350 MHz klystrons have a nominal output power of 1.2 MW at a DC-to-RF conversion efficiency of 65 %. They are modulating-anode klystrons and operate at a beam voltage and current of 95 kV and 20 A. The design is based on the CERN klystron. The 700 MHz klystron is a new development for APT. Three 700 MHz klystrons are currently under development. Two vendors are each developing our baseline klystron that has a nominal output power of 1.0 MW at a DC-to-RF conversion efficiency of 65%. A 700 MHz klystron is also under development that promises to provide an efficiency in excess of 70%. The 700 MHz klystrons operate at a maximum beam voltage of 95 kV and a maximum beam current of 17 A. The test results of these klystrons will be presented and the design features will be discussed.

1 KLYSTRON REQUIREMENTS

The design requirements for the 350 MHz and 700 MHz klystrons are included below in table 1.

The 350 MHz klystron was supplied by English Electric Valve (EEV). Two vendors developed the 700 MHz klystrons, EEV [1] and Communication and Power Industries (CPI). The design parameters for these two tubes are different but still within the requirements. EEV chose a lower perveance design with respect to CPI.

In addition to the standard 700 MHz klystron design, EEV also pursued an advanced klystron design utilizing a second, second harmonic cavity just prior to the output cavity. This klystron had to meet the requirements in Table 1 and the development was directed towards increasing the efficiency to 70%.

The 350 MHz klystrons have all been tested and installed on the Low Energy Demonstration Accelerator (LEDA) [2], and have satisfied all design requirements. The standard EEV 700 MHz klystron has been tested, demonstrated all requirements, and is being installed on LEDA. The high-efficiency EEV klystron has been tested and demonstrated compliance with the baseline design requirements. In addition, the efficiency was increased from the required 65% to 68%. Higher efficiencies were achieved but found to be inconsistent with the 1.2:1 VSWR requirement at any phase. However, at the nominal 68% efficiency into a matched load, the klystron achieves efficiencies in excess of 72% at some phases of a 1.2:1 mismatch.

Table 1. Klystron Requirements

Frequency	350 MHz	700 MHz
Output Power	1.2 MW	1.0 MW
Test Power	1.3 MW	1.1 MW
Gain	40 dB Min.	40 dB Min.
Beam Voltage	95 kV Max.	95 kV Max.
Beam Current	20 A Max.	20 A Max.
Efficiency	65 % Min.	65 % Min.
Bandwidth 1 dB	+/- .35 MHz	+/- .7 MHz
Collector Dissipation	Full Beam Power	Full Beam Power
VSWR Tolerance	1.2:1 Max. Any Phase	1.2:1 Max. Any Phase
Mod-Anode	Yes	Yes

The CPI 700 MHz Klystron has demonstrated that the klystron physics design satisfies our performance and operating requirements; however, the entire klystron package has not yet satisfied all electrical and mechanical requirements and is still in process.

2 KLYSTRON TEST RESULTS

2.1 350 MHz Klystron

The 350 MHz klystron is shown in Fig. 1. The klystron is a six cavity klystron with a second harmonic cavity. As is seen in the picture, the klystron has a horizontal orientation. Although there is some supplemental lead shielding around the collector, the klystron is operated in a lead garage, and the supplemental shielding allows for a lead thickness of 0.125" to be suitable for suppressing x-ray radiation. The klystron output window is a coaxial window. The coaxial section containing the window can be seen in the picture protruding from the top of the tube. A t-bar is used to transition from the coaxial line to waveguide. The klystron requires three cooling circuits. Up to 400 gpm is provided to the collector, and two body circuits require up to 10 gpm. The RF window on the klystron is air cooled. A small oil tank is included with the klystron for high voltage insulation and is visible in the photos.

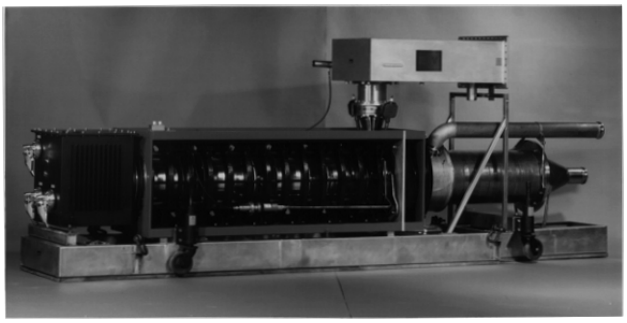

Figure 1: EEV 350 MHz Klystron.

Table 2 contains the recorded operating parameters and characteristics of one of the 350 MHz klystrons. In addition to this data the tube undergoes a 24 hour run with only 2 tube-caused trips allowed at 110 % of rated power and also must demonstrate the full 1847 kW of beam power into the collector for one hour.

Table 2. EEV 350 MHz Recorded Klystron Data

Heater Voltage	22.8 V
Heater Current	22.8 A
Main Focus Current	6.4 A
Main Focus Voltage	227 V
Output focus Current	8.2 A
Output focus Voltage	123 V
Beam Voltage	94.1 kV
Beam Current	19.63 A
Mod Anode Voltage	51.8 kV
Mod Anode Current	0.4 mA
Drive Power	93 W
Output Power	1210 kW
Efficiency	65.5 %
Body Power	3.5 kW
Output Cavity Power	3.3 kW

2.2 700 MHz Klystron

The CPI version of the 700 MHz klystron is illustrated in Fig. 2. At the level of detail allowed by the picture the differences between this klystron and the EEV klystrons is not easily distinguishable, so in the interest of space conservation only the CPI photo is included. The EEV klystrons do have a slightly longer output coax prior to the T-bar transition to insure mode purity in the window ceramic.

The physical description of the 700 MHz tube is identical to the description provided above for the 350 MHz klystron and is not repeated. The 700 MHz klystrons also is subject to the 24 hour test at 110% of rated power.

The recorded test data from the CPI 700 MHz klystron, the standard EEV 700 MHz klystron, and the high efficiency EEV 700 MHz klystron are included in tables 3 and 4. Table 4 includes results for both the EEV standard klystron and the high efficiency klystron.

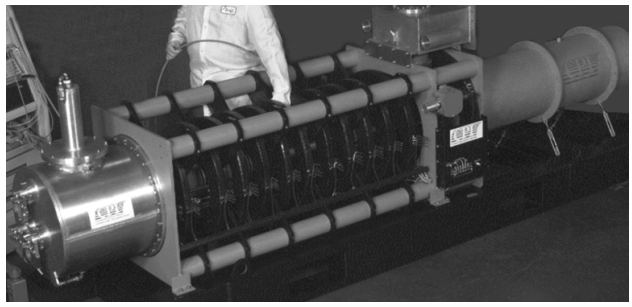

Figure 2: CPI 700 MHz Klystron

Table 3. CPI 700 MHz Klystron Recorded Data

Heater Voltage	21.2 V
Heater Current	19 A

Efficiency	65.5 %
Body Power	3.7 kW
Output Cavity Power	8.6 kW

Table 5 illustrates the efficiency of the EEV high-efficiency klystron as it drives a mismatch of nominally 1.2:1 at variable phase. The table shows that for some phases of the mismatch very high efficiencies were achieved. However, by noting the mod-anode current and body power for the high-efficiency phases of the mismatch, it can be concluded that some of the electrons are being stopped and turned around and are not only hitting the tube body but also traveling back down the beam pipe and impacting on the mod anode, increasing the mod anode current. These returned electron can lead to sideband oscillations [3,4]. During early testing an efficiency approaching 70 % was achieved into a matched load but was unstable at some phases of a 1.2:1 VSWR. The guide wavelength in WR1500 waveguide is 52 cm so each 4 cm change in position of the mismatch in Table 5 represents a phase change of 28 degrees.

Figs. 3 and 4 illustrate the power transfer curve of the CPI 700 MHz klystron and the klystron's measured frequency response. These plots are useful to the designers of the feedback circuitry to control the accelerating-cavity amplitude and phase by modulation of the klystron drive signal.

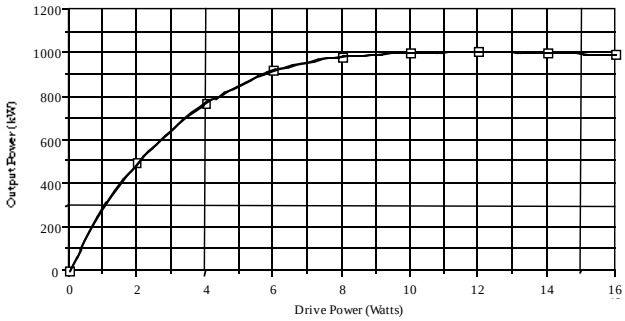

Figure 3: CPI klystron power transfer curve.

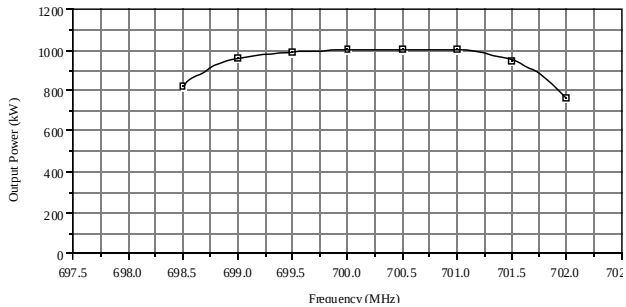

Figure 4: CPI klystron frequency response.

3 CONCLUSIONS

Successful klystron developments have been completed for the APT project. The test data show the klystrons meet or exceed all requirements. Commencing in October we will begin to gather long term reliability data on these klystrons with the LEDA accelerator.

ELECTROMAGNETIC COLD-TEST CHARACTERIZATION OF THE QUAD-DRIVEN STRIPLINE KICKER

Scott D. Nelson and James E. Dunlap
Lawrence Livermore National Laboratory, Livermore, California 94550 USA

Abstract

The first kicker concept design [1] for beam deflection was constructed to allow stripline plates to be driven; thus directing, or *kicking*, the electron beam into two subsequent beam lines. This quad-driven stripline kicker is an eight port electromagnetic network and consists of two actively driven plates and two terminated plates. Electromagnetic measurements performed on the bi-kicker [2] and quad-kicker were designed to determine: (1) the quality of the fabrication of the kicker, including component alignments; (2) quantification of the input feed transition regions from the input coax to the driven kicker plates; (3) identification of properties of the kicker itself without involving the effects of the electron beam; (4) coupling between a line current source and the plates of the kicker; and (5) the effects on the driven current to simulate an electron beam through the body of the kicker. Included in this are the angular variations inside the kicker to examine modal distributions. The goal of the simulated beam was to allow curved path and changing radius studies to be performed electromagnetically. The cold test results produced were then incorporated into beam models [3].

1 INTRODUCTION

The original kicker design was conceived to allow for the diversion of the electron beam dynamically during a long pulse; thus acting like a beam splitter. Experiments performed on the kicker [4] detail the operating parameters of the system. This paper outlines the electromagnetic cold-test measurements performed on the kicker as part of the analysis and concepts for the kicker pulser requirements.

Figure 1. The quad-kicker in the Experimental Test Accelerator (ETA-II) beamline as part of the verification experiments [4]. Note the four ports on each end of the quad-kicker. These ports connect directly to the deflection plates. Two of the white pulser cables are visible in the foreground.

Due to beamline usage and the motivations for the cold-test measurements, the kicker was tested in the LLNL Electromagnetics Laboratory using a variety of vector network analyzers (to sweep the frequency band) and time domain impulse generators and scopes.

Figure 2. The quad-kicker was tested using frequency- and time-domain scopes to cover the band for the swept frequency tests and instantaneous impulse tests.

2 KICKER PORT TESTING

Each of the eight input ports of the kicker were tested over a frequency band from 45 MHz to 500 MHz. Two ports connected to the input and output of each of the four plates through a tapered transition region through a coaxial connector. The pin on the plate connected directly to the center pin of the coax. The results of the measurements (shown in Figure 3) indicate a broadband match with the exception of resonances caused by the feed regions. The comparison in Figure 4 illustrates the feed region effects based on experience learned from the bi-kicker and quad-kicker development activities.

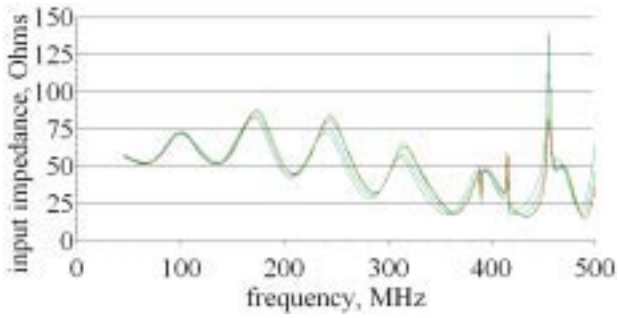

Figure 3. The input impedance of each of the ports is shown vs. frequency (margin of error is +/- 0.3 ohms). The spikes at 388.75, 414.0, 460 MHz are higher order mode resonances and correspond to Q's of 310 (quadrupole mode), 61 (dipole mode), and 29 (dipole mode) respectively.

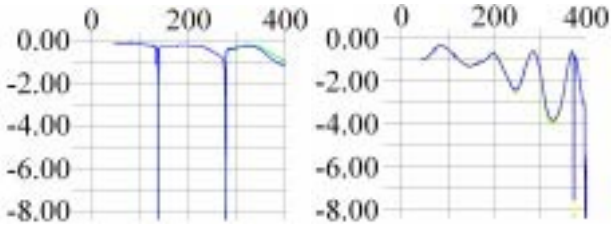

Figure 4. The input reflection coefficient (in dB) vs. frequency (in MHz) of the bi-kicker was much more uniform due to the more gradual transition region after the coaxial feeds. The quad-kicker had a more abrupt transition after the coax and has a larger input reflection coefficient. The spikes in the bi-kicker response curve are due to the grounded plate resonances and were eliminated in the quad-kicker.

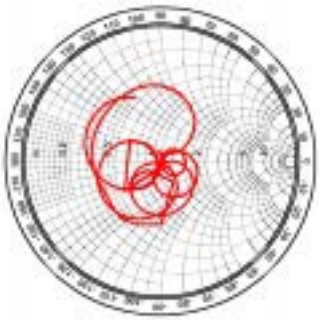

Figure 5. The complex input impedance of the kicker is shown for one of the ports (the variance between the ports is +/- 7 ohms due to fabrication differences). The three straight lines in the curve represent under sampling.

3 CROSS COUPLING TERMS

The cross-plate coupling terms of the kicker corresponded to the coupling between adjacent and opposite ends of the various plates to each other. These coupling terms represent energy that couples from the kicker pulser driven plate to those plates that are terminated, thus inducing fields onto plates that are not directly driven. These cross coupling terms are appreciable (8% and 20%) even at the lower frequencies.

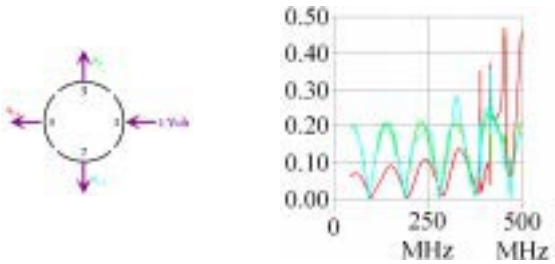

Figure 6. The magnitude of the coupling between adjacent plates vs. frequency shows significant cross coupling at multiples of 80 MHz. The adjacent plate coupling is 20% and the cross plate coupling is 8%.

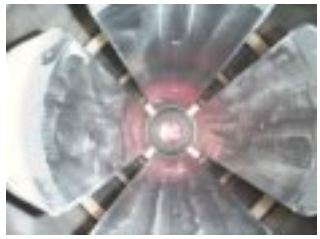

Figure 7. The quad-kicker plates are identical and each is connected to a 50-ohm coaxial port. For the experiments [4] using the existing kicker pulsers, two of the plates were driven and the other two plates were terminated in matched loads. Each plate is 78 ^{o} wide (12.87 cm radius) and is supported by rexolite.

4 FORWARD COUPLING TERMS

The kicker pulsers drive one end of the plates and the other end is mated to reduce reflections on the plate structure. The loss along the plates is less than 1 dB and the transfer function from one end of the plate to the other is shown in Figure 8.

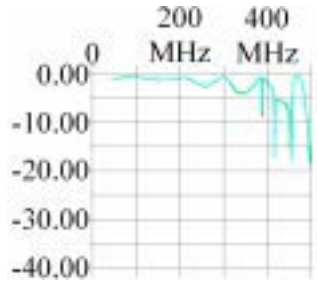

Figure 8. The transfer function (in **dB**) vs. frequency from one end of the plates to the other end. In the low frequency part of the spectrum, the curves for the various plates overlap to within 0.025 dB.

5 KICKER RESPONSE

For identification of the transient properties of the kicker and the association between a simulated beam and the kicker ports, a ramp pulse (0.95V per 300ns) was used to excite the wire-current. The resulting waveform that was induced on the downstream output port is shown in Figure 9.

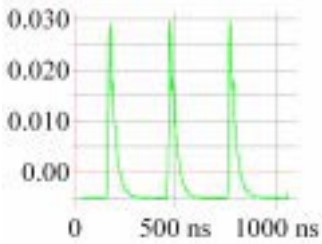

Figure 9. The effect of the 300 ns ramp pulse coupling from the wire-current to one of the kicker plates being monitored at a downstream port. Notice that after about 70 ns, the coupling stabilizes to -0.005 Volts (corresponds to -0.53%). The spikes occur at the transition of each 300 ns excitation ramp waveform.

When the central wire representing an electron beam was excited through the main body of the kicker, the ''pump-up'' time of the kicker was observed as an equivalent time constant of 70 ns. This corresponds to the cavity fill time between the simulated beam pulse and the ports.

6 AZIMUTHAL VARIATIONS

During the course of the measurements, the azimuthal variation caused by the offset-rotations of the current-wire was measured and compared against the theoretical solution for an offset wire in an ideal kicker. A comparison between this theoretical solution (dashed line) for an electrostatic coupling case and that for the experimental cases at the peak coupling points of 68.4, 139.2, and 209.4 MHz is shown in the above plot. The angular frequency spectrum of the above plots was taken to determine the relationships between the various modes (**D**ipole, **Q**uadrupole, and **S**extupole) in the kicker and those modal ratios are shown in the table below and are

	static	**68.4**	**139.2**	**209.4**	**eq (1)**
$\mathbf{V_Q/V_D}$	0.136	0.134	0.140	0.169	0.174
$\mathbf{V_S/V_D}$	0.0252	0.0315	0.0327	0.0351	0.0203

in a similar range to that determined by integrating the simple analytic representation [5] along the plate boundaries shown in Equation 1,

$$\frac{V_S}{V_D} = \frac{4q\frac{a^3}{b^4}\int_{-\phi}^{\phi}\cos 3\theta d\theta}{4q\frac{a}{b^2}\int_{-\phi}^{\phi}\cos\theta d\theta} = \frac{1}{3}\frac{a^2}{b^2}\frac{\sin 3\phi}{\sin\phi} \qquad \frac{V_Q}{V_D} = \frac{1}{2}\frac{a}{b}\frac{\sin 2\phi}{\sin\phi}, \quad (1)$$

where ϕ is the plate half-angle (39^o) but 45^o was used to be consistent with the theory since Eq(1) assumes no gaps, b is the plate radius (12.87 cm), and a is the radius to the wire position (3.175 cm). Differences can be attributed to gap effects between plates, end effects near the feeds, and simplifications of the analytic representation.

The equivalent circuit model for the kicker is composed of a series of transmission line sections and cross-coupling terms representing the plate-to-plate effects.

7 CONCLUSIONS

Although the frequency range of interest for kicker applications is in the low hundreds of megahertz range and is based on the bandwidth of the kicker pulser, there were initial concerns about beam induced effects. For this frequency range: the cross coupling between adjacent ports is less than 14 dB; the input impedance for each port is between 50 and 90 ohms; transmission along the plates experiences less than 1 dB of loss; and cavity measurements show a cavity pump-up time, and a dI/dt coupling between the current-wire and the cavity.

The input reflection coefficient for some higher frequencies can approach 30%; but these frequencies are expected to be outside of the normal operating range of the kicker. However, in making the modifications from the bi-kicker design to the quad-kicker design, the frequency band where these effects make a pronounced difference was lowered and is closer to the operating band. Thus, subsequent changes in the kicker design would need to be leery of this limit. It should be emphasized however that the elimination of the shorted plates from the bi-kicker design substantially improved the operation of the quad-kicker [4].

8 ACKNOWLEDGMENTS

Thanks go to Brian Poole for numerous conversations about kicker development and to Judy Chen and John Weir for their experimental activities. This work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48.

SOLID-STATE SWITCH MODULATOR DECK FOR THE MIT-BATES S BAND TRANSMITTER

C. Wolcott, R. Campbell, A. Hawkins, W. North (Consultant), L. Solheim, R. Trepsas, Defa Wang, A. Zolfaghari, MIT-Bates, M. Gaudreau, M. Mulvaney, Diversified Technologies, Inc.

Abstract

This paper describes how to modernize and simplify the design of a pulse amplitude modulator for klystron power amplifiers. The existing modulator design uses two parallel-connected Litton Injectron ™ Beam Switch Tubes (BSTs) in series with the cathode of an RF amplifier klystron. A vacuum-tube based modulator sends high-voltage pulses to the modulating anodes of the BSTs to produce a current pulse through the klystron. In recent years, the vacuum-tube circuitry that drives the BSTs and klystron has become difficult and expensive to maintain. The new design replaces this circuitry with a single switch, comprising multiple series-connected, high-voltage, high-current Insulated-Gate-Bipolar Transistors (IGBTs). Figure 1 illustrates the basic design of the solid-state modulator deck.

The prototype of this system along with its control and feedback circuitry has been built at the Bates Linear Accelerator Center and has been successfully tested in one of the Bates accelerator RF transmitters. The new cathode switching design will not only replace obsolete and failing technology but will also significantly improve the reliability and performance of the accelerator and the RF transmitters.

1 INTRODUCTION

The MIT-Bates linear electron accelerator uses the output of six S-Band RF transmitters to produce the high-level electric fields that accelerate the beam. Each of these transmitters contains two klystron power amplifiers. The modulator in use today uses two parallel-connected Litton Injectron™ Beam Switch Tubes (BSTs) in series with the cathode of each klystron. A vacuum-tube based modulator sends high-voltage pulses to the modulating anodes of the BSTs to produce a current pulse through the klystron. In recent years, the vacuum-tube circuitry used in the present system to drive the BSTs and the klystron has proven difficult and expensive to maintain. As part of the MIT-Bates upgrade project, a new design has been created to replace this old and obsolete technology.

2 SOLID-STATE SWITCH

At the heart of the new modulator design is the 17.5 kV 100 Amp Solid-State Switch (SSS). In the spring of 1997, MIT Bates Linear Accelerator Center awarded a contract for a prototype 20 kV, 100-Ampere solid state switch to Diversified Technologies Inc. of Bedford MA. This switch utilized the core elements of their commercial unit, the HVPM 20-150.

The switch itself consists of 8 Insulated Gate Bipolar Transistor (IGBT) modules, connected in series, and a high-frequency inverter power source for the gate drive circuitry, designed to be compatible with immersion in insulating oil. Each switch module contains four series-connected IGBTs (actually two dual-IGBT assemblies), and their associated control, over-voltage protection and diagnostic circuitry. Each IGBT is rated at 1200 V and 100 A continuous. The overall switch comprises 32 IGBTs in series, with a total voltage rating of 38 kV, shunted by over-voltage clamping which begins to conduct at a voltage of 22 kV, utilizing DTI's patented design. The eight switch modules and the associated switch power supply were each mounted on aluminum heat sinks, approximately 7" x 15". These nine component modules were integrated into an insulating framework, and installed in the solid-state switch deck.

3 SOLID STATE DECK

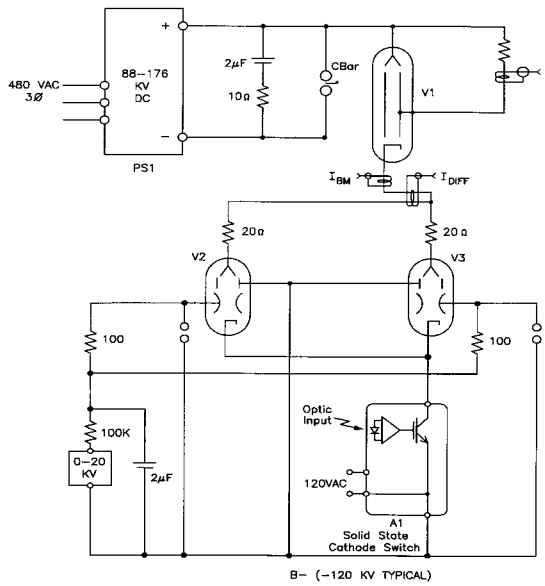

Figure 1: Basic Diagram of the Solid-State Deck

The purpose of the modulator is to send pulses of regulated current, up to 100 Amps, through the klystron power amplifier. When timed correctly, the klystron input RF power is amplified and injected into the beam line to accelerate the beam. The current pulses must have very quick rise and fall times (less than 1 μs) and must be very stable during the flattop portion of the pulse. The present design accomplishes this by sending pulses of high-voltage (up to 15kV) to the mod-anode of the BSTs. The new

design accomplishes the same thing with a constant precision DC high voltage (.001% ripple, .001% regulation) applied to the mod-anodes and by the use of the SSS in series with the cathodes of the BSTs (see Fig. 1). With the switch in the "open" condition, and with the mod-anode power supply at a nominal level, high voltage (up to 170kV) is applied across the klystron, BSTs, and the SSS connected in series. The only current flowing through the klystron in these conditions is the SSS leakage current (less than 1mA). In this situation, the cathodes of the BSTs assume the voltage, relative to the mod-anode, necessary to regulate this small current. Depending on the individual BST, this voltage could even be a small amount more positive than the mod-anode. The solid-state cathode switch is closed in response to fiber-optically-coupled pulses of light. When the switch closes, the current through the klystron rises (in less than 1 μs) to the level set by the mod-anode power supply. The switch stays closed for a time that is set by the trigger control circuitry (from 1-50 μs) and then opens again. When the switch opens, the current falls back to the leakage level in less than 1 μs. This process can take place at various pulse current levels (up to 100 Amps), various widths (up to 50 μs) and at various pulse repetition rates (up to 600 Hz.). The klystron current can be increased or decreased by increasing or decreasing the mod-anode power supply output voltage.

The peripheral equipment on the solid-state deck includes the mod-anode power supply, the dual filament power supply, and the dual solenoid supply. These power supplies are all necessary to run the BSTs.

The mod-anode power supply is a positive-output 300-Watt high-voltage power supply that is adjustable to 20 kV. This power supply, manufactured by Bertan Associates, is an extremely precise supply. The ripple and regulation specifications are both 0.001%. This amount of precision is necessary to regulate the klystron current without any noticeable pulse to pulse, phase, or amplitude jitter (the phase-pushing factor of the klystron is approximately 10 degrees per 1 percent beam voltage change, or per 1.5 percent current change). Shunting the output of the power supply is a 100,000Ω resistor and a 30 kV, 2μF capacitor that together form a low-pass filter to further attenuate any ripple on the mod-anode voltage.

The dual-filament power supply provides AC power to the filaments of each BST. Each BST filament requires 10 Amps at 12 volts to ensure that the tubes are never temperature limited. The dual-filament supply consists of two transformers. The first transformer is a SOLA AC regulator. This device takes the AC power that is floating at high voltage and converts it to a regulated 120 VAC. The second transformer is a 500 VA multi-tapped, step-down, isolation transformer. This transformer provides isolation for up to 30kV, which is necessary because when the SSS opens, the cathodes of the BSTs float at a voltage near the mod-anode power supply output. The secondary of the isolation transformer is tapped at 10.5, 11, 12 (nominal), 13, 14, 16, and 18 VAC. The taps below the 12V nominal tap are provided to run the filaments cooler in order to prolong the tube's lifetime. The taps above 12V are provided for when the tube begins to deteriorate and the filaments have to be run hotter to produce the desired klystron current. The filaments are connected to the supply in parallel and can be switched to a different tap by the use of a rotary switch.

The dual solenoid power supply provides regulated DC current (8 Amps nominal) to the solenoids of each BST.

4 PROTECTION

Along with the basic building blocks that make up the solid-state switch deck, there are many devices that are integral to the reliability, susceptibility, and durability of the design. First, all AC power circuits are protected with correctly rated circuit breakers and varistors to provide short circuit and transient protection. The SOLA AC regulator of the filament power supply also provides transient and inrush current protection. The mod-anode power supply is protected from arcs that conceivably could occur from the BST collectors to a mod-anode of one of the BSTs. The first line of defense is a 17kV arc-gap connected between the mod-anode of each BST and the negative high-voltage rail. These gaps ensure that the mod-anode power supply will never be destroyed by such a destructive occurrence. However, these arc-gaps take a small amount of time before they fire. They also work more reliably when the voltage across them ramps up slowly. The 2μF capacitor across the output of the mod-anode power supply provides the means to slow down the voltage transient and allows the arc-gaps to work more effectively. The capacitor is rated for 30kV and 5,000 Amps of transient current for this purpose. The arc-gaps also provide protection to the mod-anode of the BSTs, the filament power supply, and the SSS. If the mod-anode power supply output rises too high, all these circuits could be over-voltaged if not for the arc-gaps.

Another arc protection strategy uses the shield of the BSTs themselves. The inner geometry of the BST is such that the collector of the BST is most likely to arc to the shield electrode. On the solid-state switch deck, the shield is tied directly to B-, the reference of the deck. In this way, nearly every arc will go straight to the reference. The cathodes of the BSTs and the SSS are also protected from arcs by two components. A wire wrapped tube is connected between the cathodes of the BSTs and the SSS. In the event of an arc to the cathode, which would damage the SSS, this small inductance will limit the current and hold a portion of the voltage during the arc. The second stage of this arc protection is a very large metal-oxide varistor (MOV) across the entire SSS, which provides a great deal of transient protection. The third stage is the protection circuitry in the SSS itself. With all these safeguard strategies, the BSTs, the peripheral supplies, and the SSS are all protected.

5 INSTRUMENTATION

Signals from the SSS, the mod-anode power supply, the solenoid power supply, and the filament power supply are all transmitted from the deck, which is floating at high voltage, to the ground level instrumentation via fiber optic links.

The SSS sends a fiber optic signal from each IGBT module that indicates whether or not the IGBT module is open or closed. The mod-anode power supply sends back a 20kHz to 100kHz frequency signal that indicates the level of the power supply output. This signal is converted to a voltage and fed to a digital meter that displays the mod-anode power supply output in kilovolts. The solenoid power supply sends back a 0Hz to 100kHz frequency signal that indicates the current through the solenoids. This signal is converted to a voltage and fed to another digital meter that displays the solenoid current in Amps. The AC current to each BST filament runs through a small transformer. Across the secondary of the transformer is a resistor that is sized so that the output voltage of the transformer, when rectified, is 9 VDC when 10 Amps AC is flowing through the filament. This voltage is converted to a frequency that is sent to ground via a fiber optic cable. This frequency is converted back to a voltage and the current through each filament, in Amps, is displayed on a digital meter. In this way, all the necessary information from the solid-state deck is conveyed to ground level and displayed in the correct units.

6 CONTROL

The SSS is turned on and off by a gate signal that is converted to a fiber optic pulse. This pulse is transmitted to the SSS via a fiber optic cable and the switch is closed as long as there is light at the end of the cable. The width and frequency of the gating signal determines the width and frequency of the current pulses through the klystron. Pulse current transformers are used to monitor the collector, cathode, and body current of the klystron. The collector and cathode current can be viewed with an oscilloscope. In the event of a klystron arc, the body current transformer will produce a pulse and the SSS will be latched open. There is also a ground current pulse transformer that monitors all currents through ground. This transformer will also produce a pulse during a klystron arc but this pulse will fire the crowbar of the transmitter, thereby de-energizing the main high-voltage power supply and the energy-storing capacitor banks. It is undesirable to fire the crowbar in the event of a klystron arc. Therefore, any signal from the ground current transformer is integrated so that it does not reach its crowbar trigger level for 10μs. In this way a klystron arc may be extinguished without firing the crowbar, but any other fault through the ground path will fire the crowbar after 10μs.

There is also a pulse current transformer that monitors the amount of current difference between the two BSTs. If this current becomes too large, as in a BST arc, the crowbar is fired. With any of these crowbar events, the switch is latched in the open position. A 0-5 VDC voltage that is converted to a 20kHz to 100 kHz fiber optic signal controls the mod-anode power supply. This control signal must be as stable as the power supply in order to keep the ripple and stability percentages low.

7 PROTOTYPE PERFORMANCE

During the week of December 1, 1997 the prototype solid-state-switch-deck was installed into the oil tank of one of the Bates transmitters after having been extensively tested in air. On December 3, the deck was turned on and began to pulse. That day the transmitter was processed to a klystron current of 60 Amps with a pulse width of 20μs at 60 Hz. The system ran for 3 hours and experienced 3 major crowbars as part of processing and remained undamaged. The next day the system was processed to 80 Amps with a width of 22μs and with a pulse repetition rate of 600 Hz. The system ran at this level for 24 hours with no major failures. Figure 2 shows an oscilloscope picture of the klystron pulse current at 74 Amps at a pulse repetition rate of 600 Hz. Trace #1 is the trigger input to the control circuitry and trace #2 is the signal from the klystron collector current transformer, which has an output ratio of 0.1 volts per Amp.

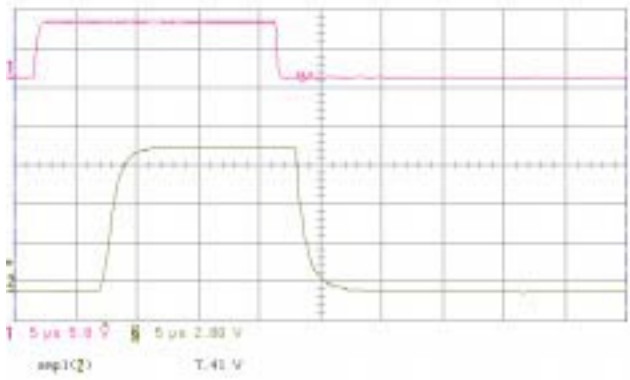

Figure 2: Klystron Current Pulse

This very successful test proved the functionality of the solid-state switch deck. The full-power 24 hour heat run did not reveal any weaknesses and there were no reliability problems associated with this test.

8 CONCLUSION

The new solid-state deck at the Bates Linear Accelerator is a vast improvement over the old modulator designs of the past. The new design uses less power, is much smaller, uses fewer components, is much more reliable, and is easier to control. The system has been thoroughly tested in the air and in the transmitters at Bates and has been proven to work successfully. This new modulator design will greatly increase not only the efficiency of the accelerator overall, but will improve the performance as well.

DESIGN CONSIDERATIONS FOR VERY HIGH POWER RF WINDOWS AT X-BAND*

W. R. Fowkes, R. S. Callin, E. N. Jongewaard
D. W. Sprehn, S. G. Tantawi, A. E. Vlieks
Stanford Linear Accelerator Center, Stanford, California 94309 USA

Abstract

RF window designs of the Pillbox type were capable of transmitting peak rf power up to about 10 MW. The power levels now being produced by advanced high frequency power sources is beyond the level that can safely be transmitted through a single rf window of conventional design. New approaches are required to keep the rf electric fields at a manageable level in the vicinity of the rf window.

This paper describes some of the recent rf window designs at SLAC and elsewhere and some of the test results. Windows that operate in larger waveguide in higher order modes such as TE_{01} and in a mix of modes such as TE_{11}, TM_{11} and TE_{12} are described. RF chokes and corona shields, circular polarization and forced electric field reduction are also discussed.

1 INTRODUCTION

The high power window presently used on all of the SLAC X-band klystrons has been reported on previously [1]. It is usually referred to as a TE_{01} reduced field traveling wave window. A pair of symmetrically located inductive irises are used to set up a standing wave in the region between the irises and the 47 mm diameter ceramic window surface. This results in "forcing" a lower impedance at the window surface that exactly matches the characteristic impedance inside the ceramic thereby causing a pure traveling wave condition inside the ceramic. This design has been tested successfully to over 100 MW in a traveling wave resonator (TWR) and has been serving as a single output window on the 50 MW XL-4 series klystrons. This design however, is considered marginal at this power level.

The new 75 MW periodic permanent magnet (PPM) focussed klystron presently uses a pair the windows described above, each passing 37.5 MW. Four TE_{10}/TE_{01} mode transducers are presently required—an expensive luxury due to the cost of the mode transducers.

2 LARGE DIAMETER TE_{01} TW WINDOW

2.1 Larger Single Window

A single window alternative has been sought that will safely handle the full 75 MW. The 47 mm TW window described above is considered to be very reliable up to a peak power level of about 40 MW where the peak rf electric field at the window is 3.4 MV/meter. Using this electric field level as a design criterion for a single 75 MW window, an increase in diameter to 65 mm would be required. This assumes of course that TE_{01} mode purity is maintained and the reduced field TW scheme is used. A problem that must be addressed in all all overmoded diameter circular windows windows is mode conversion. TE_{11} windows are susceptable to conversion to TM_{11}, TE_{12} and TM_{12} in the transitions (tapered or stepped) going from single moded to overmoded diameters. TE_{01} windows are not as vulnerable to mode conversion with increases in diameter providing the mode converter has launched TE_{01} with good purity. Gradual tapers maintain TE_{01} mode purity but are not usually very compact. Stepped transitions to larger diameters are normally susceptible to conversion to higher order TE_{0n} modes unless special attention is given to the step design.

2.2 TE01 TW Window with Compact Optimized Step

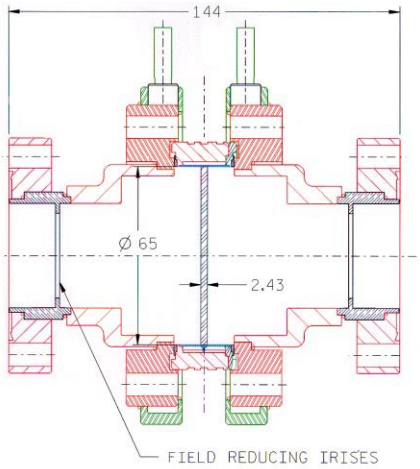

Fig. 1. Compact overmoded 65 mm diameter TE01 window. Field reduction is accomplish by a combination of the 2-stage steps and irises. The double step is optimized to cancel TE_{02} that is created at each indivdual step.

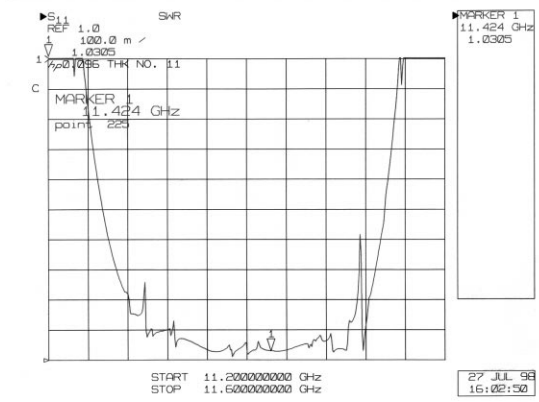

Fig. 2. Cold test results of window in Fig. 1 measured on HP 8510C NWA using old style "Flower-Petal" mode transducers which have narrower bandwidth than the window.

* Work supported by Department of Energy contract DE-AC03-76SF00515

This paper describes a compact 65 mm diameter TE_{01} TW window that is virtually free of higher order modes. The maximum electric field at the surface of this window at 75 MW is about the same as exists at for the previously described window at 40 MW; 3.4 MV/meter. The TE_{01} mode is created in 38 mm diameter circular waveguide using the recently designed compact wrap-around mode transducer [2] shown in Fig 4.

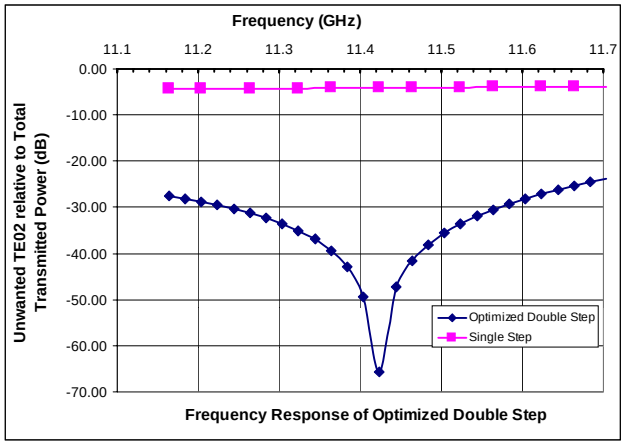

Fig. 3. Comparision of an optimized double step with a single step going from 38 mm to 65 mm with a launched TE_{01} mode.

The input and output ports for this window design are 38 mm diameter. The transition from 38 mm to 65 mm is a two-stage step designed using MLEGO© which sets up the cancellation of the TE_{02} mode excited at each step stage [3]. If one were to use a single sudden step in diameter from 38 mm to 65 mm, the resulting mode conversion is the following: S_{21} of 0.78 for TE_{01} and 0.62 for TE_{02} with only TE_{01} exciting the smaller diameter port. By going to a two-step design, the length and diameter of the intermediate step is optimized to null out the natural conversion to TE_{02}. The optimum intermediate diameter is 58.14 mm with a length of 19.48 mm. The residual S_{21} for TE_{02} drops to 0.00051. The effectivness of this optimized step is shown in the graph in Fig. 3. It is compared with a single abrupt step as a function of frequency. The unwanted conversion from TE_{01} to TE_{02} is mimized for the operating frequency of ll.424 GHz.

All this is accomplished at the expense of a residual TE_{01} mismatch S_{11} of 0.167 in the 38 mm port. This residual mismatch, however, can be used along some help from an additional iris to set up the standing wave that is necessary to force the electric field down at the surface of the ceramic. The result is a pure traveling wave inside the ceramic.

It can be shown that the optimum VSWR needed to produce the TW condition within the ceramic is

$$\sigma_{opt} = \frac{\lambda_g}{\lambda_g'}$$

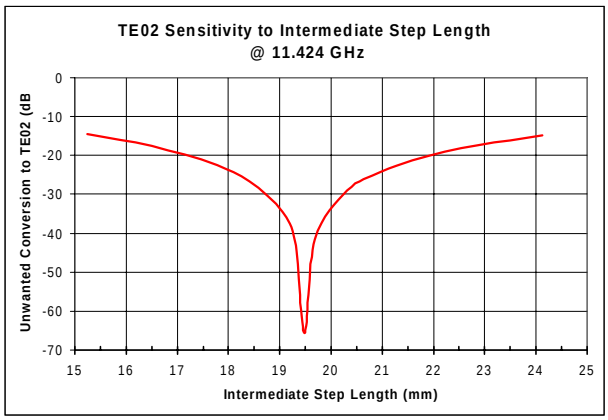
and the total normalized iris susceptance that would give σ_{opt} is given by

$$\left|\frac{B}{Y_0}\right| = \frac{\lambda_g - \lambda_g'}{\sqrt{\lambda_g \lambda_g'}} = 1.3476$$

where λ_g and λ_g' are the guide wavelengths in the large diameter outside and inside the ceramic window respectively [1]. The double-step reflection of 0.167 corresponds to a normalized susceptance of 0.3388. The difference is made up with symmetrical inductive irises each having a normalized susceptance of

$$\left|\frac{B}{Y_0}\right| = 1.3476 - 0.3388 = 1.0088$$

located properly so that the stored energy between the iris and the 2-stage step is minimum. It is important that the irises be located in the smaller (38.1 mm) port since an inductive iris will convert to TE02 in the larger (65 mm) port.



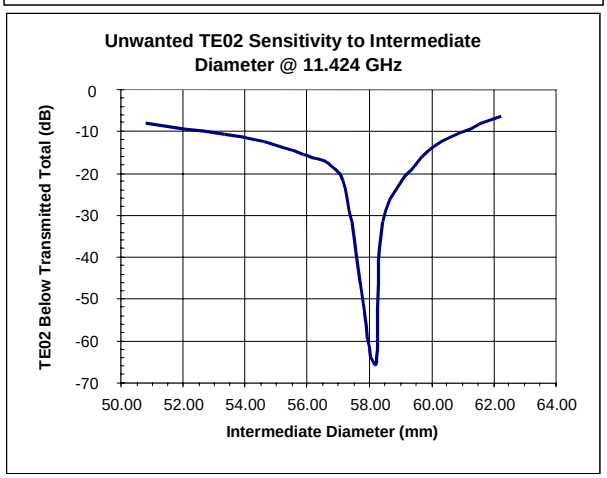


Fig. 3a and 3b. The Double step from 38.1 mm to 65 mm has been optimized to cancel out any TE_{02} conversion occurring at each step at the operating frequency of 11.424 GHz. This was accomplished using the mode matching code MLEGO. The variable parameters are the length and diameter of the intermediate step. The above graphs show the theoretical sensitivity of the conversion to unwanted TE_{02} to each of these parameters while the other is kept at the optimum value.

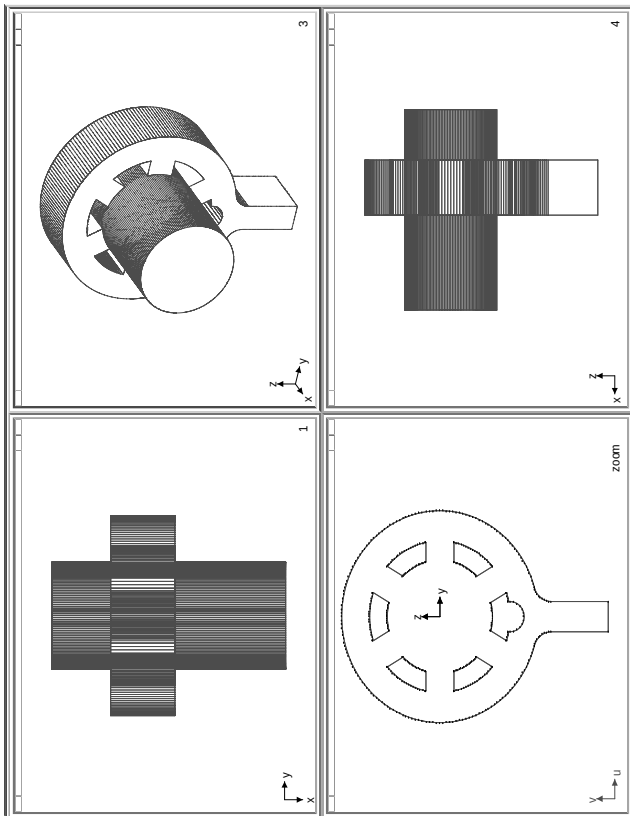

Fig. 4. HFSS output showing the geometry of the new compact Wrap-around TE_{10}/TE_{01} mode transducer that is used to excite the TE_{01} mode in 38 mm circular waveguide.

3 OTHER WINDOWS

3.1 Revisiting TE11 with Chokes

TE_{01} is preferred for technical reasons. The braze fillet is in a zero electric field region. The high cost of the TE_{10}/TE_{01} mode transducers however, diminishes the attractiveness of the TE_{01} design. TE_{11} window designs are not being abandoned entirely for some applications. A window has been designed that uses RF chokes to block RF from the region where the ceramic is brazed into its sleeve. A pair of symmetically placed inductive irises set up the reduced field TW condition similar the the TE_{01} version described earlier. The irises are necessarily thick with a full radius to reduce the local surface electric field as much as possible. A cold test version of this design was built and tested at SLAC. The diameter of the circular waveguide approaching the choke region is 27 mm while the cylinder housing the ceramic is 47 mm. This diameter is larger than necessary and was used because ceramic window blanks were available from the TE_{01} design.

This design has two main drawbacks. The surface electric field on the inside of the irises is high and there is also a strong axial component of RF electric field between the choke lobe tips and the ceramic surface, a fact that was overlooked in the beginning until it was modeled on a later version of HFSS that was capable of resolving total electric field into axial and radial components. A high power version of this design has not been built for these reasons. There was an effort to modify this design to a larger diameter but we were unable to solve the problem of mode conversion from TE_{11} to TM_{11} and TE_{12} in the larger diameter portion of the window.

3.2 Other Overmoded Windows

There have been some recent designs where the conversion of TE_{11} to combinations of TM_{11}, TE_{12}, TM_{12} were exploited successfully by Sergi Kazakov in a collaboration between BINP and KEK [4]. These designs have window diameters of either 53mm or 64 mm. These use the reduced field TW concept and in some cases the total electric field at the braze fillet has been reduced substantially and the axial component of electric field from TM_{11} is also greatly reduced.

STRATEGIES FOR WAVEGUIDE COUPLING FOR SRF CAVITIES*

Lawrence R. Doolittle
Thomas Jefferson National Accelerator Facility, Newport News, Virginia 23606 USA

Abstract

Despite widespread use of coaxial couplers in SRF cavities, a single, simple waveguide coupling can be used both to transmit generator power to a cavity, and to remove a large class of Higher Order Modes (HOMs, produced by the beam). There are balances and tradeoffs to be made, such as the coupling strength of the various frequencies, the transverse component of the coupler fields on the beam axis, and the magnitude of the surface fields and currents. This paper describes those design constraints, categories of solutions, and examples from the CEBAF Energy Upgrade studies.

1 USE OF COUPLERS

Fundamental power couplers form an important part of the design of any RF accelerating cavity, and have a history of difficult development in superconducting $\beta \approx 1$ designs[1]. Although waveguide couplers are relatively uncommon in this arena, they offer some intriguing advantages, including simplicity and the ability to operate while flexing mechanically.

The intended operation of a coupler is clear—it has to convert the TM_{01} mode of the circular beampipe (and possibly higher order modes as well) to the TE_{10} rectangular waveguide mode, eventually connected through a window and cold-warm transition to the power source.

Much of the following discussion depends on the propagation of various modes down the circular beampipe. Table 1 shows the calculation of attenuation

$$A = 20/\ln 10 \cdot \sqrt{(p/a)^2 - (2\pi f/c)^2}$$

for the cavities (designed at Cornell) used at Jefferson Lab, which have tube radius $a = 3.5$ cm. Most $\beta = 1$ cavities have similar behavior in this regard, although there will certainly be small differences due to the HOM band structure and the relative size of the beampipe. Note that the TM_{110} cavity mode couples to both the TM_{11} ($p = 3.832$) and TE_{11} ($p = 1.841$) waveguide modes, but the former decays more rapidly and is unimportant for pipes longer than 2 cm.

It is possible to ignore HOM properties of the coupler, and assert that separate HOM filter/absorbers will be used (this is the approach of Jefferson Lab's baseline design for its energy upgrade). That places stringent requirements on the HOM damping system. In particular it leaves intact a relatively tight ratio between the fundamental (which must not be absorbed) and the lowest frequency HOM (which must be absorbed). The Cornell/Jefferson Lab cell shapes set a ratio of 1.72 to 1.50 GHz for this requirement. The community's history of HOM absorbers (often designed to these tight frequency selectivity requirements) has been less than trouble-free. One might hope that moving the required absorption band edge from 1.7 GHz to 2.7 GHz could make for a simpler, more reliable filter.

Table 1: Mode attenuations in beampipe

mode	freq. (GHz)	p	attenuation (dB/cm)
TM_{010}	1.497	2.405	5.31
TE_{111}	1.72–1.97	1.841	2.83–3.33
TM_{110}	2.08–2.12	1.841	2.44–2.77

Note that the $Q_{\rm ext}$ required for HOM modes can be 100 times lower than the design point for $Q_{\rm ext}$ of the fundamental: Storage rings typically need $Q_{\rm ext}$ less than 10^4 for HOMs and 10^5–10^6 for the fundamental, and linacs typically need $Q_{\rm ext}$ less than 10^5 for HOMs and 10^6–10^7 for the fundamental.

2 A $\lambda/2$ STUB DESIGN

Cornell designed and tested a waveguide coupler for use in a storage ring. The basic design used a stub slightly shorter than $\lambda/2$, as shown in Figure 1[2, 3, 4]. The second stub is used for HOM purposes: the HOM coupler in that design was incapable of damping modes below 1.9 GHz, and there are cavity TE_{111} modes in the 1.7 to 1.9 GHz range that needed damping. The second stub enhanced coupling to these modes.

This coupler length has some interesting advantages: the fundamental can be rejected by a factor of $\sin(2\pi x/\lambda) \ll 1$. This condition does not hold for non-π TM_{010} modes and HOMs, since λ is appreciably different at other frequencies (1.7 vs. 1.5 GHz in the latter case). The resulting strong coupling to the former mode set is of great interest in a storage ring application, where the stub-on-stub design was demonstrated to give a factor of two reduction in $Q_{\rm ext}$ for the $4\pi/5$ TM_{010} mode[3].

Figure 2 shows the electric fields of this coupler in the direction of the beam axis, as computed by HFSS[7]. Examination of these shows the large resonance (14× amplitude) set up between the beamline and the end of the stub. The curve labelled "Real" is the component of a traveling wave

* Work supported by the U.S. DOE Contract # DE-AC05-84ER40150

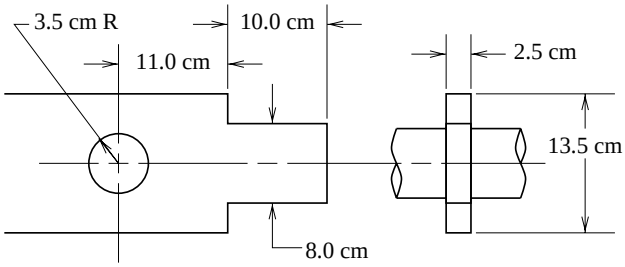

Figure 1: Schematic (interior dimensions) of $\lambda/2$ stub-on-stub FPC used by the Cornell/JLab cavity system.

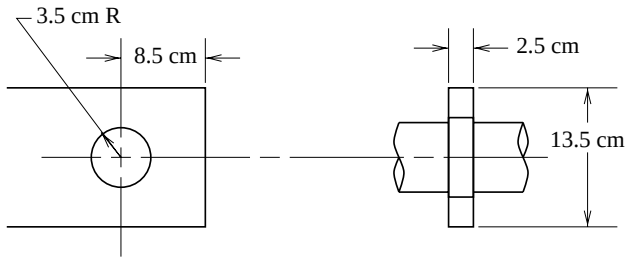

Figure 3: Schematic (interior dimensions) of $\lambda/4$ stub FPC proposed for the CEBAF energy upgrade cryomodule.

that is in phase with the evanescent fields in the beampipe. It is also the standing wave pattern when the cavity is filled, as would occur in steady state on resonance. The curve labelled "Imag" is the component of a traveling wave that is in quadrature with the evanescent fields in the beampipe. It is also the standing wave pattern when the cavity is empty, as would occur off resonance.

This design also provides a mechanism to tune $Q_{\rm ext}$ by mechanical deformation of the stub. A bow in the wide face of the waveguide will change λ, which in turn makes a large change in $\sin(2\pi x/\lambda)$ and therefore $Q_{\rm ext}$. For large changes in $Q_{\rm ext}$, this might make sense. The complexity of producing a reliable cold mechanism makes this unattractive for performing small adjustments, where an external three-stub tuner can perform adequately.

When the cavity shape was incorporated in Jefferson Lab's design for its Nuclear Physics accelerator, CEBAF, the $Q_{\rm ext}$ tunability was used to shift from the (storage ring) design point of 3×10^5 to the (recirculating linac) design point of 6×10^6. This factor of 20 reduction of $\sin(2\pi x/\lambda)$ made for touchy bench adjustments and increased concerns about how stresses in assembly and cooldown could affect $Q_{\rm ext}$. In retrospect, it might have been better to obtain some or all of the gross increase in $Q_{\rm ext}$ by increasing the length of beampipe between the coupler and end cell iris.

The coupler fields are quite asymmetric in the $\lambda/2$ stub design. The resulting beam kick was cancelled (to first order) in the CEBAF accelerator by arranging the feeds in a $++--\,--++$ pattern for the 8-cavity cryomodule. Further study of coupler kicks[5] has in some cases placed extra restrictions on the setup of cavity gradients[6]. The use of the stub to reject the fundamental mode also leads to high fields in the coupler, and the stub must be well cooled to keep it superconducting.

3 A $\lambda/4$ STUB DESIGN

The same waveguide–beamline topology can result in a near-zero coupler kick, if the stub is $\lambda/4$ long, as shown in Figure 3. Figure 4 shows E_z along the length of the coupler axis, again computed by HFSS.

For a given intensity of fundamental evanescent fields in the beampipe at the coupler location, this coupler design has a factor of 10 lower peak field in the coupler region. It passes a factor of 10 more wave intensity to its waveguide port than the $\lambda/2$ stub design. To keep $Q_{\rm ext}$ the same, therefore, one could either put more beampipe between the cavity and the coupler, or add a matching iris on the rectangular waveguide section.

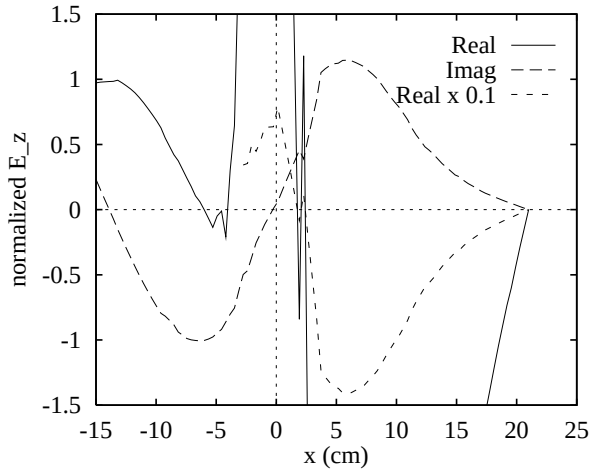

Figure 2: Electric fields in the centerline of $\lambda/2$ stub-on-stub FPC used by the Cornell/JLab cavity system.

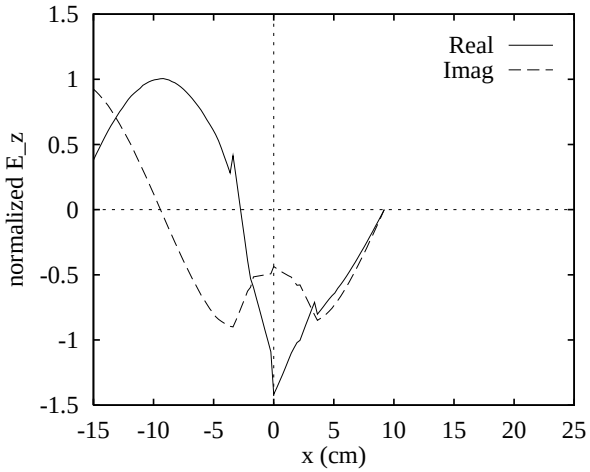

Figure 4: Electric fields in the centerline of $\lambda/4$ stub FPC proposed for the CEBAF energy upgrade cryomodule.

While the use of a matching iris may sound silly, a superconducting filter constructed out of H-plane steps in waveguide width can form an effective *narrowband* iris. An example design sets up a VSWR of 10 at 1.5 GHz, but less than 1.2 at 1.72 GHz and above[8]. It takes only 56 cm of waveguide length, zero beamline space, and does not induce asymmetric coupler fields.

4 POLARIZATION OF RF COUPLING

Normally the two polarizations of dipole (and higher rotational order) modes have slightly different frequencies, due to broken cylindrical symmetry by manufacturing defects and couplers. In the worst case, a single HOM coupler in the presence of otherwise degenerate polarizations will break the degeneracy in such a manner as to couple only one of the two polarizations. Conversely, a single coupler can function effectively if the nodal planes are pinned at a 45° angle from the coupler plane.

The lowest frequency mode (which is the hardest to separate from the fundamental in conventional HOM filters) is normally the TE_{111} dipole mode, so any attempt to extract this mode from the fundamental power coupler (waveguide or not) has to deal with polarization. The HOM coupler in the Cornell/Jefferson Lab cavity-coupler system is designed to polarize the TE_{111} mode in the ideal direction. Most measurements of mode Q's verify the success of this plan. This effect was not checked during manufacturing, however, and in two cases (in Jefferson Lab's Free Electron Laser) one of those modes shows very high Q_{ext}[9].

Some studies have shown [10] that polarized cells can be used to damp both polarizations with a single coupler. To date, no beam testing or production manufacturing of such cells has been attempted, so the cost and performance impact can not be fully characterized. The polarizing effects of the $\lambda/4$ stub waveguide coupler discussed here are rather small, so there is hope that an intentional disturbance (such as an elliptical section of beampipe near the coupler) could swamp both residual manufacturing and inherent coupler polarization, without the complexity of polarized cells.

5 RF WINDOWS

The design of windows is tightly bound to that of the coupler itself. In the original Cornell/JLab design, a cold window (originally Kapton$^{\mathrm{TM}}$, later ceramic) was used, primarily to keep the cells under clean vacuum during cryomodule assembly. That window had to meet a set of extreme design goals:

- Low VSWR over a wide frequency range (because of the HOM damping needs)
- Tolerance of high radiation flux (it's only 8 cm from the beamline)
- Low RF losses at the fundamental (since dissipation is taken by the 2 K helium circuit)
- Particulate free during assembly and operation (to avoid damaging cavity performance)

Meeting all of these needs simultaneously turned out to be a larger challenge than anticipated. Among other problems, many of the windows installed at CEBAF have developed pinholes during the years of operation[11].

The baseline design of the cryomodules for CEBAF's energy upgrade uses a single ceramic window at room temperature, away from line-of-sight of the cavities. The coupler system, window included, is not used for HOM damping, so the window can be implemented with a narrowband design (allowing a thicker ceramic with better puncture resistance). It still forms part of the beam vacuum envelope, and must be manufactured and assembled free of particulates.

6 CONCLUSIONS

The ultimate simplicity of a waveguide coupler makes it a worthy competitor to a conventional coaxial coupler. The Cornell/Jefferson Lab experience has led to clearer understanding of how to use waveguide couplers to meet design goals. A coupler based on this work is now in the prototyping phase at Jefferson Lab.

SYSTEMATIC DESIGN OF AN S-BAND PILLBOX-TYPE RF WINDOW

A. Jöstingmeier, M. Dohlus and N. Holtkamp, DESY, D-22607 Hamburg, Germany

Abstract

The scattering matrix technique and the MAFIA computer code are employed for the systematic design of an 75 MW S-band pillbox-type window. It is shown that with the standard pillbox-type design the window cannot be matched using ceramic disks with a thickness in the range from 4 mm to 8 mm. Nevertheless such disks are mechanically more robust and easier to manufacture than the usual 3 mm disks. Therefore a new design of the pillbox-type window with an additional inductive iris is presented so that ceramic disks of arbitrary thickness may be used. Furthermore it is demonstrated how the bandwidth of the window can be optimized by fine tuning the thickness of the ceramic disk. The final design of the pillbox-type window with smoothed edges is validated by the application of the MAFIA time domain module.

1 INTRODUCTION

The S-band linear collider at DESY requires approximately 2600 klystrons operating at an output power of 150 MW, a pulse duration of $3\,\mu$s and a repetition rate of 50 Hz. Until 1995 two klystrons have already been built and successfully tested [1]. The klystron has two output waveguides which are split and recombined so that each of the four rf windows has to withstand a peak transmission-power of about 37.5 MW. The production costs of the klystrons can significantly be reduced if each tube contains only two rf windows. In this paper we will report on the systematic design of such a window.

Fig. 1 presents the schematic drawing of a pillbox-type rf window. The practical use of rf-windows in the high-power regime is still a challenging task although strong efforts have been made during the past to improve their reliability [2]. The mechanismen which is responsible for an rf window failure has not yet been understood in detail. Nevertheless it seems to be clear that multipactor electron bombardment of the ceramic disk [3] is mainly responsible for a breakdown.

Computer simulations have demonstrated that the component of the electric field normal to the disk is mainly responsible for this phenomenon. Hence a long pillbox-type rf window has been suggested in [2] which has a length of more than 150 mm instead of 30 mm for the standard window. The axial electric field is effectively suppressed by this new geometry because only the TE_{11} mode is propagating in the empty circular waveguide sections of the pillbox cavity.

The higher order modes which are excited at the transition from the rectangular to the circular waveguide do not interact with the ceramic disk in a long window. Thus we can apply the scattering matrix technique taking only one propagating mode into account. From this analysis we get analytic expressions which are very useful for the window design. Only the scattering matrix corresponding to the waveguide transition will be calculated numerically using MAFIA [4]. Hence the scattering matrix technique leads to a numerically efficient formulation so that a large variety of parameter sets can be studied.

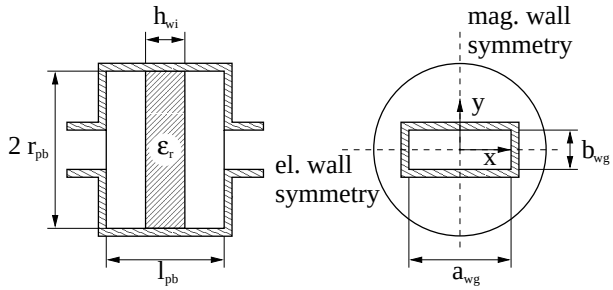

Figure 1: Schematic drawing of the pillbox-type rf window.

Pillbox-type rf windows usually contain ceramic disks with a thickness of about 3 mm. Especially if high purity alumina is to be used it is desirable to increase the thickness of this disks from the mechanical point of view. The analytic design formulas show that such windows cannot be matched if the thickness of the disk is in the range from 4 mm to 8 mm because the input reflection of the transition from the rectangular to the circular waveguide is too small. Therefore a new type of rf window is presented which contains additional inductive irises in order to increase the reflectivity of the waveguide transition.

Both features of the new window, which are an increased thickness of the ceramic disk and a long pillbox cavity, lead to a significant reduction of the bandwidth. Especially if the SLED-option [5] is taken into account the VSWR must be less than 1.1 over a band of about 90 MHz centered at 3 GHz. It is shown how a maximum bandwidth is obtained by properly adjusting the thickness of the ceramic disk.

In order to prevent the structure from arcing we have to round off the sharp edges at the waveguide transition which are characterized by $y =$ constant. Although the inductive irises do not give rise to a singularity of the electric field they are also assumed to be rounded off in the final design which is validated by the time domain module of the MAFIA code.

2 WINDOW DESIGN

Let us assume that the dimensions of the rectangular waveguide and the permittivity of the ceramic disk are

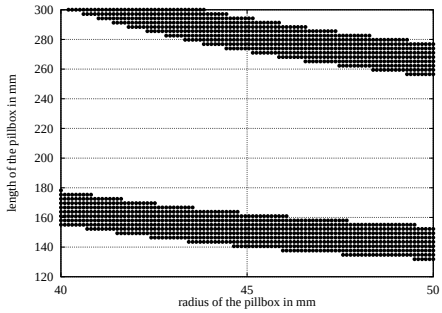

Figure 2: Distribution of possible solutions in the r_{pb} - l_{pb} plane. Parameter: $h_{wi} = 5$ mm.

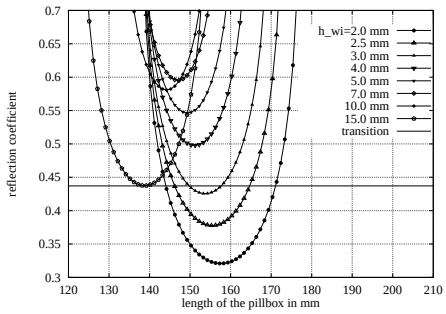

Figure 3: Required reflection coefficient of the waveguide transition as a function of l_{pb} and h_{wi}. Parameter: $r_{pb} = 46$ mm.

$a_{wg} = 72.14$ mm, $b_{wg} = 34.04$ mm and $\varepsilon_r = 10$.

From the application of the scattering matrix technique it turns out that the rf window can only be matched if the window parameters obey certain relations. Fig. 2 shows all possible solutions for which the window can be matched in the r_{pb} - l_{pb} plane assuming $h_{wi} = 5$ mm. In the considered parameter range two sets of solutions are found which are separated just by one wavelength of the TE_{11} mode in the empty circular waveguide.

For the variation of the radius of the pillbox cavity some transitions from the rectangular to the circular waveguide have been analyzed using MAFIA. Actually the radius of the pillbox cavity has been varied in steps of 2 mm. The scattering parameters at intermediate points are then found by the application of an interpolation scheme.

Fig. 3 presents the required input reflection of the waveguide transition as a function of the length of the pillbox cavity for a cavity radius of 46 mm whereas the thickness of the ceramic disk serves as a parameter. The input reflection of the waveguide transition is also given as a straight line.

Starting from $h_{wi} = 2$ mm, the required input reflection of the waveguide transition increases. For $h_{wi} = 2$ mm, 2.5 mm and 3 mm, Fig. 2 predicts two solutions for each thickness corresponding to different lengths of the pillbox cavity. But for thicker disks, the parabolas do not intersect with the straight line so that no solution exists. Only if we consider very thick disks, $h_{wi} > 10$ mm, the required input reflection decreases again. Consequently, the window can only be matched for disks in the range from 4 mm to

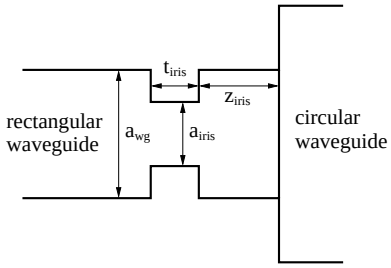

Figure 4: Schematic drawing of the waveguide transition with an inductive iris.

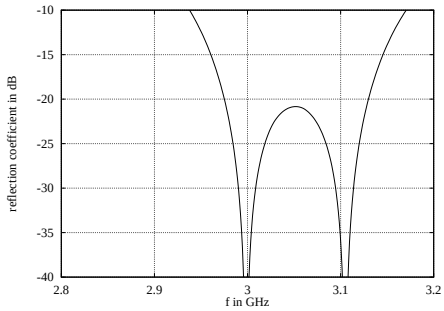

Figure 5: Reflection coefficient of the window as a function of frequency. Parameter: $r_{pb} = 46$ mm, $l_{pb} = 144.9$ mm, $h_{wi} = 5$ mm, $z_{iris} = 40$ mm and $a_{iris} = 57$ mm.

8 mm if we choose a waveguide transition with a higher input reflection.

In order to increase this quantity we introduce an inductive iris in front of the waveguide transition according to Fig. 4. t_{iris} is assumed to be 5 mm. For a given iris one gets a maximum increase of the reflectivity for $z_{iris} = 40$ mm. For the adjustment of a specific value of the input reflection, which is necessary for the proper design of a window, the width of the iris a_{iris} is used.

We have now all the data together which we need for a systematic design of the window. Let us start assuming the following parameters: $r_{pb} = 46$ mm, $h_{wi} = 5$ mm and $z_{iris} = 40$ mm. According to Fig. 3, the input reflection of the waveguide transition has to be greater than 0.55 in this case. We choose an input reflection of 0.57 which corresponds to an iris width of about 57 mm in order to show that really two solutions exist if the input reflection is larger than 0.55. Applying the scattering matrix technique, we actually find two matched windows for $l_{pb} = 144.9$ mm and $l_{pb} = 154.5$ mm. Fig. 5 shows the input reflection of the window for $l_{pb} = 144.9$ mm.

Both solutions have a bandwidth corresponding to a VSWR $= 1.1$ of approximately 30 MHz which is much too small. The bandwidth can significantly be enhanced if we make use of both solutions simultaneously. For that the two frequencies at which the window is matched have to be centered around the design frequency, see Fig. 6. This is achieved by properly choosing the length of the pillbox cavity.

The reflection coefficient at the design frequency which is related to the bandwidth of the window can then be adjusted by the thickness of the ceramic disk which is illus-

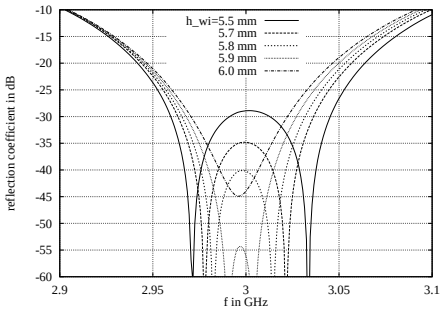

Figure 6: Reflection coefficient of the window as a function of frequency and the thickness of the ceramic disk. Parameters: $r_{pb} = 46\,\text{mm}$, $l_{pb} = 148.9\,\text{mm}$, $z_{iris} = 40\,\text{mm}$ and $a_{iris} = 57\,\text{mm}$.

#	h_{wi} in mm	Δf in MHz	
		VSWR $= 1.05$	VSWR $= 1.1$
1	5.5	–	94
2	5.7	67	83
3	5.8	60	77
4	5.9	52	72
5	6.0	44	66

Table 1: Bandwidth as a function of the thickness of the ceramic disk.

trated in Fig. 6. From Fig. 3 it is clear that the solutions move closer together if the thickness of the ceramic disk is increased. This leads to a smaller reflection coefficient at the design frequency but also to a reduction of the bandwidth. Thus one has to find a trade-off between these two quantities. In Table 1, the bandwidth of the window is given for several values of h_{wi}. E.g., the VSWR is still less than 1.1 over a frequency range of $94\,\text{MHz}$ for $h_{wi} = 5.5\,\text{mm}$. However in this case one has to cope with a reflection coefficient of $-28.9\,\text{dB}$ at the design frequency.

For the final design of the window we use a waveguide transition with rounded edges according to Fig. 7. Detailed investigations using the MAFIA electrostatic module yield that a rounding radius of $10\,\text{mm}$ leads to a field enhancement of about 30% which seems to acceptable. Furthermore it is preferred to use semicircular irises with a radius of $9\,\text{mm}$ instead of those which sharp edges which is also illustrated in Fig. 7.

Fig. 8 presents the input reflection of the final window design as a result of the scattering matrix technique and the MAFIA time domain module. The agreement between both methods is quite well. Optimizing the bandwidth yields a useful frequency range of about $80\,\text{MHz}$ and a reflection coefficient at the center frequency which is less than $-33\,\text{dB}$.

3 CONCLUSIONS

The scattering matrix technique and the MAFIA computer code have been applied in order to design a modified S-band high-power pillbox-type window. It has been shown that for a ceramic disk with a thickness in the range from $4\,\text{mm}$ to $8\,\text{mm}$ the input reflection of the rectangular-circular waveguide transition has to be increased so that

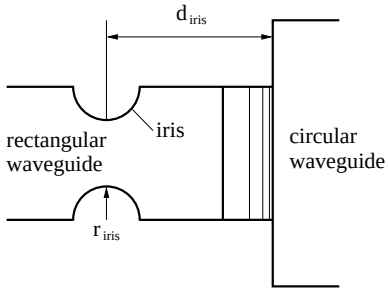

Figure 7: Schematic drawing of the waveguide transition with rounded edges.

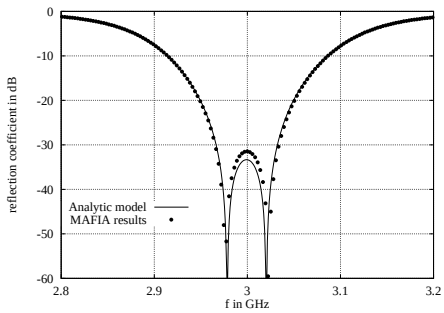

Figure 8: Reflection coefficient as a function of frequency with $r_{pb} = 46\,\text{mm}$, $h_{pb} = 150.4\,\text{mm}$, $h_{wi} = 6.1\,\text{mm}$, $d_{iris} = 40\,\text{mm}$, $r_{iris} = 9\,\text{mm}$.

the overall window is matched at the design frequency. It has been demonstrated by MAFIA computations that the required input reflection of the waveguide transition can be obtained by an inductive iris one quarter wavelength in front of the rectangular-circular waveguide transition. Moreover it has been shown that the thickness of the ceramic disk has to be properly chosen for an optimum bandwidth of the window. A final design of the window with rounded off edges has been proposed; and the performance of this structure has been checked applying the time domain module of the MAFIA computer code.

DESIGN OF A HOM BROADBAND ABSORBER FOR TESLA

M. Dohlus, A. Jöstingmeier, N. Holtkamp and H. Hartwig, DESY, D-22607 Hamburg, Germany

Abstract

For the TESLA FEL operation very short intense bunches of electrons have to be accelerated. These bunches excite a broad spectrum of HOM (Higher Order Modes) up to frequencies of some THz. Two HOM couplers per cavity are foreseen in the present design proposal in order to extract some of the low frequency HOM from the superconducting accelerating structure. In this contribution an additional HOM broadband absorber is suggested which is to be installed between two cryogenic modules at a temperature of $70\,\mathrm{K}$. Its task is to prevent that the really high frequency HOM are absorbed in the accelerator structure at the $2\,\mathrm{K}$ level. The absorption characteristics and the short range wake of four structures which make use of SiC as absorbing material are investigated using the MAFIA computer code. The proposed structures are easier to manufacture and better suited for the operation under vacuum conditions than the recently suggested waveguide array absorber.

1 INTRODUCTION

It is planned to operate TESLA in the FEL mode with very short bunches ($\sigma = 25\,\mu\mathrm{m}$) [1] which excite wakefields with spectral components up to some THz. If we do not extract these fields from the accelerating structure by a special absorber we expect a considerable reduction of the quality factor of the superconducting cavities because the photon energy gets larger than the binding energy of the Cooper pairs for frequencies larger than $700\,\mathrm{GHz}$.

This phenomenon would consequently lead to an excessive energy deposition in the $2\,\mathrm{K}$ cooling circuit which has to be prevented for the following reason: The time averaged power deposition due to the wakefields is about $25\,\mathrm{W}$ per module [1]; and a typical refrigerator requires about $800\,\mathrm{W}$ of wall plug power per Watt dissipated at $2\,\mathrm{K}$ [2]. Thus we would have to supply $20\,\mathrm{kW}$ of cooling power per module which is not tolerable.

A HOM absorber which is sketched in Fig. 1 has already been proposed in [2]. This absorber consists of an array of outward directed rectangular waveguides surrounding the beampipe. The extraction of the high frequency wakefields from the beampipe by such an array has been investigated in detail in [3]. The outward propagating waveguide fields are attenuated by the ohmic losses of the stainless steel waveguides which are considerably high for frequencies above the cutoff frequency of the fundamental waveguide mode which is $100\,\mathrm{GHz}$. Note that low frequency spectral components cannot penetrate much into the absorber.

A cutoff frequency of $100\,\mathrm{GHz}$ corresponds to a width of the waveguides of $1.5\,\mathrm{mm}$. The waveguide height is only

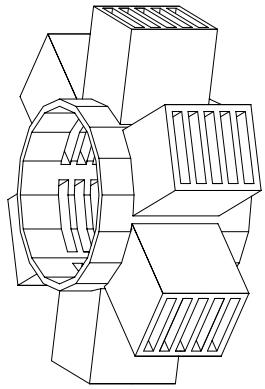

Figure 1: Schematic drawing of the waveguide array absorber.

$0.3\,\mathrm{mm}$ in order to have a high attenuation of the waveguide modes. Furthermore it is obvious that the waveguide walls should be as thin as possible for a good efficiency of the absorber. A wall thickness of $0.1\,\mathrm{mm}$ has been proposed which seems to be the lower limit from the mechanical point of view. The TESLA beampipe has a radius of $35\,\mathrm{mm}$; and approximately $100\,\mathrm{mm}$ of space are available for the absorber in the axial direction. Therefore the actual absorber consists of an array of about 140×250 waveguides in the azimuthal and the axial direction, respectively.

The manufacturing of such a structure is very difficult even if etching techniques are applied [2]. Moreover the problem of cleaning the waveguide array before it is installed in the TESLA vacuum system has yet not been solved. Thus four new absorber structures are proposed which do not have these disadvantages. The MAFIA computer code [4] is used in order to study their absorption characteristics as well as their contribution to the short range wake.

2 PROPOSED ABSORBERS

The absorbers which are investigated in this contribution are shown in Figs. 2-5. In each of these configurations the actual absorbing structure is accomodated in a shielding which is similar to a single cell of the TESLA accelerating structure. For the simulations we have assumed $r_{iris} = 30\,\mathrm{mm}$, $r_{cell} = 100\,\mathrm{mm}$ and $l_{cell} = 100\,\mathrm{mm}$.

We have chosen SiC as absorbing material because it is suitable to be used in a vacuum system; and it has a large loss-tangent which is about 0.3. This number has been confirmed by measurements at room temperature up to a frequency of $20\,\mathrm{GHz}$. For our simulations we assume that it is still valid in the THz region and that it does not change significantly if the absorber temperature is $70\,\mathrm{K}$.

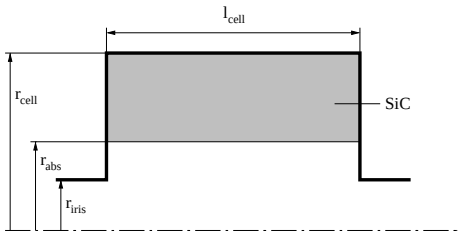

Figure 2: Solid SiC absorber.

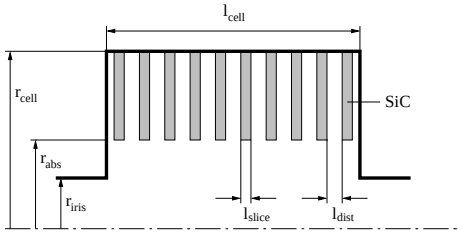

Figure 3: Laminated SiC absorber.

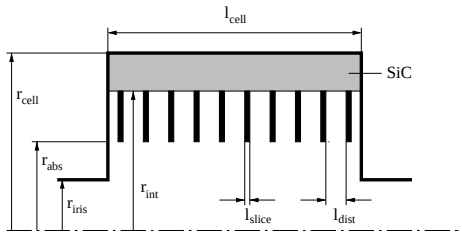

Figure 4: Combined absorber.

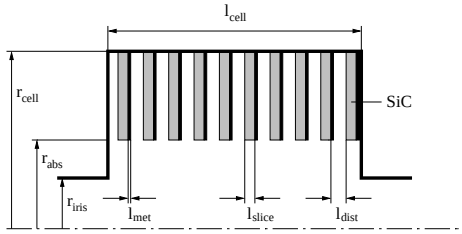

Figure 5: Metallized laminated SiC absorber.

For each proposed HOM absorber we are going to consider two versions. In the original version we have $r_{abs} = r_{iris}$. This seems to be favourable for a good coupling between the absorber and the HOM. On the other hand, the absorber itself also contributes to the beam impedance. This contribution can be decreased if we hide the absorbing structure behind the iris of the shielding cell. A bunch does not see the actual absorbing structure if the relation $r_{abs} - r_{iris} \geq \sqrt{5 l_{cell} \sigma}$ is fulfilled. In this case the short range wake of the HOM absorber is equal to that of a single accelerating cell. Bearing in mind that a module contains 72 such cells, the additionally introduced beam impedance due to the HOM absorber seems to be tolerable.

Note that in the above relation $r_{abs} - r_{iris}$ is proportional to $\sqrt{\sigma}$ which means that the absorbing structure may be arranged close to the beampipe for short bunches. Nevertheless it must also be possible to operate TESLA with $1\,$mm long bunches for which the condition for $r_{abs} - r_{iris}$ cannot be satisfied if we are interested in a good coupling between the HOM and the absorber. Thus we have to find a trade-off between the efficiency of the absorber and its contribution to the beam impedance. For our simulations we choose $r_{abs} - r_{iris} = 5\,$mm.

The first proposed absorber is a solid SiC tube accomodated in the shielding cell. This configuration is shown in Fig. 2. Since the permittivity of SiC is large ($\varepsilon_r \approx 30$) we expect considerable reflections at the SiC-vacuum interface. Therefore the second structure which is presented in Fig. 3 consists of a stack of 50 SiC washers with $l_{slice} = l_{dist} = 1\,$mm in order to reduce the effective permittivity of the absorbing structure.

The idea of the combined and the metallized laminated absorber which are shown in Figs. 4 and 5 is basically different than that of the first two structures in which all spectral components of the HOM are damped by the absorbing material in the shielding cavity. The combined and the metallized laminated absorber additionally contain a stack of stainless steel parallel-plate waveguides which attenuate the really high frequency HOM by ohmic wall losses similar to the previously discussed waveguide array absorber. In these structures SiC is used to suppress the long range wake. For this purpose it is sufficient that it has good damping properties up to a frequency of some $10\,$GHz. Hence the required bandwidth of the absorbing material is much less for these structures than that for the solid and the laminated absorber.

The difference between the combined and the metallized laminated absorber is that in the latter one the low frequency fields are continuously damped by the absorbing material while they are propagating outwards whereas they are absorbed at the ends of the waveguides in the combined absorber. The parameters of both structures read: $l_{slice} = l_{dist} = 1\,$mm and $r_{int} = 80\,$mm. Note that the actual thickness of the metallization l_{met} which is very thin can be neglected for the field analysis. In the MAFIA simulations we have assumed that l_{met} is equal to the thickness of one mesh layer.

3 SIMULATION RESULTS

The absorption characteristics of the proposed absorbers are given in Fig. 6. Here it is assumed that $r_{iris} = r_{abs}$.

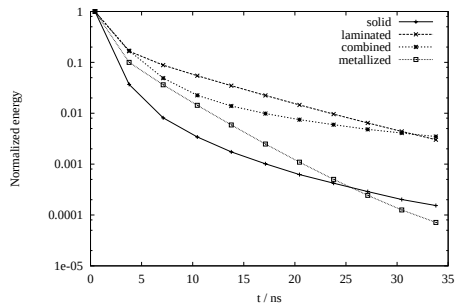

Figure 6: Absorption characteristics of the investigated structures.

The curves represent the total energy normalized to its value at the time $t = 0$. At this time the exciting bunch

has just left the absorber cell. The transient behaviour is then computed for the next 33 ns. An ultra-relativistic particle just travels 10 m during this time interval.

Two classes of absorbers can be well-distinguished with respect to their absorption efficiency. In the solid and the metallized laminated absorber the energy drops to about 10^{-4} of its initial value after 33 ns. On the other hand, the absorption of the laminated and the combined absorber is approximately two orders of magnitude less.

The transient absorption behaviour of the combined and the metallized laminated absorber and the corresponding hidden structures are compared in Fig. 7. It is expected that

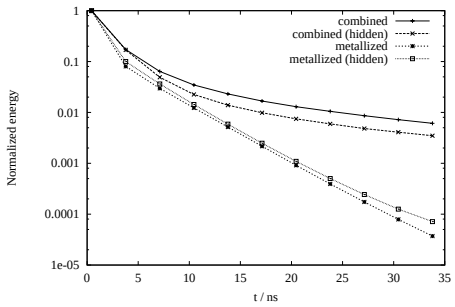

Figure 7: Comparison between the original and the hidden structure.

the hidden structures are less efficient than the corresponding absorbers with $r_{iris} = r_{abs}$. It is found that this is in fact true for the metallized laminated absorber. Nevertheless the efficiency of the hidden version of this absorber is only slightly less than that of the original structure. For the combined absorber it even turns out that the absorption can be improved a little bit if we hide the absorbing structure.

In order to illustrate the different absorption mechanisms of the metallized laminated and the solid absorber the relation between the total energy and that which is stored in the beampipe is shown in Fig. 8. Both energies are approx-

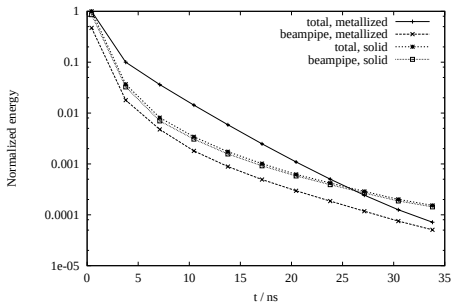

Figure 8: Total energy and energy which is stored in the beampipe.

imately the same for the solid absorber. This means that the electromagnetic field cannot penetrate significantly into the absorbing material because it is absorbed in the immediate vicinity of the dielectric-vacuum interface.

On the other hand the total energy is much larger than the beampipe energy in the metallized laminated absorber because the electromagnetic field propagates a considerably large distance into the parallel-plate waveguides before it is finally absorbed.

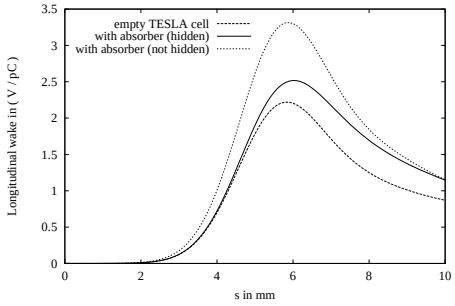

Figure 9: Short range wake of various structures for $\sigma = 1$ mm.

Fig. 9 shows the longitudinal short range wake of the empty TESLA cell, the laminated absorber with $r_{iris} = r_{abs}$ and the hidden version of this structure. The wake of the empty cell, which has a maximum value of 2.2 V/pC, is smaller than that of the two other structures as it is expected. The wake function corresponding to the non-hidden absorber is about 50% higher than this value. On the other hand, the short range wake is only 15% increased for the hidden version of the absorber which is acceptable.

4 CONCLUSIONS

Four types of HOM absorbers for TESLA which are easier to manufacture and more appropriate to be used in a vacuum system than the previously suggested waveguide array absorber have been investigated in this contribution. It has turned out that two of the absorbers, namely, the solid and the metallized laminated absorber have good absorption properties; and that the efficiency of the absorbers is not significantly decreased if we hide the absorbing structure behind the iris of the shielding. The short range wake of such a hidden structure is equal to that of a single TESLA accelerating cell for short bunches; and it is still tolerable for an intermediate bunch length. The solid absorber is less complicated concerning manufacturing and installation than the metallized laminated one. Nevertheless the simulation results for the solid absorber are based on the assumption that SiC has the same favourable attentuation properties in the THz region at a temperature of 70 K as in the frequency range up to 20 GHz at room temperature.

BIPERIODIC DISK-AND-WASHER CAVITY FOR ELECTRON ACCELERATION

H. Ao, Y. Iwashita, T. Shirai, A. Noda and M. Inoue,
Accelerator Laboratory, NSRF, ICR, Kyoto Univ.,
T. Kawakita and M. Matsuoka, Mitsubishi Heavy Industries, Ltd.

Abstract

Fabrication of the disk-and-washer(DAW) cavity is in the stage of high power model fabrication. In order to determine the final dimensions, we measured the frequencies of OFC models which were fabricated with the same fabrication process as the final cavity. This paper describes these measurement results.

1 INTRODUCTION

The biperiodic DAW [1] cavity has been investigated for these years. Basic dimensions of the DAW cavity have been studied by computer simulations and measurements on aluminum models (cold model). Eight units of such cold model were fabricated. The RF characteristics and the dependence of frequency on the number of units have been measured by these models. Before making a final high power structure, another test cavities made of OFC(OFC model) and high accuracy aluminum models(G2 model) were fabricated. The G2 model and the OFC model cavities were machined at the same shop. The OFC models were used for studying a fabrication process and final properties of cavities. The G2 models which had the same dimensions of OFC model on the drawing were used for optimization of the final dimensions. The G2 model is different from the OFC model in only two points: (i) the material is aluminum, (ii) each part is fixed by screws without brazing. Table 1 shows the frequency measurement results of these models.

	cold model	G2 model	OFC model
fa [MHz]	2857.4	2863.0	2859.6
fc [MHz]	2872.2	2873.0	2876.3

Table 1: Frequency of cold model, G2 model and OFC model. In the DAW structure, two modes should be tuned to an operating frequency(2857[MHz]). One is an accelerating mode(fa) and the other is a coupling mode(fc). In the accelerating mode, strong electric field is generated between the acceleration gap.

This results shows the slight difference in frequency among these models. The actual dimensions of each model measured by a coordinate measuring machine showed that there was no significant difference in the measurable region. The cause of frequency difference have been investigated, and it seemed to arise from the washer part [2]. The detail, however, has not been made clear yet. We discuss about this problem in a later session.

Assuming the reproducibility of fabrication process of washer part, we decided to tune the frequency to an operation one by correcting the dimensions of cavity. The frequency was measured for several sets of dimensions to accumulate correction data. All these measurement were performed on the G2-model for accuracy of dimensions.

2 MEASUREMENT RESULTS

2.1 Parameters of dimensions

Figure 1 shows the schematic view of the biperiodic L-support DAW. Frequencies were measured varying the washer radius (Rw), the inner radius of disk with supports (Rds) and the inner radius of disk without supports (Rdn).

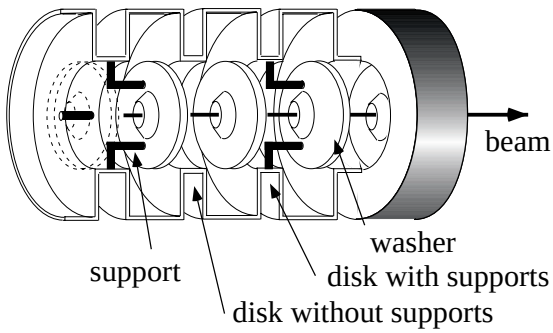

Figure 1: Disk-and-Washer structure

2.2 Accelerating mode

Coefficient of washer radius (Rw) The frequencies were measured with three washer sizes: Rw=44.0(original), 44.05, 44.5. (See Figure 2)

The frequency dependence of the number of units in Rw=44.0 or 44.05 is different from that of Rw=44.5. This is because an end plate has its intrinsic frequency tuned to 2857[MHz] (operating frequency), and thus the effect from both the end plates falls off with increase of the number of units. The intrinsic frequency of Rw=44.0 or 44.05 cavity is higher than 2857 [MHz], while that of Rw=44.5 is lower than 2857[MHz]. The coefficient for the frequency correction was calculated from the extrapolated frequencies at 24 units: the number of units in the high power model. Figure 3 shows the plots of the extrapolated value. Because the

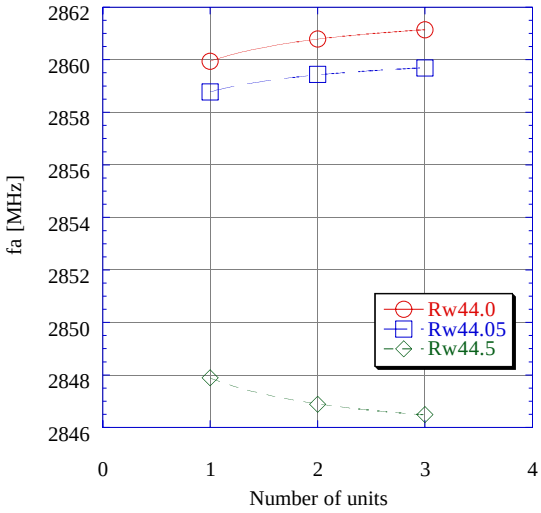

Figure 2: Frequencies as functions of the number of units at three Rw values

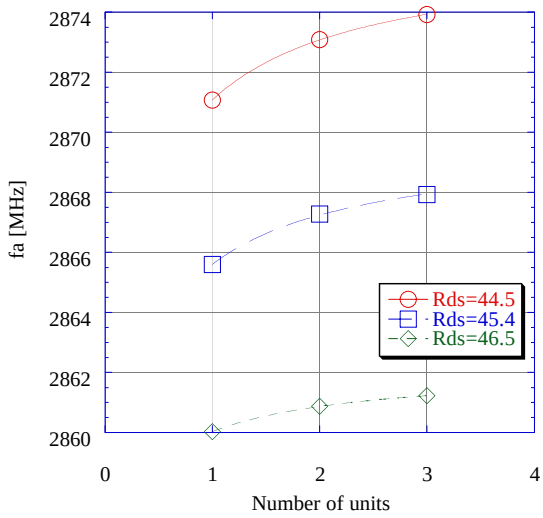

Figure 4: Frequencies as functions of the number of units at three Rds values

three frequencies (Rw=44.0,44.05,44.5) are lined up along a line, the linearity can be assumed. The correction coefficient for Rw was calculated as -32.8 [MHz/mm] from these results.

Coefficient of disk radius (Rds) Figure 4 shows the measured frequencies as functions of the number of units, in a similar way as Rw. The extrapolated frequency at 24 units was calculated for each Rds size. Thus the coefficient of Rds was obtained as -6.9 [MHz/mm]. There was a good linearity in these three points.

Coefficient of disk radius (Rdn) *N* units setup are required for *N* Rds disks and *N*-1 Rdn disks. Because there were only three G2-model cavity units, only two points data could be measured, while three data points at least are required for a curve fitting. Hence, we used the result from one unit setup, which had no Rdn disk, as the one data point. Thus the extrapolated frequency at 24 units was estimated and the correction coefficient for Rdn was obtained as -8.7 [MHz/mm].

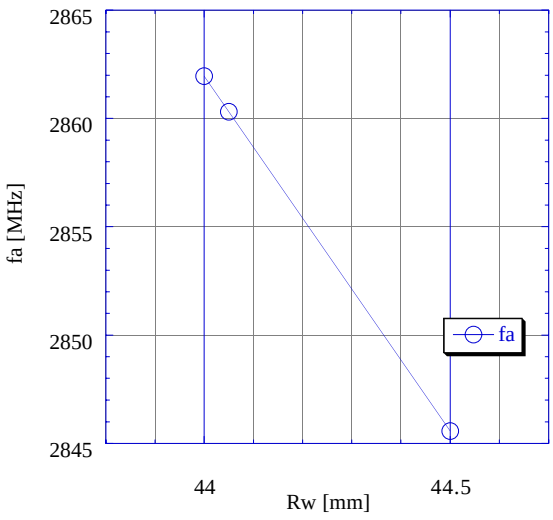

Figure 3: Correction coefficient for washer radius Rw

2.3 *Coupling mode*

Coefficient of washer radius (Rw) Figure 5 shows the measured frequencies for each washer radius. The dependence of the number of units in the coupling mode is larger than that of the accelerating mode. It should be noted that the scale of vertical axis is larger than that of accelerating mode in previous subsection. The extrapolated frequency was estimated by similar way in the accelerating mode and the correction coefficient was calculated as -32.8 [MHz/mm].

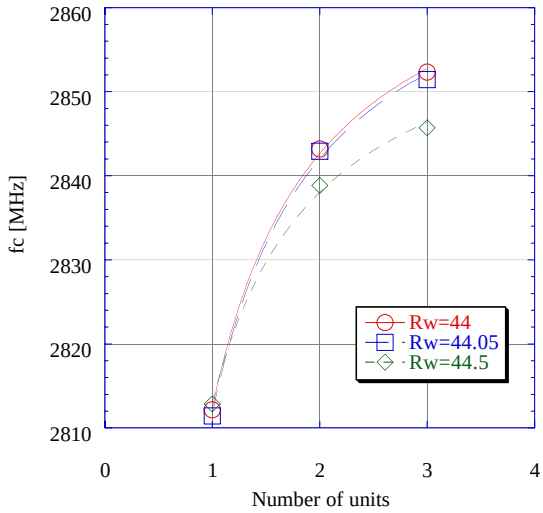

Figure 5: Frequencies as functions of the number of units at three Rw values (coupling mode)

Coefficient of disk radius (Rds) With similar way, the coefficient was obtained. Figure 6 shows the measurement results. The calculated coefficient was 9.8 [MHz/mm].

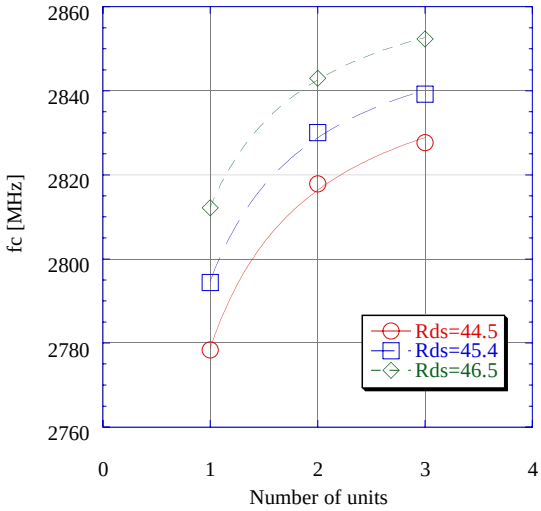

Figure 6: Frequencies as functions of the number of units at three Rds values

Coefficient for disk radius (Rdn) Figure 7 shows the measurement results, and the coefficient was calculated as 14.2 [MHz/mm].

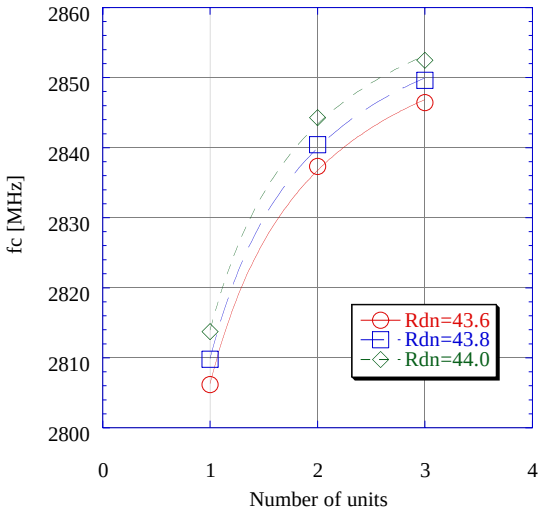

Figure 7: Frequencies as functions of the number of units at three Rdn values

3 DISCUSSION AND CONCLUSION

3.1 Correction coefficient

Because the frequency depends on the number of cavity units, an extrapolated frequency at 24 units was used to evaluate the correction value. Table 2 shows the summary about the coefficients obtained from these measurements.

	df/dRdn	df/dRds	df/dRw
fa [MHz/mm]	-8.7	-6.9	-32.8
fc [MHz/mm]	14.2	9.8	-19.4

Table 2: Summary of correction coefficient

As the coefficients of accelerating mode, df/dRdn=-9.2 [MHz/mm], df/dRds=-7.3 [MHz/mm] and df/dRw=-28.4 [MHz/mm] were calculated by SUPERFISH. These values are compatible with the measurement results. For the coupling mode, it is difficult to estimate the coefficient by SUPERFISH because the support effect was too large.

3.2 Frequency difference among three models

The frequency difference seems to arise from the washer part. Because washer has a curved surface (nose), it is difficult to measure all dimensions precisely. We tried to measure the more fine shape of nose part by a contracer (contour measuring device). An output from our device, however, is only a line drawing. The obtained data are analyzed to estimate the frequency difference. The shape of nose part is very sensitive to the accelerating frequency. It is important fabrication technology to fall in with the tolerance of frequency keeping the reproducibility of RF properties with available machining technique.

The curved surface is considered most critical point in the fabrication of the DAW. It is important fabrication technology to control the frequency with keeping the reproducibility of RF properties.

THE ESTIMATIONS FOR MECHANICAL VIBRATIONS OF STEMS-LIKE ELEMENTS IN RF CAVITIES

A.S. Levchenko, V.V. Paramonov, R.S. Ter-Antonyan
Institute for Nuclear Research, 117312, Moscow, Russia

Abstract

In such elements of accelerating cavities as stems, posts, spirals, split rings low frequency (several tens Hz) mechanical oscillations may excite. Analytical expressions for resonant frequencies are presented. If the channel for cooling liquid is placed inside the element, depending on flow parameters the source of noises may exists from turbulence. Estimation for flow parameters and possible spectrum of noises are given.

1 INTRODUCTION

A lot of rf cavities have in the design thin and long stem-like elements. It may be stems for drift tubes support in DTL structure (Fig. 1), post couplers for stabilisation of the accelerating field distribution (Fig. 1), straight (Fig. 2) or circular (Fig. 3) central conductors in double gap bunching cavities. In such thin elements small low-frequency mechanical oscillations may excite. This mechanical oscillations will lead to small changes in the resonant frequency of the cavity and amplitude modulation of accelerating voltage. If the external source of noises exists, it simplifies the excitation of oscillations. One possible source of excitation are the noises due to turbulent flow of the cooling liquid. In this paper the qualitative estimations for own frequencies of mechanical oscillations are presented and parameters of the liquid flow are considered.

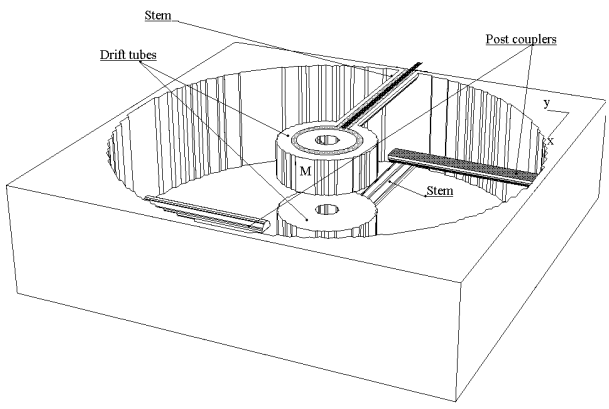

Figure 1: A sketch of DTL structure

2 MECHANICAL OSCILLATIONS

Let consider the stem with the mass m rigidly fixed at one end. At the another end of the stem the drift tube with the mass M are fixed. Two cases should be considered.

2.1 The heavy drift tube

If the mass of the drift tube $M \gg m$, we can neglect the mass of the stem m and consider oscillations of the heavy solid body at the weightless elastic stem. Supposing y is the displacement in the direction perpendicular to the stem axis one get [1] equation for small transverse oscillations:

$$I_c E \frac{d^2y}{d^2x} + M(l-x)(\frac{d^2y}{d^2t})_{x=l} = 0, \qquad (1)$$

where x is the current coordinate along the stem axis. I_c is the moment of inertia of cross section:

$$I_c = \int_S y^2 dS, \qquad (2)$$

E is the Young modulus of the material of the stem, l is the length of the stem. We suppose the mass M is concentrated in a point at the end of the stem. The eigenfrequency of this oscillations f_h:

$$f_h \approx \frac{1}{2\pi}\sqrt{\frac{3I_c E}{Ml^3}}, \qquad (3)$$

It should be pointed out here strong dependence of f_h from the length of the stem.

To simplify manufacturing procedure, DTL cavities are usually at constant radius and the radius of drift tubes is constant also. So, the stems have the same length, but the mass of drift tubes (together with the length of tubes) changes. For typical 200 MHz DTL, for example for $0.04 \leq \beta \leq 0.4$ with copper hollow stems (outer radius of the stem $R_2 = 20$ mm, the inner one $R_1 = 15$ mm, the length $l = 400$ mm, $I_c = \pi/4(R_2^4 - r_1^4)$) and drift with the mass M from 3.5 kg to 30 kg one will get estimation for $f_h \sim (58 \div 18)$ Hz.

2.2 The stem without drift tube

Another case to be considered is the case $M \ll m$ and we can assume $M = 0$. This case describes oscillations of post couplers (Fig. 1) and may be good approximation for oscillations in central conductors of bunching cavities (Fig. 2, Fig. 3). Considering small transverse oscillations [1]:

$$I_c E \frac{d^4y}{d^4x} + S\rho\frac{d^2y}{d^2t} = 0, \qquad (4)$$

and eigenfrequencies f_{ln} are:

$$f_{ln} \approx \frac{a_n^2}{2\pi l^2}\sqrt{\frac{I_c E}{\rho S}}, \qquad (5)$$

where ρ is the density if the stem material, S is the square of the stem cross section, a_n are the roots of the characteristic equation:

$$cos(a_n)ch(a_n) = -1, \qquad a_1 = 1.876, a_2 = 4.675.... \quad (6)$$

For the hollow copper post coupler with outer radius $R_2 = 40$ mm, the inner one $R_1 = 30$ mm, the length $l = 400$ mm one will estimate $f_{l1} \approx 140$Hz.

For circular central conductor of bunching cavity estimation (5) may be applied, if $R \gg R_2$, with transformation $l = \pi R$ (Fig.3).

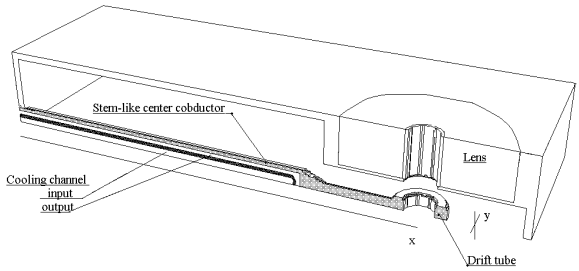

Figure 2: The double-gap bunching cavity with the straight central conductor

2.3 Oscillations of rotation

Let consider oscillations of rotation with respect the axis of the stem. Also two cases should be distinguished in comparison of inertia moments of the drift tube I_t and the stem I_s with respect to the stem axis. If $I_t \gg I_s$, the frequency for oscillations of rotation f_{th} is [1], [2]:

$$f_{th} \approx \frac{1}{2\pi}\sqrt{\frac{C}{lI_t}}, \qquad (7)$$

where C is the rotational rigidity, which strongly depends on the shape of cross section of the stem and for the coaxial tube is [1]:

$$C = \frac{\pi E(R_2^4 - R_1^4)}{4(1+\sigma)}, \qquad (8)$$

where σ is the Poisson coefficient. For cylindrical drift tube with radius R_t and the length l_t the inertia momentum I_t needed is [2]:

$$I_t = \frac{M(3R_t^2 + l_t^2)}{12}, \qquad (9)$$

and for the case considered in (2.1) ($l_t = 46 \div 380$ mm, $R_t = 75$ mm) $f_{th} \sim (300 \div 30)$ Hz.

If $I_t \ll I_s$ we can neglect I_t (the case of the post coupler) and the frequency for oscillations of rotation f_{tl} may be estimated as [1], [2]:

$$f_{tl} \approx \frac{1}{2\pi}\sqrt{\frac{C}{lI_s}} = \frac{1}{2\pi}\sqrt{\frac{\pi E(R_2^2 + R_1^2)}{2Ml(1+\sigma)}}. \qquad (10)$$

For the case considered in (2.2) $f_{tl} \approx 450$Hz.

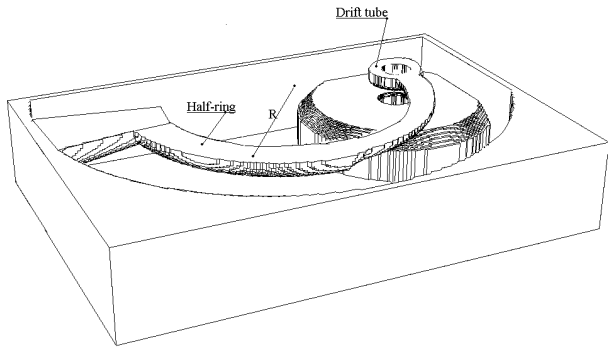

Figure 3: The double-gap bunching cavity with the ring central conductor

3 PARAMETERS OF LIQUID FLOW

It is known well that the character of the liquid flow in the channel is defined by the Reynolds number Re:

$$Re = \frac{Vd}{\eta}, \qquad (11)$$

where V ia the average velocity, d is the characteristic dimension of the channel and η is the kinematic viscosity of the liquid (for water $\eta \approx 10^{-6} m^2/sec$). If $Re \geq Re_{cr}$, the flow in the channel is turbulent. For cylindrical channel $Re_{cr} \approx 1800$, for coaxial one $Re_{cr} \approx 1000$ [3].

The main parameter in the cooling of accelerating cavities is usually the expenditure Q of the cooling liquid, because stabilised temperature of the cavity is needed. So, the average velocity of the flow may be estimated as $V \approx Q/S_c$, where S_c is the square of cross section of the channel. In most practical cases flow is the channel is turbulent , due to limited S and Q given. Another reason is because the heat exchange coefficient for turbulent flow is higher than for laminar one. (It is important to avoid case with $Re \gg Re_{cr}$, because for $Re \geq 6000$ in circular pipe the flow becomes unstable [3]. Due to this reason V is usually not higher than 5m/sec.)

In the turbulent flow the unstability with the frequency $f_{fl} \approx V/d$ can exists in the stream [3]. Estimating f_{fl}:

$$f_{fl} \approx \frac{V}{d} = \frac{\eta Re}{d^2}, \qquad (12)$$

for most practical cases $f_{fl} \geq (100 \div 200)$ Hz.

It means, that for correctly designed cooling channel the possibility of excitation for mechanical oscillation is low enough and this effect is not the main reason.

4 SUMMARY

Analytical estimations for resonant frequencies for different types of oscillations in stem-like elements are presented. It is shown that for typical dimensions of accelerating cavities the frequency range of oscillations may be from several tens Hz to hundreds Hz. This results are useful in the cavity design to take care from possible sources of noises from equipping hardware (cooling, pumping and so on).

FABRICATION OF THE C-BAND (5712 MHz) CHOKE-MODE TYPE DAMPED ACCELERATOR STRUCTURE

H. Matsumoto, T. Shintake and N. Akasaka
KEK High Energy Accelerator Research Organization, 1-1 Oho, Tsukuba, Ibaraki, 305, Japan

Abstract

The first high power model of the C-band (5712 MHz) accelerating structure for the e+e- Linear Collider project is under construction. This is a full spec version: equipped with the Choke-Mode cavity for the higher-order mode damping, the double feed coupler for the symmetric power feed at input/output, and RF-BPM for the beam-based alignment at both ends.

Fabrication of the total 91-cells and their frequency tuning were completed. The cells were assembled in one structure by the electroplating of copper.

The integrated phase shift were measured, it was within ±5 degree at operation condition. It was confirm that a Higher-Order-Mode (HOM, TM_{110}) is successfully damped by a choke-mode cavity with an SiC type rf absorber [1].

1 INTRODUCTION

In the e^+e^- linear collider for 300-500 GeV C.M. energy region, one of the most important R&D issue for the accelerating structure is how to control the beam induced wakefield effects to achieve the nano-meter size beam at collision point.

From the beginning of the linear collider project, many ideas were proposed for damping the wakefield. However, most of those were not realistic; structure was very complicated, thus it was not suitable for mass production at a reasonable cost. In 1992, T. Shintake of KEK proposed a very simple HOM-free structure, so called Shintake-type "Choke-Mode" damped structure. [2] It is a kind of an open cavity. The beam induced power (HOM power) is strongly damped by the electromagnetic radiation through a radial line into open space, while the rf power necessary for the beam acceleration is trapped inside the cavity by a choke filter.

Its concept was confirmed by the experimental test performed at ATF-KEK in 1994, where the bunched electron beam was successfully accelerated in a prototype with S-band microwave power.

Figure 1 and 2 show the C-band model. The accelerating cavity, the annular slot for the choke and a room for the HOM absorber are machined on a copper disk on a turning lathe. The vacuum seal and mechanical structure is maintained by simply stacking them and plating copper layer from outside. The SiC ceramic ring is the HOM absorber, which is mounted in the disk with a metal spring insert (MC Multilum-contact). Since all parts are axial-symmetric, which can be machined on tuning lathe, the choke-mode type cavity has a big advantage on manufacturing than the other ideas proposed before.

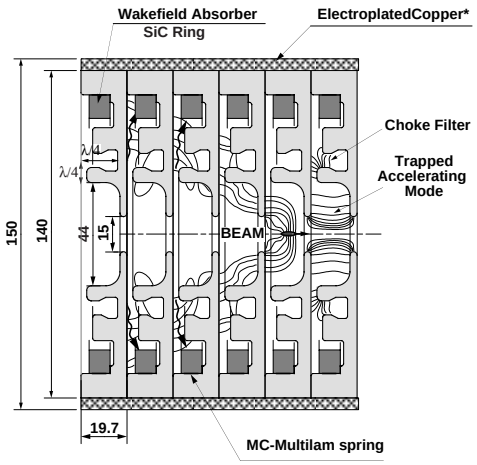

Figure 1: A cut of view of the C-band (5712 MHz) Choke-Mode structure.

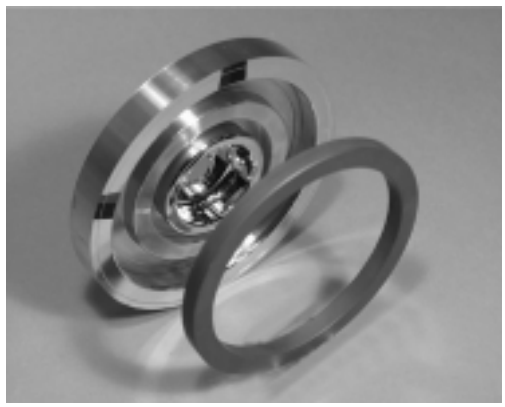

Figure 2: C-band structure with SiC rf absorber.

The Choke-Mode concept has solved the multi-bunch problem. However, there is still another type of wakefield field problem. The short-range transverse wakefield causes the bunch shape deformation, resulting in loosing luminosity. This wakefield is a strong function of the iris aperture, its is proportional to $a^{-3.5}$, thus it becomes very strong at higher frequency bands. Considering the technical difficulties related to the tight tolerance, we did not use higher frequency, but chose the C-band (5712MHz) as the best frequency. The straightness tolerance is ±50 μm (maximum bow) for 1.8 m long structure. At the higher frequency bands, straightness becomes close to ±10 μm or less for 1.8 m-long structure.

In 1996, hardware R&D on the C-band rf system was started at KEK. The first high power 1.8 m-long Choke-

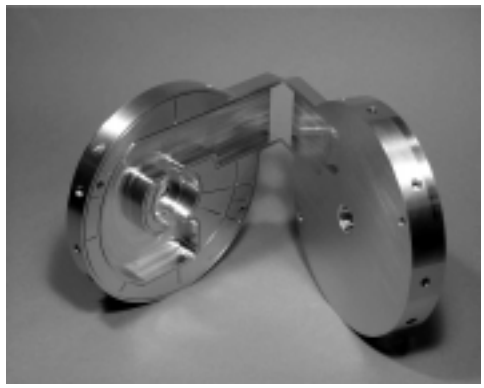

Figure 4: Machined copper parts of field symmetric double feed coupler. They will be brazed together and mounted at both ends of the structure by the electron-beam welding.

mode structure is under fabricating at MITSUBISHI HEAVY INDUSTRIES Ltd. The structure to be tested at ASSET in SLAC in December this year.

This paper describes details on fabrication of the cell and tuning on the acceleration mode. Optimization on the HOM damping performance is described in a separate paper [1].

2 CHOKE-MODE STRUCTURE

The first high-power model of the C-band choke-mode structure is composed of the regular section (89 choke-mode cells), input/output couplers attached at each end, two common-mode-free RF Beam-Position-Monitor (RF-BPM) as shown in Fig.3. A wake-field monitor is prepared in the center cell, by which we can observe the beam induced HOM spectrum, and determine the beam position. To avoid unwanted transverse kick due to asymmetric field, the double-feed coupler using J-shaped waveguide is used in the input/output couplers as shown in figure 4.

2.1 Main Parameters of the structure

The main parameter of the accelerating structure designed for 500 GeV C.M. energy linear collider is listed in Table 1. To increase the shunt impedance, we changed the disk-thickness from 4 mm of initial design to 3 mm. It improved the shunt-impedance by 13%.

3 MANUFACTURING AND ASSEMBLING

3.1 Machining of the cavity

The choke-cell, and the coupler cavity are made of the high purity Oxygen Free High Conductivity (OFHC, >99.99%) copper. The final machining uses a very high-precision tuning lathe with a diamond cutting-tool of rounded shape (R0.5). The dimensional accuracy of the accelerator cavity was kept within 2 μm, except for the rounded part of the beam hole, where it is 5 μm, which provides the frequency valuation of within ±100 kHz.

The surface roughness was kept to 30 nm at cavity inner surfaces and within 500 nm around the beam hole [3]. Since the stored energy in the choke slot is much smaller than that in the acceleration cavity, the dimensional tolerance is much looser than that in the cavity cell, it is around ±30 μm. The electric field gradient is also lower in the choke slot, thus the surface roughness of 3-6 μm is enough. Therefore, machining of choke can be made on ca standard turning lathe, and it does not increase the fabrication cost

Table 1: Main parameters of the accelerating structure

Frequency	5712	MHz
Phase shift per cell	$3\pi/4$	
Field distribution	C. G.	
Number of cells	91	cell
Active length	180	cm
Iris aperture (2a) : up-stream	1.74	cm
: down-stream	1.254	cm
Cavity diameter : up-stream	4.53	cm
: down-stream	4.33	cm
Disk thickness: t	0.3	cm
Quality factor: Q	10.7-10.3	$\times 10^3$
Group velocity : up-stream	0.035	c
: down-stream	0.012	c
Average shunt impedance: rs	53-67.3	MΩ/m
Attenuation parameter	0.53	
Filling time: T_f	286	nsec

3.2 Assembling the SiC RF Load

In order to mount the rf load on the cavity, we decided to uses a thin metal spring, which was inserted between the SiC- ring and the outer-groove as shown in figure 6. The reason why the brazing was not used is to eliminate the high temperature bonding process, which causes dimensional changes in the structure, resulting in a big error on straightness, which can exceeds the 50 μm limit.

The cooling of SiC-ring is not a big issue in this case, since the estimated wakefield power per cavity is as low as 2 W only. The leakage power of the accelerating field is also quite low, because the choke has enough isolation gain as high as -90 dB.

When a HV-discharge is happen in a choke, the acceleration field will flow into the SiC. However, it also causes the detuning of the cell frequency and the traveling

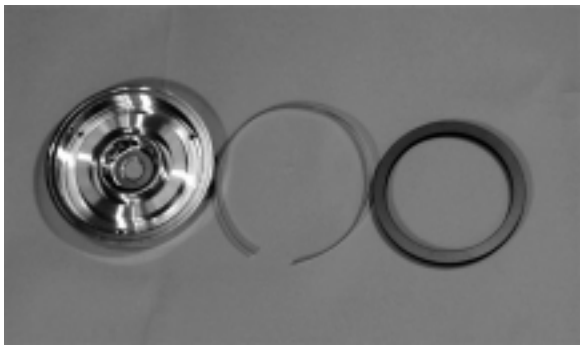

Figure 5: An SiC rf absorber components. Left: choke-mode cavity. Center: metal spring belt. Right: SiC rf absorber ring. An SiC rf-absorber ring is inserted smoothly into the outer groove by using a simple jig with pressure around 30 kgf.

rf power is reflected back to upstream. Only the stored energy in one cell will be dissipated on the SiC, which is only 0.2 J or less.

4 RF MEASUREMENT

After the precision machining, each cavity was stacked, and resonance frequency was measured. Since the relation between $\pi/2$ and $3\pi/4$ modes are known in advance, the $\pi/2$ mode frequency (cell resonance) was used for this check. The deviation from the target frequency of each cell was adjusted by slightly machining the inner dimension (2b) of the disk.

4.1 Choke Slot

The center frequency of the choke filter was measured with a special rf jig. The acceleration cavity part is electrically shorted by a metal disk, then a rf-signal is fed from the center terminal. The transmitted power through the choke is monitored by two pick-up antennas. Figure 6 shows the typical frequency response. The deviation of the center frequency from the target of all the cavities were within the specified values of ±1 MHz.

Figure 6: Frequency response of choke cavity.

4.2 Accelerating cavity

The cell resonance frequency was measured by a special jig, which detunes the neighboring cells and resonates at $\pi/2$ mode. Figure 7 show the frequency deviations from the operating point of 5712 MHz in vacuum. As can be seen in figure, all the data obtained within the specified frequency of ±200 kHz.

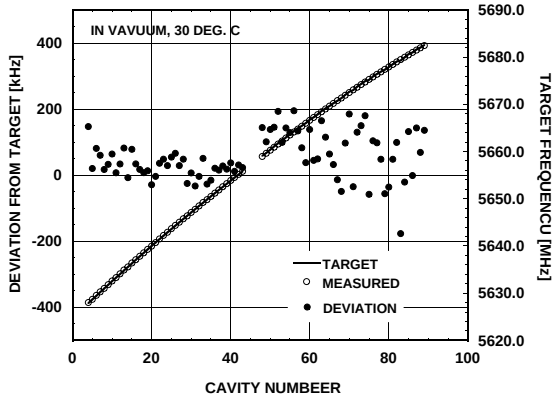

Figure 7: Frequency deviations from the target of each acceleration cavity.

5 ELECTROPLATING

To meet the straightness tolerance, we decided to uses the "Electroplating Method" (not to be confused with the prior electro-forming method), which plates a thick copper layer of 5 mm on the outer surface of stacked cavities. During this process, temperature of the structure raises, but only around 40 °C, which does not cause the dimensional changes in copper material and keeps the structure straightness [4].

6 SUMMARY

The deviation frequency from the target of the choke and accelerating cavity were obtained within each target value of ±1 MHz and ±200 kHz. An integrated phase error is around ±5° for 87 cavities.

It was confirmed that the conventional hardware technique, which has been used in fabrication of S-band accelerating structures, is enough to develop the C-band structure.

The fabrication will be completed in this fall, and its HOM performance will be tested with ASSET beam line at SLAC end of this year.

Abstract

An electroplating fabrication method has been used since 1962 for S-band frequency electron accelerating structures in Japan. The electrical contact between disk and cylinder, and the vacuum integrity are maintained by an electroplated copper layer 5 mm thick, without any metal brazing. The typical integrated phase error after plating was kept below ±2° without any frequency tuning. The mechanical straightness was within ±100 μm over the 2 m length of the S-band accelerating structure.

Since this method does not require any high-temperature processes, such as the metal brazing commonly used for accelerator fabrication, the copper material does not crystallize and maintains a higher tensile strength. That makes this method very attractive for fabrication of the high-performance structures which will be required in various future projects, and especially for e+e- linear colliders.

1 INTRODUCTION

A special requirement for a large scale e^+e^- linear collider for 300-500 GeV C.M. energy reasion is to be able to accelerate a low emittance beam while achieving a nano-meter size beam at the collision point in order to provide the required high luminosity. One R&D issue for the accelerating structure is how to control beam induced wakefield effects. The multi-bunch instability problem has been mostly solved by the Choke-Mode concept and the detuned-structure. However, single bunch instability due to short-range wake-field is still a problem. Trade-offs are involves since lower rf frequencies minimize these instabilities, while higher frequency bands provide higher shunt-impedance which is also preferable. From consideration of the required straightness tolerance, we chose a compromise at the C-band frequency (5712MHz), where the straightness tolerance becomes ±50 μm (maximum bow) for a 1.8 m-long structure. At the higher X-band frequency, straightness becomes on the order of ±10 μm for the 1.8 m-long SLAC Detuned-Damped-Strucure [2,3]. It is clear that no laboratory or industry group currently has any experience with fabricating so many structures at this extraordinary level of accuracy.

Mitsubishi Heavy Industries Ltd. (MHI) and Professor J. Tanaka of KEK developed an electroplating fabrication method (not to be confused with the prior electro-forming method) for electron accelerator structures [4,5]. Their motivation was to improve the accuracy in the phase-shift per cavity, while ensuring mass productability. They introduced a high-precision machining lathe, and succeeded in fabricating accelerating structures, which did not require frequency tuning of any method after the copper plating.

In 1978, 160 accelerating structures were made this method and installed in the 2.5 GeV PF-injector at KEK. Recently, 68 more structures were added for an energy upgrade to 8 GeV for the KEK-B project [6,7].

Figure 1 shows the temperature dependence of the tensile strength, and also the dimensional elongation of high purity Oxygen-Free-High-Conductivity (OFHC, 99.996%) copper.

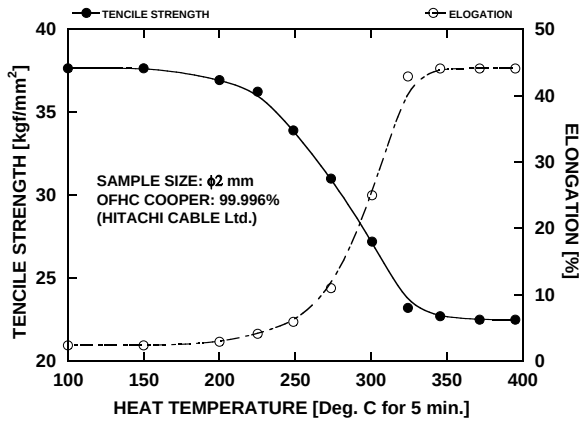

Figure 1: Mechanical properties of OFHC copper as a function of temperature. Each sample was heated up to a target temperature, and held there for 5 minutes.

As can be easily seen in the figure, at temperatures over 200 °C the tensile strength drops sharply and elongation becomes pronounced.

It is very clear that conventional brazing methods, which require temperatures of around 700-900 °C, present difficult problems with respect to mechanical performance. On the other hand, when using electroplating to join the cavities, the maximum temperature raise is only about 40 °C. From this fact, we believe that the electroplating method is a very attractive candidate for the preferred fabrication method for high-performance accelerators requiring tight mechanical tolerance and frequency control.

In this paper, we will describe the elector-plating fabrication method, and its related techniques.

2 MANUFACTURING

The regular section of the accelerating structure is composed of disks and cylinders. They are stacked alternately in series and held in place as a single structure by the electroplated outer copper layer as shown in figure 2. The disks and cylinders are made of high purity OFHC copper, and machined by a high-precision turning lathe. The electroplated copper layer is 5 mm, which provides good enough electrical contact as well as vacuum tightness without further metal bonding, such as the high-temperature brazing process.

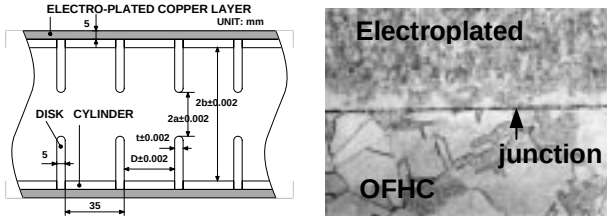

Figure 2: Figure 2: Left: cut away view of the structure. The thickness of the electroplated copper layer is 5 mm. Right: an expanded view of the electroplated layer (top), and OFHC copper (bottom). A horizontal dark black line shows boundary of electroplated copper and OFHC.

2.1 Disk and Cylinder Manufacture

The disk, cylinder, and the coupler cavity are made of the high purity OFHC (>99.99%) copper. Figure 3 shows a photograph of the machining of the disks for KEKB 8 GeV linac. The final machining uses a very high-precision tuning lathe with a diamond cutting tool of round shape (R0.5).

The dimensional accuracy was kept within 2 μm, except for the rounded part of the beam hole, where it is 5 μm. The surface roughness was kept to 30 nm at disk flat surfaces and within 500 nm around the beam hole. The inner surface of the cylinders have 30 nm of roughness. Figure 4 shows the typical surface roughness at the disk surface measured by an optical interferometer using a 600-nm wavelength monochromatic light source.

2.2 Assembly Accuracy Check

The dimensional tolerances for the disk and cylinder are ±2 μm as shown in figure 2, which corresponds 80 kHz in frequency error, and 0.34 degree of the phase error at vg of 0.01c at the S-band frequency. This result made it possible to eliminate the final phase adjustment such as the dimpling procedure which is needed after brazing the structure. The target resonant frequency of each cavity was intentionally lowered by 200 kHz from the operating frequency to allow for the mechanical compression effect associated with the electroplating process. The electroplated copper tends to shrink, and produces a small change in the resulting mechanical dimensions, mainly in that the cylinder diameter becomes smaller.

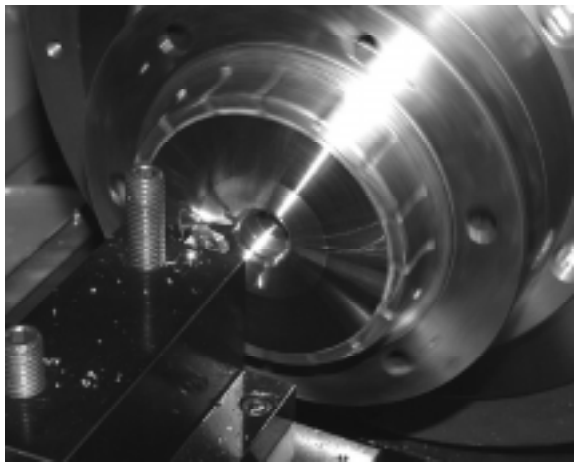

Figure 3: Figure 3: The final machining of a disk with a diamond tool.

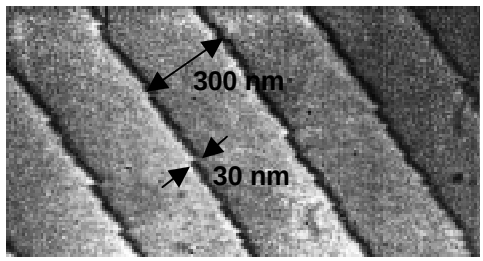

Figure 4: This photograph, taken by an optical interferometric method, shows the typical surface roughness of a copper disk machined on a precision turning lathe. The distance between dark lines is 300 nm (half-wavelength). Any deviation of the dark line from straightness shows the surface roughness. The peak to peak surface roughness is about 30 nm in this case.

2.3 High Speed Electroplating

After frequency checks of all the cavities for an acceleration structure, they are stacked together horizontally (56 cavities for 2 m length) on a precision support-bed. A steel mandrel is inserted through the staked cavities and tightened to a tension of 2500 kgf to which will be held during the electroplating. The mandrel has a bar-shape and is made of high-tensile-strength steel to maintain the tension throughout the electroplating procedure.

The oxide layer on the outside of the structure is removed by mechanical brushing, and then it is rinsed in pure water to remove any foreign matter such as dust which may be stuck on the surface. The structure is then immersed in the electroplating process fluid in a vertical bath.

A high-speed electroplating method is chosen [8,9]. In order to plate the copper at high current densities of 10 A/dm^2 or more, additives are included to the copper-sulfate. It takes 70 hours to deposit a layer 5 mm in thickness. The processing fluid mainly consists of copper-sulfite, sulfuric-acid (H_2SO_4, >95%), hydrochloric-acid (HCl, >35%) and ion-exchanged-water. During the plating the plating fluid temperature was controlled at 30 °C ± 1 °C. Also, close purity control of the plating fluid

is very important to prevent defects in the copper crystal structure such as the so called star and wrinkle defects.

The possibility of fluid leakage through a gap between disk and cylinder is very low. A key point in this is the surface smoothness. It is around 30 nm after the precision machining and the dimensional accuracy is also 2 μm. When the disk and cylinders are compressed with an appropriate contact pressure, the resulting vacuum tightness reaches the order of 10^{-4} Torr.

After the electroplating, the surface of the plated copper is machined to back to a 5 mm thickness. The hardness of the plated copper layer is really high, and is comparable to iron. This is due to the compaction force of ionized copper. During the plating the temperature rises, but only to 40 °C.

2.4 Assembling the Completed Accelerating Structure

After assembling, an accelerating section has a coupler attached at each end by electron beam welding (EBW) while pressure is applied by the mandrel. The position for the weld is designed to avoid excessive stress concentration and to obtain a good electrical contact. The structure is cooled with a water-jacket type pipe, which has both ends TIG welded to the couplers.

3 RF MEASUREMENT RESULTS

The structure is assembled from highly accurate disks and cylinders; it is easily checked for the specified resonance frequencies, thus in principle we see that it is possible to mass produce a high precision accelerating structure. However, the proof is in the final check to measure the phase shift of the all the cavities by Nodal-Shift method. Figure 5 shows the typical measured Nodal-Shift data before and after the electroplating process. The three solid lines in figure 5 are the specified phase-shifts (0°, 120° and 240°), the measured phase shifts of the cavities for $2\pi/3$ mode at the operating frequency are marked with open circles. As can be seen from figure 5, the integrated phase errors are within ±2° for the 2 m-long structure (two couplers and 54 regular cavities). After the electroplating process, the integrated phase errors slightly increase, but still only to 0.86 degree in rms. From this we conclude that the electroplating effects can be controlled quite precisely.

4 CONCLUSIONS

We conclude that the electroplating method is a attractive candidate for fabrication of the next generation advanced accelerators. As for the related technology, we have also shown that the simple frequency measuring of the assembly check can be use to obtain the same accuracy of the Nodal-Shift method. Finally, the straightness of the structure can be improved to within less than 30 μm of the target value.

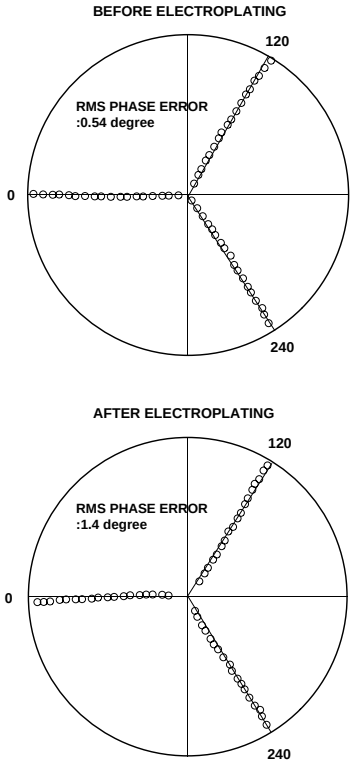

Figure 5: Typical phase characteristics of an electroplated S-band 2 m-long structure as measured by the Nodal-Shift method.

STATUS OF ENGINEERING DEVELOPMENT OF CCDTL FOR ACCELERATOR PRODUCTION OF TRITIUM*

R. L. Wood, J. H. Billen, W. T. Hunter, P. O. Leslie, R. J. Roybal, F. E. Sigler
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

The Coupled-Cavity Drift Tube Linac (CCDTL) is a relatively new RF accelerator structure which plays a major role in the APT Low-Energy Linac (LEL) design. Engineering development is pushing ahead on several fronts, including thermal management, fabrication procedures, cavity and coupling slot tuning, high-power prototype fabrication and testing, supports and alignment, vacuum, and provisions for beam diagnostics. Fabrication of the CCDTL Low-Beta Hot Model is nearly complete, and high-power RF tests will commence soon. In 1999, we will begin the fabrication of 11 meters of CCDTL to be added to the Low-Energy Demonstration Accelerator. In 2001, it will take the 100 mA beam from 6.7 MeV to 10.05 MeV, producing the world's most powerful proton beam. We are also starting the design of a CCDTL 96 MeV Hot Model to demonstrate cooling of an intermediate-beta version of the structure. The 14 cm-long, 9 cm diameter 96 MeV drift tube dissipates roughly 5 kW. This all leads to the final mechanical design of the 113 m long CCDTL for the APT plant linac.

1 INTRODUCTION

The CCDTL concept was invented in 1994 [1] to answer the stringent demands of the waste-transmutation and tritium production accelerator applications. Although several low-power aluminum "Cold Models" have been built and tested, no CCDTL has yet been operated at high power or with particle beam. Before taking that step, there are many "trivial" engineering details which must be worked out. This would be a significant effort, even if the first application were low power. Some unique fabrication and tuning methods must be developed, while vacuum pumping, cooling, resonance frequency control, and RF interfacing must be adapted from similar systems used on common Coupled Cavity Linacs (CCLs).

This paper presents the status of this engineering effort, without giving much background about how we got here, or why. The following discussion covers topics, results, and plans in four areas: mechanical prototype tests, RF cold models, the CCDTL Low-Beta Hot Model (LBHM), and the APT Low-Energy Demonstration Accelerator (LEDA), phase 3A (6.7-8 MeV) and 3B (8-10 MeV)[2].

* Work supported by the US Dept. of Energy, Defense Programs.

2 ARCHITECTURE

The APT LEL has evolved significantly since the presentation of the Conceptual Design, mostly in response to practical engineering considerations.[3][4] There are still three distinct types of CCDTL (single 2-gap, single 3-gap, and double 2-gap segments) to carry the 100 mA proton beam from 6.7 to ~100 MeV, but the transition points have been moved to eliminate mixing of types within a RF module. This mixing caused a variety of mechanical issues in earlier versions of the design, but there is not enough space to discuss them here.

Marked changes in the focusing period were made to provide needed empty space for magnets and beam diagnostics in the 10-to-50 MeV range. This in turn prompted a change from 6-cell to 7-cell CCL segments in the >100 MeV portion of the LEL [4].

This lattice change indirectly causes a "tolerance stack-up" problem in the CCDTL which is remedied by changing to 3-cell bridge couplers to join the brazed sections (see below). This solution does not work in the 10-to-21 MeV portion, where the 3-gap CCDTL type is used.

3 RF STRUCTURE MATERIALS AND FABRICATION METHODS

Several of the CCDTL's new mechanical features have been under development for the last three years. Most have to do with either fabricating or cooling drift tubes. We have previously reported on the design and predicted performance of coolant passages within the drift tubes[5]. Recently, we have performed experimental measurements which suggest that these passages are actually much more effective than originally thought[6]. We will be repeating these measurements on drift-tube prototypes from a different part of the LEL to further prove the cooling scheme before actual RF structures are built.

Material properties and brazing continue to be areas of concern, primarily with vacuum and RF attachments to OFE copper structures. Originally, we had chosen to use alumina-dispersion strengthened (Glidcop™) copper for all components which are exposed to RF and require strength, such as drift-tube stems and accelerating cavity flanges. Until recently, large equatorial flanges were planned to join the 1-to-1.6-m-long brazed sections into long RF modules. The aforementioned tolerance stack-up problem made it easy to choose to eliminate the flanges

from the design, but, as previously mentioned, we have not found a practical alternative for the 10-to-21 MeV portion of the LEL. For now, at least, there are about 15 of these flanged joints still in the plan.

Our first attempts at brazing OFE drift tubes and Glidcop™ stems into OFE cavities were very good, but recent attempts have had some problems. The 50-50 Au-Cu braze alloy has produced all leak-tight joints, but they do not look like the kind of clean cosmetic joints we want inside a high-power RF cavity. Although copper plating is expected to help, this added step may tip the scales back toward plated stainless steel.

There have also been several improvements made in our machining and braze fixturing which should insure good parts in our future fabrications.

The vehicle for much of this development is the LBHM, a 1-m-long piece of CCDTL corresponding to 7.6-8.8 MeV in the original LEDA design. At the time of this conference, all of the pre-tuning fabrication and brazing are complete, and cavity and slot tuning activity is about half complete. Following tuning, the assembly will go through its final assembly braze, be installed on its test stand, and tested at up to 135% of its intended RF fields.

4 RF STRUCTURE TUNING

Although 2-D and 3-D modeling can give us a very good understanding of the CCDTL cavities, we find that simple, relatively inexpensive aluminum "cold models" are the only sure way to determine complex 3-D properties like coupling coefficients and frequency dependency on coupling. Several cold models have been built to simulate various cavities in the 6.7-10 MeV range and we have developed many refinements in our testing and tuning methods[7].

These methods are being put to the test in the tuning of the LBHM, now underway. Despite our earlier cold modeling, we have encountered several new problems. Specifically, although the coupling slot predictions are very close, the accelerating cavity frequency predictions are off by more than 5MHz in some cases (<1%). Since the LBHM will not be used with beam, we have aggressive ways to deal with this, but this will not be acceptable on LEDA. Apparently, extrapolations from too few cold models is not a good idea, and 2MHz tuning range might not be enough, even with better data.

Our approach for LEDA phase 3A is to build more cold models, matching the 6.7 and 8 MeV endpoints, in hopes that interpolation over a short range of β will yield cavities which are closer to the target frequency. The 6.7 MeV Cold Model has already been built and is being very thoroughly tested. An extensive 8 MeV Cold Model has been designed, but we are waiting to see what new data will come from the 8 MeV LBHM and the 6.7 MeV cold model before starting fabrication. We hope to complete all work on these new cold models by December 1998.

5 ELECTROMAGNETIC QUADRUPOLES (EMQ)

The spatial constraints placed on the LEL EMQs are very stringent, requiring an innovative approach to their design. A 2-fold symmetric geometry has been developed, several prototype versions have been built and tested, and a "final" LEDA version is in the final design stage.

Because of the large number of magnets, and the overall congestion of all areas around the beam line, alignment of the magnets after installation could be a problem. For this, and to minimize personnel radiation exposure, we will be pre-aligning all of the magnets off-line, to a common standard, on semi-kinematic mounts. The calibration and pre-alignment standard has been designed, and is being assembled by General Atomics.

6 SUPPORTS AND ALIGNMENT

All alignment-critical components are mounted on hardened rails within the linac tunnel. The ultimate alignment of these components depends on the stable "straightness" of these rails. The rails are mounted atop rigid steel chassis, ranging from 2 to 4 meters in length, which are placed end-to-end for the entire length of the LEL. An afocal optical system is used to straighten the rails to within 25 μm. Internal optics and loading hardware provide means to sense and correct the mid-point deflection of each chassis, which will return the rails to within 10 μm of its original shape for almost any conceivable loading condition[8].

A detailed design and prototype are the next step. LEDA hardware is due by December 1999.

7 RESONANT FREQUENCY CONTROL/ COOLING AND VACUUM SYSTEMS

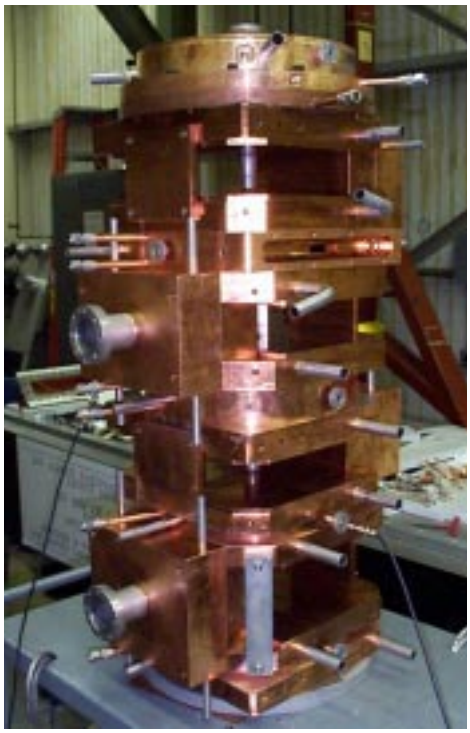
Again, the LBHM has been the vehicle for development. A cooling and resonant frequency control system has been fully implemented in miniature, by Allied Signal, for use on the 30-40 kW LBHM. The test of this system is one of the key objectives of the LBHM.

A brute-force approach has been taken for the vacuum system for the LBHM, but a conceptual design for the LEDA CCDTL vacuum system is under development at

LLNL. For maximum cost/performance and reliability, each 2 to 4 m chassis will have a dedicated large diameter manifold with 2 to 4 large ion pumps and one turbo pump attached. Detailed design of the LEDA Phase 3a hardware will commence soon, followed by fabrication, ready for installation in January 2000.

8 CCDTL LOW-BETA HOT MODEL EXPERIMENT

The LBHM will be the first high-power test of the CCDTL concept, and the driving force for fabrication and tuning method development. Various aspects of this effort are covered in the previous sections. The main objectives include the refinement of cooling and resonance control system designs, and to measure the system's ability to cope with errors in local coolant flow rates. We expect to install the completed LBHM in Oct 98, and to complete high power experiments by January 99. This data will be immediately applied to the design of the LEDA and plant accelerators.



9 LEDA PHASE 3A CCDTL DESIGN

While we await the completion of the cold modeling effort, we have proceeded with the mechanical design of the 5 meters (24 accelerating segments with 20 "sideways" coupling cavities in four brazed sections, plus the three 3-cell bridge couplers) of LEDA Phase 3a CCDTL. Unigraphics™ Parametric Solid Modeling™ is used heavily, allowing us to "complete" most of the drawings without the final dimensions. Once the missing values are finalized, software will read the physics dimensions from spreadsheets, and the models and drawings will be automatically updated. Again, we are hoping for completion of the cold models by Dec. 98, the cavity tables by Jan. 99, and completion of the LEDA Phase 3A drawing package by Feb. 99, fabrication to commence immediately afterward.

10 96 MEV HOT MODEL

Most of the work described above is aimed at the low-energy end of the CCDTL, since that will be built and operated first. But the worst case thermal problems are at the other end of the CCDTL. We are planning to build and test a 1.4m-long high-power prototype of the final two CCDTL segments (@ 96 MeV) to address this part of the parameter space. Fabrication is expected to begin by mid-1999, with tests to begin by early-2000.

The drift tubes in the 96 MeV cavity are roughly the size of a beverage can and dissipate ~5 kW of RF power. This drift-tube will require a very dense coolant passage network. Prototypes are being fabricated now, and cooling experiments conducted as before.

11 CONCLUSION

Despite less than overwhelming funding to date, significant progress has been made toward the systematic completion of the APT LEL design. Key design topics have been, or soon will be, explored, leading to the completion of the LEDA Phase 3a CCDTL over the next two years. Subsequent steps are planned to cover any and all remaining topics.

TUNING THE LEDA RFQ 6.7 MEV ACCELERATOR*

Lloyd M. Young and L. Rybarcyk
Los Alamos National Laboratory, MS H817, Los Alamos, NM 87545, USA

Abstract

This paper presents the results of tuning the 8 meter long Radio Frequency Quadrupole (RFQ) [1] built for the Low Energy Demonstration Accelerator (LEDA)[2]. This 350-MHz RFQ is split into four 2-meter-long-RFQ's. Then they are joined with resonant coupling to form an 8-meter-long RFQ[3]. This improves both the longitudinal stability and the transverse stability of this long RFQ. The frequencies of the modes near the RFQ mode are measured. We show the effect on the RF fields of an error in the temperature of each one of the 2-meter-long RFQ's. Water-cooled copper slugs distributed along the outer walls tune the RFQ. The program RFQTUNE [4] is used to determine the length of the slug tuners. The tuners are machined to length when the final tuning is complete.

1 INTRODUCTION

The final tuning of the LEDA RFQ has been completed. All the tuners have been machined to length and installed. The RF drive ports are plugged with temporary inserts that are flush with the interior wall of the RFQ. Figure 1 shows the measured fields versus position along the RFQ. The RF magnetic fields near the outer wall are measured using the bead-perturbation technique. The vane gap voltage is inferred from the measured magnetic fields by comparison to SUPERFISH calculations of the RFQ cross section every 10 cm along the RFQ. In Figure 1 the measured fields are the lines with bumps. The smooth line through the measured quadrupole fields is the design field. The measured quadrupole field agrees so well with the design field that in this figure it is difficult to distinguish between the two lines except for the fact the design field has no bumps. These bumps in the fields are caused by the tuners. In Figure 1, the crosses (+) indicate locations between tuners where the measured field is valid. These bumps in the measured magnetic fields do not appear in the electric fields on axis. The large dips in the measured quadrupole fields are caused by the bead passing through holes in the coupling plates. The coupling plates join the four 2-meter-long RFQ's.

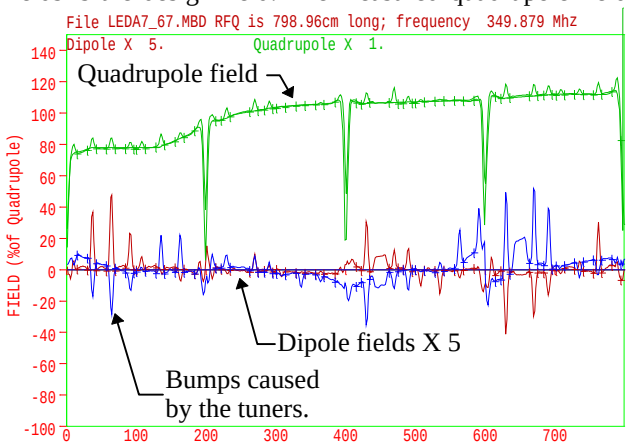

Figure 1. RFQ fields measured with the bead perturbation technique. The measured fields are within 1% of the design values. The dipole fields are multiplied by a factor of 5.

2 TUNING STEPS

The first step in the tuning of the LEDA RFQ occurred before the final brazing. Each 1-meter-long segment was checked for correct frequency and fields. The undercuts on one end of each segment have a large effect on the field tilt. Figure 2 shows the fields in section A1. The quadrupole fields are very nearly equal to the design fields, which means that the vane undercuts on the low-energy end are correct. The dipole fields of about 20% are correctable with the tuners. This measurement was performed with the tuners flush. The frequency is adjusted by machining the braze surfaces on the major vanes and moving the minor vanes in or out. Typically, the frequency of each 1-m segment was correct when the vane gaps were adjusted to the design dimensions.

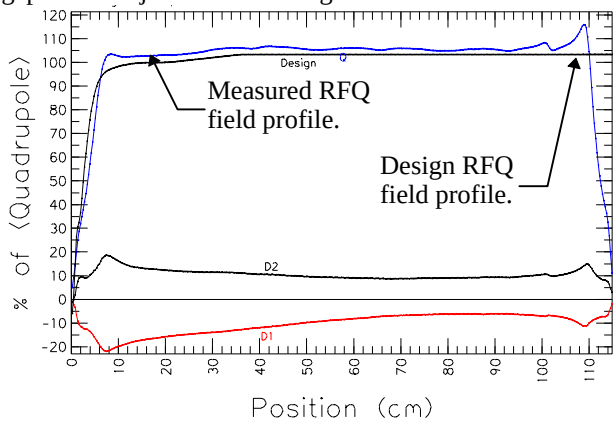

Figure 2. Perturbation measurement of the fields in section A1 before brazing. The measurement was performed with a short RFQ piece attached on the high energy end. This short piece has a vane undercut designed to properly terminate the RFQ with flat fields.

The next step in tuning occurred after the final section brazes. This step established the length of the dipole stabilizer rods. These rods, four of which are mounted on each of the end walls and on both sides of each coupling plate, adjust the frequency of the dipole modes. The

*Work supported by the US Department of Energy.

length of the rods are adjusted to approximately equalize the frequency difference between the quadrupole mode frequency and the nearest dipole mode above and below the quadrupole mode. Figure 3 shows the quadrupole modes in the frequency region near the operating mode that is free of dipole modes. This tuning scheme minimizes the dipole component in the quadrupole mode caused by asymmetric perturbations. The water cooled stabilizer rods are 1.27 cm in diameter and 15 cm long.

Step three in tuning adjusted the gap between the vane-tip ends at the segment joints. These gaps provide capacitive coupling between adjacent pairs of the four 2-meter-long RFQ's. The size of these gaps determines the capacitance between the vane-tip ends and thus the frequency of the coupling mode. The goal is to have the coupling mode frequency equal to the operating mode, which closes the stop band at the zero-phase-shift point in the dispersion curve shown in Figure 3. The fact that the dispersion curve is smooth through the operating mode shows that the frequency of the coupling mode is nearly equal to the RFQ operating mode. The operating mode has zero phase shift between the segments so the structure acts like one long RFQ. The resonant coupling provides longitudinal stability that is nearly as good as in a 2-meter-long RFQ.[5]

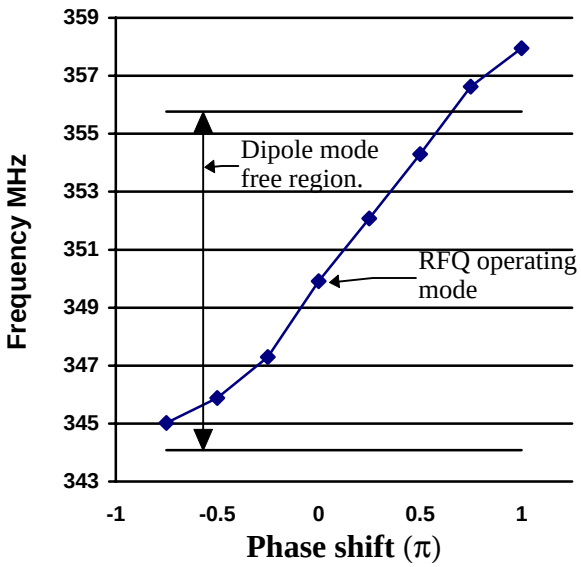

Figure 3. Quadrupole dispersion curve showing the RFQ operating mode and the frequency gap between the nearest dipole modes and the operating mode.

Step four in the tuning adjusted the RF field to the design values. This was done by moving the 128 movable tuners in accordance to the code RFQTUNE. A number of iterations were performed to adjust the field to within 1% of the design value. Figure 1 shows that the dipole component is less than 1% in over 90% of the RFQ. The D(2-4) dipole component is about 2% from 400 cm to 450 cm. When this tuning was completed the movable tuners were replace with water-cooled tuners machined to the final penetration of the movable tuners. Because the machined tuners raised the frequency slightly with respect to the movable tuners, this step was done in three stages. First 50% were replaced, then 25%, and finally the last 25%. After each stage the RFQ tuning was checked and the remaining tuners adjusted as necessary.

Step five in the tuning was to adjust the waveguide coupling irises. This RFQ is driven with three 1.2-MW klystrons. The RF power from each klystron is split 4 ways to reduce the power on the waveguide vacuum windows. The total coupling beta without beam with all three klystrons operating was chosen to be 2. The RFQ will be over coupled when all three klystrons are operating, but this RFQ is also expected to operate with only 2 of the 3 klystrons. With 2 klystrons operating, the total coupling beta without beam will be 1.33 and the RFQ will be under coupled with full beam current. A coupling beta of 1.58 would give the best match at full beam current.

A coupling beta of 2 with all twelve waveguides coupled to the RFQ requires each waveguide to be coupled with a beta of 0.167. To achieve this coupling a tapered ridge-loaded waveguide section reduces the size of the half-height WR2300 waveguide to 17.78 X 2.54 cm at the RFQ. The RF fields in this tapered section increase to the point where an iris only 9.144 cm long and 0.1575 cm wide is sufficient to achieve this coupling. The 12 RF waveguide ports were plugged with a copper piece flush with the interior walls during tuning. After the iris size was determined, the penetration of the tapered-waveguide test section was adjusted for minimum effect on the RF fields and frequency. This adjustment allows the final tuning to be completed with all the water-cooled tuners machined to length and installed before the waveguides are installed. Because the manufacturing of the tapered waveguides is taking longer than originally expected, we have completed the final tuning even though the fields may change a small amount after the waveguides are installed.

3 TUNING ERRORS

The RFQ cooling system controls the resonate frequency of the RFQ. The frequency is controlled by adjusting the temperature of the cooling water in the outer walls of the RFQ and maintaining 50° F water in the cooling passages near the vane tips. A +1° F change in temperature of the outer wall cooling water raises the resonant frequency of the RFQ by 17 kHz for constant temperature of the tip cooling water. Whereas if both the tip cooling and the wall cooling water raises by 1° F, the frequency of the RFQ will drop by 3.27 kHz. This dual temperature cooling system is required to keep the RFQ tuned to 350 MHz when dissipating 1.2 MW of RF power. The RFQ is tuned to 350 MHz at 70° F with low RF power. When it is operating, the average temperature will be ~84° F.

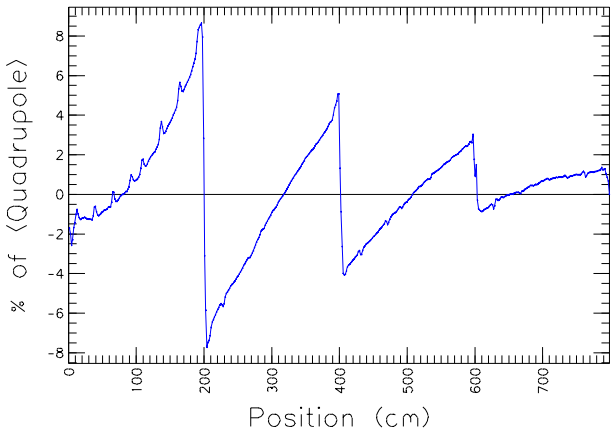

Figure 4. Change in quadrupole fields when segment "A" (0-200 cm) is tuned high in frequency by ~400 kHz. This corresponds to a cooling water temperature error of +23° F.

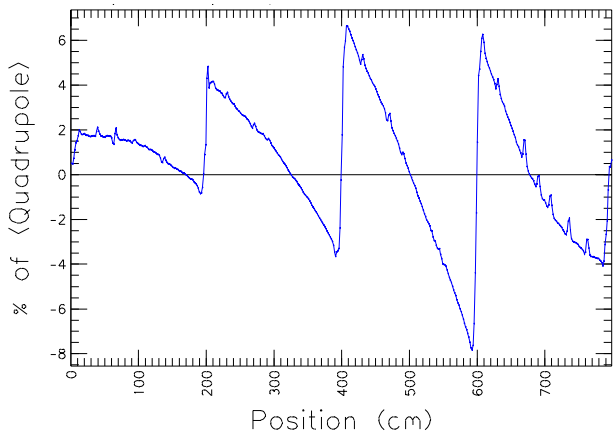

Figure 5. Change in quadrupole fields when segment "D" (600-800 cm) is tuned high in frequency by ~400 kHz. This corresponds to a cooling water temperature error of +23° F.

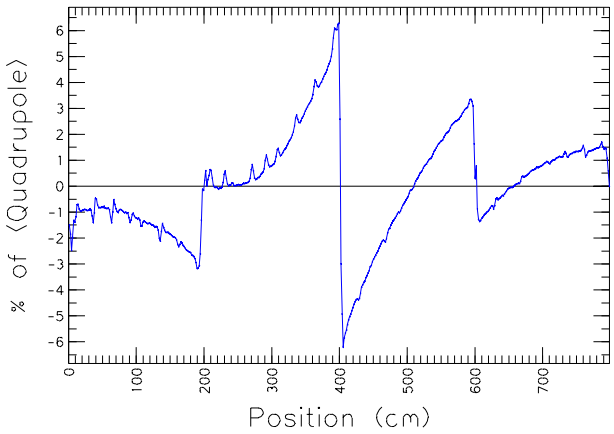

Figure 6. Change in quadrupole fields when segment "B" (200-400 cm) is tuned high in frequency by ~400 kHz. This corresponds to a cooling water temperature error of +23° F.

The cooling system has a separate cooling loop for each 2-meter section of the RFQ because each section dissipates a different amount of RF power. The cooling to the outer walls in each section have a cooling loop which mixes some of the cooling water heated by that section with the water from the outer cooling loop. This mixing ratio is adjusted manually with a remote control valve. An outer cooling loop mixes the water returning from all 4 inner loops with the 50° F supply water to control the resonate frequency of the RFQ. This outer loop is controlled by a PID feedback circuit.

The adjustment of the 4 manually controlled mixing valves will be performed by inspection of the field errors in the RFQ. RF pickup loops placed in 64 of the 128 tuners will measure the RF field distribution. Inspection of the errors in the field distribution will allow adjustment of the mixing valves. Figures 4, 5, and 6 show the changes in the quadrupole field for a temperature error in the outer wall cooling water in sections A, D, and B. The changes in the quadrupole field for section C looks like the mirror image of B. This type of perturbation does not effect the dipole component in the operating quadrupole mode.

Thus a cooling water temperature error of +23° F results in a maximum field error of only 8%. Therefore, it should be easy to set the manually controlled mixing valves to minimize the field errors by setting the mixing valves to obtain the predicted temperatures. The predicted temperatures of the 4 loops are 71, 65, 63, and 61° F respectively.

TEMPERATURE DISTRIBUTION CALCULATIONS ON BERYLLIUM WINDOWS IN RF CAVITIES FOR A MUON COLLIDER*

Derun Li, J. Corlett, W. Turner, LBNL, One Cyclotron Road, Berkeley, CA 94720, USA

Abstract

We report the temperature distribution calculations on beryllium windows in RF cavities for a muon collider. The cavity resembles a closed pill-box cavity with the conventional beam iris aperture covered by thin beryllium (Be) foils to enhance the electric fields on the beam axis. The design resonant frequency for the cavity is 805 MHz. To reduce the RF power losses, the cavity may be operated at liquid nitrogen (LN) temperature. The heating caused by RF power dissipations on the Be windows is a concern for either at the room or at the LN temperature operations. Based on the MAFIA simulations, considering the heat conduction inside the Be windows only, a pill-box and an approximated *linear* model are used to calculate the temperature distributions analytically on a flat and a tapered window, respectively. Preliminary calculations suggest that no special cooling designs be needed for 0.127 mm thickness of Be windows while the cavities operate at 30 MV/m of electric fields on beam axis with 30 μs pulse length and 10 Hz repetition rate.

1 INTRODUCTION

Significant efforts have been devoted to exploring the feasibility of designing and constructing a high luminosity muon collider. Among many technical challenges, experimental demonstration of ionization cooling for high intensity μ^+ and μ^- beams is one of the most critical paths towards the building of a muon collider. Initial simulation studies have indicated that the six-dimension phase space volume of muon beams can be cooled by as much as a factor of 10^5 or 10^6 through an ionization cooling channel [1]. The cooling channel under study is composed of 20 to 30 sections, while each section consists of liquid hydrogen absorber and RF acceleration cavities surrounded by alternating super-conducting solenoids. The muon beam loses its momentum (energy) both transversely and longitudinally while passing the absorber. Nevertheless the longitudinal momentum loss is compensated by coherent acceleration fields in the RF cavities and therefore a net transverse momentum loss is left $\Rightarrow$ **transverse cooling**! A highest possible acceleration gradient RF structure is a must for restoring the longitudinal momentum loss in the limited lifetime of the muon beam. Among few proposed RF structures [2], an interleaved $\pi/2$ standing wave (SW) structure, shown in Figure 1, is favored. The accelerating cavity cell resembles a regular closed cylindrical pill-box cavity, but with the beam iris aperture covered by thin Be foils. The structure produces an on-beam-axis field equal to the maximum surface field (e.g. $E_{\rm acc}/E_{\rm surface} = 1$) while for conventional RF structures with beam iris $E_{\rm acc}/E_{\rm surface} \approx 0.5$. Moreover the muon beams traverse these foils with negligible energy losses. MAFIA simulations indicate the cavity has an effective shunt impedance of 37 MΩ/m at $\beta = 0.87$ [2]. To further reduce RF power loss (or the costs for RF sources) the cavity may be operated at LN temperature. Potential benefits operating at LN temperature will depend on both the electrical and thermal properties of the Be windows. However, these properties at low temperature are not very well known. The thermal property in particular has strong influence on the mechanical and engineering designs for the windows and cavities. Experimental exploration on these issues is currently in progress at BNL. Nevertheless based on the limited data [4], we have estimated the temperature raise the Be windows so that proper temperature control or special cooling designs are employed if necessary. Two models, a pill-box and an approximated *linear* have been used to calculate the temperature distributions. Analytical formulae and numerical results are presented and compared. The linear model is also used for the calculation of tapered windows.

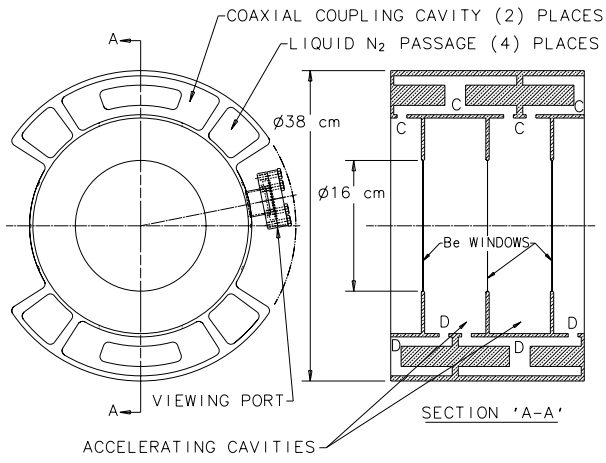

Figure 1: An interleaved $\pi/2$ SW RF structure proposed for a muon cooling experiment at FNAL. Two cavity chains are interleaved with a $\pi/2$ phase shift. Each chain operates at its own $\pi/2$ mode separately. Each cavity cell has a resonance frequency of 805 MHz. Conventional beam irises are covered by thin Be foils with radii of 8 cm. RF coupling between the cells is conducted through open slots on adjacent walls. The accelerating resembles a closed pill-box cavity and the coupling cell is a loaded coaxial type cavity.

2 RF POWER LOSSES

The electro-magnetic field continuously loses its energy to the cavity wall. In order to maintain the field, the energy loss has to be provided by rf sources. The total RF energy (power) flowing from the field into the wall can be computed by

$$P = \frac{R_s}{2} \oint_S H_t \cdot H_t^* ds, \quad (1)$$

where P is average power loss over one RF period; $R_s = \sqrt{\frac{\mu_0 \omega}{2\sigma}}$ is surface resistance of the wall; H_t is tangential component of magnetic field on the surface; S is the area of the cavity wall being studied. Equation (1) holds only if the conductor thickness and radii of curvature are much greater than δ, the skin depth. This is the case for most of the accelerator applications. H_t usually has to be obtained from numerical simulation codes such as MAFIA and SUPERFISH etc.. In some special cases (simple geometry), analytical solutions are available or can be used as good approximations. The $\pi/2$ interleaved SW structure, for example, the field in the accelerating cell can be well approximated by pill-box solutions. Using the analytical solutions and a *linear* approximation model solution in particular greatly simplify the calculation for temperature distributions. Considering the cylindrical symmetry of the accelerating cells, it is convenient to define a power loss and a density functions, $P(r)$ and $\rho(r)$ by re-writing Equation (1),

$$P(r) = \int_0^r \rho(r')(2\pi r')dr', \quad \rho(r) = \frac{R_s}{2} H_t \cdot H_t^*, \quad (2)$$

where we have assumed that only TM_{010} is the mode of our interest and $P(r)$ and $\rho(r)$ depend on r only. [1]

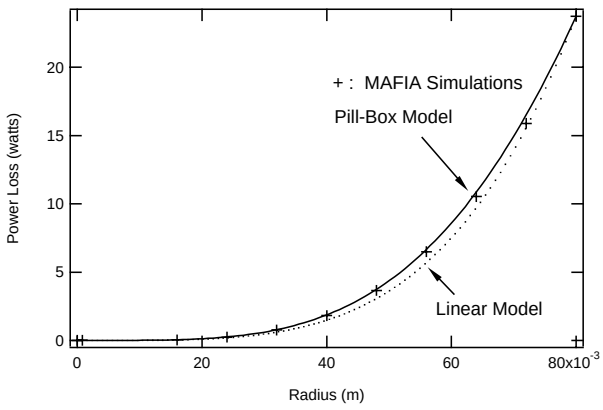

Figure 2: Power loss distribution on a flat Be window (conductivity of copper was used for this calculation, it should be easy to scale to the Be case once the data is available) calculated from the MAFIA simulations (+ sign), analytical formulae for the pill-box cavity (solid line) and the *linear* approximation (dotted line). The resonance frequency of the cavity is 805 MHz.

[1] The coupling slots in the cavities may introduce asymmetric field components, but these components are usually small and have negligible effects on on the power loss distribution.

2.1 The Pill-Box Model

For the TM_{010} mode in a pill-box cavity, its electro-magnetic fields can be expressed as,

$$E_z = E_0 J_0(kr), \quad H_\phi = H_t = \sqrt{\frac{\epsilon_0}{\mu_0}} E_0 J_1(kr). \quad (3)$$

The power loss and density functions are then given by,

$$\begin{aligned} P_{\mathrm{pb}}(r) &= \tfrac{\pi}{2}\eta R_s \left(\tfrac{\epsilon_0}{\mu_0}\right) E_0^2 \left\{ r^2 \left[J_0^2(kr) + J_1^2(kr)\right] \right. \\ &\quad \left. -\tfrac{2r}{k} J_0(kr) J_1(kr) \right\} \\ \rho_{\mathrm{pb}}(r) &= \tfrac{R_s}{2}\eta \left(\tfrac{\epsilon_0}{\mu_0}\right) E_0^2 J_1^2(kr) \end{aligned} \quad (4)$$

where $k = (\omega/c) = (u_{01}/a)$, with u_{01} as the first root of zero order Bessel function and a the outer radius of the accelerating cell; η is the duty factor of the RF source.

2.2 Linear Approximation Model

As indicated in Equation (3), $H_t \propto J_1(kr) \approx \frac{k}{2} r$ when $r << a$. We are interested only in the power loss on the Be windows with 8 cm of radii ($0 < r < R = 8$ cm and $R/a < 0.6$), we therefore may assume H_t to be linearly dependent on r, e.g. $H_t = \sqrt{\alpha} r$ and name it as the linear model. The power loss density in this case is given by,

$$\rho_{\mathrm{ln}}(r) = \alpha r^2, \quad (5)$$

which is **quadratically** proportional to r. The linear model diverges more from the pill-box solutions while r is approaching to R. To compensate this deviation, we calculate α by requiring,

$$P_{\mathrm{ln}}(r) = P_{\mathrm{Be}} \left(\frac{r}{R}\right)^4, \quad \alpha = \frac{2P_{\mathrm{Be}}}{\pi R^4}. \quad (6)$$

Where P_{Be} is the total average RF power loss on the Be window (one side). P_{Be} may come from the MAFIA simulations, analytical formulae from the pill-box model or even experimental measurement. For either cases we assume,

$$P_{\mathrm{pb}}(R) = P_{\mathrm{ln}}(R) = P_{\mathrm{Be}}. \quad (7)$$

With this assumption the power loss function by the linear model agrees well (within 6 %) with both the pill-box model and the MAFIA simulations. Nevertheless the linear model is much simpler mathematically, and therefore makes it possible for calculating the temperature distribution analytically tapered windows. As a comparison, Figure 2 shows the power loss calculations versus r on a flat Be window by different models. For all the calculations, we have assumed $E_0 = 30$ MV/m; $\sigma = 5.8 \times 10^7$ /(Ωm) (copper); $d = 0.127$ mm; $\kappa = 200$ W/mk and $\eta = 3 \times 10^{-4}$ (10 Hz repetition rate and 30 μs pulse length).

3 TEMPERATURE DISTRIBUTIONS

The RF power loss on Be windows is dissipated in the form of heat. The heat may be transfered by conduction, convection and radiation. However, the dominant form of the

transformation in metals is conduction. For the temperature distribution calculations we consider the heat conduction within Be windows only.

3.1 Heat Equation

It is well known that the conduction of heat obeys [3],

$$\frac{dQ}{dt} = -\kappa A \frac{dT}{dr} \text{ [watts]}, \tag{8}$$

where Q is the heat flow across area A, κ is a constant and known as the coefficient of thermal conductivity for the material of interest, and $\frac{dT}{dr}$ is the temperature gradient at r. Considering the cylindrical symmetry, and neglecting ionization energy loss of muons by passing through the windows, we assume the temperature distribution $T(\vec{r})$ depends on r only, e.g. $T(\vec{r}) = T(r)$. Equation (8) then can be re-written as,

$$\frac{dT}{dr} = -\frac{1}{\kappa d}\left[\frac{1}{r}\int_0^r \rho(r')r'dr'\right], \tag{9}$$

where d is the thickness of the Be window, for tapered windows d is dependent on r.

3.2 The Pill-box Solution

Substituting the power loss density function in Eq. (4) into Eq. (9), for a flat window we obtain,

$$T_{\rm pb}(r) = T_{\rm pb}(0) - \frac{R_s}{4}\eta\left(\frac{\epsilon_0}{\mu_0}\right)\frac{E_0^2}{\kappa d}\left\{r^2\left[J_0^2(kr)+J_1^2(kr)\right] - \frac{r}{k}J_0(kr)J_1(kr) + \frac{1}{k^2}\left[J_0^2(kr)-1\right]\right\}. \tag{10}$$

Where $T_{\rm pb}(0)$ is the temperature at the center of the window. Note the hottest spot is always at the center of the window (see Figure 3). We have assumed the cooling will keep the out-most edge $(r = R)$ at a constant temperature $T(R)$. The heat at the center takes the longest path to reach the cooling point even though there is no direct heating source in the center.

3.3 The Linear Model Solutions

Similarly by substituting the linear model solution in Eq. (5) into Eq. (9), we attain the temperature distribution for a flat window,

$$T_{\rm ln}(r) = T_{\rm ln}(0) - \frac{P_{\rm Be}}{8\pi\kappa d}\left(\frac{r}{R}\right)^4 \tag{11}$$

with $T_{\rm ln}(0) = T(R) + P_{\rm Be}/(8\pi\kappa d)$.

Based on the linear model solution, temperature distribution on a tapered Be window (see Figure 3) can also be calculated. We give the analytical formula below and with some numerical calculations shown in Figure 3.

$$T_{\rm ln}^{\rm tp}(r) = \begin{cases} T_{\rm ln}^{\rm tp}(0) - \frac{P_{\rm Be}}{8\pi\kappa d}\left(\frac{r}{R}\right)^4 & \text{if } r < r_0 \\ T_{\rm ln}^{\rm tp}(0) - \frac{P_{\rm Be}}{2\pi\kappa dR^4}\left\{\frac{r_0^4}{4} + \Phi(r)\right\} & \text{if } r > r_0 \end{cases} \tag{12}$$

$$\Phi(r) = \xi^3\left(1-\frac{r_0}{\xi}\right)^2(r-r_0) + 2\xi^2\left(1-\frac{r_0}{\xi}\right)(r^2-r_0^2) + \frac{\xi}{3}\left(r^3-r_0^3\right) - \xi^4\left(1-\frac{r_0}{\xi}\right)^3\ln\left[\frac{\xi+r}{\xi+r_0}\right], \tag{13}$$

where $\xi = \frac{R-r_0}{d^*-d}d$. For the tapered window simulations in Figure 3, in addition to the same parameters used in Figure 2 we have taken $d^* = 2d$ and $r_0 = 0.04$ m.

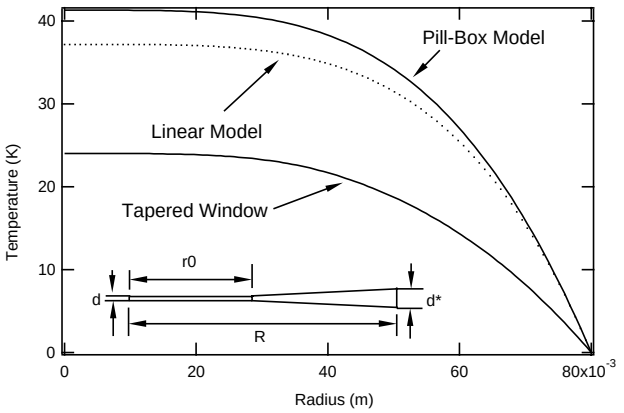

Figure 3: Temperature distribution on a flat Be window with thickness of 0.127 mm and on a tapered window with $d^* = 0.254$ mm. Note the temperature difference of $T(0) - T(R)$ is plotted here. $T(R) \approx 77$ K and $T(R) \approx 300$ K for the LN and room temperature, respectively. The temperature raise of the tapered window is about 15 K lower than the flat one.

4 CONCLUSION

Analytical formulae have been given for the temperature calculations. Numerical results presented here are for copper windows. It can be easily scaled to Be windows accordingly by $T_{\rm Be}(r) = \sqrt{\frac{\sigma_{\rm Cu}}{\sigma_{\rm Be}}}T_{\rm Cu}(r)$ once the Be data becomes available. Note both $\sigma_{\rm Be}$ and $k_{\rm Be}$ may vary with the temperature, but we did not take this into account in our models. However within small temperature range the models still give good approximations. Preliminary results show that the tapered window is better for the heat conduction and even a 0.127 mm thick flat window does not need special cooling designs and yet gives acceptable results from the viewpoint of beam dynamics for the muon cooling.

Lawrence Berkeley National Laboratory, Berkeley, CA, USA

Abstract

The conceptual design of the RFQ included in the front end injector of the Spallation Neutron Source is described. The RFQ operates at 402.5 MHz, with a maximum H^- input current of 70 mA and 6% duty factor. It is 3.72 m long and made out of four equally long modules. A brazed copper structure has been chosen due to the high power, high duty factor operation. The 800 kW peak r.f. power is coupled into the structure via eight ports, two per section. A set of tuners is provided for final frequency adjustment and local field perturbation correction. Quadrupole mode stabilization is obtained with a set of π-mode stabilizing loops. The conceptual design, assembly processes and status report are presented. This paper reports and updates the status of the design since it was last described [1].

1 INTRODUCTION

Lawrence Berkeley National Laboratory has been given the responsibility within the SNS collaboration of designing, building, installing and commissioning the Front End. This 2.5 MeV injector comprises the ion source, an electrostatic beam transport into the RFQ accelerator and the beam transport line that will deliver and match the beam into the linac. The radio frequency quadrupole (RFQ) accelerator is responsible for the bunching and acceleration of the beam from the energy of 65 keV after the source to the 2.5 MeV injection energy into the linac. A summary of the status of the SNS Front End is presented in another paper at this conference [2]. Intensive modeling has been done to support the RFQ conceptual design. The modeling results are in a separate paper [3].

2 PHYSICS DESIGN

The main parameters of the RFQ are summarized in Table 1. The RFQ accelerates the 65 keV H^- beam to 2.5 MeV in a 3.72 meter long cavity resonant at 402.5 MHz. The choice of operating frequency is dictated by the required peak output current, the desire of a compact structure and the need to inject into the higher energy sections of the linac (805 MHz) with an integer frequency ratio. This frequency also allows for the possibility of beam funneling in the first part of the linac.

Structure Type	4 vane
Total Length	3.723 m
RF Frequency	402.5 MHz
Input Energy	65 keV
Output Energy	2.5 MeV
Peak output Current	56 mA
Design Transmission	> 90 %
Rms Beam Size	0.7 mm
Norm. H rms Emittance	0.156 π mm mrad
Norm. V rms Emittance	0.156 π mm mrad
Vane-to-vane Voltage	83 kV
Peak Field	1.85 kilpatrick
Total Peak RF Power	800 kW
Beam loading	17 % @ 56 mA
RF Duty Factor	6.2%
Rep. Rate	60 Hz
Vacuum	$< 1\ 10^{-6}$ Torr

Table 1- Main RFQ Design Parameters

The RFQ is made of 449 cells, which are apportioned as 8 in the radial matcher, 48 in the shaper, 328 in the buncher ending at an energy of 780 keV, and 65 in the final accelerator section. The parameter selection is conventional, with the exception that the buncher section is slightly longer than usual to allow the longitudinal output emittance to remain below 95 keV-degree at 60 mA output and 75 keV-degree at 30 mA output, rather than increasing due to excessive bunching at lower current.

Eight-term RFQ beam dynamics simulations have been used in optimizing the buncher and acceleration section parameters, giving a normalized rms input acceptance of 0.2 π mm-mrad. In such simulations, the beam transmission is better than 95% at 60 mA of current, increasing to better than 99% at 30 mA.

The peak vane-to-vane voltage is 83 kV for a peak surface field of 1.85 kilpatrick, with a flat field distribution along the length of the RFQ to minimize longitudinal currents at the joints between the four modules that comprise the accelerator.

* This research is sponsored by the Lockheed Martin Energy Research Corporation under the U.S. Department of Energy, Contract No. DE-AC05-96OR22464, through the Lawrence Berkeley National Laboratory under Contract No. DE-AC03-6SF00098

The vane tip is machined with a constant transverse cross section of .351 cm, the same as r_0, the mean vane tip displacement from the axis.

3 RF CAVITY DESIGN

The 3.723 m long RFQ is built in four modules, each 93 cm long. The vanes and vacuum shell are made of OFE copper, with each quadrant brazed to a Glidcop (C) backbone to provide bolting strength for exterior components. The modules are joined with a copper-to-copper r.f. compression joint, backed up by a canted spring ring to provide a backup rf seal and a Viton O-ring vacuum joint. All this within the OFE part of the cavity. Figure 1 shows a conceptual view of one module.

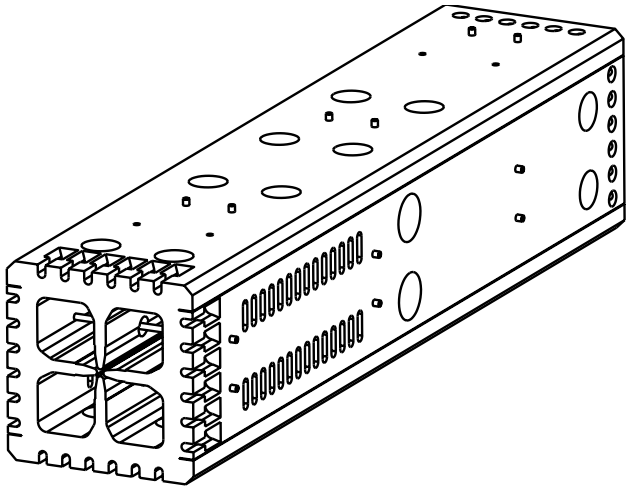

Figure 1 - Schematic view of one RFQ module

The quadrupole-dipole mode separation for the fundamental mode is 35 MHz, provided by π-mode stabilizer loop pairs [4] separated by 15.5 cm, for a total of 24 stabilizer pairs. The quadrupole mode frequency is decreased by 11 MHz and the dipole mode frequencies are increased by 36 MHz by the stabilizers. Perturbation tests show that changing the frequency of one RFQ quadrant by 1.53 MHz changes the azimuthal field symmetry by less than 2.7 percent. The RFQ is 5 free-space wavelengths long, and while no longitudinal stabilization is provided, the beam loading (for 60 mA) accounts for less-than 17% of the total power. Eight r.f. drive ports equally distributed in the four modules are expected to maintain the longitudinal field distribution within limits better than +/- 1%.

The average wall power density for 6% duty factor is 1.7 watts/cm^2, assuming the real losses to be about 67% of the ones in pure copper; computer simulations show that small areas near the vane end cutbacks approach 10 watts/cm^2. Each π-mode stabilizer rod will dissipate less than 10 watts.

The RFQ will be equipped with 80 tuners, 5 per module per quadrant, with a range of 2 MHz. Most, if not all, the tuners will be fixed, with the RFQ frequency fine control provided by a two-temperature water cooling system. In this scheme, the RFQ body is held fixed above ambient and the vane cooling channel temperature is kept at a lower and adjustable value.

4 MECHANICAL CONSTRUCTION

The RFQ mechanical design incorporates four separate vane quadrants containing the precision machined vane and cavity profiles. The quadrants are wire-brazed together to create the final cavity configuration. This design eliminates the need for demountable r.f. joints in the regions of high azimuthal r.f. wall currents. The vane and cavity wall surfaces are machined from solid blocks of oxygen-free copper (OFE). Since the copper is fully annealed during the brazing process, a 1" thick slab of GlidCop AL-15 is wire-brazed onto the rear surface of each copper quadrant to provide additional strength. This joint is obtained by brazing the copper cladding of the Glidcop to the OFE inner part. Provision has been made that no vacuum joint will cross the OFE-Glidcop braze. Figure 2 shows the final assembly of the four quadrants, as well as the external GlidCop layer.

The four completed modules are joined by means of a bolted connection. Rather than incorporating flanges at the ends of the RFQ modules, the joint design is preloaded by axial bolts recessed into the GlidCop outer layer, as shown in Fig. 1. Benefits of this type of joint include higher strength, reliable seal loading and a low profile. A slightly raised surface at the module ends around the perimeter of the cavity is used to provide a copper-to-copper r.f. compression joint. A canted spring ring seal provides back up to the r.f joint and protects an outer Viton O-ring vacuum. Canted springs are also used to ensure good electrical contact between adjoining vane tips. The r.f. and vacuum seals are all contained within the OFE portion of the cavity.

To conduct cooling water along the structure, the RFQ design uses milled channels in the back side of the OFE quadrants which are covered by the brazed-on GlidCop layer. This configuration allows internal manifolding and increased flexibility in the routing of the cooling passages. The integrity of the RFQ vacuum is maintained since no passages penetrate the ends of the modules.

This design has been studied with regards to cooling and stresses. Preliminary 2D finite element analyses have shown the RFQ operating temperature to be uniform within 3° C and thermal stresses to be 1200 psi or less.

Although the RFQ operating parameters call for a 6.2% duty factor, all thermal analyses are performed for operation at 10% to allow for possible future upgrades to a longer pulse length.

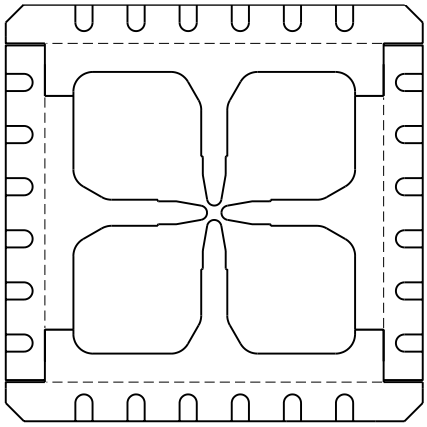

Fig. 2 – Four Quadrant RFQ cavity assembly

Vacuum ports are arranged in arrays of slots designed to attenuate the r.f. transmission into the vacuum system. The ports are incorporated identically in all four quadrants to ensure r.f. symmetry. In addition, nearby tuners are used to compensate the locally depressed cutoff frequency near the pumping ports, leveling out local variations in the vane tip voltage distribution. The RFQ vacuum level is maintained in the low 10^{-7} Torr range. All penetrations into the RFQ vacuum have been designed such that the GlidCop-to-OFE braze joint is not exposed to vacuum.

5 RF POWER SYSTEM

The peak power calculated is approximately 800 kW, including beam loading, when an additional 50% of power is allowed as the difference between the theoretical model of the RFQ and the real device built. This power is delivered by a single klystron, capable of 1.25 MW, that feeds the coupling ports via a circulator and a commercial eight-way power splitter. This splitter provides better than 40 dB of port-to-port isolation; at present no external longitudinal stabilization is planned.

The power is coupled in the cavity with a set of two coupling loops per module, with a total of eight ports. Each port will therefore carry a peak rf power of 100 kW, at a 6.2 % duty factor.

6 STATUS

A separate paper in this conference describes in detail the ongoing modeling efforts to support the conceptual design of the RFQ [3]. Benefiting from the results of such modeling, the detailed design of the first test module has begun. In the next months, a full cross-sectional size 93 cm long module will be built; it is designed with full capabilities, including vacuum, rf power, tuning and cooling. This module is intended to be identical to any of the four modules of which the RFQ will be built, apart from the specific vane modulations. The RFQ design and manufacturing procedures, as well as the operation under full r.f. power, will be tested with this device. A 1 MW klystron has been made available from the LANL collaborators and has been recently delivered to LBNL; its installation at LBNL is underway.

Upon successful completion of the first module's test, a full size prototype will be built incorporating the necessary changes that might be needed. This prototype RFQ will also be tested with beam.

7 ACNOWLEDGMENTS

The authors would like to acknowledge the generous help received from many colleagues. In particular, we would like to acknowledge the tremendous support provided by Dale Schrage and the design team for the LEDA RFQ project, by the LANL SNS collaborators Paul Tallerico and Bill Reass and by many LBNL colleagues, including R. Rimmer, K. Kennedy, J. Ayers, J. Greer and J. Remais.

Abstract

As part of the APT [1] project we have tested several cold models of a Coupled Cavity Drift-Tube LINAC (CCDTL) [2,3] 2 to 3 gap transition region. This is the region where cavities change from having 2 gaps and 1 drift tube per cavity to having 3 gaps and 2 drift tubes per cavity. We have established that frequency effects of coupling slots can be accurately predicted allowing calculation of the cavity frequencies within the allowed tuning range. The base cavity frequency is very accurately predicted by SUPERFISH and correction for stems and tuners is well established, the major uncertainty prior to these tests was predicting the frequency effect of the coupling slots. These tests have also shown that the cell-to-cell coupling for a given slot geometry can be predicted accurately enough to allow a minimum of slot tuning range to be left in the structure. A large desired field tilt between the two coupled accelerating cavities can be set up by varying the cell-to-cell couplings between the accelerating cells and the coupling cells. Further, the tilt can be predicted accurately enough to allow a minimum of slot tuning range to be left in the structure.

1 INTRODUCTION

We have tested and tuned 3 cold models (CMs) of a CCDTL 2-to-3 gap transition region. These three cold models differed only in detail dimensions, the first cold model was not extensively tested. The transition is the region in a CCDTL where the CCDTL cavities change from having 2 gaps and 1 drift tube (DT) per cavity to having 3 gaps and 2 DTs per cavity. The CMs are of structures from an early version of the APT LEDA [4], designed for a transition 8.09 MeV. A drawing of one of the CMs is shown in figure 1. In this design the transition occurred between Acc24 (accelerating cavity 24) and Acc25 (accelerating cavity 25). The CMs include ½ of a 2-gap cavity (Acc24), a complete coupling cavity (CC24-25), and ½ of a 3-gap cavity (Acc25). The current version of LEDA has the transition at 10.16 MeV between Acc49 and 50.

There were three principle issues to be addressed by these tests.

1) Could the required E_0 field tilt between the 2-gap and 3-gap cavities be established. Nominally the E_0TL for the two cavities should be equal, ignoring any additional field ramp? Since the 3-gap cavity is approximately 3/2 longer than the 2-gap cavity, the E_0 for the 3-gap cavity needs to be approximately 2/3 that of the 2-gap cavity. We needed to know if the tilt could be predicted accurately enough to minimize the required slot tuning range. The tilt is set by the difference in coupling between the respective cells and the common coupling cell.

2) Could the coupling produced by a given slot size be calculated accurately enough to allow a minimum of extra material to be left in the slot region, allowing the maximum use of available space in cramped areas? We are calculating the coupling produced by a given slot along the line described by J. Gao [1]. In addition if the coupling can be predicted accurately then the slots can be cut close to (or right on) the final dimension,

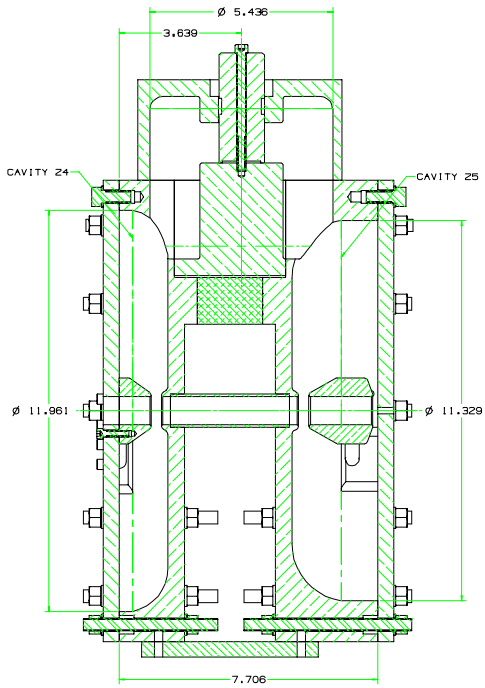

Figure 1: Drawing of transition region cold model.

* Funding provided by U.S. Department of Energy.

minimizing the coupling slot tuning required.

3) Could the frequency of the accelerating and coupling cavities be predicted accurately enough so that the cavities would be within the allotted tunable range? The base cavity frequency is very accurately predicted by SUPERFISH and corrections for stems and tuners are well established. The major uncertainty was predicting the frequency effect of the coupling slots.

2 FIELD TILT AND COUPLING MEASUREMENTS

The second cold model to be fabricated was slightly off frequency but was tunable and usable for field and coupling measurements. Table 1 shows the frequencies of Acc24, Acc25, and CC24-25 measured with the other cells shorted (with rods shorting the cavity gap along the cavity axis) as the cavities were tuned to 702 MHz with two rounds of tuning cuts.

Table 1: Measured individual cavity frequencies for the second cold model with all other cavities shorted.

Meas	1	2	3
Acc24 Fmeas	702.013	702.040	701.996
Acc25 Fmeas	705.253	702.639	702.589
CC24-25 Fmeas	707.645	702.310	701.982

During each tune step the mode frequencies were measured. These mode frequencies are used in the modal analysis program DISPER [2] to calculate the accelerating cavity frequency, the coupling cavity frequency, and the coupling for an infinite string of coupled cavities assuming that all of the coupling cavities, all of the accelerating cavities, and all of the couplings are the same. The "average" coupling, calculated by DISPER, is the best available for evaluating the cold model and is used throughout these tests. Table 2 shows the measured mode frequencies and the Acc and CC cavity frequencies and coupling calculated by DISPER. The final k_{avg} value calculated by DISPER is 4.63%, 93.72% of the target average coupling of 4.94%.

Table 2: Measured Mode frequencies, and DISPER calculated cavity frequencies and couplings.

Meas	1	2	3
0 Mode	689.900	686.764	686.602
$\pi/2$ Mode	703.300	702.369	702.337
π Mode	723.300	719.340	719.150
Disper Acc F_{avg}	703.300	702.369	702.337
Disper CC F_{avg}	708.748	702.603	702.285
Disper K_{avg}	4.66%	4.63%	4.63%

There is no way to measure the individual couplings from the coupling cavity to each of the accelerating cells, however, the field tilt that results from the different coupling values can be measured directly. The actual couplings need not be measured. The field profile was measured by performing a bead-perturbation measurement after the cavities were tuned. Figure 2 shows the plotted beadpull data. The plot shows (from left to right) the field in the gap in Acc24, the field in the first full gap in Acc25, and the field second (half) gap in Acc25. The measured field in the second (half) gap in Acc25 is not used in the analysis since the terminating wall and bore hole distort the field. A numerical integration of the fields in the Acc24 and Acc25 gaps was performed to generate a value for E_oL for each gap. The E_o value for a full Acc24 and a full Acc25 cavity was then calculated. For Acc24 the measured E_oL was simply doubled then divided by the actual full cavity length. For Acc 25 the cavity field profile from SUPERFISH was used to calculate the E_oL in the middle gap from the measured E_oL in the first gap, the result was added to twice the first gap E_oL and the sum divided by the actual full cavity length. The "measured" values for the single gap E_oL and the cavity E_o along with the SUPERFISH values are shown below for Acc24 and Acc25 in Table 3. Table 4 shows the "measured" field ratios, the target values, and the ratio of the measured to target values.

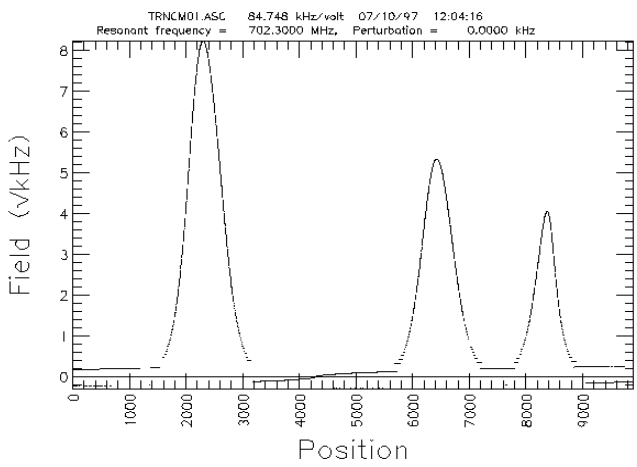

Figure 2: Results of beadpull on the cold model after frequency tuning.

Table 3: Relative single gap EoL and full cavity Eo.

	Acc24	Acc25
Measured single gap EoL	0.716757	0.445895
SUPERFISH single gap EoL	106.297	73.6647
Measured full cavity Eo	0.17124	0.094548
SUPERFISH full cavity Eo	2.5395	1.562

Table 4: Measured field ratios, and target ratios.

	Measured	Target	Meas/Target
EoL Ratio	62.21%	69.30%	89.77%
Eo Ratio	55.21%	61.51%	89.77%

The coupling can be increased by the small amount required during the assembly tuning phase, there is adequate space for the slots to be enlarged by the required amount. The E_o tilt of Acc25/Acc24 was 55.21%, 89.77% of the target 61.51%. Reducing the tilt can be done during the assembly tuning phase while the average coupling is increased.

The results of coupling and field tilt measurements with a third cold model were also quite good. The final k_{avg} value of 4.72% calculated by DISPER is 94.21% of the target average coupling of 5.01%. The E_o tilt of Acc25/Acc24 for this cold model was 58.00%, 94.30% of the target 61.51%.

3 FREQUENCY MEASURMENTS

Since we had good results with coupling and field tilt using the second cold model, the primary goal for the third cold model was to evaluate our frequency predictions.

All of the accelerating cells were designed with the intention having a small tuning range. This would be accomplished by nominally leaving a small amount of a fixed tuning ridge in place after the cell was tuned to 700 MHz. The cells would be fabricated with an additional amount of this ridge in place, hence the nominal fabrication frequency target of greater than 701 MHz. In theory, with all of the ring removed the frequency of the cells should be 699 MHz. For this model, the extra tuning ridge left in place was fixed at about 2.5mm for Acc24 and Acc25. The effect of this step on Acc24 and Acc25 is shown below for both the SUPERFISH predicted tune rate in Table 5 and the measured average tune rate in Table 6 (For these measurements, the cavity frequencies were not corrected for T, relative humidity, barometric pressure, or referred to vacuum).

Table 5: Tuning Step effects for Acc24 and Acc25.

	Acc24	Acc 25
SF Frequency with no step	699	699
Tune Step Height (in)	0.099	0.099
SF Tune Rate (MHz/in)	-22.0499	-36.0754
dF from step	2.18294	3.571464
Expected Fab Freq	701.1829	702.5715
Actual Fab Freq	700.541	702.766
Error	-0.64194	0.194536

Table 6: Tuning Step effects for Acc24 and Acc25.

	Acc24	Acc25
SF Frequency with no step	699	699
Tune Step Height (in)	.099	.099
Meas Tune Rate (MHz/in)	-16.7299	-34.3182
dF from step	1.656259	3.3975
Expected Fab Freq	700.6563	702.3975
Actual Fab Freq	700.541	702.766
Error	-0.11526	0.3685

The agreement between the expected and actual fabrication frequencies is within the tuning range provided by the tuning ridge. For Acc25 the agreement between the SUPERFISH tune rate and the measured tune rate is also good. It is not clear why it is not as good for Acc24.

4 CONCLUSION

We are quite satisfied with the results obtained with the transition region cold models. We have established that frequency effects of the slots in this region can be predicted allowing calculation of the cavity frequencies within the allowed tuning range. We have shown that the coupling can be predicted accurately enough to allow a minimum of slot tuning range to be left in the structure. Finally, we established that the required E_o tilt can be set up and that it can be predicted accurately enough to allow a minimum of slot tuning range to be left in the structure.

Abstract

We study some effects of cell misalignments in accelerator structures in which each cell is displaced the same amount and direction but with sign which alternates from cell to cell. In particular we study the manifold radiation in a damped detuned structure (DDS1) and wakefield effects in a uniform constant impedance structure. A synchronous wave aliasing phenomenon is observed. In previous treatments the effect of cell misalignment has been modeled by replacing it by beam displacement. Here we compare finite difference simulation of cell misalignment with the beam displacement model. We conclude with discussions about the relevance of our results for general misalignment profiles.

1 INTRODUCTION

In a damped detuned accelerator structure the dipole modes are detuned such that their synchronous frequencies vary with error function profile along the length of the structure, so that the frequency distribution function is Gaussian. In addition four damping manifolds, connected to each cell, extend along the length of the structure. The detuning leads to a rapid initial fall off of the transverse wakefield and the damping prevents the recoherance reappearance which would otherwise occur [1]. The utility of the manifold radiation as a source of information about beam position within the structure and about structure misalignment is discussed in [2] and [3]. The spectral distribution of manifold radiation, computed by means of the equivalent circuit theory, was found to be in good agreement with observations [2, Fig. 1]. Furthermore it was shown, by computing the effect of beam displacements localized to a few cells within the structure, that there was a strong correlation between the localization position and the frequencies emitted into the manifold [2, Fig. 2] allowing manifold radiation frequency to be mapped onto cell position. Reference [3] reports measurements of beam position which minimizes manifold radiation as a function of frequency. By assuming that this minimum position is centered with respect to the cells which provide the frequency being observed and applying the mapping function defined above, one obtains a measure of cell position as a function of cell number and good agreement with mechanical misalignment measurements.

Implicit in the above is the assumption that localized cell displacements can be taken into account by replacing them with localized beam displacements in the equivalent circuit theory. In reference [4], which discusses the computation of wake functions associated with actual beam misalignments as well as with structure misalignments, the same assumption is made. Also the computational and experimental evidence does not really support the above simple picture for sharp discontinuities (such as actually occurred in DDS1).

The remainder of this paper is devoted to a partial study of the effect of a special misalignment. We assume the cells to be displaced alternately upward and downward by equal amounts as one proceeds along the structure. Because this is the opposite of a smooth misalignment it has some bearing on the issues raised above. It is also simple enough to allow a direct test of the equivalence of localized beam displacement and cell displacement. Such a structure can be analysed by treating each cell pair as a single cell and carrying out an analysis completely analogous to the standard DDS theory. While we have carried out only a small part of such a program, a number of interesting phenomena have emerged. The concluding section includes some discusions on the applicability of what we have learned to the more general misalignment problem.

2 RELATIVE DISPLACEMENT OF 2 IDENTICAL STRUCTURES

The study of both the detuned structure without damping and the DDS begins with the study of individual cells as part of a uniform structure. Proceeding analogously here we consider a cell pair as a unit in a structure of period 2p, where p is the period of the structure when the cell to cell displacement 2d vanishes. Mode patterns and frequencies as a function of phase advance over the 2p period were obtained from the finite difference program GdfidL [5] for a typical cell, similar to cell 103 of a detuned structure. The mesh for these calculations is shown in Fig. 1. Considerable care in mesh construction is required to preserve the symmetry of the problem, obtain sufficient accuracy, and avoid the introduction of mesh artifacts as d is varied. The Brillouin (dispersion) diagram for the accelerating mode and first two dipole modes is shown in Fig. 2.

As is conventional the diagram is folded so that the phase advance range is limited to 0 to 180 degrees. Also

shown on Fig. 2 is the (folded) light line. Computations were performed for d = 0, 0.1825, and 0.365 mm. For comparison we note that the diameter of the iris aperture is 9.5926 mm.

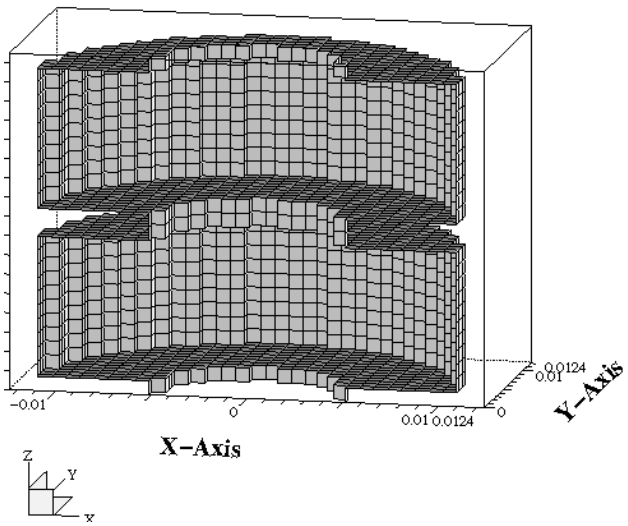

Figure 1: GdfidL mesh used for double period structure, viewed from the y symmetry plane. A coarse mesh is used to illustrate the geometrical features.

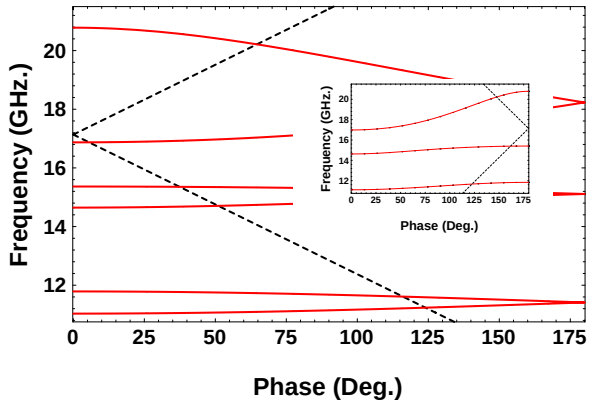

Figure 2: Brillioun diagram for double period structure with 0mm displacement of structure.

We first discuss Fig. 2 for the case d = 0. In that case the structure is periodic over the distance p (as well as 2p), and the conventional Brillouin diagram, folded with respect to p rather than 2p, is shown in the Fig. 2 inset. One sees that the single mode curves of the conventional form become doubled by folding back the 90 to 180 degree sections, leading to the paired curves of the 2p representation connected at 180 degrees. One also sees that the three synchronous frequency points (light line intersections) of the conventional representation become supplemented by three more which we refer to as alias synchronous frequencies. The longitudinal voltages for velocity of light particles vanish identically at these frequencies.

We next discuss what happens when one cell of the pair is offset to the left a distance d and the other offset to the right by d. As far as the Brillouin diagram is concerned there are small frequency shifts, varying as d^2, at each phase advance. The shifts of the six synchronous frequencies in KHz for d = 10 micrometers were inferred from the simulations to be -7.58, -13.2, 15.3, 27.5, 17.8, and -6.95 respectively, starting from the lowest frequency to the highest. Numbering them one to six, the odd numbers correspond to the alias cases. The fact that the coincidence of the curve pairs remains at 180 degrees is evidence that the mesh variation as d is varied is under control. The curves separate if the cells differ from one another.

The interaction of a v = c beam with a mode of the structure is controlled by the longitudinal voltage integral:

$$V_P(x,y) = \int_0^P E_z(x,y,z)\exp(j\omega z/c) \qquad dz$$

where P is the structure period (p or 2p in our case), and E_z and ω refer to the mode under study. We base our comparison of beam displacement with cell displacement on the behaviour of V_p and V_{2p}.

We consider the beam displacement model first. The beam displacement approximation is based upon the d = 0 structure, a structure with period p. At a synchronous point we have besides the expression given above:

$$V_p(x,y) = \int_p^{2p} E_z(x,y,z)\exp(j\omega z/c) \qquad dz$$

while for the alias synchronous modes this relation is

$$V_p(x,y) = -\int_p^{2p} E_z(x,y,z)\exp(j\omega z/c) \qquad dz$$

Thus at a synchronous point the beam displacement model yields $V_{2p}(x,y) = V_p(x-d) + V_p(x+d)$, while at an alias synchronous point it yields $V_{2p}(x,y) = V_p(x-d,y) - V_p(x+d,y)$. We recall that at a synchronous point of a periodic structure, V_p is a solution of the 2D laplace equation at all points within a region A defined by the area common to the beam apertures. Since the d = 0 structure is also rotationally symmetric about the beam axis, within A V_p is constant for the monopole case and a constant times x or y for the two dipole mode polarizations. Hence for all synchronous cases of the modes we study here, $V_{2p} = 2\ V_p$. Away from a synchronous point V_p no longer has this simple behaviour. However the departure from it is found to be very small, and the symmetry properties under reflection are preserved. It follows that

$$V_{2p} = -2d(d/dx)V_p$$

to an excellent approximation. This means that the alias synchronous modes have their x reflection behaviour reversed in parity. The monopole becomes an x dipole, the x dipoles become monopoles, and the y dipoles become quadrupoles. Note that to the extent that V_p

satisfies pure 2D laplacian behaviour the x dipoles behave like a pure monopole and the V_{2p} vanish for the monopole and y dipoles. Hence the alias dipole and quadrupole effects are very weak.

We have compared these results with the behaviour of GdfidL simulations at y = 0 and values of x over the interval [-4,4] mm. To compare different cases we require that all have the same stored energy over the [0,2p] interval. Also since the GdfidL simulations have an arbitrary overall phase, we compare absolute values of V_{2p}.

Comparisons were made at d = 0.365 and 0.1825 mm. First a few general observations. Since all modes are synchronous with respect to the 2p period, all of the V_{2p} satisfy the 2D laplace equation. The rotational invariance about the beam axis is, however, broken, and hence the simple x dependence of pure multipoles may be altered. On the other hand, one can show that the behaviour under x reflection should be preserved. Hence we expect the alias monopole to be principally dipole, and the alias x dipoles to be principally monopole, an expectation born out by the simulations.

We discuss the even numbered modes first. For the monopole case, there is no detectable difference between the displaced beam model and the simulation at 0.1825 and no detectable variation from pure monopole behaviour. For the first dipole there is a 0.1% deviation for d = 0.1825 and 0.25% for d = 0.365 and no evidence for departure from pure dipole behaviour. For the second dipole the discrepancy was 10% at d = 0.1825 and 30% at d = 0.365 and there was slight evidence for a deviation from pure dipole behaviour. We note that the voltage integral is abnormally small for this mode and therefore seems to be more sensitive to field changes associated with the displacement. The discrepancy does appear to be decreasing with d and may well become very small at d values likely occur in practice. These results provide no evidence against the use of the displaced beam approximation for calculating the transverse wakefunction as was done in [4].

For the odd numbered modes, which correspond to the aliased synchronous modes, the comparison is much poorer. The departure from pure multipole behavior is substantial but not significant at beam displacements which are likely to occur in practice. The result of most practical interest is the deflecting mode 1, which occurs at a frequency within the accelerating mode band and would thus be unaffected by manifold damping. The magnitude is 8 times as large as that given by the beam displacement model and appears to be proportional to d. The kick factor associated with it then varies as d^2, and assuming this to be the case is a factor 10^3 smaller than a typical first band dipole mode for d = 36 μm. For mode 3 the dominant monopole component is over estimated 15% for d = 0.1825 and 20% at 0.365 by the beam displacement model. The figures for mode 5 are 65 and 75% respectively. Being non deflecting and subject to manifold damping these modes are of little practical wakefield interest.

3 MANIFOLD RADIATION PHENOMENA

An equivalent circuit computation of the manifold radiation spectrum from DDS1 for beam displacements alternated from cell by equal amounts yielded a striking shift in the spectrum which we interpreted as implying that each cell was excited at its aliased synchronous frequency rather that its actual synchronous frequency. In the future we plan to investigate the extent to which this effect is localised. The other striking result was the the fact that the radiation was predominantly upstream rather than downstream, an effect which was consistent with the explanation of directional asymmetry given in [1].

4 CONCLUDING COMMENTS

While the evidence is limited to the special situations that we have studied, we attempt here to draw some tentative general conclusions. First, frequency shifts due to misalignments are unimportant compared to those likely to arise from dimensional errors in the cells. Second, for the computation of transverse wakes due to dipole modes the displaced beam approximation is reliable. These misalignment may also cause a longitudinal wake from the dipole modes, but it is small and of little practical importance. Third, we have no evidence that misalignment produces any significant effect on the accelerating mode band. The transverse wakes from aliasing are very small, and we have no evidence of transverse wakes produced directly by the RF drive.

Abstract

In order to reduce the dipole wake encountered by the first few bunches accelerated in a multi-bunch NLC scenario the DDS (damped detuned structure) was re-designed such that a much improved Gaussian fall-off occurs in the initial wake-function. From the 9 parameterised model of DDS1 we use a mapping function to allow DDS 3 & 4 to be modeled and hence avoid additional and prohibitively time consuming MAFIA runs. The equivalent circuit parameters and geometrical parameters are treated as functions of the synchronous frequency and are readily mapped onto the new synchronous frequencies. The new geometrical parameters form a family where each is associated with the iris diameter.

1 INTRODUCTION

The first ever manifold DDS was designed such that the geometrical parameters (iris radius and cavity radius) of the cells were inverse functions of error functions, Erf. Further, the mode density function (the reciprocal of the derivative of the uncoupled frequencies with respect to mode number: dn/df) was prescribed to be Gaussian. However, the short range dipole wake function, is given by twice the inverse transform of the dipole kick-factor (K) weighted density function and under a Gaussian prescription of dn/df, 2Kdn/df is markedly asymmetric. The consequence of the asymmetry is a poor definition of the minima in the short range wake function. DDS 3 & 4 have been re-designed under a Gaussian 2Kdn/df prescription with a bandwidth of 4.71 units of sigma (with sigma 2.125% of the central frequency of the Gaussian) and this leads to a significantly improved short-range wake function.

The inverse Fourier transform of the spectral function [1] allows the global wake-function to be evaluated. However, in order obtain the new spectral function, all nine parameters of the structure must be obtained for 206 cells. This is a substantial computational task in running the MAFIA code required for the spectral function and in the careful fitting procedure required for all the new functions. However, the method used herein obviates this excessive computational work and requires that we fit all the 9 circuit model parameters together with the beam kick-factor to ten functions which all depend on the synchronous frequency only. The new set of new synchronous frequencies, dictated in our case by the requirement that 2Kdn/df be Gaussian, allows the 206 x 10 new characteristic parameters to be calculated. Similarly the 5 parameters, which define the geometry of the structure (the iris radius a, cavity radius b, iris thickness t, the radial distance of the edge of the manifold from the center of of a cell, H and the height of the manifold L) are also functionally dependent on the synchronous frequency of the beam and, under a new set of frequencies, 5 x 206 new dimensions are calculated for the DDS. Thus, in order to obtain the wake function and new geometrical parameters for fabrication all that is necessary is to obtain 15 functions.

However, under this new mapping one might express some concern as to whether the properties of the fundamental (i.e. accelerating) mode have been adversely affected and so with this in mind we conducted an intensive investigation as to the deviation of the cell dimensions, parameterised by the cavity diameter 2b, from their values designed in DDS 2 (all dimensions form an invariant family parameterised by the cavity diameter b). This is detailed in section 4 and successive sections.

2 THE MAPPING FUNCTION

In our design of DDS 2 we chose eleven representative sections to obtain frequency-phase pairs from detailed MAFIA simulations and hence obtain ten model parameters (nine circuit parameters plus the cell kick-factors) for each of the eleven sections. Parameters for all sections are subsequently obtained by error function fits and interpolation. A similar procedure may be followed to determine the five geometric parameters (i.e., cell and manifold dimensions) for all the sections from those for the original eleven. This is a substantial task for each structure design. However, as we now have all fifteen parameters as a function of synchronous frequency, we can take advantage of this functional dependence to explore new design distributions and to obtain the set of section dimensions which would be needed to realize them.

Based on our fit parameters we prescribe a smooth uncoupled spectral function, $S_0(f_s)\lambda$ and impose the condition that: $2K(f_s)dn/df = S_0(f_s)\lambda$, where K is the uncoupled kick factor, f_s the synchronous frequency and, λ is a scale factor to be determined. The upper and lower

truncation bounds on the synchronous frequencies are imposed, f_{s1} and f_{sN} and the normalisation condition is obtained:

$$\lambda = N / \int_{f_{s1}}^{f_{sN}} (\tfrac{1}{2} S_0 / K) df_s \qquad (2.1)$$

Then the new synchronous frequencies are determined according to:

$$\int_{f_{sn}}^{f_{sn+1}} \frac{1}{2K} \lambda S_0 df_s = 1 \qquad (2.2)$$

This enables all the cell synchronous frequencies to be determined and hence the new ten parameters are determined.

This procedure is implemented in the following section to calculate the spectral function and associated wake function for DDS 3.

3 CALCULATION OF THE WAKE FUNCTION

In the revised design for DDS 3 we chose a truncated Gaussian distribution for the uncoupled $2Kdn/df_{syn}$ distribution, with a bandwidth of 4.71 units of sigma, (a bandwidth of 10.159% of the central frequency and sigma is 2.125% of the central frequency) and this provides a basis for the determination of the 206 synchronous frequencies. The kick factor weighted density function for DDS 3 and DDS 1 are shown in Fig 1.

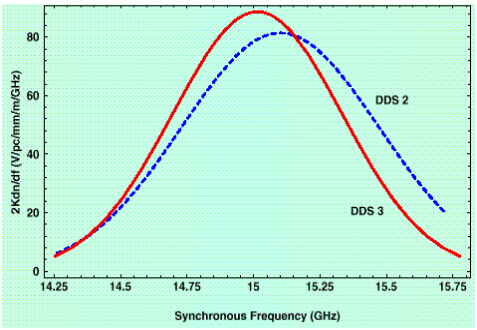

Figure 1: Twice the kick factor weighted density function for DDS 2 (shown dashed) and the corresponding function for the re-designed DDS3 and 4

It is evident that DDS 2 is markedly asymmetric and this adversely affects the sharpness and depth of the minima for the short range wake

In order to calculate the wake function we first are required to calculate the spectral function associated with the 9 mapped parameters. This spectral function calculated for DDS 3, and shown in Fig 2, maintains the Gaussian characteristics imposed upon it from the synchronous frequency distribution but modulated with oscillations of large amplitude (resulting in a large part from reflections occurring in the higher order mode couplers in the manifold).

Also, the spectral function exhibits the underlying damped mode structure as mentioned previously for DDS 2 [1] and is shifted with respect to the 2Kdn/df curves, as given in Fig. 1. The difference between the respective curves in Fig. 1 and Fig. 2 becomes more pronounced for higher frequencies and this is a consequence of the synchronous frequencies becoming more highly perturbed as one progresses down towards the higher energy end of the structure where the coupling to the manifold has been designed to be largest. These coupled synchronous frequencies will be discussed in a future publication [2]

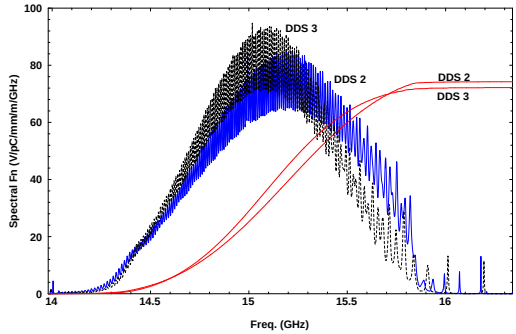

Figure 2: Spectral function for DDS 2 and DDS 3

It is important to note that the sharp, rather precipitous, fall-off in the spectral function in DDS 2 at approximately 15.8 GHz has detrimental affects on the short range wake function. In DDS 3 the spectral function falls off smoothly and gradually and this has beneficial effects on the range wake function in that it enables a faster fall-off to occur. Indeed for a perfectly smooth termination, which we refer to as our idealised case [1], it is possible to achieve more than an order of magnitude weaker wake function at the 90 bunch point.

It is interesting to note that the maxima of DDS 3 is a little larger than that of its counterpart DDS 2. However, the area under the curve (bounded by the upper & lower synchronous frequencies for each structure) corresponding to DDS 3 is slightly smaller than DDS 2. This reduction in the area of the curves is indicative of a reduced wake function at the origin (since the wake function is given by the inverse transform of the spectral function) and this is in itself a consequence of the larger iris dimension in DDS 3.

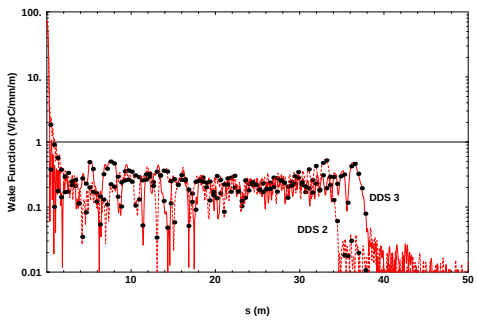

Figure 3: Long range wake function for DDS 2 (shown dashed) and DDS 3. The points are at the location of each of the bunches, of which there are ninety.

4 GEOMETRICAL PARAMETERS

Each of the five geometrical parameters are fitted with an interpolation function, the independent variable in each case being the synchronous frequency. Thence, armed with these new synchronous frequencies the new 206 x 5 parameters are readily obtained. Both a new and mapped cell parameter is shown in Fig. 4 and a manifold parameter in Fig. 5. The end points of DDS 2 and DDS 3 are identical by design so that no extrapolation is required in the determination of the DDS 3 parameters. Thus, in determining all parameters only third order interpolation between cell points has been employed, with a view to minimising any error in the generation of the new points.

It is evident from the curves that in the downstream end (or low energy end) of the structure the parameters are very close to that of the DDS 2 design whereas in the upstream end both the iris and the cavity diameter are increased significantly. This is a consequence of the asymmetry in the original design in which the kick factor weighted distribution reached too low a level in the upstream location of the structure and this has been corrected for in DDS 3. The thickness of the irises however, is reduced with respect to DDS 2, but this reduction is sufficiently small that the structure still maintains its mechanical integrity.

The manifold is tapered as one goes down the structure to enhance the coupling. This increased coupling is necessary because the modal composition of TE/TM is reduced as one moves towards the upstream end of the structure and to achieve a Q value in the neighborhood of a 1000 or so, increased coupling is required. There is a reverse in the taper towards the end cells in the upstream end and this is instituted in order to lower the cut-off frequency of the HOM (higher order mode) coupler and hence improve the match of the mitered bend of the HOMs at the lower frequency end of the band.

It is necessary to have well-matched HOM loads because the wake function is very sensitive to the power reflected back into the accelerator [1]. However, under the mapping the middle cell has effectively shifted forward by 11 cells and hence the upward taper (which occurs in cells 182 to 202 for DDS 2) maps the up-taper into a region where there are no manifold cells. Thus, in DDS 3 we change the mapped taper in this region by increasing the gradient of the taper and withdrawing its to cell 202. This will adversely affect the wake function but we are confident that its deleterious effect will minimal.

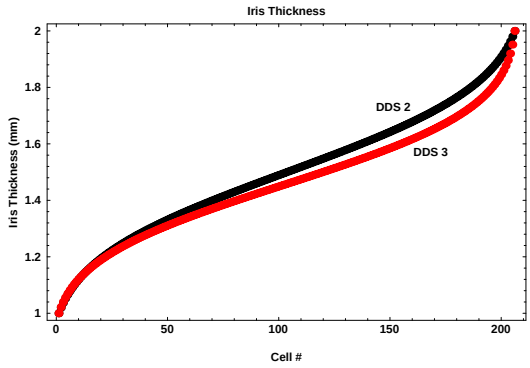

Figure 4: Cell geometrical parameters: iris thickness, t.

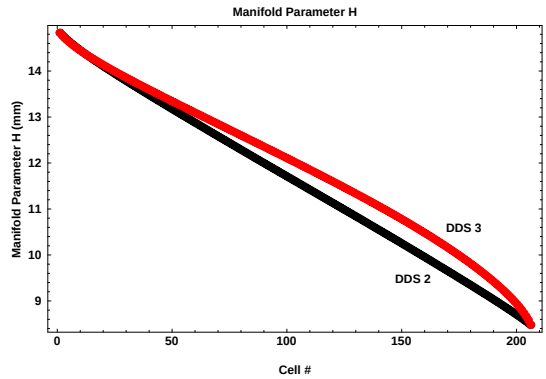

Figure 5: Manifold geometrical parameters: radial distance of the edge of the manifold the from center of a cell.

5 CONCLUSIONS

We have developed a method to rapidly design new DDSs based upon a mapping procedure. This method enables both the wake function and the new geometry of the structure to be evaluated. Indeed, we have applied this method to calculate the short range wake function for DDS 3 and we find that, on average, the wake function is reduced by a factor of 5 or more. The new geometrical parameters form an invariant family which are functionally dependent on the cavity iris diameter, 2 and the deviation of the new family of parameters from the old provides an indication as to the accelerating mode's phase advance of the new structure.

OPTIMUM OPERATING TEMPERATURE OF SUPERCONDUCTING CAVITIES

H. Safa
Los Alamos National Laboratory, Los Alamos, 87545, NM, USA
& C.E.A. Saclay, 91191 Gif/Yvette Cedex, France

Abstract

Superconducting radiofrequency (SCRF) cavities require cryogenic temperature to operate in the superconducting state where the RF power losses are extremely low. But this power has to be removed at very low temperatures using a refrigerator. While reducing the operating temperature results in lower losses for the cavities, it may severely impacts the cryogenic plant, drastically reducing its efficiency. On the other hand, the exponential dependence of the BCS surface resistance with temperature will ask for much higher refrigeration power at higher temperatures. Therefore, an optimum working temperature results, depending on frequency, accelerating field and cavity performance. This temperature should be determined by cost, performance, and risk minimization.

1 INTRODUCTION

While it is obvious that for frequencies over 1 Ghz, SCRF niobium cavities must operate in superfluid helium [1], the use of an intermediate frequency as 700 MHz for future proton linear accelerators requires a more thorough evaluation. For the sake of convenience, the APT (Accelerator Production of Tritium) high energy part [2] will be taken as an example. While reducing the operating temperature results in lower losses for the cavities, it severely impacts the cryogenic plant, reducing its efficiency (for example, going down from 2.0 K to 1.8 K will have a tremendous impact on the cryoplant's cold compressors, while achieving very little reduction of the cavity losses). On the other hand, a high operating temperature would require a very high-power refrigeration, due to the strong dependence of the BCS surface resistance with temperature (for example, operating at 4.5 K would require seven times more refrigeration power than for 2 K operation). Therefore, an optimal working temperature should exist in between these two limits.

2 COSTS ESTIMATION

2.1 Operation Cost

To properly optimize the operating temperature, all the items that may vary with this parameter should be taken into account. First, the two main items are the cryogenic plant and the electric power required to maintain the cryogenic temperature. The choice of the operating temperature will directly affect the total cryogenic power R required, which, in turn, will size the cryogenic plant. The AC electric power of the cryogenic plant can then be deduced using an overall efficiency η :

$$P_{AC} = \frac{R}{\eta} \qquad (1)$$

This will be the most important cost item in operation. The change in other operation costs of the cryoplant components (manpower, maintenance, etc.) will be assumed to be of second order when compared to AC power, and will be neglected here. Assuming a running time of 80% and an average price of (0.05 \$/kW$_e$h), the operating cost will amount to:

$$C_{op} = 0.35 \times P_{AC} \quad (\$/\text{year}) \qquad (2)$$

The total operating cost is obtained by multiplying C_{op} by the total lifetime of the accelerator.

2.2 Capital Cost

The change in capital cost C_{cap} with respect to operating temperature is assumed to be mostly due to the cryogenic plant. Green et al. [3] from Berkeley have estimated the capital costs of helium refrigerators and liquefiers based on a collection of existing systems, ranging from a few watts to 30 kW. They devised a simple formula[a] relating the cost C (in \$) to the refrigeration power R (in W)

$$C_{cap} = 12000 \left(\frac{\eta_{4.5K}}{\eta} R\right)^{0.7} \qquad (3)$$

$\eta_{4.5K}$ is the overall efficiency at 4.5 K.

These evaluations were mostly done for 4.5 K refrigerators of relatively small sizes. To take into account the additional needs for cold compressors while going to lower temperatures, a slightly modified formula will be used. The capital cost for one cryogenic system producing a refrigeration power R at temperature T will be taken as[b] :

$$C_{cap} = 3000 \left(3 + \frac{4.5}{T}\right) \left(\frac{\eta_{4.5K}}{\eta} R\right)^{0.7} \qquad (4)$$

If the accelerator requires an unusually large amount of refrigeration power, it will be assumed that the cryogenic plant is made of N identical cryogenic systems, each producing (1/N) of the total power.

$$C_{captotal}(R) = N \times C_{cap}(R/N) \qquad (5)$$

For APT, N = 3 will be taken. Although increasing the capital cost, this approach enables flexibility, enhances

[a] The factor has been adjusted to give the cryogenic power R in Watts.

[b] The temperature dependence should be theoretically already taken in account in the efficiency factor η. However, it will be assumed that the need for helium cold compressors will turn into additional costs higher than the efficiency ratios, taken here to increase linearly with (1/T). Whereas a lot of data points are available at 4.5 K, only a few are at 2 K (the most significant of these being CEBAF CHL).

availability, and relies on existing systems without requiring major technological developments.

2.3 Efficiency

The thermodynamic efficiency of the refrigerator system is roughly proportional to the ideal Carnot efficiency:

$$\eta_{Carnot} = \frac{T}{(T_a - T)} \qquad (6)$$

where T_a is the room temperature (generally taken as 310 K). Some systems can achieve up to 40% of Carnot efficiency. The efficiency goes up with size [3] and with temperature. If $\eta_r = \eta/\eta_{Carnot}$ is the ratio of the actual efficiency to the Carnot efficiency, the following approximate[c] formula will be used:

$$\eta_r = 0.035\ \mathrm{Ln}(R)\ \tanh(T/3) \qquad (7)$$

(In the case of a liquefaction mode, this efficiency is lower and has to be multiplied by a factor 75%±10%).
The overall efficiency will be:

$$\eta = \eta_r \cdot \eta_{Carnot} \qquad (8)$$

3 CRYOGENIC POWER REQUIREMENTS

The cryogenic power required is obtained by estimating the cryomodule heat loads which are the sum of the cavity losses plus a fixed heat flux amount (due to static losses, power couplers, transfer line losses, etc.). The latter losses (at the operating temperature T) are estimated for the time being to be around (10 W) per cavity in all cryomodules with an uncertainty of (± 5 W). Additional heat loads removed at the intercept temperature, assumed here to be 20 K, have to be added. Although these amount to roughly (80 W/cavity), they will play a minor role in the overall optimization and can be reasonably assumed to remain constant.

4 CAVITY LOSSES

Cavity losses will be the main item driving the optimization. The dissipated power in the cavity is :

$$P_d = \frac{V^2}{2R} = \frac{E_{acc}^2 l^2 R_s}{2(R/Q)\ G} \qquad (9)$$

where (R/Q) and G are both geometrical factors. E_{acc} is the accelerating field and l is the cavity accelerating length. Table I gives these numbers for the APT cavities. The surface resistance R_s can be calculated using the theoretical BCS value R_{BCS} (which increases exponentially with temperature) and adding a fixed residual resistance R_0 due to the residual static magnetic field, Q-disease, and surface impurities [4].

$$R_s = R_{BCS}(T) + R_0 \qquad (10)$$

[c] Ideally, this ratio should be almost constant. The variation with power is fitted from the curve given in [3]. The variation with temperature is extrapolated to other temperatures using a linear variation at low temperatures. The formula (7) used here is conservative.

The residual value is strongly dependent on the environment, as well as on the quality of the cavity niobium, fabrication, and preparation. An average value of (20 nΩ) will be taken with a uncertainty of ± (15 nΩ).

Table I - APT 5-cell Cavity Parameters

	E acc (MeV/m)	l (m)	(R/Q) (Ω)	G (Ω)
β = 0.64	4,8	0,685	85,7	151
β = 0.82	5,5	0,878	134,0	208

5 TOTAL HEAT LOADS

Considering the above uncertainties, three different cases are labeled as "average," "best," and "worst." The "average" case will be most likely observed in the actual accelerator, if all the steps and procedures are properly followed. The "worst" case will give the maximum heat load that will drive the total refrigeration capacity, whereas the "best" case would be the minimum that could possibly be achieved. Table II summarizes the heat loads in each case, from which the required power for sizing the refrigerator and calculating the operating cost can be deduced.

Table II - Residual Resistance and Non-cavity Losses in the Three Cases Considered. (All powers are in Watts)

	AVERAGE	BEST	WORST
Residual resistance R_0(nΩ)	20	5	35
Cryomodule losses /cavity	10	5	15
Total Losses (excluding cavities)	4100	2050	6150

6 RESULTS

Cost results will be given for the three heat loads cases: worst, average, and best. Most of the conclusions will be given using data from the average case.

6.1 Capital Cost

First, the "worst" case will be used to size the needed refrigeration power R (including a 50% margin). That will determine the total capital cost C_{cap}, using equation (5). This cost, together with the refrigeration power R, is shown in Figure 1 for temperatures ranging between 1.8 K and 3.0 K.

Based exclusively on capital cost, the temperature giving the lowest cryogenic plant cost is 2.70 K. But that minimum is very broad (any temperature between 2.10 K and 3.40 K would be within 15% of that minimum cost, while the formula used should not be trusted to that accuracy). An operation at 2.0 K would result in adding 22% (13.2 M$) over the lower cost.

6.2 Operating Cost

As expected, the operating cost, shown in figure 2, strongly varies with the cavity losses. There is a significant cost difference between the "best" and the "worst" case (it more than doubles at 2.0 K). This reflects

the importance of trying to increase the cavity quality factor Q. While the cost may widely change with cavity performance, there is no drastic variation of the optimum temperature. It increases from (2.00 K) in the best case to (2.50 K) in the worst, the average being (2.30 K). Again, this minimum is very broad and operating between (1.90 K) and (2.70 K) will only give less than 10% additional cost over the optimum.

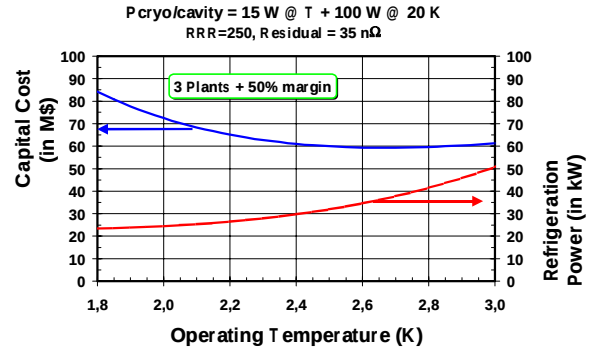

Figure 1 - Refrigeration power and capital cost as a function of the operating temperature.

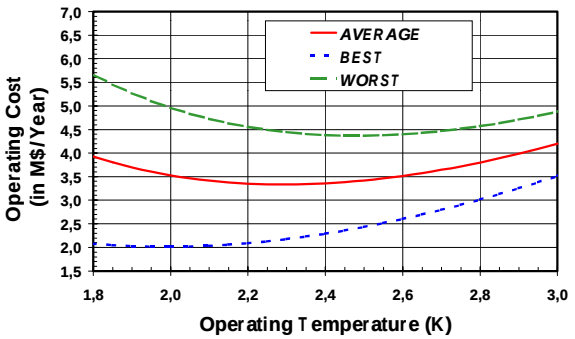

Figure 2 - Operating cost per year for the three cases considered.

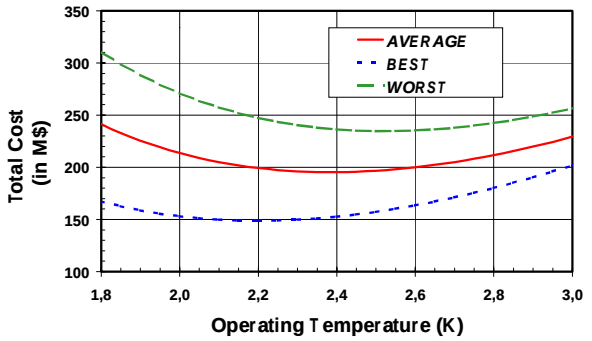

Figure 3 - Total cost for 40 years of operation.

7 TOTAL COST

The total cost is deduced by adding the capital to the operating cost integrated over the accelerator lifetime :

$$C_{Total} = C_{cap} + 40 \times C_{op} \qquad (11)$$

This total cost is plotted in Figure 3 as a function of temperature for the three cases. As expected, because the operation part amounts to 75% of the total cost, it will be driving the optimum temperature. The figures of the total cost (fig. 3) are very similar in shape to those shown in the preceding figure. The overall optimum temperature slightly shifts to higher values due to the lower capital cost. It moves from 2.20 K for the best case to 2.50 K for the worst, with a middle value of 2.40 K.

8 THE QUENCH FIELD

The above discussion implicitly assumes the cavities will reach the desired accelerating fields without any problem (no field emission, no quenches). But heat removal in a superfluid bath (He II at $T < T_\lambda = 2.17$ K) is much more effective than a normal liquid bath where nucleate boiling can occur that will limit the cavity performance at lower fields [5]. Boiling helium can also induce additional pressure vibrations that add to the microphonics induced in the SCRF cavities. This may result in a demand for additional RF input power which have to be carefully accounted for, as each additional 1% on the RF power is equivalent to adding 20% on the total cryogenic AC power. The expected quench field values in the normal fluid regime are around 50 mT as compared to more than 80 mT in superfluid helium. Therefore, superfluid operation can offer a much more comfortable margin in that respect. Moreover, the higher the helium temperature, the more heating one will have to extract from the RF surface, and the lower the quench field will be. This quench field issue is a very serious drawback that must be thoroughly addressed if operation above the λ point is decided.

9 CONCLUSION

The total cryoplant cost (including capital and operation) has been evaluated as a function of SCRF cavities temperature at a frequency of 700 MHz. The optimum operating temperature is found to be (2.4 ± 0.2) K. This optimum is broad and any operation between (2.0 K) and (2.8 K) would lead to less than a 10% excess cost. But operation in normal helium is risky, as performance may not even be achieved while gaining less than 3.5% on the total cost. Therefore, it is recommended that the operating temperature would be chosen in the superfluid helium regime (below 2.17 K).

AN ACCELERATOR-ASSISTED NUCLEAR FUEL ASSEMBLY FOR A FUTURE PROJECT AT KURRI

M. Inoue
Institute for Chemical Research, Kyoto University, Uji, Kyoto, 611-0011 Japan

Abstract

A nuclear fuel assembly assisted by a linear accelerator has been proposed as a future neutron source of the Research Reactor Institute, Kyoto University (KURRI). The injector linac provides 300 MeV, 0.3mA protons to produce neutrons by a spallation reaction. Final goal of this project is to multiply neutrons by a subcritical nuclear fuel assembly. This system is expected to bring new opportunities as a second generation neutron source at KURRI and also to play an important role in the basic studies of the future hybrid reactor.

1 INTRODUCTION

The Kyoto University Reactor(KUR) has been providing low energy steady neutrons since 1964 for various research fields such as reactor physics, nuclear physics, nuclear chemistry, biology and medicine. Strong requirements for high energy and pulsed neutrons have been arising up recently according to the advancement in each field. To meet the requirements, a "new neutron source" has been discussed in the working group of the future plan committee of KURRI. A combination of a proton accelerator and a nuclear fuel assembly is proposed as one of possible candidates.

2 INJECTOR LINAC

The primary particles to produce neutrons efficiently are high energy proton and deuteron which can be accelerated advantageously by a linear accelerator(LINAC) at high beam intensity[1]. In order to obtain intense neutrons, it is desirable that the reactor technology is effectively applied to produce neutrons in combination with a moderate size linac.

The project " Neutron Factory" is proposed. It is composed of a hybrid system of particle accelerators and a subcritical assembly. The outline of the system is shown in Fig. 1.

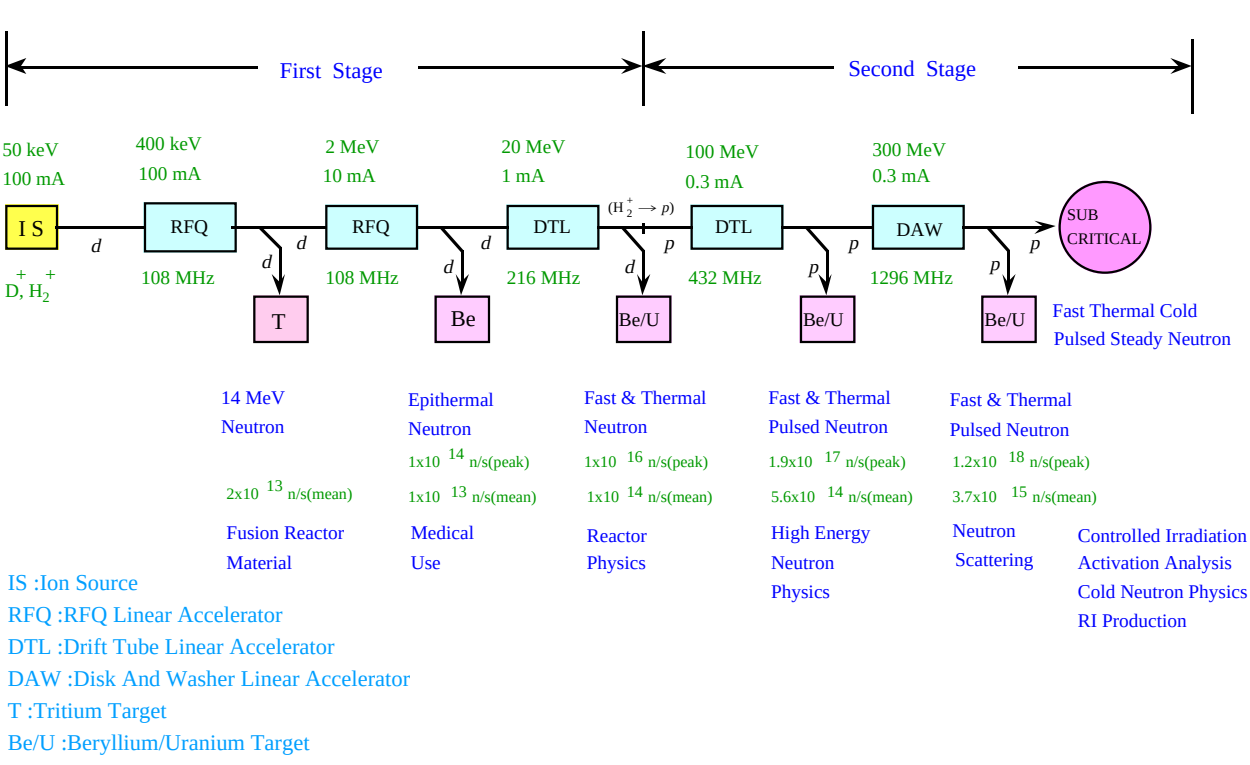

Figure 1: Block diagram of Neutron Factory

The brief report on this system has been given in Ref[2]. Deuterons or hydrogen molecules of 100 mA beam intensity extracted from a high current ion source are accelerated to 400 keV by the first RFQ . The beam energy is raised up to 2 MeV by the second RFQ at the 10% duty pulse operation. The drift tube linac(DTL) at 1% duty is employed to get the beam energy of 20 MeV . For the higher energy than 20 MeV, the proton acceleration is economical. Therefore, the 20 MeV H_2^+ beam which can be accelerated by the deuteron linac is stripped before the second stage DTL. Finally, we expect to obtain a proton beam of 300 MeV and 0.3 mA by a Disk and Washer (DAW) linear accelerator.

In each stage of the particle energy, every variety of neutrons become available as follows.

1) *14 MeV neutrons*

Among the neutron producing reactions, the (D,T) reaction has the largest cross section. It reaches 5 barns at 105 keV deuteron bombarding energy. By using 400 keV deuterons from the first RFQ, intense 14 MeV neutrons can be generated and used for the study on fusion reactor materials. Difficult problems arising from a large amount of tritium targets should be solved. For fusion reactor material irradiations, the ^{9}Be(d,n) reaction is also useful to produce neutrons with energy around 14 MeV by higher energy deuterons as proposed in the IFMIF project at JAERI.

2) *Epithermal neutrons*

The second RFQ generates about 3 MeV neutrons by the deuteron bombardment on the Be target. They can be moderated down to epithermal neutrons which are efficiently used for the BNCT. The fundamental study on the BNCT presently performed with thermal neutrons at KUR can be upgraded by utilizing high quality epithermal neutrons. To produce epithermal neutrons very efficiently, the p(^{7}Li,n) reaction by the 2.5 MeV proton is used at MIT[4]. Therefore, the 2.5 MeV proton beam by a small accelerator may be more favorable for medical use.

3) *High energy pulsed neutrons*

The 20 MeV deuterons obtained by the DTL linac can produce about 10 MeV pulsed neutrons by the ^{9}Be(d,n) stripping reaction. The DTL is operated at 1% duty and high energy neutron experiments such as the T.O.F. spectroscopy in reactor physics become possible.

4) *Intense pulsed neutrons*

The final energy and beam intensity of the primary particles are planned to be 300 MeV and 0.3 mA, respectively, which allow the mass production of high energy neutrons by a spallation reaction. We can expect the neutron intensity of 1.2×10^{18} n/s at peak and 3.7×10^{15} n/s in mean, which enables neutron scattering experiments such as the structure analysis of condensed matters.

5) *Neutrons for material irradiation*

The final goal of the Neutron Factory project is to inject spallation neutrons into a subcritical assembly to multiply them safely and efficiently. Details of the target system are studied preliminary for a simple case[3]. Intense neutrons can make great evolution in research fields such as precisely controlled irradiation of materials and the cold neutron physics which require much more neutrons than presently available at KUR.

An example of design parameters for proposed linacs is summarized in table 1. A conservative design is proposed by a working group as shown in table 1 in which higher energy section uses RF of 216 MHz and 432 MHz. The Disk-And-Washer(DAW) type is considered as an alternative design.

The deuteron beam with energies lower than 20MeV enters the Kyoto University Critical Assembly(KUCA) to be used for test experiments on the subcritical neutron target. At the 300 MeV terminal, a new target system of a subcritical nuclear fuel assembly is constructed to obtain intense neutrons for material irradiation and neutron scattering experiments.

Table 1 The example of design parameters for linacs.

	RFQ1	RFQ2	DTL1	DTL2	DTL3*
Particle	H_2^+,D^+	H_2^+,D^+	H_2^+,D^+	H^+	H^+
Energy(MeV)	0.4	2	20	100	300
Mean current(mA)	100	10	1	0.3	0.3
Duty(%)	CW	10	1	1	1
Frequency(MHz)	108	108	216	216	432
Cell number	90	67	78	138	329

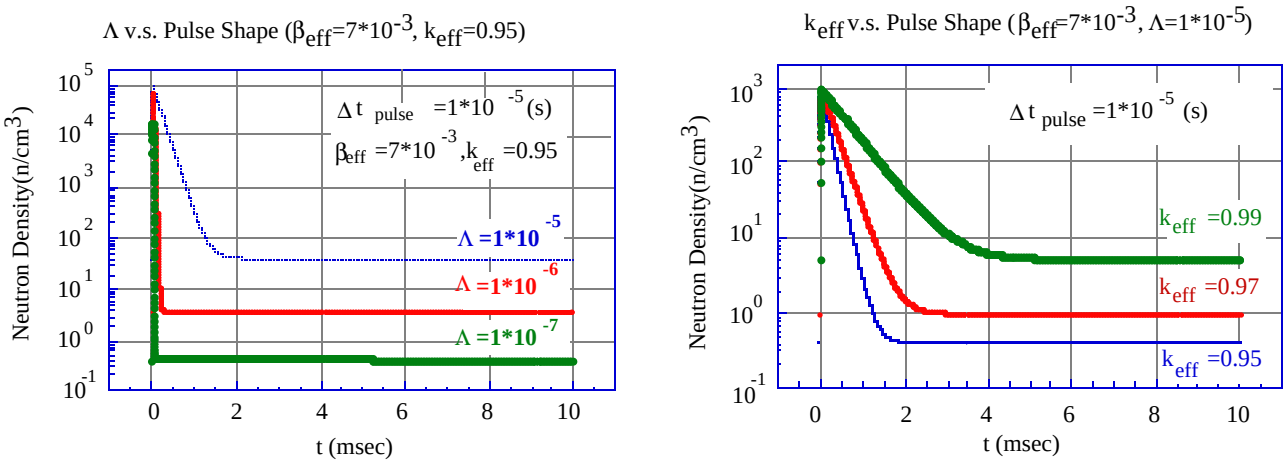

Figure 2: Dependence of the neutron pulse shape on k_{eff} and L at the equilibrium state.

3 NEUTRON PULSE SHAPE IN HYBRID REACTOR

Neutronics design calculations were carried out to obtain information on a hybrid system[3]. We report here some results of preliminary studies on the neutron pulse shape in the "hybrid" reactor calculated by the one-point reactor kinetics with an external source. It is well known that the neutron pulse shape strongly depends on values of k_{eff}, the effective delayed neutron fraction β_{eff} and the neutron generation time Λ.

Figure 2 shows the dependence of the neutron pulse shape on k_{eff} and Λ at an equilibrium state, when 100 neutron pulses with a density of 10^{10} cm^{-3} s^{-1} and a width of 10^{-5} s are introduced into the system per second. From this figure, it was found that the signal-to-noise (S/N) ratio of the neutron pulse, which is defined as a ratio between the peak and the background levels, becomes larger with reduced values of Λ and k_{eff}, whereas the peak level is maintained approximately at the same level. The decay of a neutron pulse becomes faster with reduced values of Λ and k_{eff}. The effect of β_{eff} on the decay of a neutron pulse was also investigated and was found to be remarkable when k_{eff} approaches to unity. For the neutronics design of the "hybrid" system, one should be careful that Λ and β_{eff} depends on k_{eff} on the basis of the reactor physics theory.

More detailed studies are required for the design of planned subcritical assembly. This can be performed in the first stage of the “Neutron Factory “ project by using the pulsed neutrons generated by the 20MeV linac.

4 SUMMARY

In order to offer opportunities to utilize high energy pulsed neutrons as well as low energy steady neutrons, the KURRI has started toward the realization of a multipurpose neutron source assisted by particle accelerators. The nuclear hybrid system itself is very interesting and worthwhile because it involves many technical subjects in both accelerator technology and nuclear engineering. We hope that this proposal will be discussed and polished up by those who are interested in neutrons, accelerators and nuclear systems.

At the moment there are not problems of fundamental nature in CW proton linac construction with energy of 1 GeV and current of 30 mA. That is why the main problems have economic and technical aspects [1,2]: high economic efficiency (total electric efficiency >50 %), its reliability and radiation purity, linac design have to permit modernization with changing of beam performances demanded, linac design has to apply perspective methods and materials tested in actual practice.

The most expedient way of obtaining of such proton beams is acceleration in linear accelerator with superconducting (SC) accelerating resonators .

The scheme of CW proton and negative ion of hydrogen linear accelerator (LAP) with energy of 1 GeV and current up to 30 mA with superconducting accelerating resonators (SCR) in the main part is shown in Fig.1.

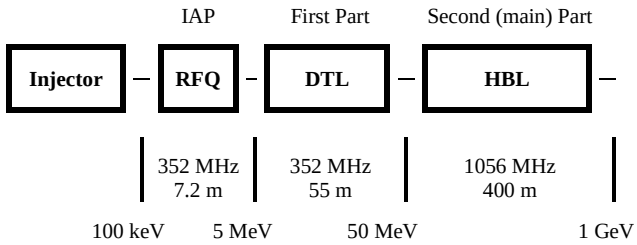

Fig.1.
1 GeV, 30 mA CW linac scheme.

The following main statements are used in its design.

1. Reliability: low voltage injector; low beam losses; CW mode; decreased number of RF channels.

2. Economic efficiency: superconducting cavities in the main part of linac; short length because of high accelerating rate.

3. Radiation purity: beam losses are not more than 10^{-4} [3] because of acceptance reserve of accelerating-focusing channels.

4. Linac consists of three parts. Initial part - RFQ structure, accelerating field frequency f_1 = 352 MHz. First part - three DTL resonators, frequency f_1 = 352 MHz. Main part - accelerating structure consists of 248 nine-cell axially symmetric cavities with elliptical shaped cells excited at the frequency f_2 = 1056 MHz.

Odd frequencies ratio $f_2/f_1 = 3$ allows if necessary to simultaneous acceleration of protons and negative hydrogen ions.

The main parameters of linac are presented in the Table 1. The parameters will not change for the case of acceleration of hydrogen negative ion beam.

The RF system and automatic control system are proposed as classic linac. For decrease of number of RF channels the possibility of excitation of several (6-2) SCR in main part by one RF amplifier is considered. Klystrons are used as RF amplifiers (1.3 MW klystrons - in initial and first parts, 400 kW klystrons - in main part).

In order to provide superconductivity in the SCR, its surfaces by layer are cooled to 2K by liquid helium. The total thermal power removed by helium is 5 kW.

Module of the main part of the linac with two SC cavities and PM quadruple lens is shown in the Fig.2.

Codes of LIDOS.Advisor package [4-7] were used for beam dynamic calculation Main problem is to prevent particle losses in high-energy accelerator part. Two main dangerous effects leaded to increase transverse beam size would be set: influence of phase motion on transverse one and random errors (within the limits of tolerances) in tuning and installations of channel elements. First effect is peculiar features of superconductng channel. In ordinary “warm” channel influence of phase motion on transverse one is weak effect, but in this case this influence is rather high because of high amplitude of accelerating field. This effect is most conspicuous in high-energy accelerator part with low (50-100 MeV) particle energy

High Beta Linac (HBL) part of LIDOS.Advisor package makes it possible to determined channel main parameters, demanded tolerances for elements installation, to reveal influence of various factors on beam parameters in the channel and at accelerator output. Initial and final particle energy, distribution of accelerating field amplitude and equilibrium phase along the accelerator, emittance, current are specified as initial information. Mean-squared errors of position of focusing lens ends, focusing fields, rotation of lens median axes, amplitude and phase of accelerating fields are used as additional initial data. Based on these data, channel random realization are calculated and statistic characteristics of beam parameters are derived. Simulations on the base of LIDOS.Advisor.HBL show that mismatching factor of transverse beam sections increases to the boundaries of

Table 1

Parameter	Initial Part	First Part	Second Part
Type of accelerator, resonator	RFQ	DTL	9-cell resonators
Injection energy, MeV	0.1	5	50
Output energy, MeV	5	50	1000
Frequency of accelerating field, MHz	352	352	1056
Number of resonators	1	3	248
Period of focusing, m	$\beta\lambda$	$2\beta\lambda$	$14\beta\lambda$
Acceptance, specified,π cm·mrad	0.27	2.0	2.0
Effective emittance, specified, π cm·mrad	0.1-0.15	0.15-0.3	0.3-0.4
Equilibrium phase, degree	-(40÷35)	-30	-30
Phase width, degree	360÷36	36÷20	60÷20
Pulse spread at output, %	0.32	0.1	0.04

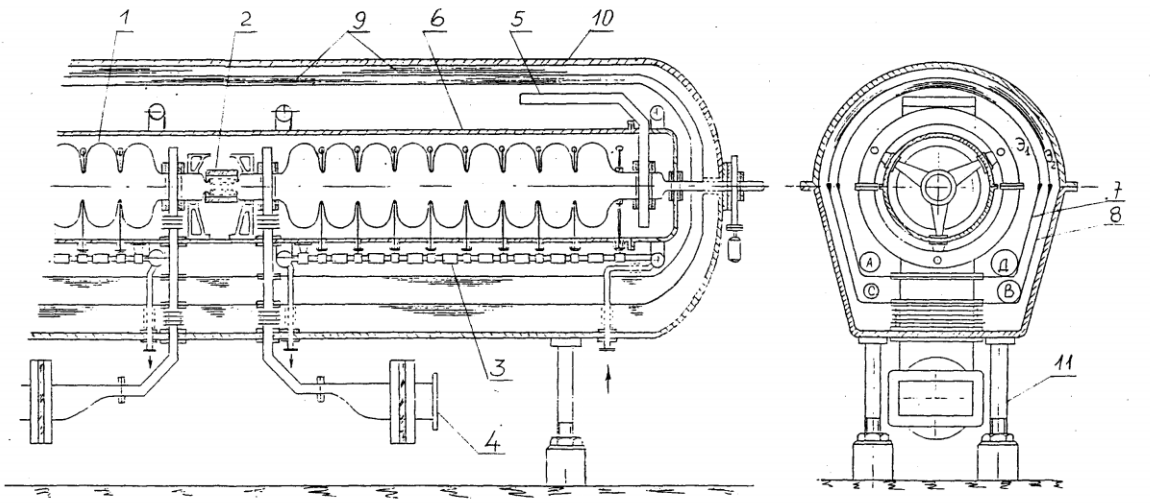

Fig.2.
Module of the main part of the linac with two SC cavities and PM quadruple lens.
1 – accelerating cavity; 2 – permanent magnet (PM) quadruple lens; 3 – nickel bar with cavity frequency fine-tuning elements; 4 – RF input; 5 – loading for high mode suppression; 6 – helium vessel; 7 – heat screen; 8 – radiation screen; 9 - superisolation; 10 - cryostat case; 11 – supports with adjusting devices; A, B, C, D – helium flow system

longitudinal oscillation separatrix up to the 1.8 – 2 in the considered case. If beam phase width at the channel beginning is 50^0, than maximal mismatching is 1.5. Beam phase characteristics at the accelerator output for the channel without disturbances and superposed beam phase portraits obtained with 50 channel random realization are shown in the Figs.3,4.

Phase width of initial beam is 50^0. Initial data were as follows: error of cavity field amplitude – 1%, error of cavity phase – 1^0, transverse displacement of quadruple lens ends – 50 mkm, error of magnetic field gradient in the lenses – 1%, rotation of lens median axes – $0{,}5^0$. Statistic characteristics of beam parameters obtained in 50 random realization are shown in the Fig.5.

Results analysis shows that because of influence of longitudinal phase oscillations and under the influence of random errors transverse beam size with high confidence coefficient will not exceed 5.5 mm. In this case the size of matched equilibrium section in the channel without errors is 3 mm.

BREMSSTRAHLUNG PAIR-PRODUCTION OF POSITRONS WITH LOW NEUTRON BACKGROUND*

E. Lessner, M. White
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

Minimization of component activation is highly desirable at accelerator-based positron sources. Electrons in the 8- to 14-MeV energy range impinging on a target produce photons energetic enough to create electron-positron pairs; however, few of the photons are energetic enough to produce photoneutrons. Slow positron production by low-energy electrons impinging on a multilayer tungsten target with and without electromagnetic extraction between the layers was studied by simulation. The neutron background from 14-MeV electrons is expected to be significantly lower than that encountered with higher-energy electron beams. Numerical results are presented and some ideas for a low-activation slow-positron source are discussed.

1 INTRODUCTION

Slow positrons are widely used in materials science and solid state physics research. Positron annihilation techniques are used to characterize vacancy-type defects in metals and alloys. Very low energy positrons are ideal probes for surface crystallography due to their shallow penetration and weak scattering with the atomic ion core.

The use of the Advanced Photon Source (APS) linac beam as a source of slow positrons has been investigated for incident electron beam energies between 200 and 400 MeV [1], [2]. Accelerator studies indicate that the electron linac is capable of producing about 13kW of incident beam power [3]. Simulation studies to optimize the target indicate that for those incident-electron energies, a high slow-positron yield can be obtained.

Activation of components in the area near the target is a potentially serious problem at positron sources. Component activation can be reduced if the input beam energy is low enough such that the cross section for photoneutron production is still quite low, yet high enough to create electron-positron pairs. In this paper, we study the production of slow positrons using electrons with energies between 8 and 14 MeV.

Monte Carlo simulation results of low-energy electrons impinging on a multilayer tungsten target are described. Positron production rates with and without electromagnetic extraction between target layers are compared. Some ideas for a low-background positron source are discussed.

2 CHOICE OF ELECTRON BEAM ENERGY

Several factors influence the choice of the incident electron beam energy for a slow-positron source with minimal neutrons. One factor is the efficiency with which the incident beam creates positrons, the other is the neutron yield. For high productivity, most of the incident electron beam should penetrate the target. The number of backscattered electrons increases exponentially with decreasing electron energy, as can be seen in Fig. 1. As shown in the figure, there is essentially no backscattering for energies above

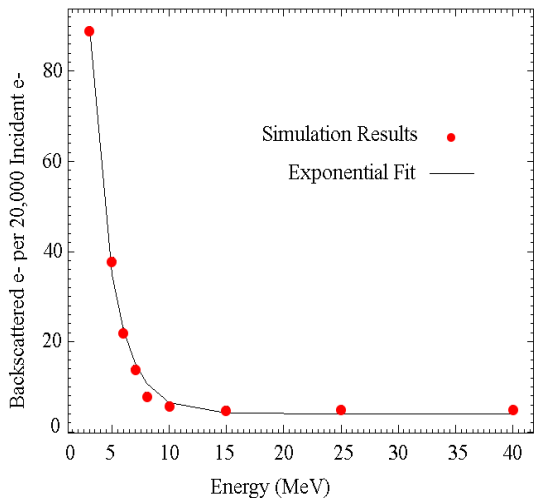

Figure 1: Number of backscattered electrons versus incident beam energy with a superimposed exponential fit.

8 MeV. At 3 MeV, about 0.5% of the incoming particles are backscattered, thus reducing overall efficiency. In our simulations, we chose an energy range between 8 and 14 MeV for the primary electron beam.

The neutron yield per incident electron in a high-Z target is low for energies below 14 MeV. The photoneutron cross-section for tungsten is about 400 mb for 14-MeV photons and becomes negligible for photons of 6-MeV energy and lower [4]. For one radiation-length-thick targets, measurements indicate that there are 2.5×10^{-4} neutrons per 14-MeV electron [5]. Shown in Fig. 2 is the photon energy distribution from 20000 14-MeV electrons impinging on a 1.2-mm tungsten target. An energy cutoff of 1.0 MeV

has been applied to the distribution prior to histogramming. Photons below 1.0 MeV are incapable of e^+e^- pair production. The distribution peaks at 1.5 MeV and has a standard deviation of 2.4 MeV. Less than 9×10^{-2} photons per electron have energies greater than 6 MeV.

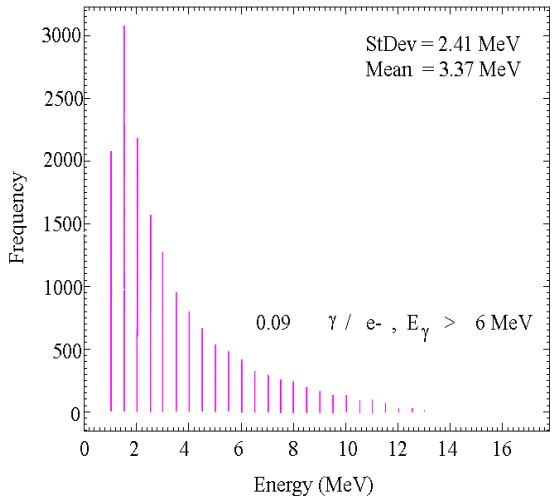

Figure 2: Photon energy distribution from 14-MeV electrons on a 1.2-mm tungsten target.

3 SIMULATION RESULTS

Our simulations were performed with the program EGS4 [6], together with a C-language user-interface code, "shower" [7]. We studied the positron-production efficiencies of single-block and multilayer targets at several energies. Optimized multilayer targets are able to produce more positrons than single-block targets for a fixed incoming beam energy. For multilayer targets, we examined the production rates with and without electromagnetic extraction between target layers.

The forward positron production as a function of single-block tungsten target thickness is shown in Fig. 3 for 8-MeV and 14-MeV electrons. For the higher-energy beam, the production peaks around target thicknesses of 2.5 mm. The production from the 8-MeV beam roughly follows a similar curve. The variations seen in the figure are within the statistical fluctuations of the Monte Carlo process. The number of positrons increases by a factor of 4.5 for a 1.75 increase in beam energy. For target thicknesses greater then 2.5 mm, many positrons are lost in the material decreasing the yield.

Figure 4 shows the forward positron production for a three-layer tungsten target of 1.2-, 0.6-, and 0.6-mm-long segments, respectively. The incident electron beam energy is 14 MeV.

In the figure, circles indicate the number of positrons produced when no electromagnetic field is applied between layers, and squares indicate the production when electromagnetic extraction is applied. In the latter simulations, the total output lepton distribution from each segment was removed and only the photon distribution was used as input to the simulation of the following segment. This possibly leads to an underestimation of the positron count after the second and third layers. In practice, energetic electrons would not be removed by the applied field, though the total beam divergence would be increased, and they could contribute to the positron creation through bremsstrahlung. As shown in the figure, photons produce 68% of the total positron count in the second segment, and 89% in the third segment.

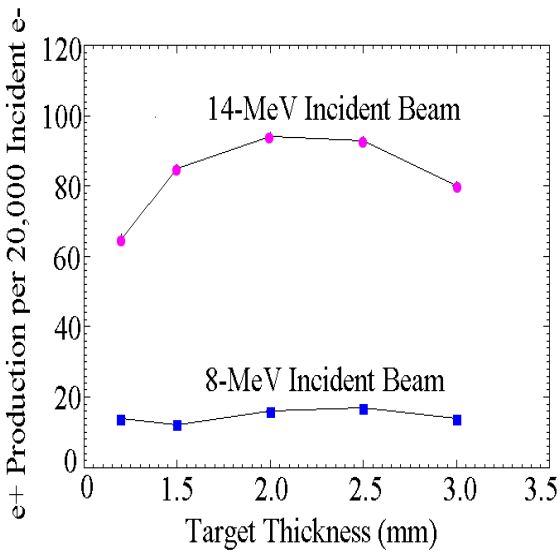

Figure 3: Positron production as a function of target thickness for two electron energies.

We used our high-energy simulation results as a guide to optimize the multilayer target for a 14-MeV incident beam. Specifically, we analyzed the positron production as a function of target thickness and the output electron and photon mean energy variations to determine the optimal segment thicknesses of a multilayer target. At 400 MeV, the best target configuration is a 10.5-mm-long, five-layer target. The 10.5-mm length is determined by the optimized single-block target length.

The highest production differentials between layers occur when there is a 25% variation in thickness from the first to the second layer and none or a small variation in thickness between the last two layers. The output electron mean-energy change from layer to layer is also a factor. Yield is best when the energy decreases by about 50% in the first two layers, and by 30% to 10% in the last layers. These observations, together with the single-block target results at low energies, led to a three-layer target with segment thicknesses of 1.2, 0.9 and 0.9 mm, respectively, as a candidate for an optimized low-energy target. Further simulations showed that the positron production is in-

creased by 26% when the last-segment is 0.6-mm long. For the optimized 1.2-/0.9-/0.6-mm target, the total number of positrons whose energies are $\leq$ 6 MeV is 1.3e$\times 10^{-2}$ per incoming 14-MeV electron.

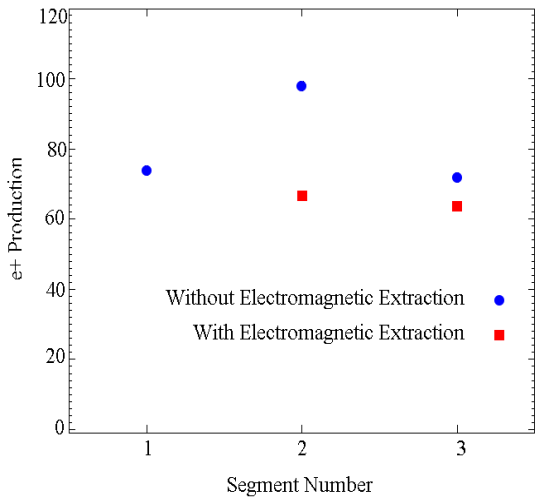

Figure 4: Comparison of the number of positrons produced by 14-MeV electrons on a three-layer target, with and without electromagnetic extraction between layers.

4 OPTIONS FOR A LOW-ENERGY POSITRON SOURCE AT APS

The linac's DC thermionic electron gun has been supplemented by a thermionic rf gun [8], and additional thermionic and low-emittance photocathode rf guns will soon be installed. These guns will be able to handle the task of storage ring injection, thus allowing the DC thermionic gun to be used for other purposes.

The DC gun is currently being re-packaged for greater space efficiency. The gun, together with its buncher and accelerating structure, could be located in the linac tunnel under the rf photocathode gun girder. Assuming good beam optics, at least 13 kW of beam power could still be obtained at 150 MeV. If used to produce a low-energy, high-power beam, the gun and its associated rf structures could operate semi-independently of the APS. The bunchers and accelerating structure could receive rf power from the output load of one of the linac accelerating structures. We estimate that the linac could produce a few kW of beam power in low-energy mode. Available beam power in such a low-energy machine could be significantly increased by changing from pulsed to CW operation, and using superconducting rf structures.

5 CONCLUSIONS

A slow-positron source with reasonable slow-positron yield and with a relatively low neutron background could be constructed. For an incident 14-MeV electron beam, we estimate that a flux of 10×10^{7} positrons per second can be achieved, assuming a conservative moderation efficiency of 10×10^{-3}.

Plans are now underway to measure the positron and slow positron yields at another local facility with beam characteristics similar to what we have considered in this paper. Use of low-energy electrons to drive a slow positron source has the advantage that it could be a semi-independent setup. Various configurations for such a source have been investigated. Some options allow operation of the slow positron source in parallel with other APS operations, while operation of other configurations is more constrained.

An additional advantage of the low-energy driver is that extraction and guide voltages for the unmoderated positrons can be lower, since they are produced at lower energies. The disadvantages are lower positron production rates per incident electron. The beam power and thus the positron production rate can be improved by increasing the electron current. At high power and low energy, target ablation will likely be a problem. Detailed thermal analysis must be carried out, and careful monitoring of the target and support structures must be envisioned.

THE KEK-PF SLOW-POSITRON FACILITY AT A NEW SITE

T. Shidara, T. Kurihara, A. Shirakawa, A. Enomoto, H. Kobayashi, K. Nakahara
KEK, 1-1 Oho, Tsukuba-shi, Ibaraki-ken, 305-0801, Japan

Abstract

The KEK-PF slow-positron facility was relocated to the 1.5-GeV point of the upgraded electron/positron injector linac relevant to the KEKB project. A dedicated linac for slow-positron use is also installed utilizing the remnants of the injector linac reformation. We expect a slow-positron intensity of more than 100 million positrons/sec with a maximum primary beam power of 1 kW for their application in various fields of solid-state physics.

1 INTRODUCTION

The KEK slow-positron facility, aiming at the use of slow-positron beams (ranging from eV to keV) in various fields of solid-state physics, was constructed. A slow-positron flux of $1x10^8$ positrons/sec was successfully achieved [1, 2] utilizing our 2.5-GeV electron linac [3, 4] with a 2.0-GeV, 2-kW primary electron beam power.

Although we had opened this facility to slow-positron users [5, 6], we had to relocate our facility relevant to the upgrade plan of the KEK 2.5-GeV linac. There are two major goals of the upgrade [7, 8]: 1) to increase the energy of electrons and positrons to 8 and 3.5 GeV, respectively, and 2) to increase the bunch intensities of positrons by roughly one order. In accordance with this upgrade plan, we must relocate our KEK-PF slow-positron facility to the 1.5-GeV point of the upgraded linac (the KEKB J-linac).

2 LAYOUT OF THE RELOCATED KEK-PF SLOW-POSITRON FACILITY

There are two primary-electron-beam sources for our slow positron facility; the 1.5-GeV beam of the KEKB linac and the test linac. The nominal beam power of the 1.5-GeV beam is 0.75 kW (an energy of 1.5 GeV, charge of 10 nC/pulse, a pulse length of 10 ps and a pulse repetition rate of 50 pulse/s). A dedicated linac for slow positron use only (the test linac) was installed utilizing the remnants of the J-linac upgrade plan. An average beam power of 1 kW can be expected from the test linac. A slow-positron intensity of more than 10^8 positrons/sec is easily expected in both cases.

Figure 1 shows the relocated KEK-PF slow-positron facility, which locates at the 1.5-GeV point of the KEKB J-linac. It comprises beam lines for the primary electron beams, a target-moderator assembly, a slow-positron beam-transport line and relevant assemblies.

The primary electron beam is injected into the target. The extracted slow-positron beam is directed by a 30-m long beam-transport line with an axial magnetic field of 100 G to an experimental area. Twelve sets of steering coils were installed along the slow-positron beam-transport line in order to adjust the slow-positron beam trajectory. A high-voltage station capable of applying 60 kV was installed in order to vary the energy of the positron beam. A device controller, combining a personal computer and a programmable sequence controller through optical fiber, has been adopted to control the monitors and power supplies at a high-voltage potential. Penning-trap electrodes are also installed at this station in order to make a dc beam from a pulsed beam.

At an experimental area, a slow-positron beam switch system, which comprises a pair of beam deflecting coils and two pairs of Helmholtz coils with magnetic-field directions crossing each other, was installed. This system enables us to direct slow-positron beams to several experimental stations one by one without breaking the vacuum.

As for experimental equipment, a transmission-type positron microscope, a positronium time-of-flight (TOF) apparatus, and a 2D-ACAR (two-dimensional angular correlation of annihilation radiation) equipment are now being prepared.

3 PRESENT STATUS

All components of the KEK-PF slow-positron facility were relocated. The accelerating structures and necessary magnets of the test linac have already been installed in the linac tunnel.

The commissioning of the slow positron beam was started from this April. We have already achieved a slow-positron intensity of more than 10^7 positrons/sec utilizing the 1.5-GeV J-linac beam as its primary beam source. Utilizing this positron beam, the 2D-ACAR equipment was checked and adjusted.

4 FUTURE PLAN

If we reinforce its primary beam source by adding other two accelerating units to the present test linac, we will be able to achieve a beam power of 6 kW from the upgraded test linac. This enables us to produce more than 10^9 positrons/sec in our slow-positron facility.

5 SUMMARY

The KEK slow-positron facility was relocated to the 1.5-GeV point of the KEKB J-linac relevant to the KEKB project. A dedicated linac for slow-positron use is also installed utilizing the remnants of the KEKB J-linac

upgrade plan. We have already achieved a slow-positron intensity of more than 10^7 positrons/sec utilizing the 1.5-GeV J-linac beam as its primary beam source and we expect more than 10^8 positrons/sec with a maximum primary beam power of 1 kW.

ACKNOWLEDGMENTS

The authors are greatly indebted to the Director General, Prof. H. Sugawara as well as to the staff of the KEK administration department for their encouragement and continuous support of this slow-positron project. They should also express their gratitude to prof. Y. Kimura, the director of the Institute of Materials Structure Science and to Prof. M. Kihara, the director of the Accelerator Laboratory, KEK, for their support. The staff of the KEK electron/positron linac is also gratefully acknowledged for machine operation and support.

FARADAY CUP MEASUREMENTS OF THE PLASMA PLUME PRODUCED AT AN X-RAY CONVERTER*

T. Houck, M. Garcia, and S. Sampayan
Lawrence Livermore National Laboratory, Livermore, California 94550 USA

Abstract

The next generation of radiographic machines based on induction accelerators is expected to generate multiple, small diameter x-ray spots of high intensity. Experiments to study the interaction of the electron beam with the x-ray converter are being performed at the Lawrence Livermore National Laboratory (LLNL) using the 6-MeV, 2-kA Experimental Test Accelerator (ETA) electron beam. The physics issues of greatest concern can be separated into two categories. The multiple pulse issue involves the interaction of subsequent beam pulses with the expanding plasma plume generated by earlier pulses striking the x-ray converter. The plume expands at several millimeters per microsecond and defines the minimum transverse spacing of the pulses. The single pulse issue is more subtle and involves the extraction of light ions by the head of the beam pulse. These light ions might propagate at velocities of several millimeters per nanosecond through the body of the incoming pulse resulting in a moving focus prior to the converter. In this paper we describe Faraday cup measurements performed to quantify the plasma plume expansion and velocities of light ions.

1 INTRODUCTION

Radiographic machines based on induction accelerators produce an intense x-ray spot by focusing a short pulse of high current electrons onto a high Z material. Nominal parameters for the electron beam could be 50-100 ns pulse width, several kiloamperes, and 10-20 MeV. Producing a small and stable (constant diameter and position) x-ray spot is essential for radiographic imagining. The electron beam quality has been considered the limitation on the quality of the x-ray spot. For example, the emittance of the beam determines the smallest focus spot, and energy variation combined with transport focusing misalignments produces beam motion. Continuing advancements in induction accelerator technology has improved beam quality to a level where the interaction of the beam with the converter may be the limitation for the next generation of radiographic machines. Two areas of concern are the emission of light ions [1] that can "backstream" through the beam due to space charge potential, and interference between the beam and the plasma generated by previous pulses during multiple pulse operation.

*The work was performed under the auspices of the U.S. Department of Energy by LLNL under contract W-7405-ENG-48.

An on-going experimental program at LLNL is studying the interaction of an electron beam with the x-ray converter [2]. The goal is to quantify the effects of the plasma plume generated at the interaction on the initial and subsequent beam pulses, and to develop an appropriate x-ray converter configuration. Below we report on measurements from faraday cups incorporated into the experimental setup to characterize the plasma plume and determine the existence of backstreaming light ions.

2 EXPERIMENTAL LAYOUT

The faraday cups were comprised of two, electrically isolated, concentric cylinders as illustrated in Fig. 1. The inner cylinder could be biased up to 1.2 kV with respect to the grounded outer cylinder. Two geometries were used. The forward cup (refer to Fig. 2) had an OD of 5 cm and an aperture of 1.9 cm while the back cup had an OD of 1.3 cm and an aperture of 0.4 cm. The low ratio of aperture to cup length was to minimize the escape of secondary electrons generated by the impact of the positive ions with the inner cylinder. The forward cup was located about 25 cm from the beam/target intersection at an angle of 30° from the beam axis. The back cup was located about 5 cm from the intersection point and 75° from the beam axis. As shown in Fig. 2, the cups were situated at the entrance and exit, respectively, of a solenoid operating with an on-axis peak field of approximately 3 kG.

The inner cup discharged to ground through the 50 Ω input of an oscilloscope, permitting the rate of charge interception (current) to be measured. The sensitivity of the cups to ion density, assuming single ionization, is:

$$n_{\min} = \frac{I_{\min}}{Aev} \text{ , where} \qquad (1)$$

$n_{\min}$ is the minimum density, I_{min} is the minimum detectable current, A is the aperture area, and v is the ion velocity. For the forward and back cups, and for a nominal v of 5 mm/μs, $n_{\min}$ is $2\text{x}10^{8}$ cm^{-3} (I_{min} was 40 μA) and $5\text{x}10^{10}$ cm^{-3} (I_{min} was 480 μA), respectively.

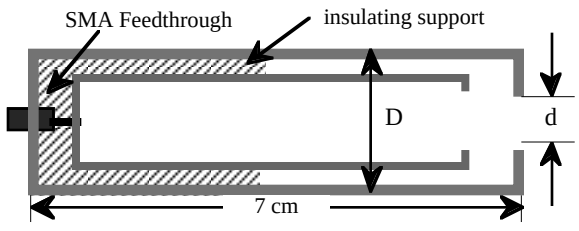

Figure 1: Schematic of the Faraday cup.

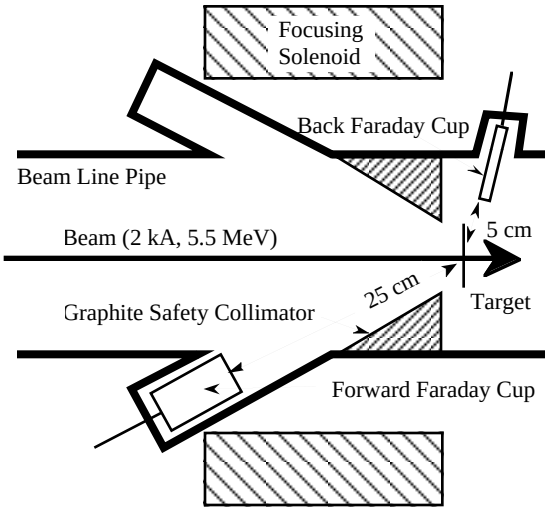

Figure 2. Schematic showing relative positions of the faraday cups with respect to the beam line and target.

The x-ray converter was comprised of a rotating wheel that held several "targets" to permit multiple shots before the x-ray converter had to be replaced. The majority of data was taken for tantalum targets of three thicknesses; 1 mm, 0.25 mm, and 0.1 mm. In addition, 1 mm thick stainless steel and 0.25 mm tungsten targets were used.

3 MEASUREMENTS

The faraday cup measurement consisted of the current (voltage) measured at the input (50 Ω termination) of an oscilloscope. See Fig. 3 and 4. Information that could be estimated from the measurements, with qualifications, included velocity, density, and beam radius. A third faraday cup was located approximately 50 cm upstream of the converter and recessed to avoid exposure to the plasma plume. This cup was directed at the beam line and served as a background reference for the other cups.

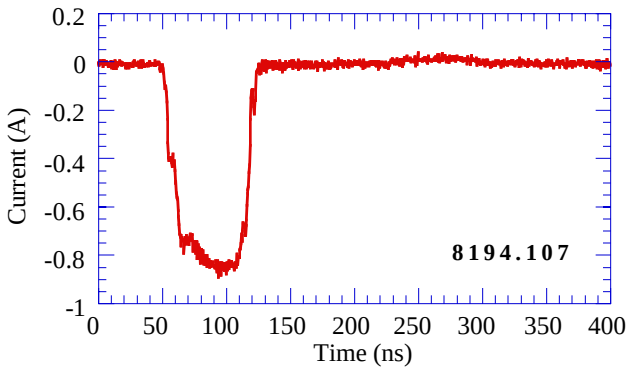

Figure 3. Typical output from the forward faraday cup.

3 .1 Prompt Signals (< 1 μs)

A large signal was generated by the faraday cups during beam passage. A typical signal from the back cup is shown in Fig. 3 and displays the same pulse shape as the beam current monitors installed on the beam line. The small positive signal between 250-300 ns was caused by cable reflections. The forward cup produced a similar signal, but a factor of 10 to 20 smaller in amplitude.

Estimates for the energy and density of extracted ions from the target are > 250 keV and 10^{12} cm^{-3} near the x-ray converter [3,4]. For protons, this equates to a velocity of 7 mm/ns and currents of 20-100 mA at the faraday cups. However, the signals would arrive within 50 ns of electron beam passage. Numerous comparisons were made of signals at the cups with and without the x-ray converter installed to discern such a signal with no success.

3 .2 Plume Velocity

Typical signals from the back and forward cups are displayed in Fig. 4. The back cup tended to have a single peak although the signal to noise ratio could have masked some features. The forward cup signal normally exhibited two peaks with the amplitude of the first peak varying from about 10% to over 130% of that of the second peak.

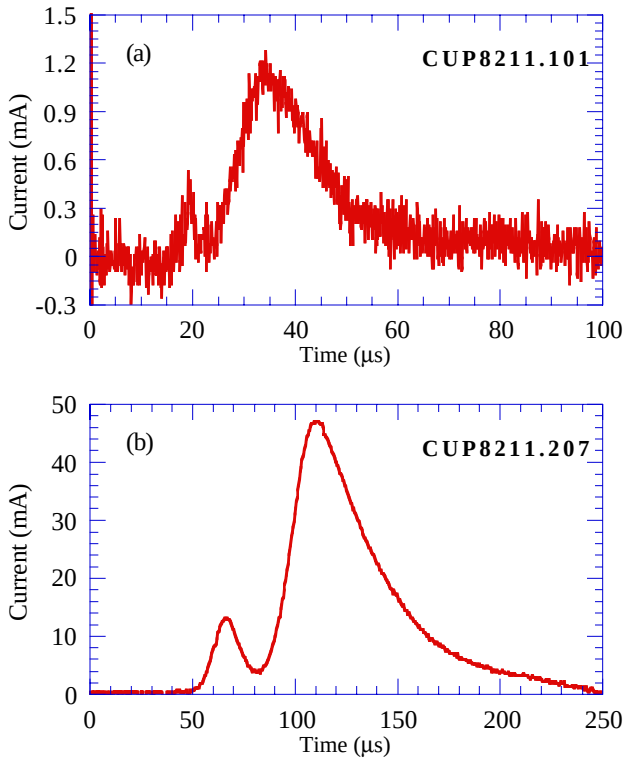

Figure 4. Typical output signals from the (a) back and (b) forward faraday cups. Beam interaction with the converter (1 mm thick Ta) occurred at time 0.

An estimate of the velocity can be made by assuming that the plasma was ejected promptly at beam time and quickly reached terminal velocity. With these assumptions the velocity would be simply the distance to the respective cup divided by arrival time at the cup after beam passage. The velocity can be related to spot size assuming a self-similar, isentropic expansion of a spherical gas cloud:

$$v = 1.64\sqrt{\frac{2E}{m}} = 2.32\sqrt{\frac{dE/dz}{\pi r^2 \rho}}, \text{ where} \qquad (2)$$

E is the energy deposited into a mass m by the beam, dE/dz is the rate of energy deposition along the axis, r is the radius of the beam spot, and ρ is the mass density. While approximate, eq. (2) indicates that the velocity should vary inversely with spot size and be insensitive to target thickness. In Fig. 5, the velocity of the leading edge of the plasma plume at the forward cup (25 cm/ time of arrival) is plotted as a function of x-ray spot size for two thicknesses of Ta targets. The x-ray spot sizes shown for the 1 mm targets were measured using the roll bar technique [5] while for the 0.25 mm targets a higher resolution pin hole camera [6] was used. Eq (2) was in general agreement with measured velocities and spot sizes.

The plume velocity measured at the forward cup consistently was faster than measured at the back cup. For the distances that the cups are located from the target, the plasma plume could be expected to be expanding approximately spherically. Thus, the velocity should not be strongly dependent on the angular locations of the cups with respect to the beam. A second explanation suggested by Fig. 6, a plot of the velocity ratio between the cups as a function of target thickness, is that the beam diameter expands during transit producing a larger spot size on the back surface. Ratios are shown for the leading edge and for the peak signal.

3 .3 Plasma Density

Equation (1) can be used to crudely estimate the plasma density. Current in the Faraday cups is the combined effect of the collection of ions and electrons, and of the ejection of electrons in reaction to ion impact. Heavy ions like Ta with kinetic energy of several eV are quite likely to eject electrons on striking metal surfaces. Escape of secondary electrons increases the current signal and collection of plasma electrons lowers the current signal. Attempts to bias the inner cylinder did not produce significant changes to the cup signal. Probably of more importance is the orientation of the cup with the magnetic field lines of the focusing solenoid. The forward cup was positioned such that the magnetic field would tend to preclude the flow of electrons into or out of the cup. However, the orientation of the back cup would enhance flow. The heavy ions would not be significantly affected. The relative long length of the back cup to its aperture should minimize the escape of secondaries, with the net result of a low estimate of the density at the back cup.

Table 1: Estimated density (10^{10} cm^{-3}) at faraday cup.

Ta thickness	1 mm	0.25 mm	0.1 mm
Forward Cup	30	5	1
Back Cup	50	100	30

4 SUMMARY

No evidence was found for fast, backstreaming, light ions. However, the plasma plume was found to expand at 3-4 mm/μs (peak density) with a leading edge velocity of 7-8 mm/μs in agreement with theoretical models.

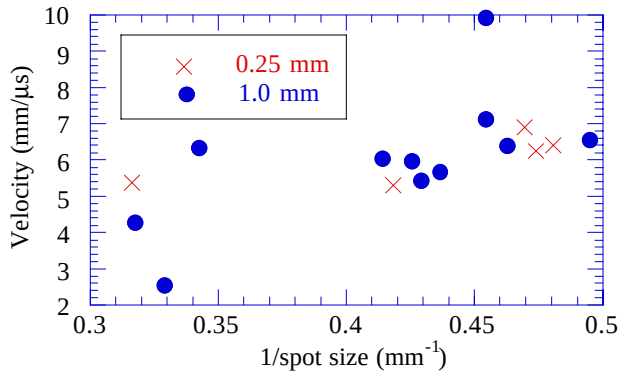

Figure 5. Velocity of the leading edge of the plume for Ta targets of two thicknesses as a function of spot size.

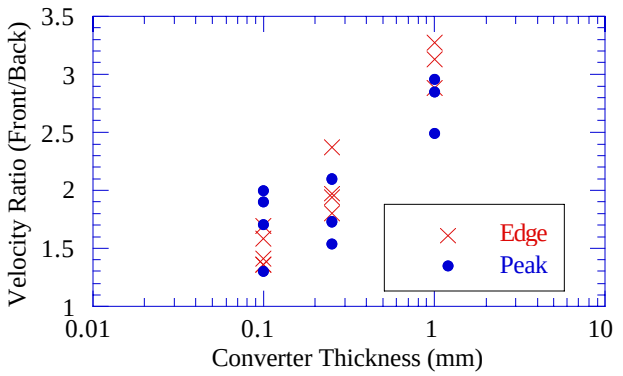

Figure 6. Ratio of the plume velocity at the forward and back faraday cups as a function of target thickness.

5 ACKNOWLEDGMENTS

We thank Phil Pincosy, Y-J Chen, Darwin Ho, and George Caporaso for their helpful explanations of the physics of the interaction. Cliff Holmes constructed the faraday cups. John Weir and the ETA crew provided the accelerator and experimental support.

Abstract

As part of the Dual Axis Radiographic Hydrodynamic Test Facility II (DARHT II) and Advanced Hydrotest Facility (AHF) programs, we have began investigation of the possible adverse effects of (1) backstreaming ion emission from the Bremsstrahlung converter target and (2) the interaction of the resultant plasma with the electron beam during subsequent pulses. These effects would primarily manifest themselves in the static focusing system as a rapidly varying x-ray spot. To study these effects, we are conducting beam-target interaction experiments on the ETA-II accelerator (a 6.0 MeV, 2.5 kA, 70 ns FWHM pulsed, electron accelerator). From these experiments and the multiple diagnostics we have implemented, we are able to determine spot dynamics and characterize the resultant plasma for various configurations. Our data to date shows the first effect to be minimal. We report on the details of our experiments and our preliminary experiments to study the second effect.

1 INTRODUCTION

We are presently working on Linear Induction Accelerator (LIA) based radiography projects under the US Department of Energy (DOE). These projects, known as the Dual Axis Radiographic Hydrodynamic Test Facility II (DARHT II) and the Advanced Hydrotest Facility (AHF), are an element of the DOE's strategy of science based stockpile stewardship (SBSS). This program focuses on assuring the safety and reliability of the nuclear weapon stockpile without underground testing. The DARHT II is presently being built at Los Alamos National Laboratory and it is planned that AHF will be built at the Nevada Test Site. Both are national facilities optimized to address weapons issues with minimal environmental impact. The DARHT II machine is a multi-pulse, single-axis flash radiography machine. The AHF machine is a multi-pulse, multi-axis flash radiography machine designed for full 3D imaging. These machines are being designed to be capable of taking a sequence of closely spaced radiographic images so as to produce a time sequenced image of the test object.

On AHF, the process of producing these radiographic images consists of generating a 10-15 shot burst of electron beam pulses at a 1 MHz repetition rate. Each electron beam pulse is approximately 20 MeV energy, 6 kA current, and 200 ns long. These pulses are further chopped into a series of 50 ns sub-pulses and are redirected through a series of magnets to converter targets at each axis. The 20 MeV electron beam impacting the converter target generates an intense x-ray cone which produces a radiographic image on a fast detector array.

The converter target consists of an 0.5-1 mm thick tantalum or tungsten foil. The electron beam is focused to <1 mm and allowed to impinge on this target to create the x-ray pulse. Two effects are of concern. As the electron beam interacts with the target surface, a plasma quickly develops. As the beam electrons creates a strong space charge field in front of the target, ions can be extracted and accelerated in a direction opposite to the electron beam prorogation. These ions partially neutralize the beam space charge and defocusing of the beam results.

The second effect results from the direct interaction of electron beam with the target plasma on subsequent electron pulses. Such an interaction, depending on the interaction length and plasma density, may have an adverse effect on the beam propagation and the resultant spot on the converter target.

Our on-going experimental program at LLNL is to study the interaction of the electron beam with the x-ray converter target. In these experiments, we focus on the dynamics of the spot behavior using optical transition radiation (OTR), measuring x-ray spot blur across an edge (so called "roll-bar" technique), and a gated, multiframe, imaging pinhole camera. Further, we are characterizing the properties of the plume by using Faraday cups, interferometers, and a gated spectrometer. We report on our progress thus far.

2 EXPERIMENTAL

The overall layout of the experiment is shown in Fig. 1. Imaging instruments consist of gated, image intensified cameras for observation of Optical Transition Radiation (OTR) from the target surface. Ion diagnostics consist of multiple Faraday cups to observe plasma velocities and to obtain estimates of the plasma density. In addition, to resolve the spatial extent of the plasma as a function of time, an interferometer cavity imaged onto a fast gated or streak camera was implemented. An 0.5 m gated spectrometer allows observation of target optical

emissions for species identification and inference of plasma temperature.

As the principal objective of our experiment is to observe the dynamic behavior of the x-ray spot, we have implemented one method of direct observation of the beam spot and two methods to observe the x-ray spot. The first method of observation of the x-ray spot is with a so called "roll-bar" technique. This technique infers spot size from the blur across a hard edge. The second method is by the use of a time resolved x-ray pinhole camera. This latter device consists of tungsten pin-holes imaged onto an x-ray photocathode and amplified with a gated micro-channel plate (Fig. 2). The camera we are using creates 6 sequentially gated images so as to produce a 6 frame movie of the hard x-rays produced from the target interaction during the 70 ns (FWHM) beam pulse. Calculations show optimum sensitivity of the camera to be from 1-2 MeV with a 20% decrease at 5 MeV.

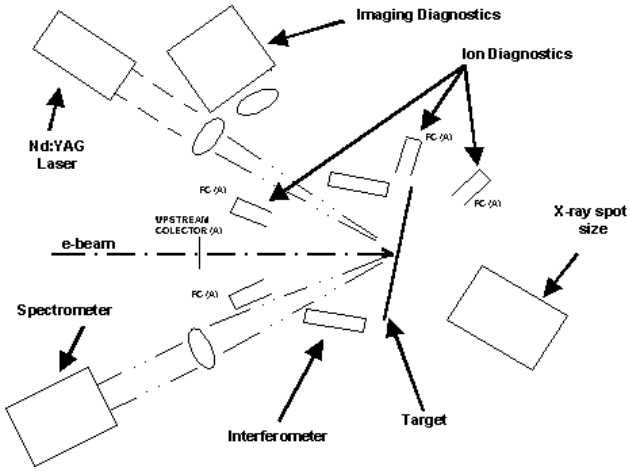

Figure 1. Target experiment layout

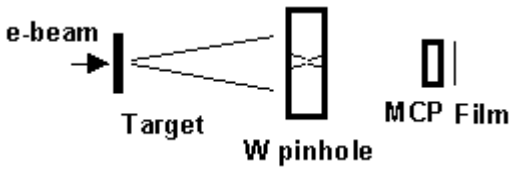

Figure 2. X-ray pinhole camera.

To simulate the effect of a high repetition rate multipulse, we have implemented an 0.8 J Nd:YAG laser focused on the target. The laser beam can be positioned and timed so as to produce a plasma of sufficient density so as to simulate target debris as would encountered in a mutipulse electron beam system.

3 RESULTS AND DISCUSSION

Results from the Faraday cup measurements indicate a plasma velocity dependence on spot size, beam parameters, and target thickness [1]. No evidence was found for fast, backstreaming, light ions. The plasma plume was found to expand at 3-4 mm/μs (peak density) with a leading edge velocity of 7-8 mm/μs in agreement with theoretical models.

Target emissions as measured with the spectrometer showed evolution of a prompt line spectra evolving to a black-body like spectra with a peak at about 600 nm when integrated over 8 μs after beam time.

Observations of OTR did not show strong promise as a radius diagnostic when used in conjunction with converter materials of interest (Ta and W). Calculations show that energy deposited into the target at these fluences elevates the material temperature in excess of 1 eV within 4 ns. As a result, prompt thermal radiation with a decay exceeding 1 ms results and observation of a time varying spot becomes difficult. The radiation is so intense and spectrum sufficiently broad that even with the inclusion of high quality short wavelength pass filters in the optical chain, extraction of the OTR signal was not possible.

Roll bar measurements were also performed. As scatter and depth of field issues can reduce the system resolution, a significant effort was necessary to optimize the trade-off between scintillator thickness (used in conjunction with a gated or streak camera for imaging) and pixel noise. Never-the-less, system resolution was limited from 0.75-1.5 mm. Correlation was also attempted with the OTR images under identical accelerator tuning conditions. Generally, we observed reasonable correlation (order 50%) between these measurement techniques. Additional reporting of this data is contained in a separate paper [2].

Figure 3 shows a representative sample of image data from the x-ray pinhole camera [3]. In this particular data, the orientation of the target was changed from 15° off normal (top) to normal incidence (bottom).

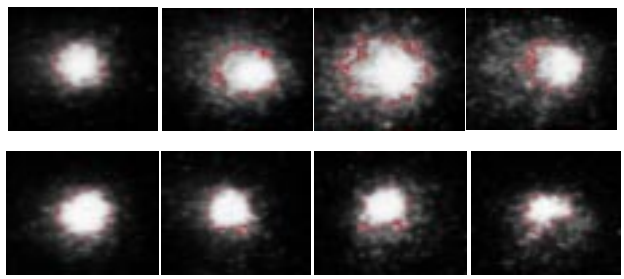

Figure 3. Time resolved x-ray spot comparison between 15° off normal (top) and normal incidence (bottom).

The top images were taken with the target at 15° off normal show expansion and filamentation of the beam. Gate time of each image is approximately 6 ns and spacing between images is 7-10 ns.

This effect can be explained by the asymmetric foil focusing forces which occur at the target as result of the angled target. The lower images, taken with the beam at

normal incidence with all other remaining conditions identical, show an almost constant spot diameter. An intensity profile through the center of other similar images taken at a 1 mm spot diameter (FWHM) and 1.4 kA are shown in Figure 4. Again, these data show an almost constant spot radius with a variation of approximately 25%. Shown with these data, is the expected expansion of the spot resulting from backstreaming H^+ ions. From this comparison, we have concluded that backstreaming ion defocusing is not a strong effect with these beam parameters.

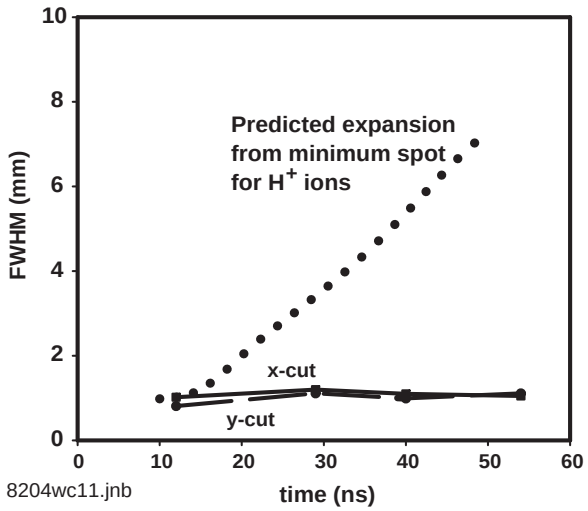

Figure 4. Time resolved images of x-ray spot (6 ns gate time, 10 ns intervals).

Figure 5. Spot expansion resulting from a laser induced plasma.

Initial data from the interaction of the electron beam with a laser induced plasma is shown in Figure 5. The beam maintains a 1 mm (FWHM) core and the 2σ threshold expands from 1.5 mm to 12 mm (last frame). With this particular data set, the laser was fired at approximately 100 ns before beam time and co-located with the electron beam position on target. Faraday cups indicate an expansion velocity of approximately 5 cm/μs and density at the Faraday cup (spaced 24 cm from the target) of 2 x 10^{10} cm^{-3}. Combing these data indicates an interaction length of 0.5 cm and an inferred density within that region of 5 x 10^{18} cm^{-3}. Initial analysis of the data shows this behavior is dominated by a backstreaming ion affect.

To minimize the interaction of the plasma with the beam, we are considering dynamic targets in our baseline development program. Such a technique will provide fresh target material pulse-to-pulse and also add a transverse component to the plasma so as to inhibit a direct beam-plasma interaction.

The dynamic target delivery scheme required study of several relatively mature technologies: high velocity fly wheels, shape charge jets, and both the burning propellant and compressed gas driven versions of high performance guns, i.e., light gas guns..

The fly wheel offers a significant advantage over all of the other methods because it does not need to be synchronized with other hardware in the system or the test object. Velocities are limited to 5 mm/μs, however. Shape charged jets offer the advantage of a very short cycle time for the total operation of injection of the target material. They also can reach the required velocities but work is required to create the necessary target crossection. Gas guns have the capability for deliver of materials with the velocity required to meet the replenishment need of the radiography systems. Velocities of 8 mm/μs, consistent with the target requirements, are not uncommon from these guns and some research guns are proposing speeds of nearly a factor of 2 faster Calculations have been performed with a basic two-stage system and indicate that a total system jitter for the gun will be 1.5 μs for a gun operated in the 5 mm/μs range.

4 SUMMARY

We have described our ongoing experiments to determine the effects for a multipulse Bremsstrahlung converter target used for radiography. An ion backstreaming and plasma interaction effect have been defined as the two of the most predominant mechanisms which could degrade the focal spot on the target. The first effect was studied, no obvious effects were found. Study of the second effect was initiated and appeared to be dominated by an ion effect. Alternative target systems are being studied to minimize this second effect.

RF POWER DISTRIBUTION AND PHASING AT SSRL INJECTOR LINAC

Sanghyun Park
Stanford Linear Accelerator Center, P.O. Box 4349, Stanford, California 94309, USA

Abstract

At the Stanford Synchrotron Radiation Laboratory injector linac, each of three linac sections was powered by an XK-5 klystron for 5 years starting from 1990. The RF power from the second klystron was then branched out to drive the thermionic RF gun. Due to dwindling performance of XK-5's, two of them were replaced by one SLAC type 5045, which powered the RF gun and the first two linac sections. In the summer of 1997, the linac system was further modified to have one 5045 power all three sections and gun. During this process a 5dB waveguide directional coupler was developed, and RF phasing was done by cold tests and by beam-based tuning of the waveguide network at full power. The remaining two XK-5's are currently being utilized at the Gun Test Facility located in the injector linac vault to drive a photocathode gun followed by a linac.

1 INTRODUCTION

The SSRL Booster synchrotron[1] accelerates a bunch of 10^9 electrons from 100 MeV to 2.3 GeV at the rate of 10 bunches per second, which is limited by the White circuit, before it is injected to the SPEAR storage ring. When the stored beam current reaches 100 mA, the beam energy is ramped to 3 GeV for user run.

In order to maximize the injection rate in terms of mA/min, it is very important to maintain a shot-to-shot reproducibility and a long term stability of the linac beam energy, which is proportional to the square root of the RF power. To this end, all the DC voltages applied to the klystron (focusing magnet and core bias) and modulator (PFN and thyratron reservoir) are regulated through switching or linear power supplies. Constant voltage transformers stabilize the AC power to the klystron cathode and thyratron heater.

The beam voltage and the input RF power is selected in such a way that $\delta P_O/\delta P_I = 0$ when the beam voltage stays constant (output power saturation). In general, higher klystron beam voltage requires less RF input power for the RF output power to saturate. Therefore, one sets the beam voltage first and adjusts input RF power level by a PIN diode-based attenuator until the klystron output is saturated. If the power is not right for the desired linac beam energy, the klystron beam voltage is changed and the process is repeated.

Another factor that affects the beam energy is the temperature at the gun and linac. For them to stay tuned at the operating frequency of 2.856 GHz, there are two systems that supply temperature controlled water (TCW); one for the gun and the other for linac that operates in different temperature range from the gun. The temperature regulation is better than 0.1^{O}F in both systems. Considering the thermal expansion coefficient of copper at $1.7\text{x}10^{-5}$ / ^{O}C, the resonance frequency of both structures remains unchanged within 3 kHz.

2 RF POWER DISTRIBUTION

When 4 linac sections are powered by one klystron, which is the case with the SLAC main linac, the RF power from the klystron is divided evenly twice by three of 3-dB hybrids so that each section is driven by equal level of RF power. When the number of linac sections to be driven is three, the power needs to be divided by 1:2 ratio, then the main line is evenly divided by a 3-dB hybrid. This is how the SSRL injector linac is powered by a single klystron.

The power branching ratio of a 3-dB hybrid is 1:1, and deviation from the design value is usually very small. Any other coupling between 3 and, say, 15 dB requires multi-hole narrow wall coupler. While it is possible to achieve precision coupling in calculations, errors from the process of machining make it very hard to predict what the actual coupling would be.

Therefore, the sequence of building a high power waveguide directional coupler is to choose a design of smaller coupling. For example, if a 5-dB coupler is to be made, choose a 7-dB coupler, duplicate the coupling strip of some 10 pairs of holes. Then clamp the two waveguide pieces together, with the strip inserted in between. Take data on coupling and phase delay at the main line and coupled port. In order to increase the coupling, the width and/or the length of all the holes are to be made larger. One repeats the process of mechanical modification of the coupling holes and cold tests until the coupling is within the tolerance. The final stage is to braze all the components together. As it turns out, the

brazing process does not alter the RF characteristics of a directional coupler very much.

The heart of a multi-hole directional coupler is the coupling strip. A sketch of it is shown below. The most important dimensions are A (6.016 in.= λ_g), B (=λ_g/4), and C (= 0.600 in.).

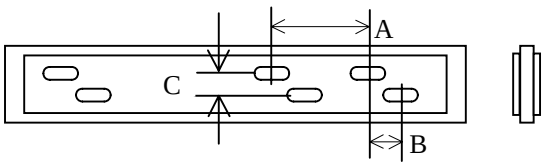

Figure 1: A coupling strip for a multi-hole narrow wall waveguide directional coupler. Only three pairs are shown for clarity. The endview is shown at the right.

This copper strip has overall dimension of 1.686 in. width, 21.632 in. long, and 0.375 in. thick. The mesa on either side is 0.086 in. above the middle part, and is to be mated with the waveguide. The holes are 0.3 in. wide rectangles, ending with a semi-circle at the ends. Each has overall length of about 1.5 inches. Typically, there are 10 pairs. If this number is reduced, directivity is also lowered. With the dimensions A, B, and C remaining the same, the hole size determines the coupling coefficient.

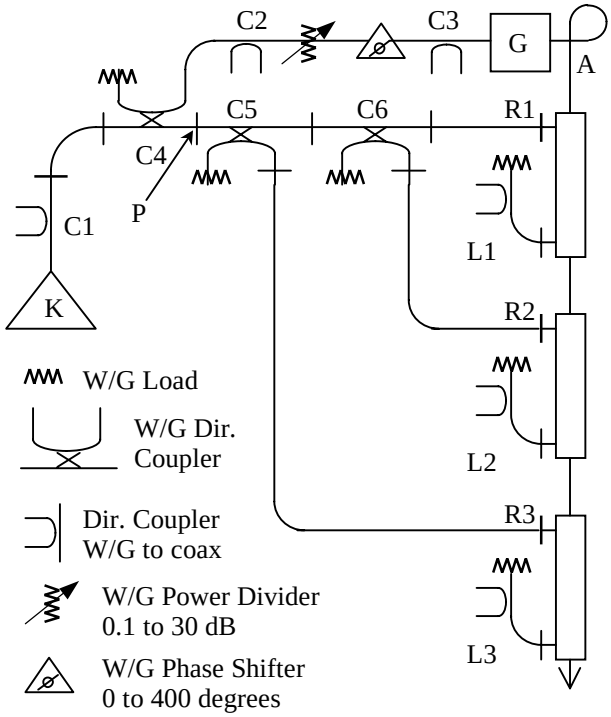

Figure 2 : The system layout of the S-band RF power distribution at the SSRL injector linac including the RF gun (G). The klystron (K) is a SLAC type 5045. The directional couplers C1 and C3 are for the power level monitoring, and C2 at 37 dB coupling is to drive another klystron, such as XK-5, for the Gun Test Facility. [2]

In the Fig.2, C4 has 8.5 dB coupling. The coupled out power is reduced by the power divider and drives the RF gun (G) at about 2 MW. The thermionic electrons bunches at about 2 MeV are compressed from about 100 ps to about 1 ps or shorter by the alpha magnet (A). At this point, there are about 3000 bunches. In order to minimize the beam loading to the linac, all but 4~5 bunches are diverted to the beam dump by the chopper (not shown). C6 in Fig.2 is a 3-dB hybrid.

The C5 measured coupling was 5.21 dB at 2.856 GHz. For the best efficiency, this should have been 4.77 dB, or exactly 1:2 branching ratio. Assuming that L1~L3 are all perfectly phased, and ignoring any parasitic losses, the energy gain by the linac is given by

$$\Delta E = 10.7\left(\sqrt{rP} + \sqrt{2P(1-r)}\right)$$

where ΔE is in MeV, r is the branching ratio at C5, and P is the RF power in MW at the C5 input. At 5.21 dB, r is $10^{-0.521}$ = 0.301 and ΔE = 117.1 MeV at 40 MW. At the same power, if r is 1/3 (4.77 dB), energy gain is 117.2 MeV. As one can notice from this example the energy dependence on the C5 coupling coefficient is very weak. If r<1/3, more power is available at the first two sections. If it is more, then the third section adds more to the total gain while the first two add less. Therefore the coupling requirement is then 4.8±0.5 dB.

3 RF PHASING BEWTEEN LINACS

As has been shown in the previous section, the linac energy is insensitive to how the power is divided up to drive each linac section. When it comes to the phasing, one has to be extra careful to maximize the energy at a given RF power. Here the gun is out of the picture for two reasons: one is that at about 2 MeV, the initial energy out of the gun is only a small perturbation to the total energy of the beam, which is steered into the booster synchrotron. The other is that the gun RF power is adjusted in amplitude and phase by the power divider and the waveguide phase shifter, as shown in Fig. 2.

The three linac sections are aligned to a straight line passing through the electrical centers of each. They are separated from each other by $34\lambda_0$ longitudinally, which is 140.510 inches. Then the requirement for maximum acceleration is that the RF phase must be the same at all three RF input ports. Therefore the phase lengths from the C5 input (P in Fig.2) to the L1~L3 input have to be adjusted to make them the same.

In a straight section, male (female) Skarpaas flange adds 0.641 (0.559) in. to the tip-to-tip copper waveguide length, including one half the thickness of copper gasket. In waveguide directional couplers, 3-dB hybrids, H-mitres, H- bends, and E-bends, the path length is very different from geometric length. Therefore the phase

length of each individual component must be measured with a vector network analyzer in the air, to arrive at the side arm length of a U tube at the final leg of the waveguide network. Of course the vacuum inside gives rise to mechanical deformation of the waveguide that leads to a change in path length, but it is small enough to ignore in the first order.

Once all the parts are fabricated and assembled, the entire network of waveguide from C5 to male flanges for RF input to each linac sections was moved by one inch away from linac. Then modulator flanges[3] were inserted, and entire network starting from the point *P* to linac sections L1~L3 was pumped down to about 1 torr. This flange is about 0.5 inch thick. One side is Skarpaas male and the other female for vacuum seal. It has germanium diode at the center of broad side. When it is reverse biased at –20V at 1 kHz it causes total reflection.

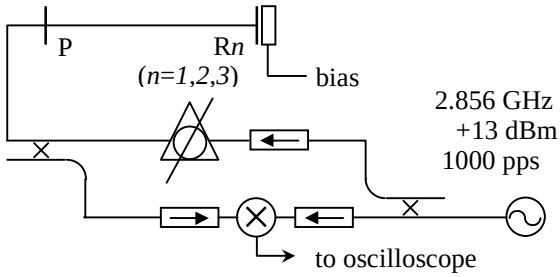

Figure 3 : Circuit diagram for phase measurement of the reflected wave, for P to R*n* path lengths.

By adjusting the phase shifter, the mixer output can be made zero. If the phase shifter setting is $\phi 1$ for n=1, the difference in phase readings shows the phasing error of each branch. The error correction is done by squeezing the waveguide wall. The guided wavelength of RF is

$$\lambda_g = \lambda_0 / \sqrt{1-(\lambda_0/2a)^2}$$

where a =2.840 in. is the inside dimension of broad wall. By squeezing the narrow wall to make a smaller, the guided wavelength λ_g is made longer. If broad wall is squeezed, it forces the narrow wall to bulge out resulting in a shorter λ_g. This procedure is performed using a C-clamp while monitoring the null on oscilloscope. The accuracy of this method is better than $\pm 4^o$ of RF phase.

At the conclusion of the process above, it was found that one modulator flange was inadvertently reversed in direction. After the commissioning, additional efforts were made to correct the error caused by the mistake. Hardware was assembled around the waveguide inside the linac vault, to have it squeezed by hydraulic jacks operated from the outside, while the system is up to full power. The assembly consists of two pairs of steel bars (one inch square, 12 inches long, and tapered 3 inches both ends), aluminum holder, two hydraulic jacks, two dialed indicator gauges, and a TV camera to read the gauges. For better reliability and safety, a phase bridge was made to monitor incremental phase as shown below.

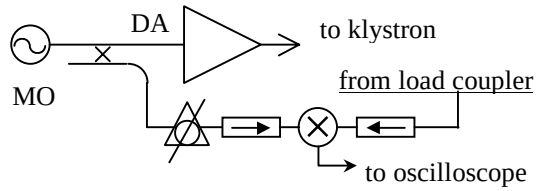

Figure 4: Linac incremental phase monitor. The master oscillator (MO) has +14 dBm cw output. The drive amplifier (DA) has 7μs pulse length at 10 Hz.

The manual phase shifter was set to produce a null reading. Then setting was changed by 2.856^o, to be nulled by squeezing the waveguide remotely. At every step of phase correction, the linac beam energy was measured by a bending magnet. The ΔE plot against $\delta\phi$ was close to a sine curve. At the end, the energy gain from the phase correction was peaked at 2.5 MeV.

4 CONCLUSION

The linac system has been modified to have one klystron drive the RF gun and all three linac sections for improved stability and reliability. A 5-dB coupler was produced for the purpose. Now it became possible to design and fabricate precision high power directional coupler of any coupling coefficient through interpolation of existing designs and analyzer measurements prior to assembly. RF phasing between klystron and linac sections was accomplished locally at low power (20 mW), and remotely at full power (40 MW), to achieve highest possible linac beam energy for a given klystron output power.

5 ACKNOWLEDGEMENT

This work was supported by US DoE through SLAC AIP project. Technical supports from SSRL Vacuum, MSG, and EDM groups are gratefully acknowledged. Contribution from J. Weaver has been indispensable. The author regrets to announce that he passed away on 2 July 1998 after more than two years of illness.

Abstract

Large masses of magnetic core material are required for many of the induction accelerator-based projects currently under study; the quantities required exceed 10^7 kg for a linear heavy-ion fusion driver, so core performance and cost are critical issues. We have evaluated cores of amorphous alloys from AlliedSignal and MRTI (Moscow Radio Technical Institute) and nanocrystalline alloys from Hitachi and Vacuumschmelze. The cores were of moderate size, between 1 and 11 kg. We characterized the materials in terms of the flux swing ΔB from $-B_{remanent}$ to $+B_{saturation}$, and the energy loss versus dB/dt. We found sources for each material that could coat, wind, and then anneal the cores. This required the development of thin coatings that withstand 350-550° C anneal temperatures. The result is core performance near the ultimate small sample performance of each material, with higher ΔB and lower losses than the earlier approaches of using as-cast material or rewinding after anneal, in both cases usually cowinding with thin mylar (~4μm thick). We are beginning system code studies of tradeoffs between ΔB and losses.

1 INTRODUCTION

In a previous paper[1] we showed that tape wound magnetic induction cores, processed by annealing after winding, produced superior performance to cores wound of as-cast material and not annealed, or to cores wound with previously annealed material. Annealing after winding is advantageous both to gain the full flux swing, and to wind while the material is still ductile. With annealing after winding, we achieved performance near the ultimate small sample performance[2]. The major technical challenge in annealing cores after winding is providing an interlaminar insulation[3], that reduces eddy current losses at high magnetization rates. The insulation must withstand annealing temperatures the order of 360° C without applying mechanical stress to the amorphous metal ribbon, and must meet other requirements related to cost, lifetime and packing fraction which have been described in greater detail [1]. Two insulation techniques were used, mica paper in ribbon form of 18 μm thick, and inorganic coatings of <1 μm thick.

In this paper, we extend the previous work with measurements on cores manufactured from alloys produced by four manufacturers: the amorphous alloys 2605SC and 2605SA1 from AlliedSignal (USA), 9KCP, 30KCP, 2HCP, and 7421 from Amet (Russia); and the nanocrystalline alloys FT-1H from Hitachi (Japan), and VitroVac 800 from Vacuumschmelze (Germany). The 2605SC was insulated with mica paper, wound and annealed by LLNL (USA) [1]. The other materials were coated, wound, and then annealed: FT-1H by Hitachi (Japan), the four Amet alloys by MRTI - Moscow Radiotechnical Institute (Russia), 2605SA1 and VitroVac 800 by National-Arnold Magnetics (USA).

2 RESULTS

Our experimental methods for measuring core parameters have been discussed previously [1]. Briefly, we discharge a 1 μfd capacitor bank through a thyratron switch into 1 to 32 primary turns wrapped around the minor cross section of the toroidal cores. The core has been reset to $-B_{remanent}$. We measure the current through the primary and the voltage across a 1-turn secondary. The flux swing ΔB and the losses u(J/m^3) are referenced to the area and volume of alloy, determined by weight, not the geometrical area and volume of the core, i.e., we correct for the packing factor. The digital oscilloscope calibration was checked by the manufacturer to be within specifications (errors<1% of full scale), the voltage probe attenuation was adjusted to be within 1% over the range of time bases used (10-100 ns resolution), and the current transformer/terminator were also checked to be within 1%.

We summarize our findings in Table 1. We list each alloy by the manufacturers designation, and each core with an abbreviation of its manufacturers labeling. Each row represents a different core, except for 2605SA1, where data from one core is analyzed at 4 different flux swings, to allow direct comparison of the losses at the same flux swings as other alloys can achieve. We note that the loss increases more rapidly than the square of the flux swing (see scaling in Eq. 1 below) so that one can tradeoff increased core capital costs for reduced pulser capital and operating costs.

The usable flux swing ΔB_u is slightly smaller than $\Delta B_{max} = B_{saturation} - (-B_{remanent})$. It is obtained by applying four criteria to a sampling of the 20-70 data records of primary current and secondary voltage for each core, each record at a different level of pulser charge or number of primary turns. The four criteria are:

(1) The primary voltage is dropping;
(2) The current is beginning to rapidly increase above its average level;
(3) The loss per unit flux change approximately doubles; and
(4) The core impedance drops to 0.1-0.25 of peak value.

While these criteria are only semi-quantitative, the uncertainty in the flux swing is usually within 0.1 T. A more precise, engineering, determination of the usable flux swing depends on the design of the pulser and the requirements on the precision of the core voltage output. The values listed in Table 1 are a reasonable match to the assumptions of the systems code[4] with which we are evaluating accelerator architectures and components. This code assigns portions of the flux swing to the rise and fall of the pulse voltage, before and after the beam passes, while the central portion of the pulse must accurately match the desired pulse form in order to properly accelerate and shape the beam. The sag in the voltage can then be assigned to the fall time. For comparison, ΔB_{max} and the loss u(J/m3) for a 1 μs pulse duration are also listed. We note that ΔB_{max} in Table 1 is generally less than published small sample values; this may indicate that further development is needed in core manufacturing technologies.

The losses are fit with the 2-term loss criterion of Faltens' [1],

$$u\left(\frac{J}{m^3}\right) = C_1\left(\frac{\Delta B}{2.5T}\right)\left(\frac{t}{25\mu m}\right) + C_2\left(\frac{\Delta B}{2.5T}\right)^2\left(\frac{1\mu s}{\tau}\right)\left(\frac{t}{25\mu m}\right)^{1-2}$$

where τ(μs) is the pulse duration, and t(μm) is the thickness of the ribbon with an exponent of 1 or 2 (an exponent of 1 is used in here). We set t = 25 μm to compare cores made with alloys of unknown thickness. The ultimate capabilities of the different materials would be more fairly compared if the tape thicknesses were used in Eq. 1. C_1 (which represents dc hysteresis losses) and C_2 (which represents the fast-pulsed losses due to eddy currents and domain wall motion) are determined by a least-squares fit to the data.

The data and fit are shown in Figs. 1-3 for 2605SC, 2605SA1, and VitroVac 800 respectively. The fit is seen to be best for the VitroVac 800, but lies above the data

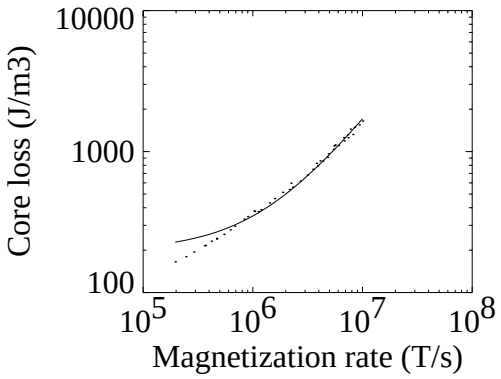

Fig. 1. 2605SC C-14 data shown by dots, fit by line, $\Delta B = 2.3$ T.

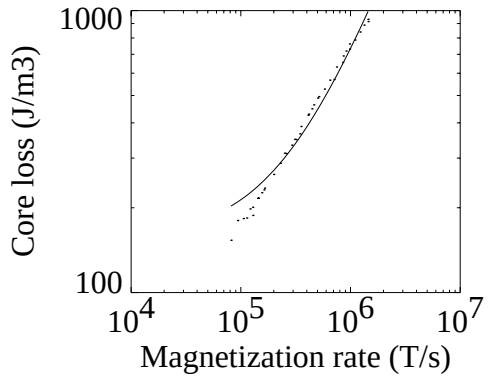

Fig. 2. 2605SA1 NA-97 data, $\Delta B = 2.7$ T.

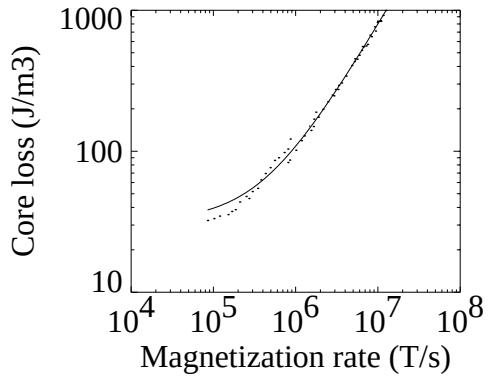

Fig. 3. VitroVac 800 NA-2 data, $\Delta B = 2.1$ T.

for low magnetization rates in each example. In some cases, the fit is very poor, e.g. core 08-01 where C_1 is negative. We are looking at alternative models with which to better characterize the data.

The consistency of amorphous metal cores has been an area of concern, see for example, Ref. [5] where the standard deviation in loss per volume ranged from 14-29% for 3 sizes of 38 cores of 2605SC. While we don't have sufficient cores of any one alloy to obtain reliable standard deviations, we compute 3% with 2605SC and we find three other alloys that also have <10% standard deviations of loss: FT-1H, VitroVac800, and 2HCP. The first two are nanocrystalline alloys. The MRTI cores (the bottom 10 rows) come in three geometries: The inside diameter of the cores is listed in the last column of Table 1. Cores with diameters near 0.1 m have masses between 1.6 and 2.3 kg. Cores with diameters near 0.3 m have masses between 5.4 and 6.1 kg. All of the MRTI cores use 0.020 m wide ribbon, except for 08-01 that uses material slit to 0.009 m wide and weighs 2.5 kg. We see that cores with a similar geometry are grouped more closely than those of different geometry.

The capital cost of cores is minimized with 2605SA1, which is manufactured in large quantities for use in 60 Hz transformers. Its cost varies from $20/kg in small quantities to an estimated <$4/kg in lots larger than 10^5 kg. It also has the largest flux swing, which minimizes the amount of core material needed. However it has the highest loss per pulse, at the same flux swing its losses are about 1.5-2 x that of 2605SC, and at maximum flux swing they are near 3x that of 2605SC. And compared with nanocrystalline, the losses are 3-7x higher.

The operating costs of an accelerator are minimized with the nanocrystalline alloys: the losses are down a factor of 7 compared with 2605SA1 at maximum flux swing. However, more material is needed, by at least the ratio of the flux swings (2.7/(1.9-2.15) = 1.25-1.4), and by more if a large build-up is needed. The material is also more expensive: most of the components are similar to those in the amorphous alloys 2605SC and 2605SA1, the major difference is the addition of 3% niobium. The niobium will increase the ultimate cost of the materials in large quantities by ~$1/kg of alloy. The additional capital costs will be partially offset by the reduced cost of pulsers. These and other tradeoffs are being investigated with a systems code [4].

Abstract

A beam position monitor using a coaxial reentrant RF cavity has been designed and tested. Main advantages are the small size, the high precision, excellent linearity, and the broadband operation. The measured resolution is 10 microns on the low current beam of the TTF linac. The expected resolution is 700 nm for the high current beam of TTF.

1 INTRODUCTION

High resolution beam position monitors (BPM) will be needed for the future linear colliders. Large band-widths will also be important to operate fast feedback systems. We have designed and tested on TTF (Tesla Test Facility) a broadband BPM which can also be operated at liquid helium temperature.

The TTF superconducting linac at DESY is now in operation with a low charge injector delivering bunches at 216 MHz. In the next step an RF gun will provide high charge (8 nC) bunches at the frequency of 1 MHz. The BPM is suited to both operating modes. In the first case the tests have shown a resolution of 8 μm. In the second case a resolution of 0.7 μm is expected.

2 PRINCIPLE OF THE BROADBAND BPM WITH A REENTRANT CAVITY

A reentrant cavity (fig.1) has a small size and the broad band is well adapted to the measurement of high charge short-bunched beams, such as they will be in future colliders [1]. The beam coupling impedance is advantageously weak. The measurement frequency is chosen well below the monopole (TEM) and dipole (TE011) modes of the cavity, and below the cut off frequency f_c of the dipole TE_{11} mode of the cavity considered as a coaxial transmission line (table 1). The beam excites an "evanescent" TE011 mode [2], in proportion of its displacement off axis, damped towards the bottom of the reentrant cavity. The energy is concentrated in the gap where the antennae are located. The higher order modes are damped much more strongly so their contribution is negligible and the linearity of the measurement is ensured.

If U_1, U_2, U_3, and U_4 are the voltages induced on each antenna, U_m the voltage induced by the monopolar mode on each antenna, I the beam current, x and y the beam displacements from the axis, then the transfer impedance is defined by:

$$Z_t = \frac{U_m}{I}$$

and the dipolar constant L is defined by:

$$x = L\frac{U_1 - U_3}{U_1 + U_3} \qquad y = L\frac{U_2 - U_4}{U_2 + U_4}.$$

Zt and L are calculated analytically in [2] and the BPM sensitivity is

$$S = 2\frac{Z_t}{L}.$$

3 FABRICATION OF THE CAVITY

The BPM precision at room and cryogenic temperatures (cooling without deformation) relies on the axial symmetry obtained by machining the cavity with a lathe. The beam pipe radius is 78 mm and the gap of the reentrant cavity is 8 mm. A demountable cavity was fabricated (figure 1) and severe tolerances were applied on the radii and the perpendicularity of the assembling surface (2/100). The concentricity of the cavity walls actually measured on the cavity is better than 20 μm.

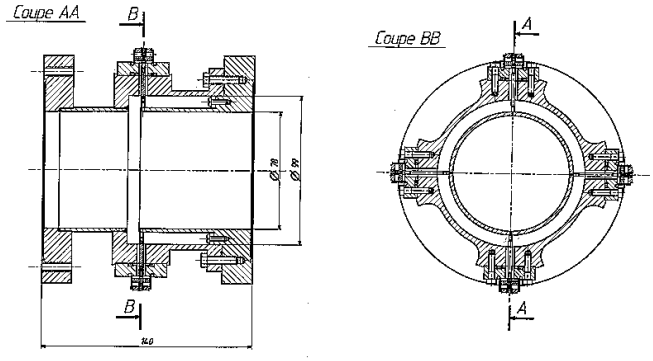

Figure 1: BPM cavity

The feedthrough have a standing wave ratio below 1.02 at 650 MHz. They ensure vacuum tightness between the linac 10^{-11} vacuum and the 2 K helium bath. To achieve broadband operation the cavity is strongly overcoupled by fixing the antenna tips to the inner diameter of the cavity. The external Q factor is about 4.

4 RF MEASUREMENTS OF THE CAVITY ALONE

The transmissions between two opposite antennae have been measured with a network analyser for two positions of the antennae: pulled out or fully pushed. The first

position (resonant mode) is used to spot the precise resonance frequencies and the second one (broadband mode) to visualize the bandwidth really used in the operation mode (figure 2 and table 1).

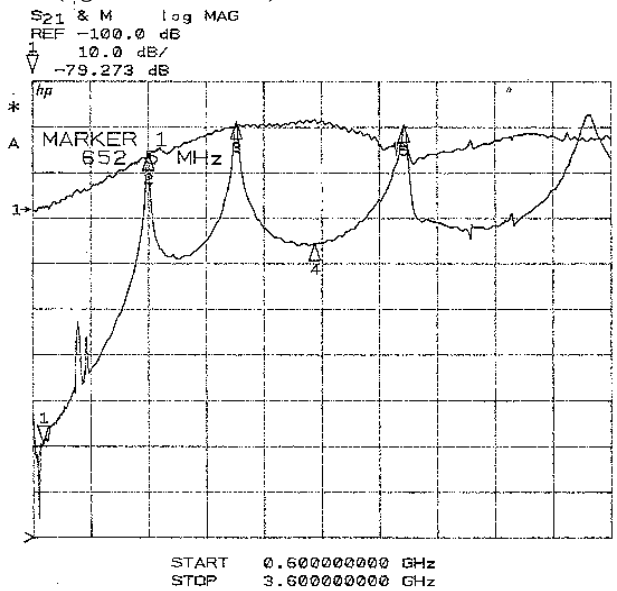

Fig. 2: Cavity transmission, broadband(1) and resonant(2)

5 SIGNAL PROCESSING

A 180° hybrid junction is connected to each pair of opposite antennae, yielding directly the sum and difference RF voltages proportional to the beam current and position. These RF signals are then filtered, amplified, and demodulated with a superheterodyne reception. To achieve a good balance between the 4 ports the hybrid coupler is placed in a box as close as possible to the cavity. And a "perpendicular balance" is done: A reference signal is input through the horizontal antennae while attenuators and phase shifters are adjusted to cancel the vertical power output.

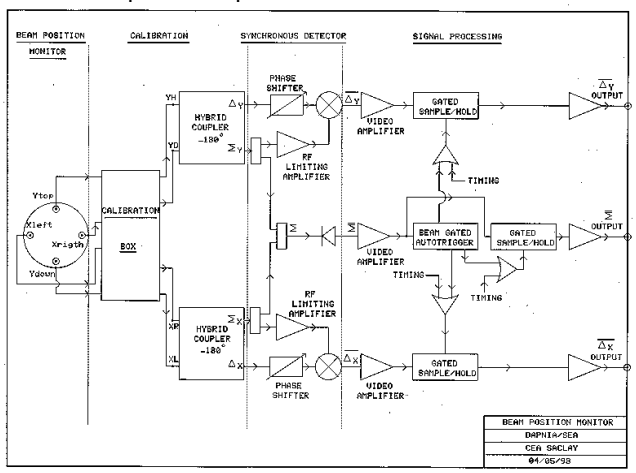

figure 3: BPM electronics

The acquisition board yields analog output for noise measurements and digitized 14 bit output for the control system. The software used is EPICS.

6 CALIBRATION ON A TEST BENCH

A test bench has been assembled to calibrate the BPM without beam, at room temperature. The beam is simulated by a moveable rod. The cw RF power equivalent to the beam current is injected through transition cones as shown on figure 11. The cones have a reflection coefficient of 0.25.

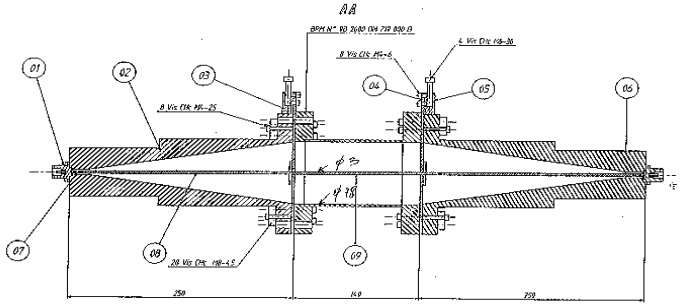

figure 4: Test bench for the BPM cavity and electronics

The characteristics measured with a network analyser are compared with the theoretical values in table 1. The linearity is shown in fig. 5. The noise measured is 20 mV for a 4 V/mm signal, so the resolution is 5 µm.

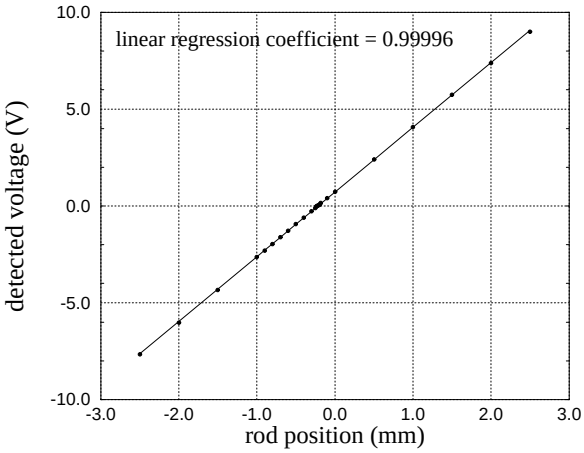

Fig.5: BPM test on bench

The precision after calibration is given in table 2. Micrometric shifters should be used to evaluate the relative precision better.

Table 1 (measurement frequency = 0.650 GHz)

	calculated	measured
fc (GHz)	1.0	
f TEM (GHz)	1.24	1.20
f TE011 (GHz)	1.7	1.658
Z_t (Ω)	6.2	8
L (mm)	37.5	
S (mV/mm/mA)	0.331	0.26

Table 2

absolute precision	0.2mm
relative precision	<50µm

7 MEASUREMENTS WITH THE TTF BEAM

One BPM has been tested inside the capture cavity cryostat at 2 K and the other at room temperature.

a) Absolute precision Δ: The BPM error Δ_{bpm} and the alignment error Δ_{align} give:

$\Delta = \Delta_{bpm} + \Delta_{align} = 0.2$ mm + 0.1 mm = 0.3 mm.

b) Beam current measurement: The beam current is measured between 0.1 mA and 8 mA. By adding a high gain preamplifier the dark current emitted by the cavity (as low as 100 nA) can also be measured.

c) Resolution: The measured noise is 40 mV when the RF amplifier is 54dB and the video amplifier has a gain of 100. With the 5 V/mm BPM calibration for a beam current of 8 mA this leads to a resolution of 8µm.

e) Linearity: The x and y beam displacements were measured with an 8 mA, 35 µs, 10 Hz beam while horizontal and vertical steerers were varied. The steerers are 1.513 m upstream. Their linearity is such that $\delta x/I_{steerer}$ = 2.188mm/A with a precision of .002 mm/A over the range -4V, +4V. (The DC power supplies are stabilised to 10^{-3}).

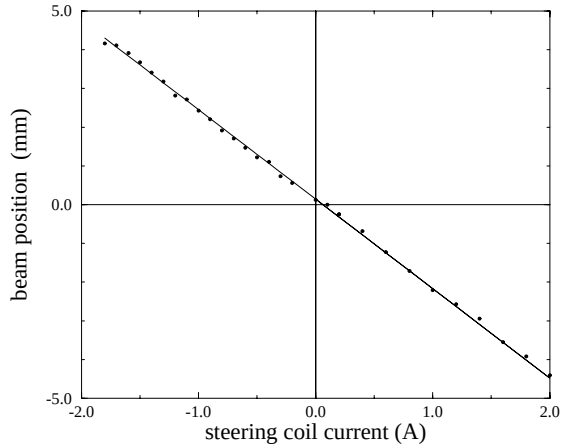

Figure 6: Measurement of the TTF beam position

The linearity in y is observed with a regression coefficient of R = 0.9996 (fig. 6). In that example a fluctuation of the beam position is seen with a standard deviation of 150 µm, about 5% of the beam size.

8 EXPECTED RESOLUTION IN THE CASE OF INJECTOR 2

The short bunch signal is filtered at the output of the hybrid coupler. Bessel filters of order 7 have been chosen as they have the less distorted time-domain response and shortest rise time. The 4 MHz bandwidth Bessel filter entirely determines the time response of the electronic chain. The 10 ps bunch can be considered as a Dirac impulse and the input current is: $I_{in}[A]=8x10^{-9}x\delta(t)$. Calculating the output current from the transfer function of the filter we find an envelope amplitude of $8x10^{6}xI_{in}$ with a time response width fitting inside the 1 µs bunch separation. A comparison with the current of the injector #1 shows that a factor 12 is gained on the sensitivity. As the noise level will be unchanged (since the same electronics are kept except for a modified acquisition card) the resolution will be: 8 µm / 12 = 700 nm.

9 CONCLUSION

a) Results of the tests (low bunch charge)

The axial symmetry of the RF cavity allowed a high fabrication precision (2/100) and the absolute precision of the BPM was measured on a test bench (0.2 mm).

On the Tesla Test Facility the BPM was tested at 2 K and at 300 K; the beam position is measured in the ranges 0 to 1 mm, and 1 mm to 10 mm; the beam current and the dark current can be measured. The pass-band is 4 MHz due to the RF filter chosen. The acquisition time is 1 µs. The resolution (at low bunch charge) is 8 µm.

b) Plans for injector 2 (high bunch charge: 8 nC)

By modifying slightly the acquisition card (changing the sample-and-hold amplifier) the BPM is presently being adapted to the high charge 1 MHz bunches of the injector #2. The resolution will be 700 nm if nothing else is changed (same RF amplifier, same RF filter).

c) New technical developments

Changing the RF amplifier to a low noise amplifier and broadening the pass-band of the RF filter from 4 MHz to 20 MHz will increase the resolution in the case of high bunch charge beams. A resolution of 100 nm should be obtained at 8 nC bunch charge.

d) New applications

It is possible to use the BPM without the present electronics (4 MHz band-width) and benefit from the real bandwidth of the BPM cavity and hybrid coupler (about 200 MHz) if a degraded resolution (about 100 µm) is accepted. This is presently tested to measure the HOM impedances of the TTF 9-cell superconducting cavities. Resonances due to the HOM are excited by an offset of the beam position and a modulation of the beam current at frequencies from 5 MHz to 100 MHz. The growth of the resonances inside the 35 µs bunch train is observed with an oscilloscope and a spectrum analyser.

An other application is to build a new acquisition board with flash components. In that case the BPM would have a 25ns measurement time and could be inserted in a fast position feedback loop.

HEAT TRANSFER COEFFICIENT IN SERPENTINE COOLANT PASSAGE FOR CCDTL*

P. Leslie, R. Wood, F. Sigler, A. Shapiro, A. Rendon
Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Abstract

A series of heat transfer experiments were conducted to refine the cooling passage design in the drift tubes of a coupled cavity drift tube linac (CCDTL) [1]. The experimental data were then compared to numerical models to derive relationships between heat transfer rates, Reynold's number, and Prandtl number, over a range of flow rates. Data reduction consisted of axisymmetric finite element modeling where the heat transfer coefficients were modified to match the experimental data. Unfortunately, the derived relationship is valid only for this specific geometry of the test drift tube. Fortunately, the heat transfer rates were much better (approximately 2.5 times) than expected.

1 INTRODUCTION

The objective of this experiment was to use experimental results combined with numerical simulation to measure heat transfer rates in drift tube coolant passages for the cavities in the Accelerator Production of Tritium (APT) [2], Low Energy Demonstration Accelerator (LEDA) [3] CCDTL Hot Model. The hot model is a full scale, copper brazed structure that will be exposed to full RF fields, but will not have beam through it. A goal of the experiment is to refine the design of the cooling passages and coolant systems for the LEDA CCDTL. The results of this experiment were used to give a better estimate of the heat transfer rates within the drift tube coolant passages and are just a first look at the drift tube thermal problem. Since the experiment is not error-free, the Nusselt equation coefficients determined are probably not an exact representation of all the physics of the problem, but a match with this empirical data using the specific geometry of the test item.

In the CCDTL, the drift tube is located within an RF cavity and provides a region of no electric field which shields the beam when the electric field would decelerate the beam (for an in-depth description, see [4]). A great deal of RF power is dissipated on the outer surface of the APT drift tubes. A method was developed to form an elaborate network of cooling passages within the body of each drift tube [5]. The coolant passages within the drift tubes are rectangular, short, and curved, a situation which is not well covered in the literature.

In the literature [6], the heat transfer coefficient in long, straight, circular passages is given as

$$\bar{h}_c = \frac{k_{water}}{D_{Tube}} * 0.023 * Re^{0.8} * Pr^{0.4} \qquad (1)$$

where k_{water} is the thermal conductivity of water, Re is the Reynold's number, Pr is the Prandtl number. Since these drift tube passages are not round, the convention is to use the equivalent hydraulic diameter for a rectangular cross section which is given by

$$D_h = \frac{4A}{P} \qquad (2)$$

where A is the flow area and P is the wetted perimeter. It is much more difficult to account for the passages being short and curved. The complex three dimensional geometry of the drift tube coolant passages make it difficult to determine an effective heat transfer coefficient directly from published data. It was necessary to use a finite element, thermal/structural model to extract an approximate value for the heat transfer coefficient. From that data, an approximate relationship between the Nusselt number, the Reynold's number, and the Prandtl number for this geometry was derived.

2 SETUP

The test setup consisted of a water chiller, approximately 5 gallon reservoir, a flow meter with range of 0 to 2 gpm, water filter, 17 heater cartridges, rheostat, 100X amplifier, a modified drift tube slug placed on a styrofoam base with styrofoam "popcorn" completely over it, tubing to connect these components together, two thermocouples to measure drift tube temperatures, another thermocouple to measure coolant inlet temperature, a two pass thermopile to measure the coolant temperature rise through the drift tube, and a data acquisition system to record the data. Figure 1 shows a schematic of the setup. For data reduction purposes, the flow rate was determined from the heater power and the temperature rise within the coolant from inlet to outlet. Much depends on this measurement, so a two pass thermopile was used to increase the sensitivity of the measurement and lessen the effect of noise in the data.

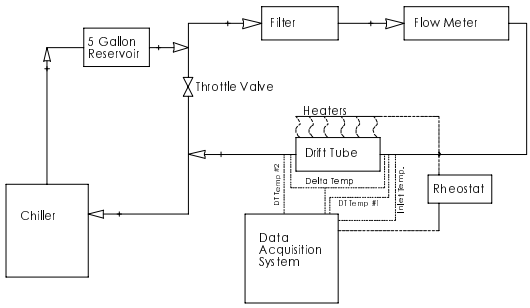

Figure 1. Schematic of the experiment.

* Work supported by the US Department of Energy, Defense Programs

The drift tube slug used in the heat transfer experiments was a three passage drift tube that is identical to those from which CCDTL hot model drift tubes were made. Figure 2 shows the cross sectional drawing showing the 3 concentric cylinders and the 3 coolant passages. The center, longitudinal holes were drilled in 1 inch each side (not shown in Figure 2) with a type T thermocouple inserted into each. These thermocouples were labeled Body Temp 1 and Body Temp 2. Because the water temperature increases with each successive passage, the area of the drift tube that dissipates the most power and/or most affects the cavity frequency needs to be cooled first. So the placement of the drift tube coolant passages is not arbitrary and the experimental drift tube passages closely resembled an actual drift tube.

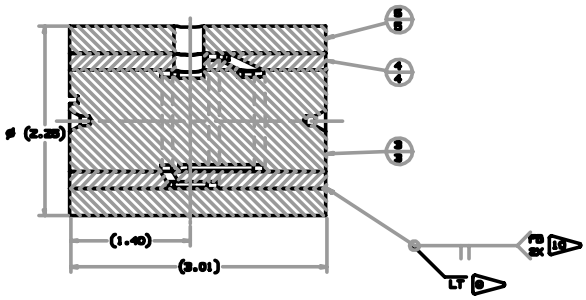

Figure 2. Drift Tube Slug Showing Cross Sections of Cooling Passages.

The heater cartridges were placed in longitudinal slots cut into the drift tube slug with thermal conducting grease, copper shim stock wrapped around, and hose clamps to keep them in place. Figure 3 shows the assembly in the styrofoam box with associated hardware prior to filling the box with styrofoam "popcorn" and topping it with a foam pad. The inlet thermocouple and the thermopile were installed into the hardware at the ends of the copper tubes protruding from the drift tube shown in Figure 3.

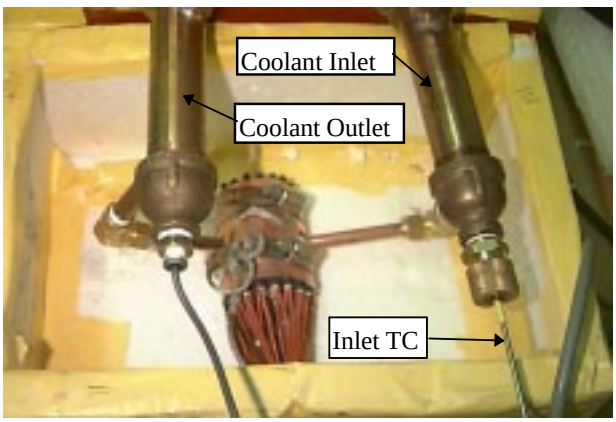

Figure 3. Drift Tube in Styrofoam box.

The reservoir was used to increase the thermal mass of the system so each time step was more closely steady state. The rheostat was used to control the power to the heaters. The data acquisition system consisted of a computer running Labview software, two Keithley 2002 Multimeters, three type T thermocouples with electronic "ice point" and one type T thermopile, and the data was recorded into text files for easy transfer to other data manipulation software. A thermistor was used to monitor the outlet temperature, but it was not recorded.

3 THERMOCOUPLE CALIBRATION

The process began by identifying the offset inherent in the system. This was done by setting the thermostat on the chiller to its lowest point of 42° F. Once the system reached this temperature, the flow rate was throttled way down (~0.30 to 0.35 gpm) to minimize heating due to pressure loss across the drift tube, the thermostat on the chiller was raised to approximately 110° F, and the data acquisition system began recording the data. The heaters and rheostat were turned off and unplugged from the wall. It took the system 2 to 2 ½ hours to reach approximately 75° F and much longer if the desired system temperature was near 100° F. When the system reached ~75° F, the data recording was stopped, the flow rate was turned up, and the temperature on the chiller was set down to its lowest point.

4 TEST PROCEDURE

Each measurement was assumed to be steady state due to the high thermal conductivity of copper and the 5 gallon reservoir added to increase the thermal mass of the system. The chiller system's compressor cycled too much to hold the temperature constant so it was used only as a pump and as a means to cool the entire system to an initial <45° F condition. Quasi-steady state data was then taken as the drift tube heaters gradually drove the system temperature upward.

When the system temperature was 42° F, the heaters and rheostat were turned on, near 1000 watts, and the desired flow rate was set. Once the system reached quasi-steady state, the chiller thermostat was set to 100° F and the data was then recorded as the system temperature gradually climbed to >100° F. The process took 1½ to 2 hours, depending on the flow rate. Figure 4 shows a plot of the data collected at one specific flow rate.

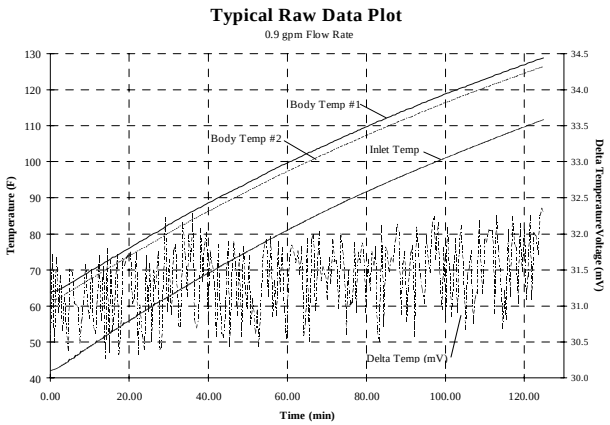

Figure 4. Data Collected During Experiment.

The thermocouple data was smooth with very little noise; however, the thermopile data (Delta temperature)

had a 3% noise range throughout due to the sensitivity of the measurement. This is believed to be stray electrical noise, not variations in the flow rate. Once the inlet temperature reached approximately 100° F, the data collection was stopped, the heaters and rheostat were turned off, and the chiller thermostat was turned down to its lowest setting. It took approximately 1 hour to return to the 42° F starting point. The procedure was then repeated using a different flow rate.

5 ANALYSIS

The analysis was performed in two sections. The first was to analyze the data collected to determine the delta temperature between the outlet and inlet. The thermocouple calibration was "backed out" and the resulting measurements converted to temperatures. As can be seen in Figure 4, there was a significant range of data for the voltage measurement which translates over to the temperature measurement. To smooth out this data, a weighted time average was taken from the surrounding data points. The weighted average equation is

$$\overline{X}_N = \frac{X_{N-2} + 3X_{N-1} + 5X_N + 3X_{N+1} + X_{N+2}}{13} \qquad (3)$$

where X_{N-x} was a data point x steps before or after the N^{th} data point. All quantities (temperatures and heater power) were averaged this way. This smoothed data was then entered into a spreadsheet [7] that calculated the average heat transfer coefficients and temperatures for each passage on the drift tube.

The second part of the analysis used numerical simulation, specifically COSMOS/M finite element analysis (FEA) software [8]. An axisymmetric model was generated within COSMOS where the boundary conditions were taken from the spreadsheet [7] which calculated the average heat transfer coefficients, average coolant temperatures, and the heat flux from the heaters. The model was then thermally analyzed to determine the nodal temperatures in the model. The comparison between the measured data and the numerical data was made by averaging the two measured body temperatures and comparing them to the average nodal temperatures that correspond to those thermocouple's location. One iteration required modifying the heat transfer coefficient, applying the calculated boundary conditions to the FEA model, running the thermal analysis, averaging the temperatures at the nodes corresponding to the thermocouple's location, and comparing it to the averaged measured body temperature and repeating until the two averages were within ±0.03° F (even though the accuracy of the measurement was much worse). These iterations were performed at 4 to 5 temperatures within the measured temperature range for each flow rate.

6 RESULTS

Four flow rates were analyzed in this experiment: 0.9, 0.7, 0.5, 0.3 gallons per minute (gpm) which corresponded to approximately 15, 12, 9, and 6 feet per second (fps) (4.57, 3.66, 2.74, and 1.83 m/s) flow velocity in the coolant channels, respectively. The Reynold's numbers corresponding to these flow rates are 15,549; 11,159; 8,275; and 5,291, respectively. The data can be fairly well described by the following equation.

$$Nu = .0862 * Re^{.75} * Pr^{.42} \qquad (5)$$

Figure 5 compares the data to this equation graphically.

The design flow velocity within the passages of the drift tube is a critical factor due to erosion of the copper passages at higher flow velocities. A rule of thumb is to keep flow velocities within copper coolant channels below 15 fps (4.57 m/s) to minimize this erosion. Therefore, there was no need to test a flow rate higher than 0.9 gpm.

Note that, for this geometry, the heat transfer rates are ~2.5 times greater than predicted by Eqn (1) (long, straight, circular passages). For the design on the APT/LEDA CCDTL Low Beta Hot Model drift tubes, a value of 1.5 times better was used to offset any experimental errors that may have influenced the data and to stay on the conservative side of the design. Thorough tests of the Low Beta Hot Model will be done to verify and refine these results.

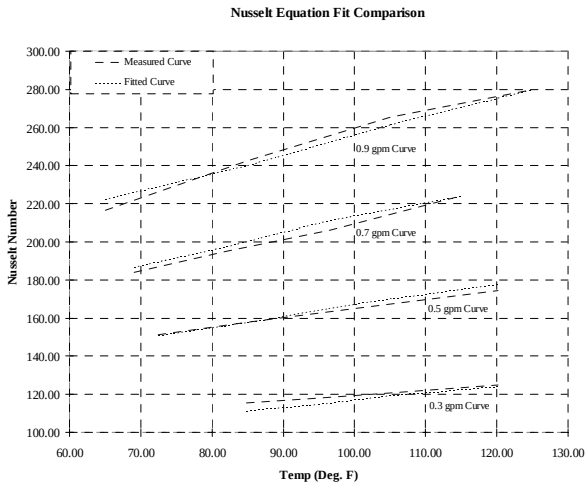

Figure 5. Data fit comparison.

DOUBLE DYNAMIC FOCUSING FOR LINEAR COLLIDERS

J. Irwin†, SLAC, 2575 Sand Hill Road, Menlo Park, CA, USA

Abstract

Dynamic focusing refers to the use of secondary beams to form final-focus lenses for the primary high energy beams of linear colliders. In double dynamic focusing an initial lens-lens beam collision focuses the lens beams for their collision with the primary beam. This paper describes the techniques for the formation of a uniform lens shape from an initial Gaussian shape, the necesary main- and lens-beam parameters and their scaling, and requirements for a 1 TeV c.m. application. Advantages of this scheme include the complete elimination of the conventional final focus and collimation systems, elimination of beamline elements within the detector, and the promise of looser main-beam linac alignment, energy spread and ground motion tolerances.

1 INTRODUCTION

1.1 Motivation

Our original motivation was a search for a viable final focus system for linear colliders above 1.5 TeV cm. Now our motivation is the complete elimination of the final focus and collimation systems and reduction of backgrounds and cost in all future colliders, including the next linear collider (NLC) [1].

1.2 A simple large momentum-bandpass focusing system

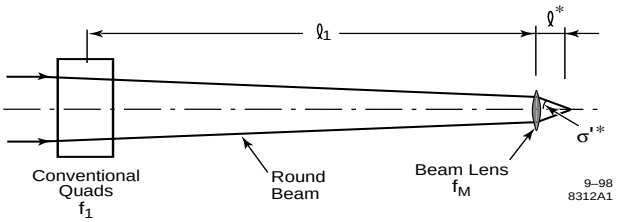

Figure 1. A schematic of a simple final focus system. A very strong lens is placed 1 cm from the IP. The total length is about 4 m.

We will use a secondary beam to create a small strong lens about 1 cm from the IP [2, 3]. Figure 1 shows the full system, with final conventional quads outside the detector at a distance $l_1 \geq 4m$. If the focal length, f_1, of the convential quads is chosen equal to l_1, and the focal length of the beam lens, f_M, is chosen so that a ray originating at the convential quad is focused to the IP, then the final spot size demagnification is $\rho = l^* / l_1$, and

$$\sigma^{*2}(\bar{\delta}) = [\rho^2 + (\lambda^2 - 2\rho)\bar{\delta}^2 + \bar{\delta}^4]\,\sigma_1^2$$

where $\lambda = l_1 / \beta_1$ is the demagnification to the beam lens. If $\lambda < \sqrt{2\rho}$, a condition easily satisfied, the second order term in $\bar{\delta} \equiv \delta / (1+\delta)$ is actually negative. Under these circumstances the bandpass of the system is given by $\bar{\delta}^2 < \rho$, which for a typical demagnification of 1/400 gives $\bar{\delta} < 1/20$, implying a huge momentum bandpass.

1.3 Double dynamic focusing

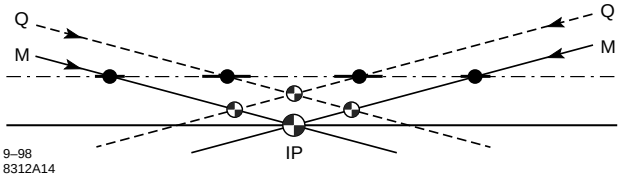

Figure 2. An overview showing the trajectories of the lens beams and main beams. There are three collisions: lens-lens, 2 lens-main and the final main-main. This figure also shows the "crabbing" of the beams and the fact that all beams lie on a common line as they traverse the IP.

Figure 2 shows an overview of the incoming lens and main beams. Because room-temperature colliders must have multi-bunch beams, a non-zero crossing angle is required. Crab cavities are used to twist the bunch so that they pass through each other as if head-on, and by control of their relative phases, they place the bunches along a common transversely-moving line.

The two lens beams must necessarily collide before their interaction with the main beam. This collision can be put to advantage for either aligning the lens bunches or to completely focus the lens beam. It is the latter case which we refer to as double dynamic focusing.

2 LINEAR COLLIDER IP PARAMETERS

With dynamic focusing, arguments for the flat beam geometry are all but eliminated. Round beams are favored because they require lower main-beam bunch charge (facilitating a lower lens-beam energy) and have a larger IP vertical size and β-function. Presumably, for main- linac efficiency, main-beam current is held constant. A lower short-range wakefield is advantageous, but long-range wakes could be worse. Damping ring rf design is changed dramatically. At 1 TeV cm with $n_\gamma = 1$, round IP parameters are $N = 0.7\ 10^9$, $\sigma = 12\,nm$ and $\sigma_z = 60\,\mu m$.

†Work supported by the Department of Energy, contract DE-AC03-76SF00515.

3 DYNAMIC FOCUSING PARAMETERS

3.1 Lens beam charge per bunch

For a charge $\bar{N}_Q$ in a uniform disk of radius R_Q the focal length is given by $\frac{1}{l^*} = \frac{2\bar{N}_Q r_e}{\gamma_M R_Q^2}$. This condition yields $\bar{N}_Q = N_{Q_0}\frac{R_Q^2}{2\sigma_M^2}$ where $N_{Q_0} = \frac{(\gamma\varepsilon)_M}{r_e}\xi$, and $\xi = \frac{l^*}{\beta^*}$ is the inverse demagnification from the beam lens to the IP. Since the fraction of the main beam not incident on the uniform disk is given by $\Delta N / N = \exp[-R_Q^2 / 2\sigma_M^2]$, the exponent will lie between 3 and 4.

3.2 Uniform lens distributions

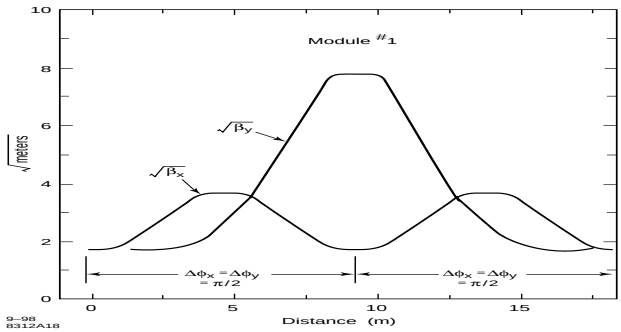

Figure 3. A module for inserting an octupole in a beamline.

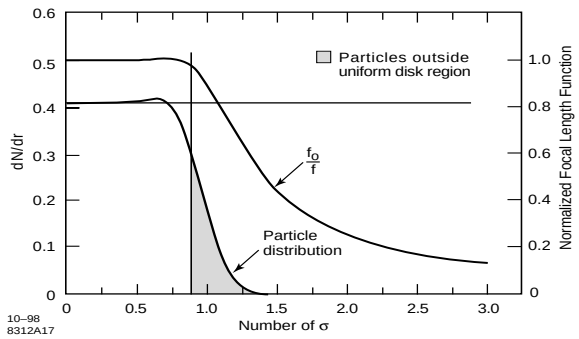

Figure 4. An example of a particle distribution and its focal length function achieved with a 3-octupole system. 85% of the distribution is accurately focused.

A Gaussian distribution can be made almost uniform by using 3 octupoles in 3 similar modules (see Fig. 3), each rotated by 60 degrees from the previous module. An example of a distribution achieved in this way is shown in Fig. 4. The lens-lens collision can further reduce the population in the tails for the main-lens collision.

3.3 Pinch effect

Figure 5 shows the lens beam colliding with the main beam. Each beam focuses the other and the ratio of the focal lengths is the beam-power ratio: $f_M / f_Q = (\gamma N)_M / (\gamma N)_Q$. The focusing of the lens beam will cause a change in its focal length for the latter part of the main beam. This is improved by arranging that the lens beams diverge when they meet the main beams. See Fig. 6. Ignoring effects of disruption, the luminosity loss due to the change in focal length is about $\frac{\Delta L}{L} \approx \frac{1}{120}\left(\frac{l^*}{f_Q}\frac{\sigma_z}{\beta^*}\right)^2$.

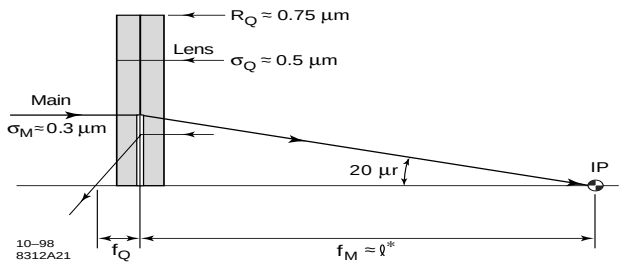

Figure 5. The lens beam, moving to the left, is pinched by the main beam moving to the right.

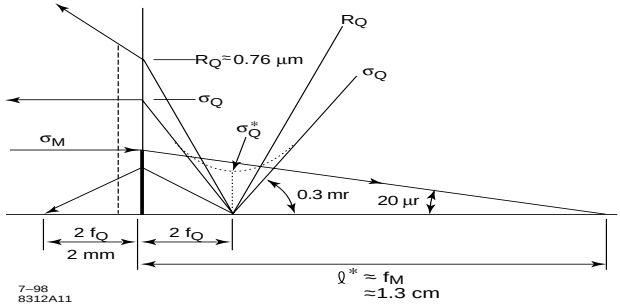

Figure 6. A lens beam which is diverging when it meets the main beam will reduce the pinch effect.

3.4 Parameter summary

Figure 7 summarizes the relationships of the parameters in this problem. $c_p = \sqrt{120(\Delta L / L)_p}$ comes from the pinch-loss equation and n_{l^*}, the number of l^* chosen for the focal length of the lens-lens collision, equals 1 for double dynamic focusing and 2 for self alignment. A possible parameter choice for 1 TeV cm [ξ=30, $\gamma_M / \gamma_Q = 100$, D=0.9, and H=3] lies very close to the zero 2nd order chromaticity condition.

These parameter relationships scale well to higher energies, and dynamic focusing appears viable up to 10 TeV cm. At 1 TeV cm it may be possible to put the lens

beam in a storage ring. At higher energies a modified scheme including a linac will be necessary. See Fig. 8.

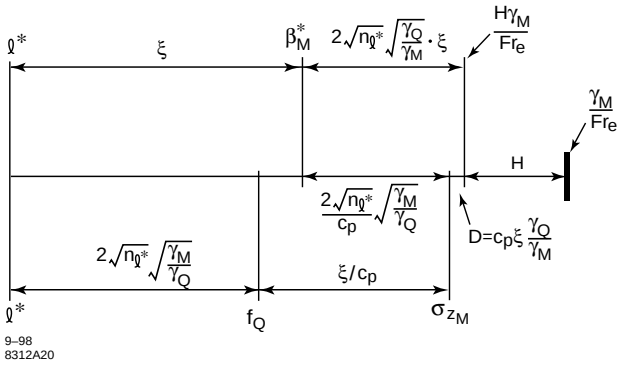

Figure 7. A log-scale diagram showing the relationship of the parameters in a "double" dynamic focusing system. See text.

4 OPTICAL BENCH CONDITIONS

4.1 Jitter

In addition to a uniform lens profile, it is crucial to have small beam jitter because the lens position determines the focal point for the main beam. With the demagnifications assumed, the inter-bunch lens-beam jitter would have to be 1% for the self-aligning case and 0.1% for double dynamic focusing. 1% is the ZDR specification for the NLC damping ring, and appears achievable. 0.1% probably requires a feed-forward loop after extraction from the lens-beam damping ring. Such a scheme is indicated in fig. 8. The main obstacle is the short inter-bunch spacing, presumably at S-band or less. An accurate fast BPM is under study. Lens train alignment can be achieved by using precursor bunches in the lens train.

4.2 The crab cavity

Crab cavity phase tolerance are an order of magnitude tighter with round beam parameters: the relative phases should drift no further than 0.01 degrees X-band. Systems for evaluating the feasibility of this tolerance are being developed.

5 SUMMARY

The prospect of total elimination of the final focus and collimation systems offered by dynamic focusing is very attractive. Additionally backgrounds in the IP region can be dramatically reduced, removing the tension between luminosity and backgrounds present in the SLC operation. Lens-beam energy should be minimnized to reduce cost. The minimum will depend on the lens quality that can be achieved, but appears to be less than 1% of the main beam energy.

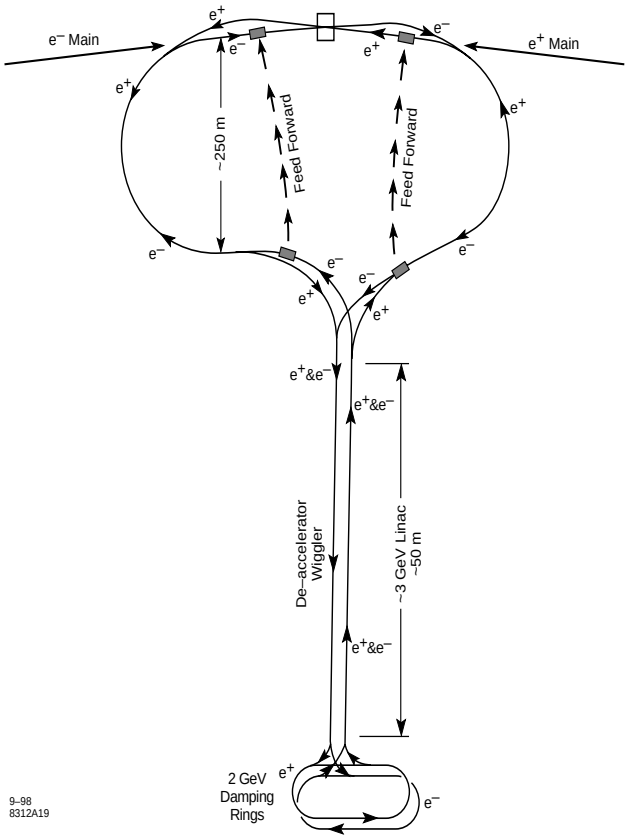

Figure 8. A possible geometry for the lens-beam system. The lens beam is stored in a 2 GeV damping ring between collisions, accelerated to the required collision energy, then decelerated and re-injected into the damping ring. A feed-forward scheme removes bunch to bunch jitter.

2 MeV LIA INJECTOR DESIGN

L. Zhang, N. Cheng, G. Dai, H. Wang, L. Chengjun, J. Deng, B. Ding
Institute of Fluid Physics, CAEP P.O.Box 523-56, Chengdu, China, 610003

Abstract

This paper describes a design for 2 Mev LIA Injector. The injector is composed by eight accelerating cells in which for four accelerating cells form an anode and others make a cathode. A foilless diode or a diode with a tungsten mesh anode is used in the injector, and the voltage for the diode is 2 Mev. The electron beam current is more than 3kA in the end of injector. The pulse power system, beam transport system. Auto-control system and auxiliary system also are discussed.

1 INTRODUCTION

The purpose for the injector is to produce a high-brightness, low energy spread electron beams [1,2]. The injector is consisted of 8 accelerating cells, foilless diode, solenoid magnet and pulse power system. The length of the injector is 6 m. In order to satisfy the requirement of resistant match, the cathode bar and anode bar are formed as cylinder stairup-like. Internal diameter of anode accelerating cell is bigger than that of cathode for accommodating focusing solenoid. The cathode is cold cathode field-emission and the cathode material is velvet. We use solenoid producing a focusing magnet to transport electron beams.

2 DESIGN OF THE INJECTOR

It is necessary to improve beams brightness, lower beam energy spread and control transversal movement of beams. We make following design.

2.1 The design of diode

To design a diode, first of all, we must optimize the shape of diode by using foilless anode or tungsten mesh anode so that the field in the cathode is uniform. This is beneficial to increase the brightness of electron beams. The optimizing choice is carried out by using numeral simulation and experiment. The experimental result shows that a plane diode can produce a high-quality electron beam which brightness is higher than 1.5×10^{8}A/(m·rad)^{2}

2.2 The system design for pulse power

To realize the wide flat top in the diode, the pulse power source need good synchronism [3]. Then the influence of resistant variance should be controlled. in the process of electron emission, the plasma moves toward anode and the emission current gradually increased, the resistance of diode decrease. In this way, the diode voltage induces. The way to induce this kind of influence of to choose the proper resistance of accelerating cavity and proper diode shape. While design pulse power system, we use a Max generator and Blumlein line to produce a 250 kv 110 ns pulse. The Max generator charge four Blumlein lines and each line provide pulse power to two accelerating cells. We use spark gap switch to control the synchronism.

2.3 The system design for beam transport

Eight solenoids are used to build up a beam transport magnet, two solenoids for introducing electron beam out the diode, one solenoids for producing a compensate magnet field at cathode, four solenoids in the accelerating cavity for transporting electron beams and others for adjusting output beams.

2.4 Auto-control system and auxiliary system

We use personal computer and Bitbus net to build up our auto-control system. A personal computer is used as central control computer and several industrial control computers are used as station. A data analyze system for analyzing experiment result is also accomplished. The auxiliary system includes vacuum (4×10^{-4} Pa), pure water (5 MΩcm), gas (N_2, SF_6) and oil.

3 CONCLUSION

The injector should arrival following criterion:

$$energy \geq 2Mev$$
$$beam \geq 3KA$$
$$pulsewidth \geq 60ns$$
$$energyspread \leq 1.5\%$$
$$emission \leq 0.28\ cm \bullet rad$$
$$brightness \geq 1.5\times10^{8}\ A/(m \bullet rad)^{2}$$

The 2 Mev LIA injector was resemble in 1997 and the first experimental result show that our design is reasonable.

ADVANCED CONCEPTS FOR HIGH-GRADIENT ACCELERATION*

D. H. Whittum
SLAC, Stanford University, Stanford, California 94309 USA

Abstract

The promise of high-gradient accelerator research is a future for physics beyond the 5-TeV energy scale. Looking beyond what can be engineered today, we examine basic research directions for colliders of the future, from mm-waves to lasers, and from solid-state to plasmas, with attention to material damage, beam-dynamics, a workable collision scheme, and energetics.

1 INTRODUCTION

The technology of colliders could be scaled to energies well beyond the frontier of high energy physics today, but for limits to physical size. To reach beyond the next-generation machines requires not scaling nor engineering, but basic research in beam physics. The need for "advanced accelerator research" is not new; the subject extends back decades, to the beginnings of high-energy physics, the invention of the klystron by the Varian brothers, the resonant-cavity accelerator by Hansen, and strong-focusing by Christofilos. However it is only in the last decade that it has become recognized as the critical path for experimental particle physics in our lifetime. Here we consider one view of the latest chapters in the story of high-gradient accelerators for colliders.

In Sec. 2, we review the relevance of high-gradient to a collider. We then review the state of research in high-gradient acceleration mechanisms. Solid-state accelerators are covered in Sec. 3, and plasma-accelerators in Sec. 4. Conclusions are offered in Sec. 5.

2 COMPACT COLLIDER

Efforts to conceive of a compact collider meet with numerous difficulties. For example, if one were to extrapolate the "conventional" picture of a collider [1] to 5-TeV center-of-mass energy, a luminosity of 10^{35} $cm^{-2}s^{-1}$, and an accelerating gradient of 1 GeV/m, one would hear objections at every turn. At conventional frequencies, one would need a multi-GW power source that doesn't exist. Even if one had such a source, it would ablate the accelerator structure surface in a single pulse, due to Ohmic heating. At high frequencies, the peak power requirement would be lower, but Ohmic heating would still be untenable, due to copper fatigue from thermal cycling. In addition, high-frequency structures are difficult to fabricate. Even if one could fabricate 10^5 of them, and align them, their wakefields would destroy the beams. Even if the beams survived the linac, then to focus them one would need a 20 km optical system. With such a big machine, why bother with high gradient? In collision the beams would pinch each other producing mostly backgrounds, so why bother at all?

These problems can be taken either as discouragement, or motivation. Actually it appears that most of them are simply symptoms of a naive collider concept. A different concept for a collider has been described by Zimmermann [2], as seen in Fig. 1, with parameters as in Table 1. To avoid beam disruption, neutralized beams or $\gamma\gamma$ collisions are employed. To form a compact final focus, chromatic correction is abandoned. Instead, it is assumed that each main linac is followed by two much shorter accelerators operated at harmonics of the fundamental. To improve luminosity for a given site-power, one combines single bunches from the linac. This requires a half-chicane, and synchrotron radiation there requires that bends be gentle, extending over 1.3 km. Control of single-bunch beam dynamics in the linac is consistent with permanent magnet quadrupoles.

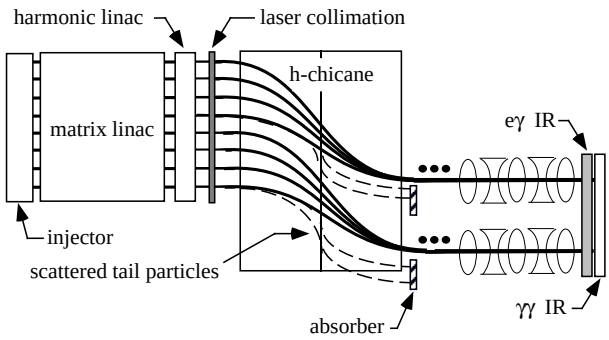

Figure 1: A new concept for a compact collider, as described by Zimmermann [2].

Even if one accepts that such concepts could be reduced to practice, one significant problem remains: how to make a high-gradient linac? This linac should be frugal with stored energy per unit length, and should be consistent with multi-beam collisions, either through beam-combining as seen in Fig. 1, multiplexed collisions, or a continuous focus in the interaction region. For example, if one could collide each of 50 bunches, the luminosity corresponding to Table 1 would approach 10^{35} $cm^{-2}s^{-1}$. In the meantime, work of [2] suggests that the collider problems-of-principle soon may be reduced to just

one: the accelerator. Let us consider then recent work on advanced accelerator concepts.

Table 1: Example Parameters for a Compact Collider.

parameter	W-Band example
center of mass energy	5 TeV
gradient	1 GeV/m
collision spot-size	1.8 nm
normalized emittance	10^{-7} m-rad
charge per linac bunch	60 pC
frequency	91.392 GHz
repetition frequency	120 Hz
main linac length	2.5 km
harmonic linac length	0.1 km

3 SOLID-STATE STRUCTURES

At high-gradient, solid-state structures are prone to breakdown [3] and cyclic stress arising from pulsed Ohmic heating [4]. Associated with breakdown are the phenomena of field-emission and trapping. A discussion of the phenomenology can be found in [5]. To summarize, breakdown is inhibited on short time-scales. Trapping occurs for gradient-wavelength product $G\lambda$>1.6 MeV. All such considerations favor short-wavelength for high-gradient. For G>1 GeV/m, frequencies of 10^2 GHz and higher are indicated. However, it is difficult to conceive of a resonantly-excited structure that can survive the Ohmic heating associated with such gradients. Thus pulsed-heating is the first motivation for research into new structure concepts.

There are four research directions one might pursue to lower cyclic stress limits: disposable (plasma) accelerators, advanced materials, composite structures, and active circuits. Plasma accelerators are discussed in the next section. Advanced materials include dispersion-strengthened conducting alloys [6], and dielectrics. Dielectric accelerators include wakefield-driven [7], and resonantly-driven [8] structures. Lin has analyzed a composite structure employing a diamond layer to reduce pulsed heating [9]. Diamond is attractive due to its high thermal conductivity, high dielectric strength, and low loss tangent [10,11]. Active circuits have been studied for some years, for applications external to the accelerator [12]; incorporation into the structure is a relatively new area [13]. One new concept for an active accelerator is seen in Fig. 2, employing a high-Q resonant cavity coupled by switches to loaded transmission lines, forming a matrix of accelerating cells. [14]. For the active element, silicon is inadequate at high-fields, and thus plasma and diamond are of interest. Use of diamond as the photoconductor requires 220-nm photons; carrier lifetime is adequate depending on the purity.

While the ultimate gradient attainable in a solid-state accelerator is unknown today, it appears that application of strengthened copper alloys, diamond layers, and active circuits may permit more than an order of magnitude improvement in stress-limited gradient.

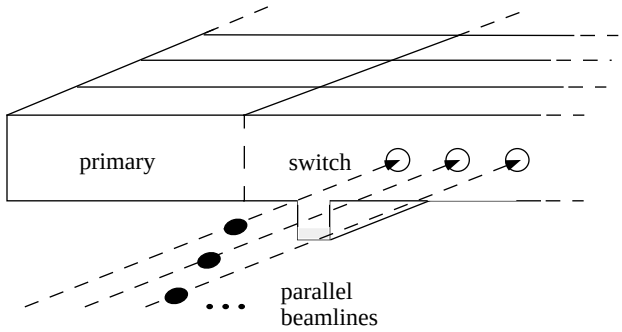

Figure 2: A new concept for an accelerator, employing an active circuit and parallel beamlines.

Structure fabrication and bench-measurement are critical to structure development. At W-Band (75-110 GHz) such work is being pursued by Kang, *et al.*, [15] via deep X-ray lithography, and D.T. Palmer via electrodischarge machining [16]. The primary challenge for fabrication at present is bonding. Brazing appears difficult due to the detuning effect of fillets; diffusion bonding is discussed in [16]. Meanwhile, good tune and quality factor have yet to be demonstrated in a multi-cell W-Band structure. In the meantime, other fabrication techniques merit attention, particularly where they may be extensible to the THz range [17].

A short-wavelength structure also requires a power source. To-date power levels adequate for 1-GeV/m fields have been demonstrated up to 140 GHz [18], and there in a mode consistent with the two-beam accelerator (TBA) concept. For TBA-driven colliders one is interested to assess drive beam stability at beam currents consistent with the stored energy requirement for the linac, typically 10^1 J/m. Tube concepts at 10^2 GHz meanwhile are making rapid progress at the 10^{-1} MW level [19,20], and a 10^1 MW design study is complete [21].

For structure dimensions in the 10^{-5} m range, lasers are adequate to produce GeV/m gradients, limited by structure damage [22]. However, it is important to keep in mind that for first-order accelerators [R/Q] is a crucial figure of merit for the energetics of the machine. Theoretical maximum in idealized cylindrical or rectangular geometries is 221 Ω, and this diminishes rapidly as the volume of the accelerating cell or the beam-port is enlarged. Higher-mode losses must be accounted for, particularly for small beam-ports [23].

For all short-wavelength solid-state structures, machine issues are in an early state. A glimpse of what is to come can be seen in the work on SLC collimator damage [24]. For structure protection, laser and resonant spoliation and collimation are being pursued [2]. Associated beamline instrumentation will require: manipulation of THz frequencies and beyond for bunch-length and beam-timing

information; beam position monitor resolution below the 10^{-7} m level for orbit analysis; single-pulse emittance measurement [25] for tune-up; use of the structure as a self-registered beam-position monitor [26] for control of emittance.

Given the benefits of harmonic-acceleration for energy-spread compensation [2], a linac proposed to operate at frequency f, should be accompanied by concepts for frequencies extending up to 10^2 f. Thus one is inevitably interested in structure development across the spectrum. Note that harmonic structures need not meet the same stringent requirements as the main linac structures, so that [R/Q], efficiency and gradient can be lower.

Structure research for the injector is equally critical. While the parameters of Table 1 are consistent with expected scalings for rf photocathode guns, the scaled field approaches 1 GV/m. Thus the problems of high-gradient appear in the injector as well. Possible alternatives include a pulsed photocathode-gun [27]. An injector providing a low-emittance, high-polarization electron beam remains a critical problem.

4 PLASMA STRUCTURES

The first plasma wakefield experiments employed a uniform plasma, demonstrating the principles of operation with injected beam; plasma wakefields were observed to exhibit a high Q, of order 10^2, in the linear regime (small $G\lambda$) [28]. In the intervening years, the plasma beat-wave accelerator has produced 2 GeV/m, and the laser wakefield accelerator, 100 GeV/m [29]. In a uniform plasma, however, the laser-driven concepts are limited by the diffraction of the drive pulse; thus observed beam spectra extend up to only 10^2 MeV.

To extend the interaction length numerous groups are presently pursuing experimental studies of laser-driven wakefield acceleration in a hollow plasma channel as seen in Fig. 3. Such a channel can serve as an optical fiber, permitting acceleration over many Rayleigh lengths [30]. With these efforts, and continued work on beam-driven wakefields [31], it is quite likely that a 1 GeV beam spectrum will be produced from a plasma accelerator, within the next year.

As the plasma accelerator concepts develop into a new generation of experiments, oriented on 1-GeV spectra and staging, it is timely to compare them quantiatively to the conventional multi-cell accelerator. Schroeder, *et al*., have recently analyzed the plasma channel in such a fashion [32], providing the first rigorous characterization as an accelerator. Let us summarize this work briefly.

In a uniform channel, there are two free parameters, the plasma frequency ω_p and the channel radius, b, measured in units of the plasma skin-depth $B=\omega_p b/c$. The accelerating mode of a plasma channel may be characterized by an [R/Q] (per plasma period) a function only of B, and a resonant frequency scaling with ω_p and a function of B. Moreover, Schroeder has discovered that for this monopole excitation, and for each higher azimuthal harmonic, the channel supports *only one* synchronous mode. This is possible since the channel is axially uniform, eliminating diffractive losses, and the plasma susceptibility is negative, suppressing Cherenkov losses.

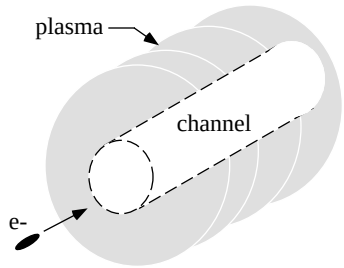

Figure 3: A hollow channel in a plasma can function as an accelerating structure.

The "single-mode" character of the channel implies lower parasitic losses than in a scaled conducting structure, and permits *shorter* bunches and *higher* single-bunch charge than in a scaled collider design. Analysis of the dipole mode shows that for multi-bunch operation, channels can be stagger-tuned to inhibit beam break-up. However, multi-bunch operation requires good Q for the accelerating mode and this requires a sharp-edged channel [33]. The high Q of the uniform plasma has not yet been demonstrated experimentally in the channel geometry, and vigorous efforts are underway to produce and diagnose tailored plasma channels [30].

The promise of this work is an accelerator concept superior in principle to the conventional circuit, immune to damage, and operating with an existing power source. The first challenge for such a disposable accelerator is accurate structure fabrication and diagnosis "on-the-fly", at the machine repetition frequency. To operate a series of such structures in concert, phasing and alignment must be provided for. Finally, incorporation into a multi-beam collision scheme should be addressed.

5 CONCLUSIONS

While the naive extrapolation of the conventional collider concept is fraught with problems, more sophisticated collision schemes are conceivable. In the last two years, we have seen new results emerge across the spectrum that appear capable of solving the problems of the compact collider, and its high-gradient linac. Work summarized here was not arrived at by scaling known technology, nor by contemplating only what can be engineered. Advanced accelerator research today is simply basic physics research, carrying us into the state- of-the-art in laser science, micro-fabrication, instrumentation and mm-wave and infrared technology --- and to the frontiers of plasma, beam, and high-energy physics. The results of

recent years suggest that the next-generation colliders will not be the last.

6 ACKNOWLEDGEMENTS

Collaboration with Carl Schroeder, Sami Tantawi, Jonathan Wurtele, and Frank Zimmermann was essential. Conversations with Wim Leemans were most helpful. I thank Angie Seymour for her support.

HIGH INTENSITY INJECTOR LINACS FOR SPALLATION SOURCES

K. Bongardt, M. Pabst, FZJ, Jülich, Germany
A. Letchford, RAL, Didcot, U.K.

Abstract

A review is given of the layout and the design problems for recently proposed spallation neutron sources with up to 5 MW average beam power. The accelerator part consists of an H^- - injector linac followed by compressor rings. Different to the design of high intensity proton linacs are the low energy front end and the restrictions at high energy for loss free ring injection. The linac energy spread has to be reduced by a bunch rotator requiring an unfilamented beam in longitudinal phase space. Uncollected ring injection losses should be kept below 10^{-4}. Due to intensity limitations of the H^- ion source a funneling line is needed at the front end. For loss free ring injection the linac pulse has to be chopped after the first RFQ. Special emphasis is given to either transverse or longitudinal halo production due to mismatch of a high intensity bunched beam. Concerning particle loss in the linac itself the loss rate has to be smaller than 10^{-7}/m for unconstrained hands on maintenance. Design criteria are discussed for 10% pulsed RF systems. Comments are given about the use of pulsed superconducting cavities above 200 MeV beam energy.

1 PROPOSALS FOR HIGH POWER SPALLATION SOURCES

Recent proposals for spallation neutron source facilities require up to 5 MW average beam power. The accelerator part consists of a high intensity pulsed H^- linac followed either by a compressor ring or a rapid cycling synchrotron. The high intensity compressor rings are summarized in ref. [1,2]. Detailed proposals exist for the following projects :

1.1 Japanese Hadron Facility (JHF)

The JHF aims at an interdisciplinary facility based on a high intensity proton accelerator [3]. It is planned to replace the existing KEK 12 GeV booster synchrotron by a high intensity 3 GeV booster. A 3 GeV, 200 μA proton beam , upgradeable to 800 μA, can be sent either to a spallation source target or a muon production target or nuclear physics area. By adding a 50 GeV proton synchrotron an average current of 10 μA can be given to a Kaon area or a neutrino experimental hall.

The H^- - injector linac has to accelerate a 30 mA peak current beam up to 200 MeV in a first step. The repetition rate is 25 Hz and the pulse length 400 μ sec, leading to 200 μA average current [4]. This results in a 3 GeV, 0.6 MW spallation neutron source. The final goal is to accelerate 60 mA peak current up to 400 MeV, leading to 800 μA average beam current at 50 Hz rep. rate. This would lead to a 3 GeV, 2.4 MW spallation source facility.

Quite recently the Japanese government decided to provide an additional fund to supplement the KEK 1998 budget. With this additional fund the JHF project team is preparing to construct a high intensity linac up to 60 MeV.

1.2 Neutron Science Project (NSP) at JAERI, Japan

The Japan Atomic Energy Research Institute (JAERI) is proposing the Neutron Science Project NSP. The objective of the NSP is to explore technologies for nuclear waste transmutation and basic research science in combination with a high intensity proton storage ring [5]. The 1.5 GeV linear accelerator is required to operate with H^+ and H^- particles in a pulsed or CW mode. 5 MW average H^- power is envisaged for a spallation neutron source facility, whereas 8 MW CW H^+ beam can be provided for nuclear waste transmutation experiments.

Above 100 MeV a 5 cell superconducting (SC) cavity at 600 MHz is foreseen with 16 MV/m peak surface field. Single SC cavities at β=0.5 have reached peak surface fields of 44 MV/m at 2.1 K already [6].

1.3 Spallation Neutron Source (SNS) Project

Oak Ridge National Laboratory is coordinating for the Department of Energy in the US the SNS project [7]. As a first step a 1 MW beam power facility with one target is envisaged with a final energy of 1 GeV. The whole facility is upgradeable up to 4 MW beam power and a second target station.

Design parameters of the first step are for the H^- injector linac pulse current of 30 mA for 1 msec long pulses. The 4 MW upgrade will be achieved by doubling the ion source current and installing a funnel line at 20 MeV. The high energy part of the linac is a conventional room temperature 805 MHz coupled cavity linac (CCL).

The project will be built by a consortium of 5 DOE laboratories. Lawrence Berkeley National Laboratory (LBNL) is responsible for the SNS linac front end [9], Los Alamos National Laboratory (LANL) is designing the linac [8]. The transport line between linac and compressor rings and the compressor ring layout itself is the responsibility of Brookhaven National Laboratory (BNL).

1.4 European Spallation Source (ESS)

The 5 MW beam power short pulse ESS facility [10] consists of a 6% duty cycle H^- linac with 1.334 GeV final en-

ergy. The pulse compression to less than 1μ sec is achieved by two compressor rings in a shared tunnel. Various R+D work is going on, especially for building an ESS test stand with ion source, chopper and RFQ at Rutherford Appleton Laboratory (RAL) U.K. and continuing beam loss studies [11].

2 BASE LINE LAYOUT OF HIGH INTENSITY INJECTOR LINACS

The dominating design feature of a high intensity injector linac is to bring particle losses down to about 1 W/m and to guarantee less than 10^{-4} uncollected ring injection losses. All accelerator sections have to be designed to be far away from the space charge limit.

As an example, the layout for the 5 MW H^- injector linac of ESS is shown in Fig. 1. Both RFQs operate at 175 MHz followed by a conventional 350 MHz drift tube linac (DTL) up to 70 MeV. The high β CCL operates at 700 MHz. Different from a proton linac is a bunched beam chopping line at 2 MeV between two 175 MHz RFQ structures and a bunch rotation cavity at the linac end. For achieving loss free ring injection, the linac pulse has to be chopped at the ring revolution frequency and the energy spread has to be reduced by the bunch rotator.

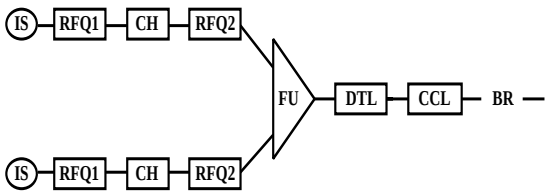

Figure 1: ESS linac layout: IS: I ion source, CH: chopper, FU: funneling, BR: bunch rotator

2.1 Low Energy Front End

Ion source requirements of more than 100 mA, 10% duty cycle H^- currents cannot be met with existing ion sources. R and D prototype programs are going on for all the above mentioned spallation source projects. For ceasiated RF-driven H^- volume sources a current of 70 mA at 7% duty cycle will be reached soon [9,12].

The beam transport between the H^- ion source and the first RFQ can be space charge compensated or uncompensated [9]. Integrated ion source RFQ test stands are set up for both possibilities.

Cooling problems for a 10% duty cycle RFQ are not so severe as for a CW H^+ RFQ, but more demanding than in RFQ structures built up to now. Field stability at 10% duty cycle can be achieved by 'π-mode stabilization loops' (PISL) for 4 vane structures [13]. Less than 1% unwanted field contamination has been experimentally verified. The 4-rod RFQ offers some advantage over the 4-vane design in terms of RF properties and ease of manufacture. The limited cooling capacity of a conventional 4-rod RFQ can be overcome [14], allowing up to 10% duty cycle. New RFQ-codes are available, taking into account rod or vane shaped electrodes, 8 term potential function, dipole components and complete 3d space charge subroutines [15].

A bunched beam transfer line at about 2 MeV is a good solution for a clean chopped beam with sharp edges and small longitudinal emittance increase. Chopping efficiencies of about 60% are required for loss free ring injection. Fast traveling wave choppers with 3 nsec rise time are under development [16]. Layouts of a chopping line with regular betatron oscillations as equal as possible in both planes results in quite small rms emittance growth [2].

The use of a funneling scheme implies a second bunched beam transfer line, but relaxes the constraints on the chopping line and on the ion source considerably. The peak current per ion source is halved and the first RFQ can operate at lower frequency. In a funneling section with conventional elements the two beams are merged together by an arrangement of septum magnets and an array of RF deflection elements. Care has to be taken to match the dispersion and its angle to zero even under space charge conditions [2]. By implementing a Two-Beam Funnel RFQ [17] lower energies for the funneling section seem to be possible.

2.2 Halo Production due to Mismatch in Bunched Beams

The major problem of the design in high current proton linacs is the loss of particles at higher energies. Particle loss leads to activation of accelerator components and reduces the flexibility of hands on maintenance. As a rule of thumb, hands on maintenance is possible if the loss is less than 1 W/m. In a linac losses occur radially due to the formation of a beam halo. The beam halo consists of a 'small' number of particles which oscillate around the beam core. In addition filamentation of the particle distribution in the longitudinal phase space can cause activation problems when injected into compressor rings. The design goal is less than 10^{-4} uncollected lost particles at ring injection.

In recent years substantial progress has been achieved by identifying the parametric resonance condition as a major source of halo production of DC and bunched beams. For realistic particle distributions with nonlinear space charge forces particles even inside the core have a tune spread. Parametric resonances can occur between single particle tunes and the frequency of the oscillating mismatched beam core [18].

Due to the two transverse and one longitudinal bunch dimensions 3 eigenmodes exist for a bunched beam. The frequencies of these modes can be approximately expressed by the full and zero current transverse and longitudinal tunes only. There exists a pure transverse quadrupolar mode and high and low modes which couple the transverse and longitudinal directions. The high mode represents a 'breathing' of the ellipsoidal bunch. For the low mode the bunch breathes in transverse direction but the oscillation in

the longitudinal direction is of opposite phase. For exciting the high or low mode only, the longitudinal mismatch is normally different in amplitude than the transverse ones [18,19].

For a mismatched bunched beam a 1/2 parametric resonance between a single particle tune and the frequency of an eigenmode is always excited radially by the quadrupolar mode. The high or low mode can excite a parametric resonance in the transverse and/or the longitudinal direction.

Fig. 2 and Fig. 3 show Monte Carlo simulations with 20000 particles which interact in full 3d for a 70 MeV bunched beam transfer line. A 6d waterbag distribution is used as input. The transverse and longitudinal tune depressions are 0.7 and 0.8 respectively. The transverse temperature is 1/3 of the longitudinal temperature. Shown is the 99.9% total to rms emittance ratio in the x-direction. In Fig. 2 the matched case is compared to a 20% quadrupolar mode excitation. A substantial increase of the 99.9% emittance is visible due to the 1/2 parametric resonance excitation. In Fig. 3 the same emittance ratio as in Fig. 2 is shown but comparing the matched case with a 20% radially and 30% longitudinally excited high mode. Here, no single particle tune is as large as half the high mode frequency and, as predicted, no resonance effect can be seen [18,19].

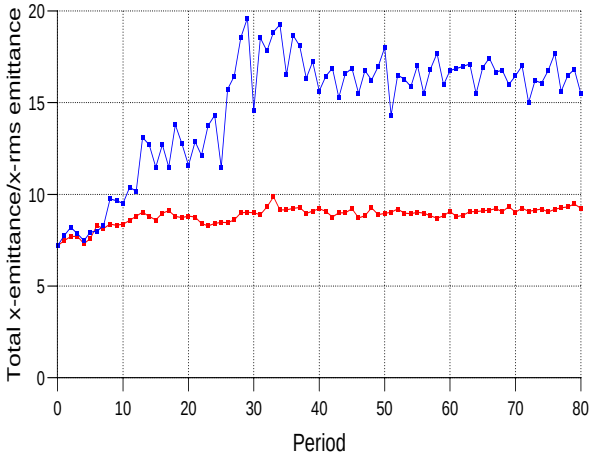

Figure 2: 99.9% total to rms emittance ratio for a matched (bottom) and a quadrupolar mode excited case (top)

During the startup period of high intensity linacs more than 20% initial mismatch is expected especially in the longitudinal plane. For a spallation source linac with its additional restriction on loss free ring injection a design is required where the transverse and longitudinal halo production is insensitive to all kinds of mismatch. Linac designs with both transverse and longitudinal tune depressions above 0.8 and transverse to longitudinal temperature ratios between 1/3 and 2 fulfill these conditions if no high mode envelope instability is excited [18]. The 214 mA ESS CCL has design parameters which meet these conditions for most of it's length and transverse and longitudinal halo formation is acceptable for a 20% initial mismatch. Space charge dominated designs with tune depressions below 0.4 [20] or large temperature anisotropy [21] can lead to chaotic single particle motion [22] and enormous halo production due to mismatch which is absolutely unwanted for high intensity injector linacs.

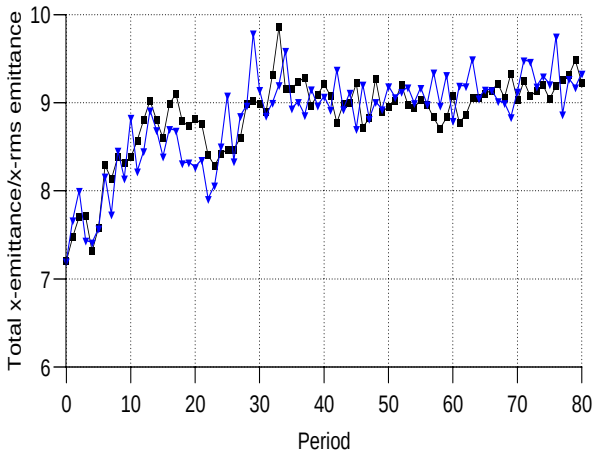

Figure 3: 99.9% total to rms emittance ratio for a matched (squares) and a high mode excited case (triangles). Please note the enlarged scale

2.3 High β Transfer Line

The transfer line from the H^- linac to the compressor rings differs in some respects from the H^+ transferline between a high intensity H^+ linac and a high power target station either for tritium production or waste transmutation. In both lines the linac beam is not kept bunched. Space charge forces are small but still effective, especially in the longitudinal plane [23] resulting in an increase of the energy spread.

For loss free ring injection into a circular machine the energy spread of the linac bunches has to be reduced by placing a bunch rotator at some distance behind the linac. After bunch rotation there should be less than 10^{-4} particles outside an energy spread of $\pm$ 2 MeV as a typical figure. For the ESS bunch rotation system there are less than 10^{-4} particles outside $\pm$ 0.8 MeV for the matched case, but more than 10^{-4} outside $\pm$ 1 MeV for the mismatched case. Longitudinal space charge effects are still visible after the bunch rotation system.

Uncorrelated RF amplitude and phase errors of $\pm$ 1% and $\pm$ 1^o respectively can cause an oscillation of the beam center by as much as 1 MeV [24]. As the energy spread collimation has to be guaranteed for all bunch currents including much larger RF tolerances during the start up procedure achromatic bending systems have to be installed in the high β transfer line. The influence of a conducting pipe has to be considered as the bunch length is equal or larger than the pipe radius. [23]

3 PULSED RF SYSTEM

The high β section from about 100 MeV onwards is the most expensive part of the whole linac for both the capital cost and the operating cost. Typically operating frequencies are between 600 and 800 MHz. Cost optimization of the accelerating gradient leads to about 2.8 MV/m for 10% duty cycle pulsed operation. Including focusing quadrupoles and diagnostic elements this value corresponds to an average real estate energy gain of 2 MeV/m for a room temperature linac design.

The layout of the RF system is a trade off between capital cost and overall RF efficiency. Conventional 2.5 MW peak power klystrons at 805 MHz, 8% duty cycle, with a modulating anode and a floating deck modulator are proposed for the SNS [25]. Such a RF system is expected to be very robust, can almost be built today and does not need circulators for protecting the klystron. The klystron efficiency is 60% at 100 kV beam voltage.

Prototyping is necessary for a 2.5 MW peak power, 7% duty cycle cathode modulated klystron with a transformer coupled bouncer type modulator. More than 65% RF efficiency is expected for 120 kV beam voltage at 1.4 msec pulse duration. No circulator is required. The modulator cost can be substantially decreased by connecting 2 klystrons to one modulator. The modulator efficiency is about 85%, the pulse flatness better than $\pm$ 0.5% [26]. A test stand with commercially available IGBT switches (EUPEC FF 800) mounted on individually water cooled boards has been set up in order to study temperature rise and life time problems at 50 Hz repetition rate for ESS.

Low voltage 2 MW peak power HOM-IOT (higher order mode inductive output tube) without a modulator are expected to be an attractive solution in the near future due to their smaller size and lower production costs compared to high power klystrons. Prototyping is needed therefore. A 1MW CW, 700 MHz HOM-IOT is under development for the Los Alamos APT project [27] requiring only 40 kV beam voltage for an anticipated RF efficiency $>$ 70% [28]. For a 700 MHz HOM-IOT with 2 MW peak power pulsed at 7% duty cycle, only 65 kV beam voltage is required and an efficiency of $>$ 70% is expected [29].

Attention has to be given to the RF control system. For H^- injector linacs uncorrelated amplitude and phase errors have to be limited typically to $\pm$ 1% and 1^o respectively in order to prevent intolerable oscillation of the beam centre at the linac end. The strict amplitude and phase tolerances counteract in some respects the use of high peak power multi beam klystrons (MBK) as power splitting is mandatory here. Circulators are necessary for protecting the MBK. Doubling the number of cells per tank is not recommended as the field flatness is proportional the square of the cell number.

4 SUPERCONDUCTING HIGH β LINAC

Superconducting cells are a very interesting option for the high β linac. Superconducting cavities are now being routinely used in many accelerators. Experience gained during building these machines strongly suggests that RF superconductivity is approaching mature technology, even if it is still far from its limit. In order to accelerate a high intensity proton beam from 100 MeV to about 1.3 GeV, various technical and physical difficulties have to be overcome, which do not exist in the acceleration of low intensity relativistic electron beams.

For the 100mA CW APT proton linac a 5 cell 700 MHz superconducting cavity at 2 K is proposed from 217 MeV on [27]. Focusing is provided by conventional quadrupole doublets located in the warm region between cryomodules. Only 2 different cavity length are foreseen with an on axis accelerating gradient of about 5 MV/m. The real estate energy gain in the SC linac is 1.5 MeV/m. Each 5 cell SC cavity is equipped with 2 power input couplers, limited to 210 kW each. The 5 cell cavities are arranged in cryomodules fed by 1 MW DC klystrons. About $\pm$ 3% amplitude and $\pm$ 5% phase errors in each cavity are tolerable caused by the power splitting procedure.

The layout of a SC high β linac for 10% pulsed H^- injector differs in some respects from the layouts for a CW proton linac. Normal conducting, 700 MHz, 10% pulsed coupled cavity linacs for energies from 100 MeV on have an real estate energy gain of 2 MeV/m. For msec long pulses the achievable accelerating gradient in a SC cavity is almost the CW value limited by the peak surface field especially at β values below 0.5, corresponding to 150 MeV proton energy. Peak surface field values of 25 MV/m for a 2 K 5 cell cavity around 600 MHz are expected to be reached quite soon. The corresponding accelerating gradients inside the SC cavity are 6 MV/m at 200 MeV and 10 MV/m from 900 MeV on leading to a real estate energy gain of 3 MeV/m. 5 different geometries are needed for such a SC linac. 240 kW and 600 kW peak power is needed for a 5 cell cavity at 200 MeV and 900 MeV respectively. Substantial R+D is needed for developing input couplers at about 600 MHz, capable of handling 1 MW peak reflected power during the 100 μsec long filling time, corresponding to 4 MW peak forward power. Circulators are mandatory for klystron protection.

The input coupler power limitation can in principle be overcome by having 2 couplers per cavity. As pointed out before power splitting is a problem for a high intensity H^- linac due to the $\pm$ 1% and $\pm$ 1^o amplitude and phase error limits in each cavity. Another difficulty for the RF control system is the field stabilization at the beam arrival time, complicated due to microphonic noise varying from cavity to cavity and pulse to pulse. The startup cavity frequency can oscillate by $\pm$ 30 Hz, intolerable with $\pm$ 1^o phase error. Unlike electron linacs phase errors in different cavities connected to one klystron do not add up to a common energy fluctuation [30]. Large but predictable RF errors due to Lorentz force detuning may be compensated by stiffening the cavities and applying digital feedback and feedforward from lookup tables [31].

Below 200 MeV or β = 0.6 elliptical shaped SC struc-

tures suffer from mechanical instability problems [5]. The real estate energy gain is lower compared to a 10% pulsed room temperature linac due to the uneconomic use of space in a low β cryomodule. Also the RF control problems are more severe here due to the reduced cavity bandwidth.

Different groups have R+D plans to study β=0.5 cavity structures [5], new fabrication techniques [32] and pulsed RF control problems including power splitting [33].

For a 10% pulsed H^- injector linac limiting the peak surface gradient to 25 MV/m in the SC cavity for an energy range from 200 MeV to 1.5 GeV, the SC linac has 2/3 of the length of a competitive room temperature one. The capital costs are expected to be equal or even slightly higher for the SC option. A 5 MW average beam power spallation neutron source needs about 75 MVA AC power where about 12 MVA can be saved with such a superconducting linac

HIGH BRIGHTNESS ELECTRON SOURCES

J.B. Rosenzweig
UCLA Dept. of Physics and Astronomy, Los Angeles, CA 90095

Abstract

The production of unprecedentedly high brightness electron beams is a critical aspect of many applications, from free-electron lasers to advanced accelerators. The preferred method for obtaining these beams is the radio-frequency photoinjector. The physics and technology aspects of this device are reviewed here, along prospects for future progress in high-brightness beam development.

1 APPLICATIONS

Several applications of high brightness electron beams are driving the worldwide development of electron sources. These include free-electron sources of coherent radiation, such as self-amplified spontaneous emission free-electron lasers [1] (SASE FEL) and Compton scattering sources [2]. In the FEL, the beam is the lasing medium, and must thus be very dense to provide high gain. A measure of this is the brightness, which is the ratio of the current (linear density) to the square normalized rms emittance

$$B \equiv \frac{2I}{\varepsilon_n^2}. \qquad (1)$$

The brightness is a measure of the practical focusibility of a beam. Other applications include very high peak current, short pulse, and moderately low emittance beams which are needed to drive wake-field accelerators [3], and linear collider sources of polarized electrons [4]. For the FEL and wake-field accelerator, a high-brightness, pico-second electron beam is a critical technology. The need for these sources in linear colliders is not as clear, as positron sources are additionally needed, and the necessary emittances may not be achieved without damping rings.

The demanded parameters for typical future applications are given in Table 1. The pulse lengths needed are given in the absence of pulse compression, which may be necessary for all applications. The parameters for the TESLA linear collider may be approachable by electron sources using slightly exotic, asymmetric rf structures [5]; for other designs, damping rings will be required.

Table 1: Electron source parameters for applications. Emittance and pulse duration are rms quantities.

Application	I (A)	ε_n (mm-mrad)	σ_t (psec)
SASE FEL	200	<2	<3
Wake driver	>1000	<100	<2
TESLA-LC (polarized)	800	1 (y), 20 (x)	<3

2 RF PHOTOINJECTORS

The state-of-the-art in high brightness electron sources is achieved with the rf photoinjector. This type of device, an example of which is shown in Figure 1 (the Neptune photoinjector at UCLA [6]), uses a photocathode source embedded in a high gradient rf gun. The laser pulse which excites photoemission in the gun is very short, at the level of picoseconds or below. For promptly emitting photocathodes this implies that one can create the psec electron pulses of the sort given in Table 1 in this device.

The gun is followed by a transverse focusing element (usually a solenoid), which aids in beam size and emittance control. It additionally must be post-accelerated to bring the beam to a usable energy, and to mitigate space-charge effects. This acceleration is accomplished in a booster linac, which may be physically separated, or integrated into the same rf structure as the gun.

As the effects of space-charge and wake-fields during the acceleration process often conspire to lengthen the pulse. Because of this, it is often necessary to include in the rf photoinjector system a magnetic chicane [7] for pulse compression. The chicane can give additional capabilities and design flexibility in advanced electron sources.

The analysis, design, and operation of rf photoinjector sources entail a working understanding of many diverse areas of beam physics, and accelerator and laser technology. We begin by discussing the physics of these beams, which is dominated by space-charge and violent acceleration effects.

3 PHOTOINJECTOR BEAM PHYSICS

3.1 Longitudinal dynamics

The longitudinal dynamics in an rf photoinjector are characterized by violent acceleration. This is due to two effects: the need to mitigate detrimental space-charge effects, and the requirement that the beam be captured in the rf wave within the initial cell of the standing wave rf cavity. This can be quantified by defining a unitless parameter which must exceed approximately unity [8]

$$\alpha \equiv \frac{eE_0}{2k_{RF}m_e c^2} = \frac{\gamma'}{k_{RF}} > 1 \qquad (2)$$

This parameter allows a classifcation of injector types: high gradient injectors have $\alpha \cong 1.5 - 2.5$, whereas the lowest gradient injectors operate with $\alpha \cong 1$. The typical range of peak on-axis accelerating field encountered for a common rf wavelength, $\lambda_{RF} \equiv 2\pi/k_{RF}$ = 10.5 cm, is eE_0 = 60 – 150 MeV/m. These high gradients allow good

control of the beam dynamics, but only within limits, as the space-charge field at the cathode due to the surface charge density there can easily be near the applied rf field. Thus we have the requirement

$$E_0 >> 4\pi e\Sigma_b = 2eN_b/\sigma_r^2 \ . \qquad (3)$$

This inequality guarantees only that the beam fields are perturbative. If in addition we wish to ensure that the beam not lengthen appreciably during acceleration, then we require a short acceleration length $\gamma'^{-1} = (k_{RF}\alpha)^{-1}$,

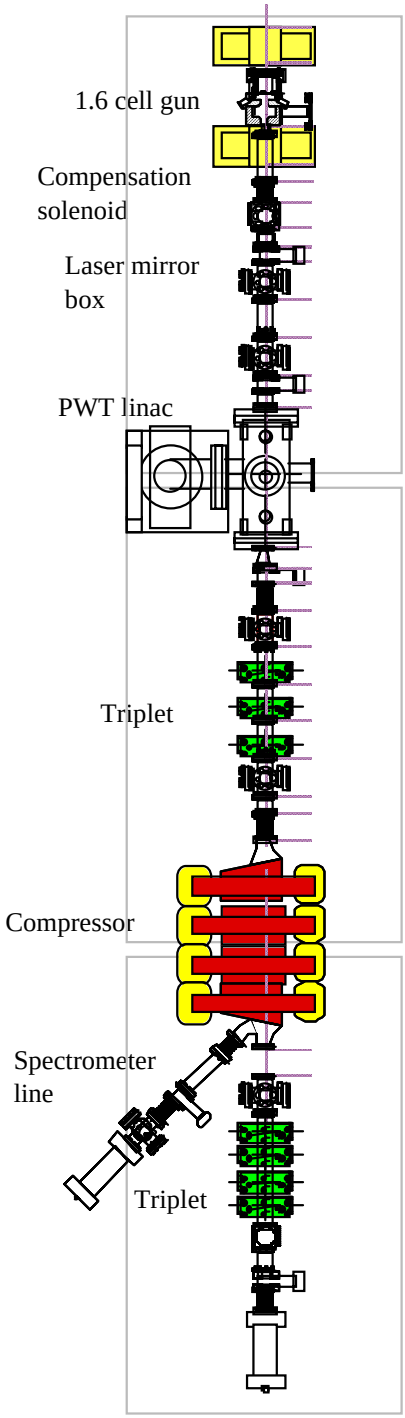

Figure 1. The Neptune photoinjector at UCLA.

$$c\sigma_t \geq \gamma'^{-1} \ . \qquad (4)$$

When inequalities 3 and 4 are satisfied, the beam pulse length may be preserved, and even compressed by rf focusing effects during capture in the initial cell.

Longitudinal bunch compression in photoinjectors is now a commonly employed, yet not completely understood, tool. Magnetic chicanes have been employed in a number of photoinjector facilities; space-charge limits on compressibility, and the effects of non-inertial space-charge and radiation fields on emittance growth [9] are the subjects of present and future experiments.

3.2 Transverse dynamics

Violent acceleration carries with it large transverse forces, which for an accelerator cavity terminate on a conducting (cathode) plane, gives a net first order kick to an off-axis accelerating particle. Further, this kick is rf phase dependent, and thus for a finite pulse length beam, an effective "rf" emittance is [8]

$$\varepsilon_{RF} \propto \gamma k_{RF}^2 \sigma_r^2 \sigma_z^2 \propto \alpha k_{RF}^3 \sigma_r^2 \sigma_z^2 \ . \qquad (5)$$

The first order rf kick can be thought of as originating at the end of the structure. All other irises in the rf structure have a balance in first order inward/outward kicks, but have a second order alternating gradient focusing (of strength $\propto \gamma'^2$) [10]. The combined effect of the rf focusing can be included in envelope and matrix treatments of the beam dynamics. The analytical model has been recently verified experimentally [11].

Photoinjector beams are generally space-charge dominated. The rms envelope equation, including acceleration and space charge, can be written as

$$\sigma'' + \left(\frac{\gamma'}{\gamma}\right)\sigma' + \left[k_\beta^2 + \frac{\eta}{8}\left(\frac{\gamma'}{\gamma}\right)^2\right]\sigma = \frac{I}{2I_0\gamma^3\sigma} + \frac{\varepsilon_n^2}{\gamma^2\sigma^3} \ . \qquad (6)$$

The emittance term is negligible for these beams (cold plasma, or quasi-laminar flow limit), with ratio of defocusing terms

$$\rho = \frac{I\sigma^2}{2I_0\gamma\varepsilon_n^2} >> 1 \ . \qquad (7)$$

For high-brightness beams this situation persists until the beam is very energetic (>100 MeV), or at tight focus.

As the enclosed current in bunched beams depends on longitudinal position, or "slice", within the bunch, the differential defocusing of the slices can produce a sheared total projected phase space. This leads to emittance growth, or, in systems with proper external focusing, emittance oscillations.

A useful heuristic model for understanding the process of emittance oscillations is shown in Figure 2. In this case, we suppose that a beam is injected with size smaller than the equilibrium sizes of the slices. As the equilibria in amplitude are dependent on the current at a given slice, the subsequent oscillations are larger for smaller currents, but the (plasma) frequency of oscillation is the same

($\omega_p = k_\beta c$). Thus the beam edges, which define angles in phase space, line up, regardless of slice, twice per oscillation, at the beam minimum and maximum. At these points, the projected emittance is also a minimum. The process of emittance compensation is essentially the arresting of these oscillations after an integer number of beam plasma periods. The plasma oscillations are adiabatically terminated, of course, by acceleration, which diminishes the strength of the space-charge.

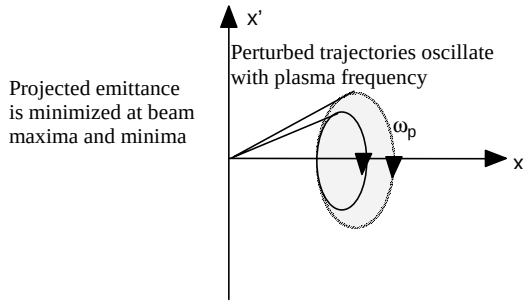

Figure 2. Emittance oscillations caused by slices about rotating in phase space about different equilibria.

The recently developed analytical theory of emittance compensation is based on Eq. 6, and examines a new type of equilibrium laminar flow (analogous to Brillioun flow) the invariant envelope [12]

$$\sigma_{\text{inv}} = \frac{2}{\gamma'}\sqrt{\frac{I}{3I_0\gamma}} \tag{8}$$

The invariant envelope has the property that the phase space angle $\sigma'_{\text{inv}}/\sigma_{\text{inv}} = \gamma'/2\gamma$ is independent of current. This guarantees that once all slices are aligned in phase space, they remain so. Slices not aligned to the invariant envelope oscillate in a Liouvillian space about the invariant envelope, giving rise to emittance oscillations. It should also be noted that the beam becomes smaller as it accelerates, driving the residual emittance down as $\gamma^{-1/2}$.

The model for the compensation of time-dependent space-charge forces is well understood analytically, through simulation, and experiment. New theoretical work concerning the role of nonlinear forces in optimized beam transport, is now underway.

3.3 Scaling of Designs

One recent advance in the understanding of photoinjector beam physics is the development of charge (Q) and wavelength (λ) scaling laws [14]. Charge scaling allows change of design charge while keeping dynamics of compensation identical, thus permitting a high Q, low brightness design (*e.g.* TTF) to a low Q, high brightness design (*e.g.* TTF-FEL). Wavelength scaling allows the taking of a design from one rf wavelength, and move it to a different value of λ. This permits expertise to be shared among different laboraratories, and the performance of seemingly disparate devices to be compared. It also is a tool which can, as we will see below, point to promising new directions in source development.

In charge scaling, we do not change external forces (or wave-numbers), and must therefore preserve plasma wave-number. This in turn implies that we preserve bunch density and aspect ratio, or $\sigma_i \propto Q^{1/3}$. Deviations from strict Q-scaling arise from space charge at cathode, and rf effects, as the beam size changes relative to rf wavelength. Following this scaling, it can be shown that the emittance arises from two components: space-charge, which contributes $\varepsilon_x^{sc} \propto \sigma_x^2 \propto Q^{2/3}$, and rf/chromatic focusing effects, which contribute $\varepsilon_x^{rf} \approx \sigma_z{}^2\sigma_x^2 \propto Q^{4/3}$. PARMELA simulations of a family of Q-scaled cases in an S-band emittance compensated injector gives the results shown in Fig. 3.

The fit for the data shown is

$$\varepsilon_x \cong \sqrt{\tfrac{4}{5}Q^{4/3} + \tfrac{1}{2}Q^{8/3}} \tag{9}$$

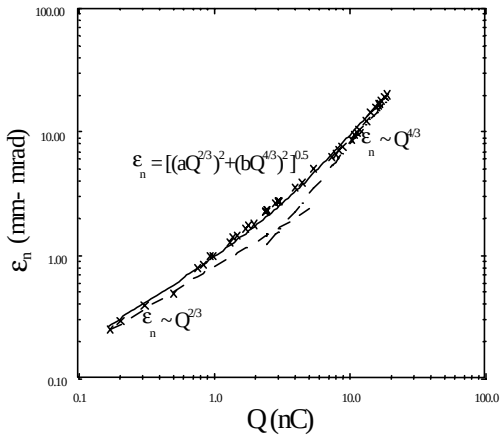

Figure 3. Emittance for family of Q-scaled cases in an S-band emittance compensated injector.

For wavelength scaling, we must preserve longitudinal dynamics, which requires α = constant, or $E_0 \propto \lambda^{-1}$. To additionally preserve the energy spread and beam aspect ratio, we have that all beam dimensions scale as $\sigma_i \propto \lambda$. Further, making the betatron frequency scale properly requires that the solenoid field $B_0 \propto \lambda^{-1}$, and the scaling of the beam-plasma frequency requires $Q \propto \lambda$.

There are no inherent deviations from λ-scaling laws, and use of these laws can be shown to yield an emittance scaling of $\varepsilon_x \propto \lambda$. Note also, that brightness scales as $B \propto \lambda^{-2}$; the advantage of short λ operation is apparent.

Nevertheless, several aspects of scaling to short λ merit discussion. Technologically, the laser laser pulse length and jitter are as well as emittance measurements are more difficult at short λ. The scaling of external forces requires large rf fields, which may be "natural" - high-gradient implies short λ because of breakdown limits, power considerations, etc. The scaling of the focusing fields is less natural, however, as the current density in the solenoid scales as $J_{sol} \propto \lambda^{-2}$. In addition, many applications require a certain charge per bunch. With large charge, short wavelength implies rf dominated operation. The optimum emittance and brightness occur

at a certain wavelength in the transition between the space-charge and rf-dominated regimes — for Q=1 nC, the optimum deduced from Eq. 9 is approximately 9 GHz.

4 TECHNOLOGY

Many of the performance limitations in photoinjectors are technological, not fundamentally physical. We now review the status of rf photoinjector technologies.

4.1 RF cavities

Rf cavities for photocathode gun use have gone through considerable development in the last decade. The most successful designs have been the low-α, integrated photoinjectors typified by the LANL devices, and the high-α short (1.5-6 cell) guns pioneered at BNL.

The high-α S-band gun has been improved recently by making the photocathode cell of length 0.625 times a π-mode standing wave cell. This improves the ratio of peak on-axis to wall fields, and provides stronger rf focusing near the cathode, enhancing the emittance comp-ensation process. The coupling to the waveguide is perf-ormed only in the full cell, using symmetrized slots or a coaxial coupler, with on-axis coupling to the 0.5-cell.

The integrated photoinjector, in which a large number of cells are coupled together, cannot be easily coupled on axis in the π-mode while maintaining good mode separation. The solution employed at LANL entails coupling through on-axis vestigial cells in a π/2-mode configuration. A new S-band design being pursued by a UCLA/DULY Research collaboration uses a plane wave transformer (PWT) structure. This structure has excellent coupling through a coaxial region outside of the accelerat-ing mode-supporting disks. The emittance compensation optics in this device were the first to be derived from analytical theory [12]. It is interesting to note, however, that the optics in the PWT could have been deduced by scaling of the L-band optics of the AFEL injector at LANL — they are nearly identical when scaled. Scaling of the PWT design to X-band is in fact discussed below.

4.2 Lasers

Several years ago, the necessary drive laser pulses (picoseconds, total energy from tens of μJ to tens of mJ) were very difficult to achieve [14]. The amplification process often used flash-lamp pumping and chirped-pulse amplification, both of which tend to introduce unwanted fluctuations in pulse energy. This problem has been mitigated by use of diode-pumping technology. Advanced development in photocathode drive lasers now concentrates on production of long pulse trains [15], and on obtaining an illumination which is relatively uniform in time and transverse position, to make the space-charge forces as linear as possible. This goal may now be in reach through use high-bandwidth, short pulse lasers (*e.g.* Ti:Sapphire) combined with Fourier-plane filtering, as well as soft aperturing and relay imaging of the pulse.

4.3 Photocathodes

The search for a robust, high quantum efficiency (QE) cathode is now localized on two types of materials. Metals such as magnesium have been found to be prompt, with fsec response, but with QE no better than 10^{-3} (with uv illumination) and significant dark current. In addition, metal cathodes are surprisingly sensitive to vacuum conditions, and typically must be "laser cleaned" to produce anything approaching uniform emission.

A more promising candidate for high-brightness cathode development is Cs_2Te. This material is relatively immune to vacuum problems, can be revived after contamination, has QE as large as 15%, and a low inherent emittance. On the other hand, it still requires uv illumination to photo-emit, and is undoubtedly slower in emission delay than a metal photocathode.

Linear collider electron sources demand polarization. The development of a polarized photocathode in an rf gun, which entails addressing vacuum, field, and charge limitation problems, is only now beginning. Testing of GaAs cathodes in a high gradient rf gun has been reported at the CLIC Test Facility [16].

5 PRESENT PERFORMANCE

The state-of-the-art in beam parameters obtained from rf photoinjectors has advanced rapidly in the last few years.

- The charge measured from these devices has been as high as 100 nC [16,17]. Pulse trains with as much as mC have been reported.
- The pulse length, which is typically space-charge limited, has been measured at the level of a picosecond, for relatively low charge. For higher charge, the highest current reported is a few kA [16]. Picosecond pulses can be measured by streak cameras (which also provide imaging information) or rf sweeping techniques. At this pulse length, and below, it is now popular to use coherent transition radiation interferometry, which can resolve times as small as 0.2 psec.
- The normalized rms emittance has been measured in a variety of laboratories [18] to be at the level of 2 mm-mrad/nC. This is expected to be reduced by a factor of two with the advent of shaped laser pulses. The measurement of the emittance in space-charge dominated beams has presented a challenge in its own right, with the standard quadrupole scan method being prone to space-charge induced problems in interpretation. Nevertheless, at BNL these problems have been overcome, and a time-resolved emittance measurement, which verified the slice-model of emittance compensation reported [19]. Alternatively, a slit-based measurement system can be employed which mitigates space charge and allows single shot reconstruction of the beam's phase space.

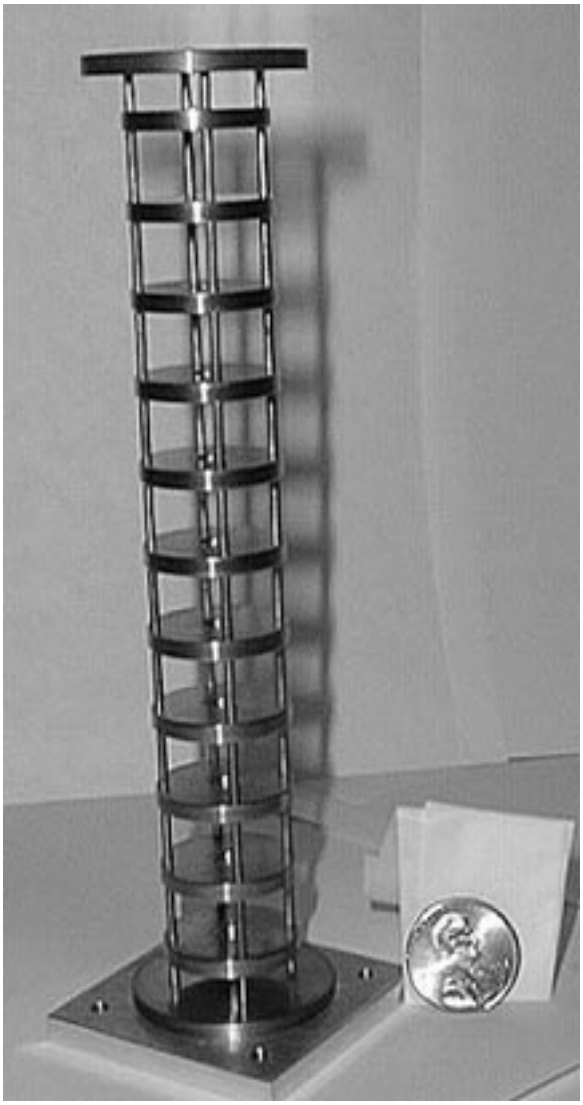

Figure 4. Interior of 11.4 GHz PWT cold test structure.

6 FUTURE DIRECTIONS

The choice between integrated and split photoinjectors is not simple, as there are advantages and unattractive features to both. The split photoinjector is flexible; one can choose booster linac gradient/phase, and gun-linac drift length for compensation can be optimized. One can naturally include a compressor. One actually must choose a high gradient in the gun, or the drift section will produce pulse lengthening and larger residual transverse emittance — the TTF gun is run at relatively α. As the defocusing kick at the gun exit is proportional to the beam size, the compensation solenoid must be stronger, and is difficult to build at short λ. Also because of the exit kick, the beam size oscillation is larger, and this produces larger residual emittances.

For an integrated injector, the gradient in the structure is lower, and the scaling to short λ is easier. At lower gradient however, the space-charge pulse lengthening near the cathode is larger than that in a high-gradient gun, but because of continuously applied longitudinal focusing in the structure, the bunch does not appreciably lengthen after the initial cell. The needed solenoid field lower is also lower, again allowing easier scaling to short λ. As the beam exits the structure small (near the invariant envelope) the rf kick at the structure exit is not large, and the rf-derived emittance can be greatly mitigated.

It can thus be seen that the high gradient gun generally produces shorter pulse lengths, but the integrated injector gives better emittance performance at a given λ. But if one chooses a short λ, then the achievable pulse length becomes smaller. Because of this, we have proposed, and are now seriously developing a scaled X-band version of the PWT injector at UCLA, in collaboration with DULY Research and LLNL. Simulations of an 11.4 GHz injector indicate [5] that this device can produce 120 μm rms bunch lengths at 1 nC, with ε_n = 0.8 mm-mrad, for a brightness, $\varepsilon_n = 3 \times 10^{15}$ cm^{-2}, which is a factor of 30 times greater than the present state of the art. In this development we are concentrating on the issues of structure cooling and solenoid design, which both become quite challenging in X-band. A cold-test model of an 11.4 GHz structure's interior is shown in Fig. 4. Development of the injector will probably take place at 8.6 GHz, however, due to availability of rf power, and solenoid design issues. It should also be noted that this is near the optimum value of λ predicted to minimize the emittance at 1 nC.

Abstract

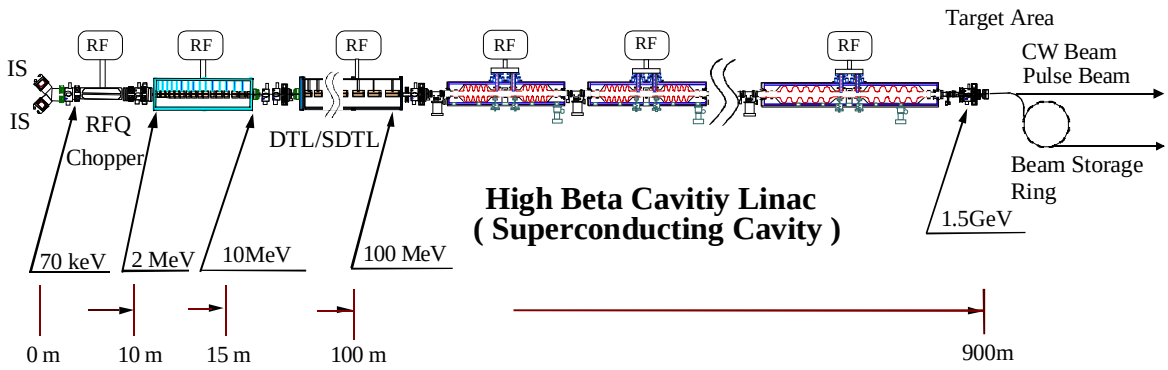
JAERI has been proposing the Neutron Science Project (NSP) which will be composed of a high intensity proton accelerator and various research facilities. The accelerator with an energy of 1.5GeV and a beam power of 8MW is required to operate both with pulse mode for basic research fields and CW mode for nuclear waste transmutation studies. A superconducting (SC) linac is a main option for the high energy portion from 100MeV to 1.5GeV. A beam test with an ion source and an RFQ has been performed with a current of 80mA and a duty factor of 10 % at the energy of 2MeV. A hot test model of DTL has been fabricated and tested with a duty factor of 20%. A test stand for SC linac cavity with equipment of cryogenics, vacuum, RF and cavity processing and cleaning system has been prepared to test the fabrication process and physics issues. The vertical test of a β=0.5 (145MeV) single cell SC cavity has been made resulting in a maximum electric field strength of 44MV/m at 2K.

1 INTRODUCTION

JAERI has been proposing the Neutron Science Project which aims at exploring the fields of basic science and nuclear technology using a high intensity proton accelerator[1]. The design studies are being carried out for a high intensity pulsed and cw spallation neutron sources for basic research fields of material science and biology and for accelerator-driven transmutation technology of long-lived radioactive nuclides from nuclear power generation The major facilities to be constructed under the project are, 1) a superconducting proton linac with a proton energy of 1.5GeV and a maximum beam power of 8MW, 2) a spallation neutron target station with input beam power of 5MW for neutron scattering, and 3) a research facility complex for accelerator-driven transmutation experiment, neutron physics, material irradiation, isotopes production, RI beam experiment for study of exotic nuclei. A conceptual layout for the NSP LINAC is given in Fig.1.

JAERI had originally planned to build a pulsed linac with an energy of 1.5GeV and a peak current of 100mA with 10% duty factor. The design study has been made to confirm technical feasibility to accelerate high peak current with high duty operation from the beam dynamics point of view. In this accelerator development, the R&D work has been performed on high brightness ion source, radio frequency quadrupole linac (RFQ), drift tube linac (DTL) and RF source, as well as the conceptual design of the whole accelerator components.

JAERI has altered the original plan by proposing an option of superconducting (SC) linac to meet requirements for a variety of basic research fields mentioned above and an ultimate goal for waste transmutation[2]. This SC linac will be operated in pulse as a first stage for the spallation neutron source and upgraded in CW for engineering test as a second stage. These two operational modes, pulse and CW operation, will be realized with time sharing manner, not simultaneously, and is the most challenging technical issues for the accelerator development.



I S : High Brightness H Ion Source
RFQ : Radio Frequency Quadrupole Linac
DTL : Alvarez Type Drift Tube Linac
RF : Radio Frequency Power Source

Fig. 1 A conceptual layout of the JAERI NSP-LINAC

The SC linacs have several favorable characteristics as follows; the large bore radius results in low beam loss, the length of the linac can be reduced, and high duty and CW operation can be made for engineering purposes. The possibility to inexpensive operation cost may be also expected in comparison with normal conducting (NC) option.

Several R&D items have been studied for high intensity accelerator development; 1) the beam dynamic calculation including the high β linac. 2) the development of the negative ion source and the fabrication of high power test models for CW-RFQ and CW-DTL. 3) the SC cavity development, 4) the high intensity proton storage ring and 5) high power RF source development. A specification of the JAERI NSP LINAC is given in Table 1.

Table 1 A specification of JAERI NSP LINAC

Particles	Negative and positive ion
Energy:	1.5GeV
Beam current:	
1st stage;	Pulse average 1mA, peak 16.7mA (duration 2ms, repetition rate 50Hz)
2nd stage	CW<5.33mA Pulsed average<5.33mA, peak 30mA
Low energy:	RFQ &DTL/SDTL Normal-
High energy:	Conducting linac: 200MHz
Chopping:	Superconducting linac: 600MHz 60% (intermediate pulse width of 400ns)

2 2MeV RFQ BEAM TEST AND DTL HIGH POWER TEST

The R&D work for the low energy portion has been carried out as a first step in the development with a positive hydrogen ion source and a pulsed RFQ. This R&D-RFQ is a four-vane type and designed to accelerate 100mA (peak) of protons to 2MeV with a duty factor of 10%. The low power tuning, the high power conditioning and the beam tests were carried out[3]. The layout of the 2MeV RFQ and the R&D results are shown in Fig.2. The proton beam from the 100keV ion source was focused by the two solenoids to match the RFQ acceptance. The maximum RFQ output current, which was currently achieved, was 80mA at the ion source extraction current of 155mA with 10% duty factor. The transmission in the low energy beam transport (LEBT) from the ion source to the RFQ was about 65% with the proton fraction of about 80% in the ion source beam. The maximum transmission rate through the RFQ was obtained to be 90% at the most optimum ion source condition. The rms emittance values from the ion source and RFQ are minimum to be 0.15 πmm.mrad and about 0.62 – 0.76 πmm.mrad at the beam current of 170mA, respectively. These emittance values are not satisfactory and the further improvement is needed.

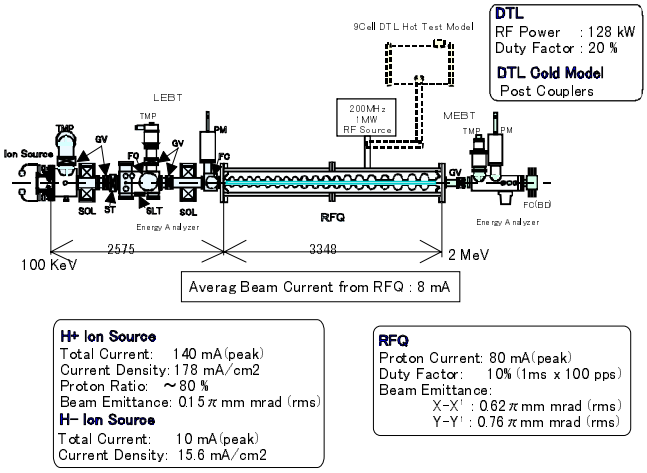


Fig.2 The R & D Results of Low Energy Accelerator Parts

An R&D-DTL hot test model with 9 cells for mock-up of the first part of the DTL has been fabricated to study the RF characteristics and the cooling capabilities. The 20% duty operation was achieved with a RF power of 128kW. The further test of CW operation with this hot model is being prepared. The 1/3 scaled DTL cold model installed with post couplers and 60 DT cells, which corresponds to the energy region of 2-10MeV, was also fabricated. The effects with post coupler such as field distribution, the detuning sensitivity and mode spacing were tested. The parameters of post coupler configurations (total numbers and positioning) has been obtained for stabilization of the accelerating fields[4].

3 LOW ENERGY PART BE LOW 100MeV FOR THE NSP LINAC

3.1 New Design for the Low Energy Part

In order to realize the short pulse for basic research with the proton storage ring and the final CW operation, new R&D's are carried out including negative ion source and CW-RFQ/CW-DTL in addition to the SC linac development. At the high energy part of DTL, the SDTL (separated type of DTL) proposed by Kato[5], KEK, has been studied. The SDTL, which has higher shunt impedance and simpler mechanical structure than DTL, is an attractive option for CW operation in the energy region of 50 - 100MeV where the SC linac can not be applicable.

3.2 Ion Source

A negative ion beam is required for basic research to inject the beam into the storage ring which produce 1 μs pulse. The beam extractor of the existing positive ion

source used for previous beam experiment was modified to produce negative ion beams from source ion plasma by providing the transverse magnetic field. The characteristics of the negative ion beam have been examined with the maximum observed beam current of 21mA at an arc discharge power of 35kW[6].

A new negative ion source has been fabricated to accumulate experimental data to fulfil the requirement to the NSP linac. A schematic drawing of the ion source is shown in Fig. 3. A plasma chamber is installed outside the insulator to change easily the configuration of the cusp magnet fields. The vacuum pumping system is also improved. The preliminary data have been obtained to be 11mA beam extraction without Cesium from the test experiment.

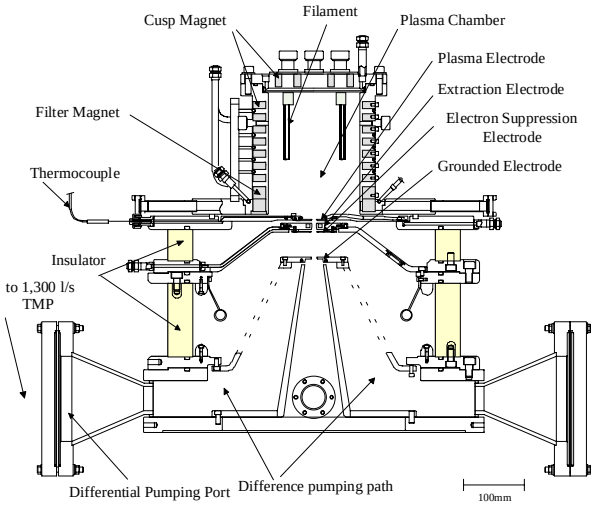

Fig.3 A schematic drawing of new negative ion source

3.3 RFQ for Pulse and CW operation

The low energy part should be capable for the CW mode operation as well as the pulse mode, because the SC linac has been operated with CW. The scheme to prepare two independent RFQs together with ion sources for pulse and CW operation is considered to meet these two different operational conditions[7]. The pulse mode RFQ is optimized at a beam current of 30mA. The maximum peak electric field of 1.65Ek is chosen. The CW mode RFQ is optimized below a current of 10mA with lower electric filed of 1.5Ek. Figure 4 shows design parameters vs length for the pulse mode and the CW mode RFQs. The beam simulation is performed with the PARMTEQ and PARMTEQM codes. The similar performance for transmission rate and transverse and longitudinal emittances were obtained with the calculations. Because the most important problem for the R&D-RFQ was found to be the RF contact between vane and tank, the RFQ will be made as integrated type by brazing between vane and tank. The high power model 50cm long was fabricated and tested with a power of 60kW and a duty factor of 20%.

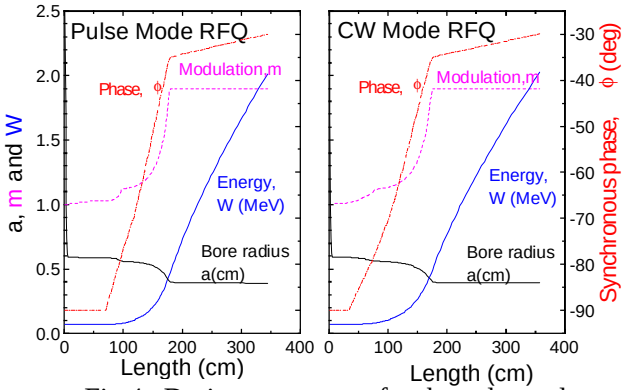

Fig.4 Design parameters for the pulse and the CW RFQs

3.4 CW-DTL/SDTL

The parameters for the CW-DTL are also re-evaluated to match the CW operation for the SC linac design concept. The SDTL concept has been also adopted to improve the performance for CW operation. Relatively low accelerator gradient of 1.5MeV/m is taken in order to reduce the RF power consumption and the RF heating. The expected maximum magnetic field gradient for the focusing magnet is about 50T/m using the hollow conductor type Q-magnet. The end point energy for the SDTL is 100MeV which is determined from the beam dynamics and mechanical consideration of the high β structure.

The beam dynamics study is conducted to obtain the optimized parameters for each accelerator structure. An equipartitioned design approach is taken for the DTL/SDTL to maintain the good beam quality and to prevent emittance growth causing beam losses. Figure 5 shows a concept of the CW-DTL and SDTL[4].

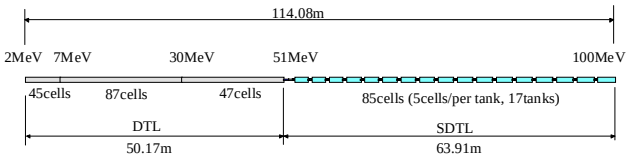

Fig. 5 A concept of DTL and SDTL

4 HIGH ENERGY ACCELERATOR PART

4.1 The layout of the superconducting linac

In the SC linac part, the proton velocities β gradually change from 0.43 to 0.92 corresponding to the energies

for 100MeV and 1.5GeV. Accordingly, the length of the cavity is also changed. Main concern is the strength of the cavity under the vacuum load for the low β (β<0.7) region. The mechanical structure calculations with the ABAQUS code have been made to determine the cavity shape parameters as well as electromagnetic ones with the SUPERFISH code.

are shown in Fig.7. The equipartitioning factor of about 0.9, which is defined by $\gamma_0(\varepsilon_{nx}/\varepsilon_{nz})(z_m/a)$ where z_m and a are radius and longitudinal half length of ellipsoidal bunch, respectively, shows the design parameters nearly equipartitioned. There is only 1% increase of the transverse and the longitudinal rms emittances.

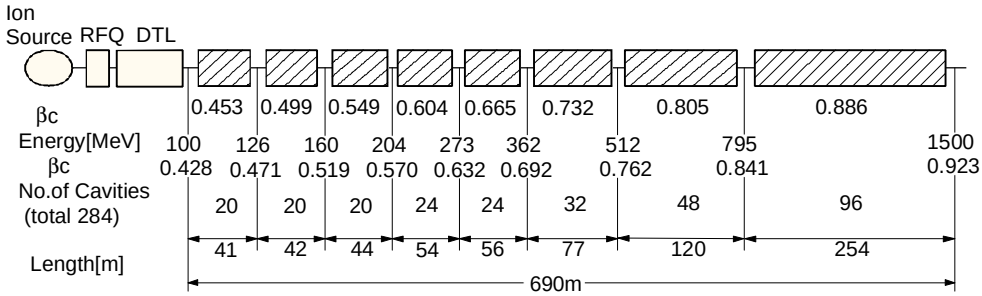

Fig. 6 Basic parameters for superconducting(SC) linac.

In order to determine the layout of the SC accelerating structure, the case of the SC linac, which is composed of 8 different β sections has been studied[8]. The cavities in each β section will be made with identical 5 cells and designed at the specific beam energy but also can be operated at slightly different beam energy with lower efficiency. The maximum peak surface field is set to be 16MV/m. Two cavities are laid in one doublet focusing period. The conceptual layout and basi parameters of the superconducting linac are shown in Fig. 6. The structure of the cryomodule, input/HOM couplers and tuning devices etc. are being designed based on the KEK-TRISTAN (high energy e+, e- colliding machine) experiences. Using these parameters, calculations for the beam dynamics have been made with the modified PARMILA code. The equipartitioned design approach is also taken for the SC linac. The design and beam simulation results of the SC sections such as wave numbers, the beam sizes and the equipartitioned factors

4.2 Fabrication and test of a superconducting cavity

The test stand for a superconducting cavity development with the cryostat 80cm dia. x 350cm long and a clean room has been constructed[9]. Two sets of single SC test cavities have been fabricated for β =0.5 which corresponds to the proton energy of 145MeV. Fabrication process such as cold rolling and press of pure Niobium metallic sheet, electron beam welding, surface treatment (barrel polishing, electro-polishing and high pressure water rinsing, etc.) has been performed based on the KEK experiences for 500MHz TRISTAN cavity. Vertical tests have been conducted to examine the RF and mechanical properties. Figure 8 shows the results of performance test for two prototype cavities. The measurements were made several times for each cavity. The maximum surface peak field strength of 24MV/m at 4.2K and 44MV/m at 2.1K have been successfully

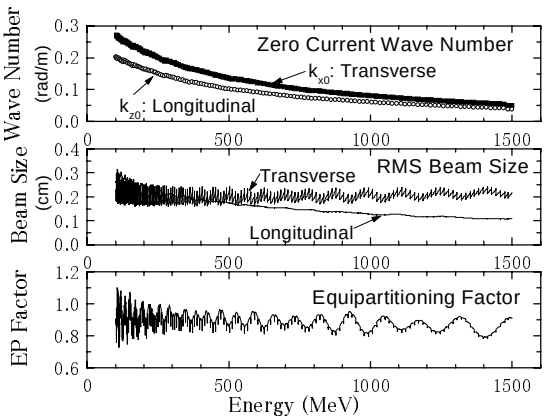

Fig.7 Design and beam simulation results of the superconducting linac section

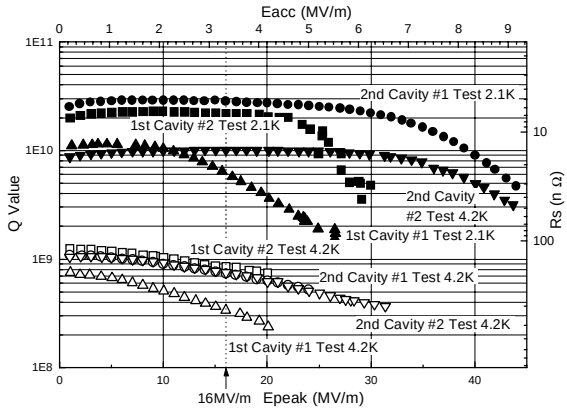

Fig.8 Results of the performance tests for two prototype cavities; Q valuses as a fuction of the surface peak electric field (Epeak)

obtained for 2nd cavity. The Q values of 2.8×10^{10} at 2K and 7.3×10^{8} at 4.2K were obtained at E_{peak}=16MV/m[10]. This result was reconfirmed at the recent 2nd experiment although the Q values this time was lower to be 1×10^{10} at 2K because some deterioration of the surface condition occurs during the intermediate period. Those test results have satisfied the specification for the conceptual layout of the superconducting linac.

5 RF SOURCES

The RF sources are main components to determine the availability and reliability, and most costly parts for the accelerator system. Two frequency choices, 200MHz and 600MHz, have been selected in the conceptual study for low energy and high energy part, respectively, where total peak RF powers of about 300kW for RFQ, 9MW for DTL/SDTL and 25MW for SC linac are required for pulse operation. Due to the different two mode operations and gradual upgrade path, optimization for RF configuration is one of the most important technical issues. An RF system based on the Grid tube (Tetrode) Klystron and IOT has been carried out[11]. As an example, Figure 9 shows RF power requirements for 8 different β sections for each operating condition in the SC linac.

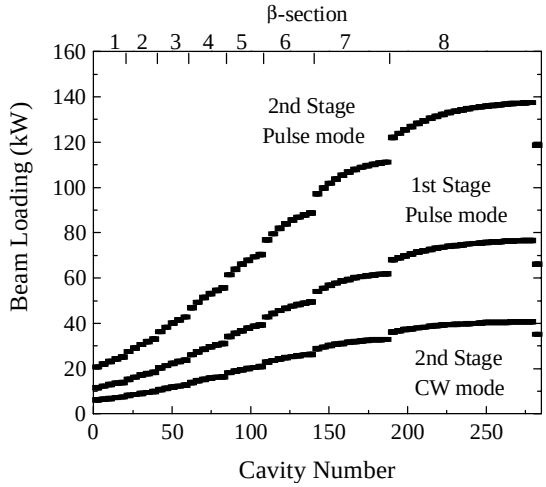

Fig.9 Beam loading for each cavity

6 SUMMARY

The R&D work for the prototype linac structures has been performed. The good performances of the components such as ion source, 2MeV-RFQ, RF-source have been achieved. The test stand for the SC cavities was constructed. The vertical SC cavity test has been successfully conducted resulting in the satisfactory maximum surface electric field strength for the SC proton accelerator. The design work on the RFQ and DTL/SDTL as well as SC cavities for the CW operation is performed.

7 ACKNOWLEDGEMENT

The authors would like to thank Drs. S. Noguchi, K. Saito H. Inoue and E. Kako of KEK for discussion and help on the SC cavity development. They also thank Drs. T. Kato and Y. Yamazaki of KEK, and Dr. R.A. Jameson of LANL about the beam dynamics calculations and accelerator system optimization.

THE TESLA FREE ELECTRON LASER – CONCEPT AND STATUS

J . Rossbach, for the TESLA FEL Collaboration
Deutsches Elektronen-Synchrotron, DESY, 22603 Hamburg, Germany

Abstract

The aim of the TESLA Free Electron Laser (FEL) is to develop and realize an Angstrom wavelength, high gain FEL in parallel with the TESLA superconducting e+/e- linear collider. As a first step, an FEL for the VUV wavelength regime is now under construction at DESY, making use of the TESLA Test Facility (TTF).

The VUV FEL at the TTF comes in two phases, which are both approved. The paper describes the over-all layout of each phase and the status of components.

1 FREE ELECTRON LASERS FOR SHORT WAVELENGTH

Over the past 30 years, synchrotron radiation has turned into a most powerful research tool that has been applied in many fields of science ranging from physics, chemistry and biology to material sciences, geophysics, and medical diagnostics. This rapid progress was driven by the development of new, increasingly brilliant sources based on electron storage rings. Due to the recent progress in accelerator technology the possibility has been opened up to complement storage ring based sources by ultra-brilliant Free-Electron Lasers operating in the soft X-ray regime.

In a Free Electron Laser (FEL), an electron beam radiates photons at much higher power and better coherence than it does due to spontaneous synchrotron radiation. The key point is that electrons moving in a transverse magnetic field of alternating polarity (undulator) may amplify an existing electromagnetic radiation field (see e.g. [1]). For properly chosen phase and wavelength (see eq. 1) the scalar product of the electron's velocity vector and the electric field vector does not vanish on average, resulting in an average energy transfer between the electron beam and the radiation field. As a consequence of this interaction, depending on the relative phase, some electrons get accelerated and others decelerated. This results in a longitudinal density modulation of the electron beam at the optical wavelength during the passage through the undulator. With the onset of this "micro-bunching", coherent emission at the resonant wavelength sets in which results in an exponential growth of the power in the radiation field (high gain mode), characterized by the gain length L_{gain} :

$$I(z) = I_0 \cdot \exp(z / L_{gain})$$

Similar to synchrotron radiation sources, there is no fundamental limit in the choice of the photon wavelength.

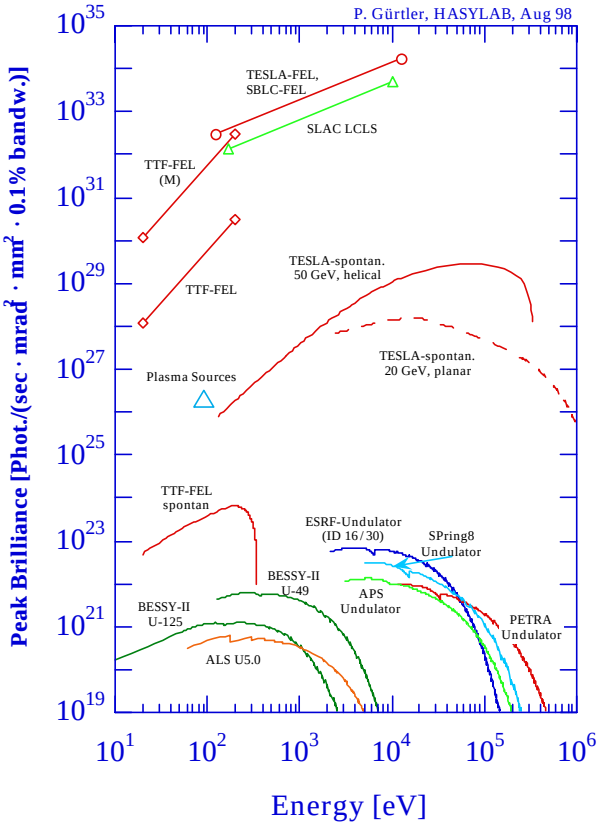

Fig. 1. Spectral peak brilliance of short-wavelength FELs compared with third generation radiation sources and plasma lasers. For comparison, the spontaneous spectrum of an X-ray FEL undulator at 20 GeV is also shown.

The photon wavelength λ_{ph} of the first harmonic is related to the period length of a planar undulator λ_u by

$$\lambda_{ph} = \frac{\lambda_u}{2\gamma^2}\left(1 + \frac{K^2}{2}\right) \quad , \qquad (1)$$

where $\gamma = E/mc^2$ is the relativistic factor of the electrons and $K = eB_u\lambda_u/2\pi mc$ the 'undulator parameter', e being the elementary charge, m the electron rest mass, c the speed of light, and B_u the peak field in the undulator. It is seen that very short photon wavelength can be achieved if only the electron energy (i.e. γ) is chosen sufficiently high.

For most FELs presently in operation, the electron beam quality and the undulator length result in a gain of only a few percent per undulator passage, so that an optical cavity resonator and a synchronized multi-bunch electron beam have to be used. For the TESLA FEL however, we aim at very short wavelength, for which normal-incidence mirrors of high reflectivity are not

available. Thus we have to provide an electron beam quality (emittance, peak current, energy spread) good enough and an undulator long enough to reach the power saturation level within a single passage. At the saturation length $L_{sat} \approx 4\pi L_{gain}$, the electrons run out of resonance due to their energy loss.

Since the desired wavelength is very short, there is no conventional laser to provide the "initially existing radiation field". Instead, one may consider the spontaneous undulator radiation from the first part of the undulator as an input signal to the downstream part of it. FELs based on this principle of Self-Amplified-Spontaneous-Emission (=SASE) [2,3] are presently considered the most attractive candidates to deliver extremely brilliant, coherent light with wavelength in the Angstrom regime[4-6]. Compared to state-of-the-art synchrotron radiation sources, one expects full transverse coherence, larger average brilliance, and, in particular, up to eight or more orders of magnitude larger peak brilliance (see Fig. 1) at a pulse lengths of about 200 fs FWHM. An important step has been done recently in demonstrating a SASE FEL gain larger than 10^5 at 12 μm wavelength [7].

2 SASE FEL RADIATION

Theoretical description of SASE distinguishes three steps of the process: The start-up-from-noise (or lethargy) regime, the steady-state regime and the saturation regime. The steady-state regime, where a well-defined external electromagnetic input wave is linearly amplified resulting in exponential growth, is accessible for analytical and numerical treatment since many years. The start-up from noise process, however, is much more difficult to analyze, since it is determined by statistical properties and by mutual interaction of more than 10^9 radiating particles. Fully 3-dimensional simulations became available only recently. One of these codes uses Cartesian coordinates and performs direct solution of the paraxial equations for the radiation field and is thus capable of dealing with arbitrary undulator field errors [22]. The other one [23] uses a Greens-function approach for calculation of the radiation field, is much faster and includes far-field mode analysis of the radiation. Results of these codes are in perfect agreement with a SASE proof-of-principle experiment performed recently in Los Alamos at 12 μm wavelength [7, 23]. Finally it is noted, that fluctuation properties of SASE FEL radiation have been analyzed both in the linear and in the saturation regime [24]. Experimental results obtained for the linear regime are again in agreement with theory and simulation, while experimental results on saturation are not yet available.

3 THE TESLA FEL CONCEPT

TESLA aims at a 500 GeV e+/e- collider with integrated X-ray laser Facility [6]. The TESLA linac is indeed exceptionally well suited for a short-wavelength Free Electron Laser: Excellent beam quality is maintained during acceleration and a large variety of pulse train patterns can be provided to users.

The problem with SASE FELs is that, in going to shorter and shorter wavelengths, several technical problems arise such as:

- Some 100m long undulators
- Small (normalized) emittance around 1 π mrad mm for a 1 nC bunch charge
- Bunch compression down to 25 μm bunch length

The ambitious goal of an 1 Å FEL is approached in three steps. Table 1 summarizes main parameters of both electron and photon beams for all these steps.

1. **TTF FEL Phase 1** (approved) [8]: A SASE FEL experiment at wavelength down to 42 nm using the 390 MeV TESLA Test Facility (TTF) linac at DESY[9], see Fig. 2. Besides proving the principle, technical components will be tested: the rf photoinjector, bunch compressors, a 14m long undulator, diagnostics for both electron and photon beams. First operation is scheduled for 1999.

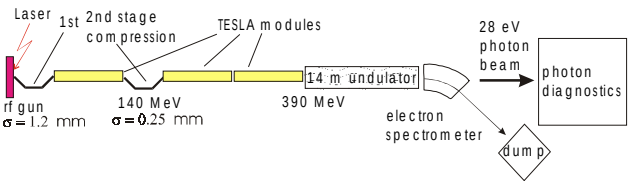

Fig. 2: Schematic layout of phase 1 of the SASE FEL project based on the TESLA Test Facility at DESY.

2. **TTF FEL Phase 2** (approved) [10,11]: By adding 5 more TESLA modules [12], the linac will be upgraded to (at least) 1 GeV, bringing the wave-length down to 6 nm, see Fig. 3. The undulator will be 27m long and the rms bunch length will be reduced to 50 μm by a further compressor stage. Open to users by the year 2003, this facility will give the opportunity to develop experimenting techniques with extraordinary photon beam characteristics like high peak power, short pulse length and fluctuating, spiky substructure typical for SASE FEL photon pulses [13].
3. **TESLA** linear collider with Integrated X-ray Laser (in its technical design phase) [5,6]. For large field gradients, even a superconducting linac has to operate in a pulsed mode. Thus there is room for adding further rf pulses between those driving the high-energy physics beam. By adding a specialized injector providing the electron beam properties needed for the FEL, one can utilize a linear collider installation for driving an X-ray FEL without mutual interference. The plan is to eject the electron bunch train for the FEL at the required beam energy (e.g. at 50 GeV) in the TESLA tunnel, and then transport it to the TESLA interaction region, where a big enough area could accommodate both the high energy physics experimental halls and the X-ray laboratory. A schematic of a switchyard distributing the bunch train over different radiation facilities is shown in Fig. 4.

Concerning the necessary electron beam parameters, all the critical issues are being addressed during phases 1 and 2 (see also Table 1): An rf photoinjector with small emittance and many thousand bunches within each rf pulse [14], bunch length compression by magnetic chicanes including control of coherent radiation effects [15], acceleration without beam degradation [16], and long undulators combined with a periodic FODO lattice [17,18]. In the remainder of this paper we briefly address some key issues of these components.

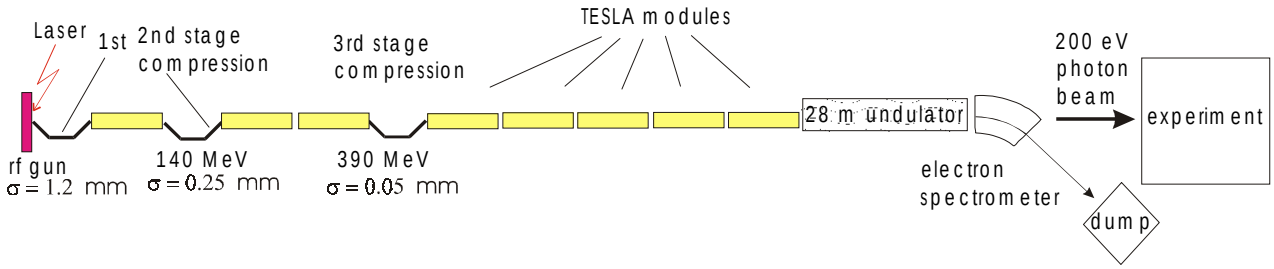

Fig. 3. Schematic layout of phase 2 of the SASE FEL project based on the TESLA Test Facility at DESY. The linac consists of 8 TESLA modules, each 12.2m long. The over-all length of phase 2 is some 300 meters.

Parameter	**Units**	**TTF FEL Phase 1**	**TTF FEL Phase 2**	**TESLA X-ray FEL***
beam energy	GeV	0.300	1.000	25.0
λ_{ph} (radiation wavelength)	nm	71	6.4 (193 eV)	0.1
λ_u(undulator period)	mm	27.3	27.3	50
Effective undulator length	m	13.5	27	87
rms beam size	μm	70	50	18
ε^n (normalized emittance) in the undulator	π mrad mm	2.0	2.0	1.0
peak electron current	A	500	2490	5000
No. of electrons per bunch		6.24E+9	6.24E+9	6.24E+9
No. of photons per bunch		1.7E+14	4E+13	7E+12
rms energy spread σ_γ/γ	10^{-3}	1.7	1.00	0.04 at entrance
rms bunch length σ_S	μm	250.	50.	25
L_g (power gain length)	m	0.6	1.00	4.1
P_{sat} (saturated peak power)	GW	0.3	2.6	65
Average brilliance [photons/s/mm^2/mr/0.1%]		up to 2E+21	up to 6E+22	8E+25
bunch train length	μsec	800	800	1052
Number of bunches per train		Up to 7200	up to 7200	Up to 11315
Repetition rate	Hz	10	10	5

Table 1: Main parameters of the TESLA Test Facility FEL (TTF FEL), phases 1 and 2 [10] and of the TESLA X-ray FEL[6]. The insertion devices are planar hybrid undulators. These values should be used as a guideline only since experimental experience has still to be gained in this wavelength regime.
*) For the TESLA X-ray FEL there will be a beam switchyard serving a number of FELs operating at different wavelengths down to 1 Angstrom, and using different beam energies. The parameters given are typical for the 1 Angstrom case.

4 THE PHOTOINJECTOR

The electron source consists of a 1½ cell , 1.3 GHz normal conducting resonator and a photocathode located at the mid-plane of the first (1/2) cell, where the accelerating field is maximum (approx. 45 MV/m). The klystron must provide 4.5 MW power at up to 800 μs pulse length for the long bunch train that can be accelerated in the s.c. linac,. Thus, since the gun cavity is normal conducting, thermal load is a critical issue. The mechanical design provides direct water cooling of the irises and avoids any brazing between water channels and vacuum. For achieving minimum emittance in all 3 dimensions, the design criteria are

- High accelerating gradient to reduce transverse space charge effects.
- Coaxial rf input coupling to reduce rf asymmetries in the cavity.
- Optimum position of the solenoid focussing field to achieve, in the subsequent drift space, “space charge compensation” [19].
- Short laser pulses.

5 THE BUNCH COMPRESSOR

In phase 1, two stages of longitudinal bunch compression are foreseen to reach the high peak current (500A) that is needed to achieve high FEL gain. This compression is done at beam energies high enough so that space charge forces are tolerable. The key compression step is at 140 MeV from 1 mm to 0.25 mm rms bunch length and consists of a 4 dipole magnet chicane. While magnet chicane compression, using path length differences of particles with different momenta, is the only possible way for ultra-relativistic particles, this method unavoidably involves radiation effects when electrons pass the dipole magnets. It has been shown [17,20] that space charge forces and coherent radiation need to be treated simultaneously in order to describe properly beam dynamics. Radiation effects are the dominant contribution to emittance growth in our chicane, see Fig. 5.

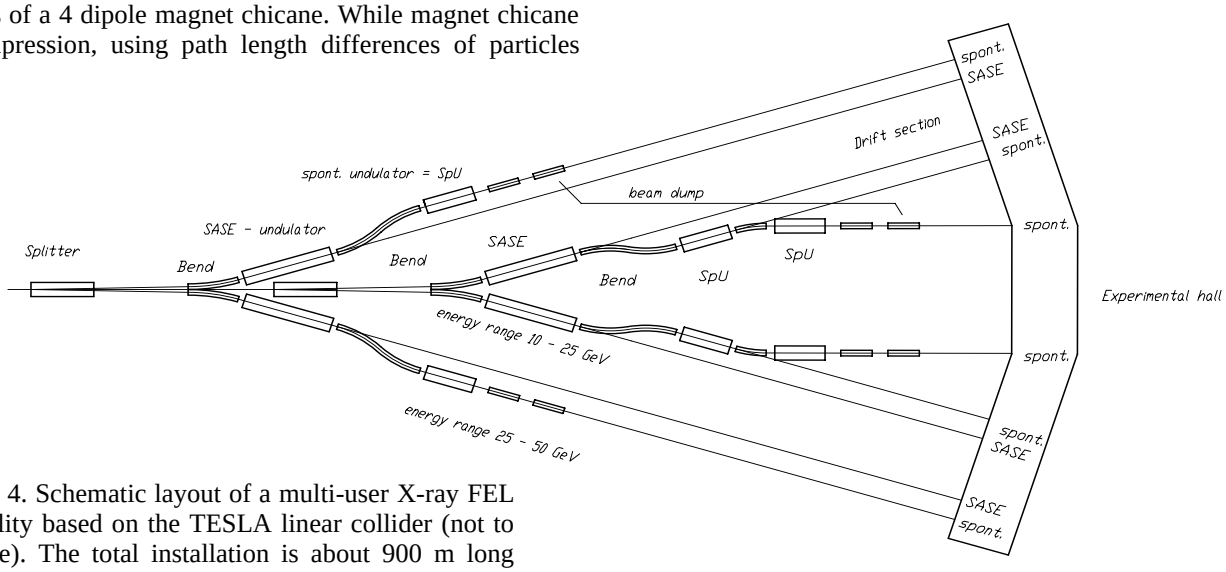

Fig. 4. Schematic layout of a multi-user X-ray FEL facility based on the TESLA linear collider (not to scale). The total installation is about 900 m long and 200 m wide and would be located on the same site as the linear collider interaction region.

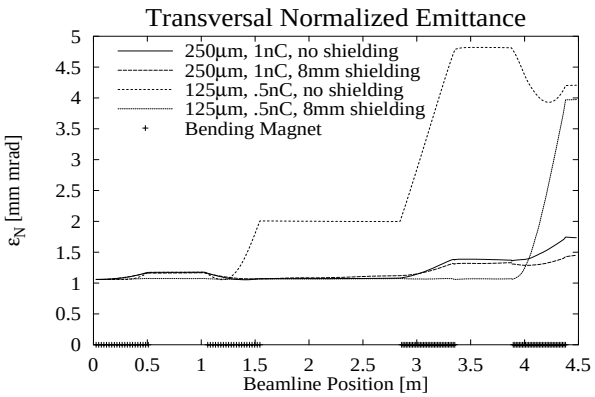

Fig. 5: Evolution of the uncorrelated emittance at the longitudinal center of the electron bunch passing bunch compressor 2. Coherent radiation and space charge are taken into account in this simulation [17]. Two different parameter set are considered, corresponding both to 500 A peak current in the bunch. It is seen that the 125 μm case is more heavily affected.

Significant suppression of coherent radiation by the metallic vacuum chamber is expected at a vacuum chamber height below 8 mm. For experimental verification of this theoretical prediction, the chamber height of bunch compressor 2 will be varied during phase 1 operation. Another issue of test operation will be the stability of rf phase vs. laser phase, since this determines stability of the bunch length, particularly in view of compressor 3. Phase stability below 1 ps has been demonstrated for both the laser and the klystron, which should be sufficient to reach 50 μm rms bunch length in phase 2.

Although compression takes place at high beam energies, space charge turns out to be critical for the whole TTF FEL beam line, from the gun to the undulator, and needs to be taken into account even in the linear optics calculation.

6 BEAM DYNAMICS IN THE ACCELERATOR

Besides space charge and coherent radiation, also wakefields may degrade beam quality. In spite of the low rf frequency of TESLA, longitudinal wake fields are still a concern due to the extremely small bunch length (or to be more precise, due to the large time derivative of the bunch current). It has been shown in [16] that the wake potential of a short bunch is considerably modified while the bunch is passing a longer and longer accelerator structure. For the TTF, the asymptotic case of an infinitely long, periodic structure is reached well before the end of the linac. The bunch still generates extremely high frequency components >680 GHz for which Niobium is known to loose superconductivity. Absorption of these frequency components in the Niobium walls does not seem to be a problem regarding superconductivity, nevertheless, but it may increase the dynamical cryogenic load on the 2K Helium level [21]. Experimental studies on this issue is a subject of TTF FEL, as well as the optimum technical realization of higher order mode absorbers

and additional wake fields due to surface roughness of the vacuum pipe.

7 LONG UNDULATORS

The main technological challenge of the FEL undulator is that the electron beam trajectory must be straight within a tolerance of 10 μm over several meters. This is particularly difficult to achieve since strong quadrupole focussing is superimposed to the undulator field in order to realize the small β function of about 1 m which is optimum for maximum FEL gain. The undulator for TTF FEL phases 1 and 2 is made in permanent magnet, hybrid technology with modules 4.5 m long each [17], see Fig. 6. Since it is impossible to guarantee this straightness from undulator field measurement alone, a beam based alignment strategy has been worked out using a large number of high-resolution beam position monitors [18].

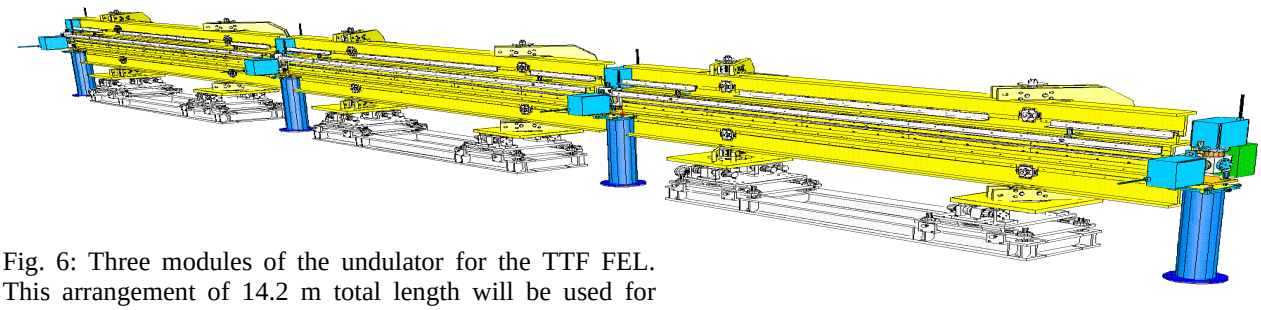

Fig. 6: Three modules of the undulator for the TTF FEL. This arrangement of 14.2 m total length will be used for phase 1. 10 correction coils and 10 beam position monitors per module are squeezed into the 12 mm magnet gap.

THE LINAC COHERENT LIGHT SOURCE AT SLAC*

P. Emma
Stanford Linear Accelerator Center, Stanford, California 94309, USA

Abstract

A design study [1] has been completed at SLAC for a linac-based Free Electron Laser (FEL) known as the Linac Coherent Light Source (LCLS), which aims at the production of high peak power coherent x-rays with a wavelength of 1.5 Å. A 1-nC electron beam produces coherent radiation through self-amplified spontaneous emission (SASE) in a long undulator with a projected peak output power of ~10 GW. The design utilizes the last kilometer of the SLAC linac, not used by the PEP-II project, to compress and accelerate a single electron bunch, generated by a photocathode rf gun, to a peak current of ~3.4 kA at 15 GeV. We describe here the acceleration, compression and preservation of this high brightness electron beam through the S-band linac and related transport lines, and outline some of the required beamline modifications. Specific challenges such as emittance growth generated by coherent synchrotron radiation, compensation of the correlated electron energy spread after compression, and overall pulse-to-pulse machine stability issues drive the parameter choices and system designs outlined here.

1 INTRODUCTION

The LCLS is based on the principle of Self-Amplified-Spontaneous-Emission (SASE) where high power, transversely coherent, radiation is generated in a single pass of a high peak current electron beam through a long undulator eliminating the need for optical cavities, which are difficult to build in the x-ray spectral region.

The requirements on the electron beam are, however, quite demanding and, until recently, difficult to achieve. The LCLS will utilize the experience and technical advances gained at the Stanford Linear Collider (SLC) [2] and the Final Focus Test Beam (FFTB) [3] and make use of recent progress in the production of intense electron beams with radio-frequency photocathode guns [4].

With the advent of the PEP-II asymmetric B-factory, which employs only the first 2/3 of the 3-km SLAC linac, the final kilometer will be available to accelerate and compress an electron beam up to 17 GeV. With these developments, as well as ongoing studies for the next linear collider (NLC) [5], SLAC is in an ideal position to construct a linac based x-ray FEL. This was first proposed in 1992 [6]. This new '4th generation' source will produce coherent radiation many orders of magnitude greater in peak power and brightness than present 3rd generation sources, opening new research potentials in chemistry, physics, biology and other applied sciences. The main parameters, at the undulator, are outlined in Table 1.

Table 1: LCLS parameters at 15 and 1.5 Å operation.

Parameter	unit	15 Å	1.5 Å
Electron beam energy	GeV	4.54	14.35
Repetition rate	Hz	120	120
Normalized emittance†	μm	2.0	1.5
Peak beam current	kA	3.4	3.4
Coherent energy spread†	%	<0.2	<0.1
Incoherent energy spread†	%	<0.06	<0.02
Bunch length†	μm	20	20
Beam size†	μm	37	31
Field gain length	m	3.7	11.7
Undulator period	mm	30	30
FEL parameter	10^{-4}	12.9	4.7
Peak brightness	10^{32} ‡	1.2	12
Average brightness	10^{22} ‡	0.42	4.2
Peak saturation power	GW	11	9
Peak spontaneous power	GW	8.1	81

† RMS, ‡ photons/sec/mm^2/mrad^2/0.1%-BW

Table 1 shows parameters at the low and high energy ends of the operational range, with radiation wavelengths of 15 and 1.5 Å, respectively. The 100-m, permanent magnet, planar undulator will be located in the existing FFTB tunnel, directly following the linac. The accelerator is divided into several sections to provide two-stage bunch compression. A schematic layout of the accelerator is shown in Fig. 1 which includes the RF-gun (at the 2-km point in the linac), four linac sections (Linac-0…3), two dog-leg transport lines (DL1,2) two bunch compressors (BC1,2) and the undulator. System parameters and electron beam quantities are indicated at various points.

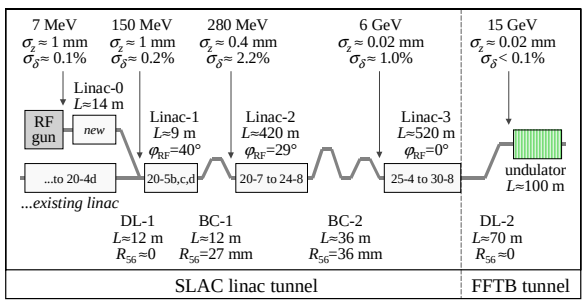

Fig. 1: LCLS accelerator and compressor schematic.

The first linac (Linac-0) is a new section installed adjacent to the existing linac which accelerates the 1 mm

* Work supported by the Department of Energy, contract DE-AC03-76SF00515

long bunch to 150 MeV and also compensates the space charge induced transverse emittance growth. The first bend section (DL1) injects the beam into the main linac and provides emittance and energy spread diagnostics. Linac-1 (L1) accelerates the 1 mm bunch 'off-crest' to 280 MeV and generates an energy correlation along the bunch such that the first chicane bunch compressor (BC1) shortens the bunch to 0.38 mm. L2 then accelerates the bunch to 6 GeV and also generates an energy correlation so the double chicane system (BC2) compresses the bunch to its design value of 20 μm. Finally, L3 nominally accelerates the beam to 15 GeV (a range of 4-17 GeV is available) and also cancels the remaining correlated energy spread with its geometric wakefield. The high-energy dog leg (DL2) is designed for energy and energy spread analysis, transverse emittance measurements, final beam transport, and variable matching into the undulator.

All of the linac sections, except L0, are existing and require only minor modifications. Both L2 and L3 (~950 meters of linac) require primarily quadrupole power supply modifications, while L1 (9 meters) requires the insertion of a few quadrupole magnets. The bunch compressors and DL1 will be composed of some new and some existing magnet designs and replace a total of 15 3-meter rf structures (4 klystrons) for an energy loss of ~2% of the nominal 50 GeV SLAC linac. DL2 and the post-undulator electron beam dump will use the existing FFTB tunnel as well as its magnets.

The peak current required for 1.5-Å SASE saturation in the 100-m undulator is dependent on the final emittance as shown in Fig. 2. Plotted is the 'slice' emittance, defined as the transverse phase space area over of a small slice (~0.5 μm) of the 20 μm bunch length. Conversely, the whole-bunch emittance, 'projected' emittance, may be significantly larger, with little impact on saturation. The LCLS design budgets a 50% slice emittance increase over the entire accelerator. Considering most dilution mechanisms affect the projected emittance, rather than the slice, this is a relatively conservative budget.

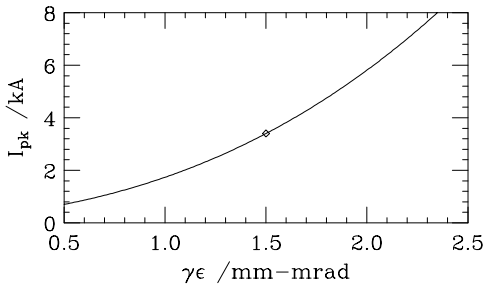

Fig. 2: Peak current required for 1.5 Å SASE saturation in the 100-m undulator vs. rms normalized 'slice' emittance.

2 LONGITUDINAL DYNAMICS

To achieve the high peak current in the undulator, the bunch must be compressed in a series of magnetic chicanes. These will be arranged and located along the linac such that non-linearities in the compression and acceleration process (wakefields, rf curvature, and 2nd order momentum compaction) are mutually canceled. With a careful arrangement the compression process is more linear which reduces the minimum bunch length achievable. An optimum choice of parameters cancels the final correlated energy spread, minimizes transverse emittance growth effects and desensitizes the system to phase and charge variations.

2.1 Bunch Compression

The bunch is compressed by accelerating at an off-crest rf phase, thereby introducing a correlated energy spread along the bunch. This is followed by a bending section, a magnetic chicane, with linear path length dependence on particle energy. The peak current generated by the rf photocathode gun is ~100 Amps. Generating the 3.4 kA necessary for 1.5-Å SASE saturation at $\gamma\varepsilon = 1.5$ μm requires a compression factor of ~35. For a single stage compressor using an rf phase of φ_0, the relative change in final bunch length, $\Delta\sigma_f/\sigma_f$, produced by a change in initial beam phase, $\Delta\varphi$, (timing jitter at the gun) is given by [7]

$$\frac{\Delta\sigma_f}{\sigma_f} \approx -\left(\frac{\sigma_i}{\sigma_f} \mp 1\right)\Delta\varphi \cot\varphi_0 \ , \qquad (1)$$

with 'under-compression' ($<\pi/2$ phase space rotation) expressed by the minus sign and 'over-compression' the plus sign. For $\varphi_0 = 20°$ and a compression factor of $\sigma_i/\sigma_f = 35$, initial phase jitter of just $\Delta\varphi = 0.1°$ S-band (0.1 psec) results in final bunch length (undulator peak current) jitter of $\Delta\sigma_f/\sigma_f \approx 16\%$.

Clearly, a single stage compressor is too sensitive. Furthermore, the final bunch length of a single stage compressor is limited by non-linearities, such as rf curvature, which make single-stage compression from 1 mm to 20 μm very difficult. A two-stage compression system, however, brings about cancellations which can reduce this phase jitter sensitivity by an order of magnitude. This also allows the first compressor to be located early in the accelerator so that the next linac section accelerates a shorter bunch. The reduced transverse wakefield of the shorter bunch provides looser quadrupole and rf-structure alignment tolerances. Conversely, a single compression stage needs to be placed at a high enough energy so that space charge forces are not significant for a 20 μm bunch. This extends the length over which the long bunch is accelerated tightening alignment tolerances. For these reasons, a two-stage compressor is used.

The compressors are simple 4-dipole chicanes with no quadrupoles. These offer ease of adjustment and the dispersion function is closed to all orders in energy.

The first compressor (BC1) is at 280 MeV and shortens the bunch from 1 mm to 385 μm rms at a correlated energy spread of 2.2% rms. The second compressor (BC2) is a double chicane designed to reduce and

compensate the transverse emittance growth generated by coherent synchrotron radiation (CSR) [8] (explained below). BC2 is at 6 GeV and compresses the bunch from 385 μm to ~20 μm rms at a correlated energy spread of 1.0% rms. Bunch length diagnostics, using e.g. CSR [9], are included after each bend section. Table 2 summarizes the chicanes.

Table 2: Bunch compressor chicane parameters.

Parameter	unit	BC1	BC2	
			chic-1	chic-2
Beam energy	GeV	0.28	6	6
Total length	m	2.8	13.2	13.2
Momentum compac.	mm	27	31	4.5
Dipole length	m	0.2	1.5	1.5
Bend angle/dipole	deg	7.1	3.4	1.3
Drift between bends	m	0.75	3.35	3.35
Max. dispersion	m	0.12	0.29	0.11

Fig. 3 shows a simulation of longitudinal phase space before and after each compressor. The non-linear correlation after BC1 (Fig. 3b) is primarily due to the long bunch on the S-band rf curvature in L1. It is later compensated by the geometric wakefield of L2 resulting in the nearly linear correlation of Fig. 3c. Finally, after BC2, the large correlated energy spread (Fig. 3d) is cancelled by acceleration and the strong geometric wakefield of the L3 linac (see Fig. 4, lower right).

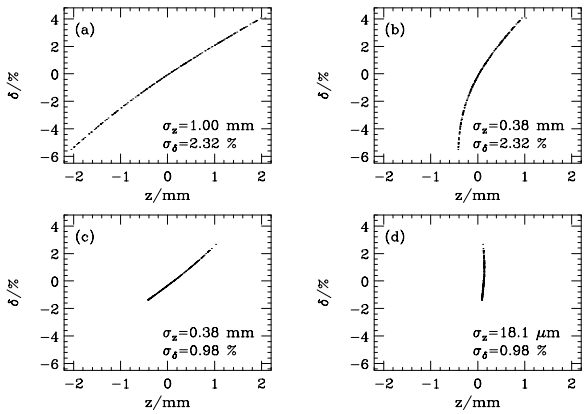

Fig. 3: Longitudinal phase space on fixed scales at (a) BC1-start, (b) BC1-end, (c) BC2-start and (d) BC2-end (bunch head at left).

The core of the beam (85%) is shown, prior to the undulator, in Fig. 4. The final energy spread is 0.035% rms with a very acceptable incoherent component (over a 0.5 μm slice) of 0.006%. Large energy tails (~1%) which encompass 15% of the bunch charge are not shown. The simulations [10] include geometric wakefields, the sinusoidal character of the rf accelerating field, the 1st and 2nd order momentum compaction of the chicanes, and the incoherent energy spread generated by synchrotron radiation in BC2 and DL2. The resistive wall wakefields of L3/DL2 and CSR effects of BC2/DL2 are not included in the figures, and are expected to contribute <0.05% rms to the coherent energy spread, some of which is correctable through small adjustments in the rf phasing.

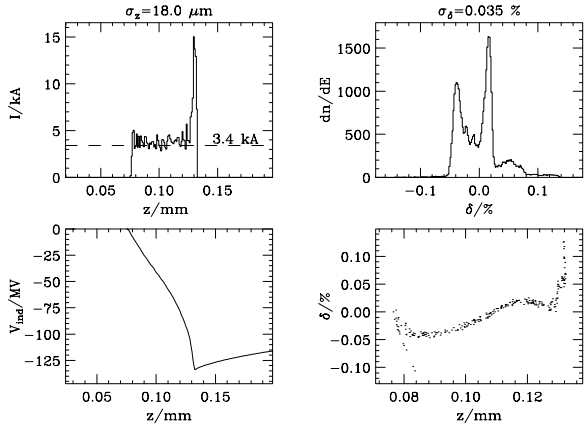

Fig. 4: Longitudinal phase space (low-right), axial (up-left) and energy (up-right) distributions and L3 bunch induced voltage (low-left) at undulator input (15 GeV).

The chosen chicane locations, the intermediate bunch length, and the rf phases form a system with significantly looser tolerances on pulse-to-pulse gun jitter. Gun timing jitter of 0.8 psec rms or initial bunch population jitter of 3% rms will each produce a 10% rms peak current jitter. Although challenging, they are achievable.

2.2 Coherent Synchrotron Radiation

When a microbunch follows a curved path, as in a chicane, the bunch radiates at wavelengths which may be large compared to the bunch length. This coherent radiation produces an energy-spread-generating wakefield along the bunch which can induce significant transverse emittance growth; a potential problem for many future microbunch accelerators.

In the LCLS, this is controlled by using a double chicane [11] for the 2nd bunch compressor. Chicane-1 of the double system is designed to partially compress the bunch, keeping the emittance growth due to incoherent synchrotron radiation less than 2%. A second chicane is then added with reduced bend angles and separating optics (four quadrupoles forming a **–I** transfer matrix) to complete the compression and approximately cancel the net CSR emittance increase. Fig. 5 shows a schematic.

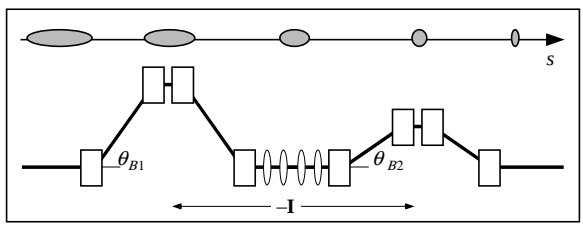

Fig. 5: Schematic of the double chicane compressor.

The cancellation can be understood by imagining an electron which loses energy in the *n*th dipole (n = 1...4) of chicane-1. In this steady-state model, the CSR-wakefield

increases with compression, but its shape along the bunch, is preserved through the chicane. The electron will then receive an extra horizontal kick, with respect to an on-energy electron, in the *n*th bend. This same electron, with its unchanged relative axial position, will lose even more energy in the *n*th bend of chicane-2 (because of the shorter bunch there), but due to the **–I** transfer matrix between paired bends and the weaker bends of chicane-2, the net horizontal kick is zero. This assumes the electron does not shift axially with respect to the remainder of the bunch as would occur in the case of over-compression or a highly non-linear phase space transformation. The double chicane also significantly weakens the CSR effect by using strong bends when the bunch is long (chicane-1) and weak bends where the bunch is short (chicane-2).

Calculations of the CSR-induced emittance dilution have been made using both a simple steady-state model and also the DESY *WAKE* code [12] which includes CSR field transients and bend-to-bend coupling effects. These calculations predict an emittance growth after BC2 of 0.3% and 3-5%, respectively. Fig. 6 shows the dispersion, bunch length, and the CSR induced energy spread and emittance growth through the BC2 double chicane for the steady-state model. CSR effects in DL2 are similarly controlled with a ~1% emittance growth expected.

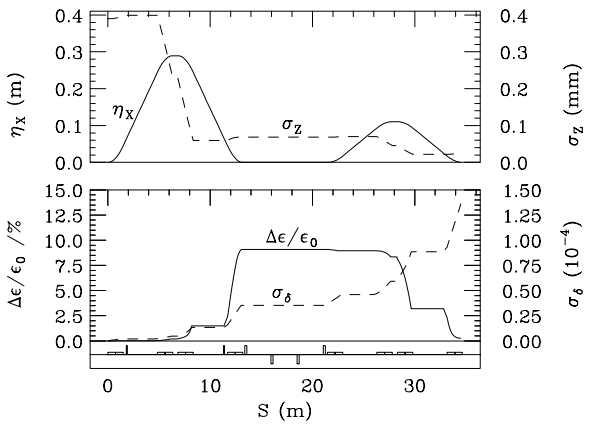

Fig. 6: The dispersion (η_x), bunch length (σ_z), and the CSR rms energy spread (σ_δ) and emittance growth ($\Delta\varepsilon/\varepsilon_0$), generated in BC2 calculated with the steady-state model.

3 TRANSVERSE DYNAMICS

The four separate S-band linac sections each have different beam parameters which motivate different lattice parameter choices. The lattices are designed to minimize 'projected' emittance dilution due to wakefields and dispersion which are generated through component misalignments. For example, a large beam energy spread and short bunch length require weak focusing.

3.1 RF Gun and Booster Linac

The high brightness electron beam is initially generated in a 1.6-cell S-band rf photocathode gun driven by a 500 μJ UV laser system with temporal pulse shaping capability and <1 psec stability. The injector is required to produce a single electron bunch of 1-nC and 100 A peak current at a repetition rate of 120 Hz with normalized rms emittances of 1 μm. The gun design includes a solenoidal field, located near the copper cathode, which initiates a compensation of the space charge induced transverse emittance growth. The L0 booster linac completes the compensation and provides acceleration to 150 MeV. L0 is a new beamline constructed parallel to the existing linac and is displaced 1 meter horizontally. It includes four 3-meter rf-structures and no quadrupole magnets. Following L0 is an adjustable optical matching section and an emittance diagnostic section. The first dog leg, DL1, provides energy diagnostics and bends the beam onto the main linac axis (L1). The existing 3-meter rf-structure there is removed to provide space for injection.

3.2 Linac-1

L1 initiates the compression process by accelerating off crest, thereby generating the necessary energy-*z* correlation so the first chicane, BC1, will compress the bunch. L1 is composed of three existing 3-meter rf-structures. Because of the large rf phase angle and the long bunch, the rms energy spread in L1 rapidly increases from 0.2 to 2.2%. Therefore, both dispersion and transverse wakefields are potential emittance dilution mechanisms. Space charge forces here are insignificant.

The quadrupole spacing and strength requirements were determined by simulating several different lattice schemes using the computer code *LIAR* [13]. This computer program calculates the transverse emittance dilution induced along a linac by wakefields and dispersion via random quadrupole, BPM (beam position monitor), and rf-structure misalignments. It also provides various steering algorithms and empirical emittance correction techniques. With 300 μm rms quadrupole, BPM, and rf-structure transverse misalignments and one quadrupole added after each 3-meter structure, the optimum phase advance per cell is found to be near 75°. The expected emittance dilution over L1 is then ~5%.

3.3 Linac-2

The energy spread is large (1-2%) over the entire 430-meter length of L2, and the bunch is only partially compressed making L2 the most problematic linac section for emittance preservation. The lattice choice for L2 was made, as for L1, using *LIAR*, including misalignments, and varying the phase advance per cell and quadrupole spacing. By increasing the density of quadrupoles, the expected emittance dilution can be reduced, but the gains do not clearly justify the additional costs. Therefore, the existing quadrupoles are used in their present locations with an optimum phase advance of ~70°/cell. Fig. 7 shows the dilution versus phase advance per cell after 'one-to-one' steering for the existing quadrupole spacing. Note, only the 'projected' emittance is affected here.

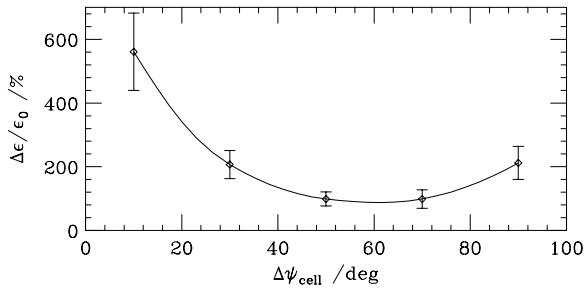

Fig. 7: Emittance after L2 vs. phase advance/cell. Quad, BPM and structure misalignments of 150,150 and 300 μm rms, respectively, and steering are applied (10 seeds).

Even though the L2 uncorrected emittance growth can easily reach 100%, localized trajectory oscillations ('bumps'), as used in the SLC and FFTB, can be applied to restore the emittance. Simulations of trajectory-based emittance corrections are performed using *LIAR*. 'Bumps' of ~300 meters in length, with 100-300 μm peak amplitude, are used to empirically minimize the measured emittance in both planes. Beam position and angle, per plane, are varied near the beginning of L2 to optimize emittances at the end. As at the SLC, oscillations are terminated with an orbit controlling feedback system. A high resolution 4-wire-scanner emittance diagnostic section is planned for the end of L2. Fig. 8 shows emittance bump correction simulations. Using 100 misalignment seeds, an average projected emittance growth of ~100% is corrected to <10% in both planes. At the FFTB, with the SLAC linac, this technique has been used to preserve an initial vertical emittance of 1.5 μm to ~50% dilution [7] while accelerating a 1-nC, 0.5-mm *long* bunch over a linac three times the length of the LCLS.

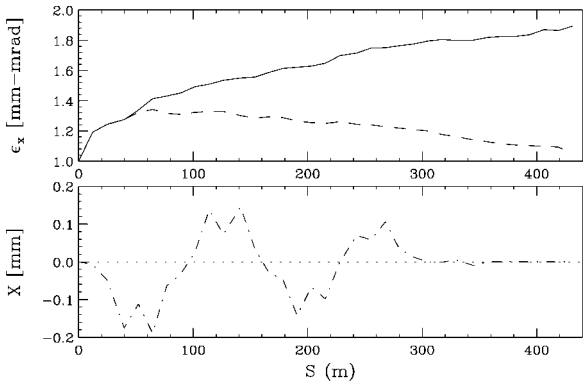

Fig. 8: Emittance along L2 before (top-solid) and after (top-dash) bumps applied. Curves are an average over 100 seeds. The bottom plot shows a typical oscillation.

3.4 Linac-3

The short bunch of L3 effectively eliminates transverse wakefields, and the rms energy spread shrinks from 1% to <0.1% due to acceleration and the strong longitudinal wakefield of the short bunch. In this case the dominant emittance dilution mechanism is due to dispersion generated by quadrupole and BPM misalignments. The dispersion can be minimized by a weak focusing lattice. *LIAR* simulations were run for L3 using the existing linac quadrupoles and varying the phase advance per cell. In this case an optimum was found at ~30°/cell with an expected emittance dilution of <10%. A 4-wire-scanner diagnostic section presently exists at the end of L3. Finally, DL2 will include high resolution energy, energy spread and emittance diagnostics prior to the undulator.

4 SUMMARY

The LCLS offers a unique opportunity for the creation of a coherent x-ray beam with unprecedented gains in peak power and brightness using, for the most part, existing components, techniques and facilities at SLAC. Although the design is based on a consistent and feasible set of parameters, some components, such as the RF-gun, undulator construction and CSR compensation, require further research and development to guarantee performance. The present proposal includes a 3 year R&D phase with pre-fabrication engineering beginning in FY2001, construction in 2002 and major systems commissioning starting in 2005.

MODELING AND DESIGN OF KLYSTRON

Y. H. Chin
KEK, 1-1 Oho, Tsukuba-shi, Ibaraki-ken, 305, Japan

Abstract

We have developed a new method for a realistic and more accurate simulation of klystron using the MAGIC code. MAGIC is the 2.5-D or 3-D, fully electromagnetic and relativistic particle-in-cell code for self-consistent simulation of plasma. It solves the Maxwell equations in time domain at particle presence for a given geometrical structure. It uses no model or approximation for the beam-cavity interaction, and thus keeps all physical processes intact. With MAGIC, a comprehensive, full-scale simulation of klystron from cathode to collector can be carried out, unlike other codes that are specialized for simulation of only parts of klystron. It has been applied to the solenoid-focused KEK XB72K No.8 and No.9 klystrons, the SLAC XL-4 klystron, and the BINP PPM klystron. Simulation results for all of them show good agreements with measurements. We have also developed a systematic design method for high efficiency and low gradient traveling-wave (TW) output structure. All these inventions were crystallized in the design of a new solenoid-focused XB72K No.10. Its predicted performance is 126 MW output power (efficiency 48.5%) with peak surface field of about 77 MV/m, low enough to sustain a 1.5 μs long pulse. It is now in manufacturing and testing is scheduled to start from November 1998.

1 JLC KLYSTRON PROGRAM

The 1-TeV JLC (Japan e^+e^- Linear Collider) project[1] requires about 3200 (/linac) klystrons operating at 75 MW output power with 1.5 μs pulse length. The main parameters of solenoid-focused klystron are tabulated in the second column of Table 1. The 120 MW-class X-band klystron program at KEK[2], originally designed for 80 MW peak power at 800 ns pulse length, has already produced 9 klystrons with solenoidal focusing system. To reduce the maximum surface field in the output cavity, the traveling-wave (TW) multi-cell structure has been adopted since the XB72K No.6. Four TW klystrons have been built and tested. All of them share the same gun (1.2 microperveance and the beam area convergence of 110:1) and the buncher (one input, two gain and one bunching cavities). Only the output structures have been redesigned each time at BINP. XB72K No.8 (5 cell TW) attained a power of 55 MW at 500 ns, but the efficiency is only 22%. XB72K No. 9 (4 cell TW) produced 72 MW at 520 kV for a short pulse of 200 ns so far. The efficiency is increased to 31% and no sign of RF instability has been observed. The limitation in the pulse length attributes a poor conditioning of the klystron. The latest tube, XB72K No.10, was designed at KEK, and is being build in Toshiba.

Apart from the solenoid-focused XB72K series, KEK has also started a PPM (periodic permanent magnet) klystron development program. The design parameters are shown in the last column of Table 1. Its goal is to produce a 75MW PPM klystron with an efficiency of 60 % at 1.5 μs or longer pulse. The first PPM klystron was designed and build by BINP in the collaboration with KEK. It has a gun with beam area convergence of 400:1 for the microperveance of 0.93. The PPM focusing system with 18 poles (9 periods) produces the constant peak magnetic field of 3.8 kG. The field in the output structure is still periodic, but tapered down to 2.4 kG. There are two solenoid coils located at the beam entrance for a smooth transport of a beam to the PPM section. It achieved 77 MW at 100 ns, but there is a clear sign of RF instability at higher frequencies. The DC current monitor in the collector shows about 30 % loss of particle when RF is on. The second PPM klystron, XB PPM No.1, is being designed at KEK.

Table 1: Specifications of X-band solenoid-focused and PPM-focused klystrons for JLC.

	XB72K	PPM
Operating frequency (GHz)	11.424	11.424
RF pulse length (μs)	≥ 1.5	≥ 1.5
Peak output power (MW)	75	75
Repetition rate (pps)	120	120
RF efficiency (%)	47	60
Band-width (MHz)	100	120
Beam voltage (kV)	550	480
Perveance ($x10^{-6}$)	1.2	0.8
Maximum focusing field (kG)	6.5	
Gain (dB)	53-56	53-56

2 MAGIC CODE

After a series of disappointing performance of XB72K series, several lessons had been learned. First, KEK should have its own team to specialize the klystron design and overhaul the design process. Second, a new klystron simulation code was needed for a more realistic design of klystron, particularly, that of a TW output structure. The one-dimensional disk model code, DISKLY, had been used by BINP for design of the TW structure from XB72K No.5 till No.9. This code uses an equivalent circuit model (port approximation) to simulate a TW structure and tends to predict the efficiency much larger (nearly twice larger) than the experimental results. For the design of a new klystron, XB72K No.10, we have developed a method to use the MAGIC code[3] to simulate and design a klystron. MAGIC is the 2.5-D or 3-D, fully electromagnetic and relativistic particle-in-cell code for self-consistent

simulation of plasma. It solves the Maxwell equations directly at particle presence by the finite difference method in time like ABCI [4] or MAFIA. It requires only the geometrical structure of the cavity and assumes no model (neither port approximation nor equivalent circuit) for the beam-cavity interaction. The static magnetic field can be applied to a structure. Advantages of MAGIC are its accuracy and versatility. Even an electron gun can be simulated with results in good agreements with measurements. Simulation results can be imported/exported from one section of klystron to another, allowing a consistent simulation of the entire klystron without loss of physics. Only disadvantage is that it is time consuming.

3 FUNCTIONAL COMPARISON OF AVAILABLE CODES

Table 2 shows the functional comparison of computer codes available for klystron simulations. MAGIC is the only code that can simulate all parts of klystron from gun to collector. ARSENAL[5] is closest to MAGIC in functional performance, but cannot handle a TW multi-cell structure. CONDOR[6] can simulate a TW structure, but requires a beam input from a gun that needs to be simulated by other code such as EGUN[7]. In the migration of beam and fields from one code to another, two programs must be well matched to avoid any incomplete transfer of information and resulting unphysical phenomena.

Table 2: Functional comparison of available codes.

	Dimen-sion	Gun	Bun-cher	Single -cell output cavity	Multi -cell output cavity
MAGIC	2.5, 3	O	O	O	O
EGUN	2.5	O	×	×	×
CONDOR	2.5	×	O	O	O
FCI [8]	2.5	×	O	O	×
ARSENAL	2.5	O	O	O	×
JPNDISK	1	×	O	O	×
DISKLY	1	×	O	O	×

4 SIMULATION METHOD USING MAGIC

We divide a klsytron into three sections:

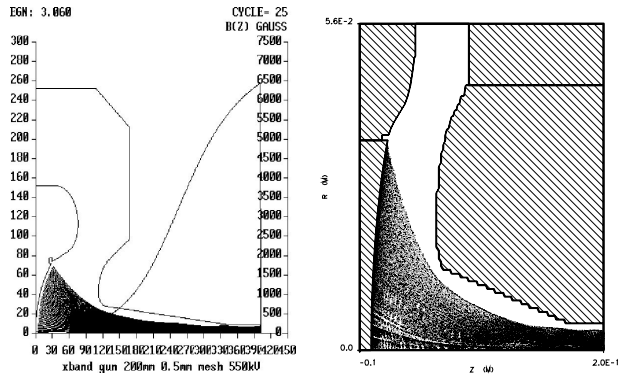
- Electron gun
- Buncher section (an input, gain and bunching cavities + drift space)
- TW output structure

The simulation techniques are described in detail in Ref. [9]. Here, we briefly summarize them.

3.1 Electron Gun

The gun simulation is done by specifying an emission area (cathode) and an applied voltage along a line between a wehnelt and an anode. The number of emitted particles can be specified per unit cell volume and unit time-step. The applied magnetic fields (both B_z and B_r) must be specified over the structure, not just on beam axis. They can be calculated using codes such as POISSON (for solenoid field) and PANDIRA[10] (for PPM). These programs requires the exact configuration of coils, yokes, or permanent magnets and their properties as input.

Figure 1 shows the comparison of beam profile simulated by EGUN and MAGIC for the XB72K-series gun. They look nearly identical. The simulated perveance for three different guns and the measured values are tabulated in Table 3. MAGIC simulations are in excellent agreement with the measurements, while the EGUN tends to produce a 5-10 % larger value than the measurements. This behavior was also reported in simulation of SLAC 50 MW PPM klystron by EGUN [11].



(a) EGUN (b) MAGIC

Figure 1: Beam profile from the XB72K gun simulated by (a) EGUN and (b) MAGIC.

Table 3: Comparison of the simulated perveances and the measured values.

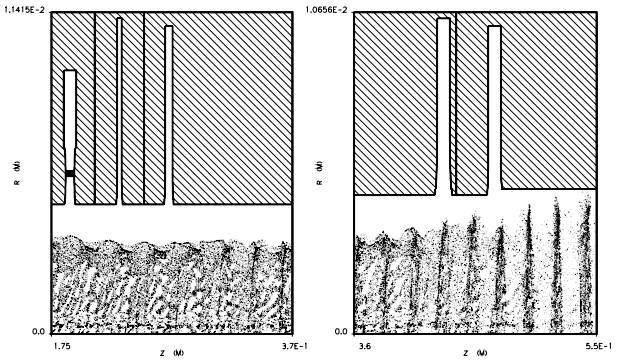
		Micro perveance		
Klystron	Frequency (MHz)	MAGIC	EGUN	Measured
XB 72K (KEK)	11,424	2.03	1.89	2.05
PV3030 (KEK)	2,856	1.19	1.10	1.2
5045 (SLAC)	2,856	1.99	1.78	2.0

3.2 Buncher Section

The input cavity needs a different treatment from other cavities, because the RF power is given externally, rather than being induced by a beam. Since a beam stays almost

as DC while passing the input cavity, the beam induced voltage is negligible. Therefore, we just need to specify the applied RF voltage along an electric filed line between the cavity gap. The field distribution of the fundamental mode should be computed by MAGIC priory and used as input. Other cavities need to be tuned to correct fundamental frequencies by adjusting the cavity aperture on mesh. The beam-induced voltage in cavities are monitored to measure the necessary RF cycles for saturation. In most of cases, about 200-300 RF cycles are enough. To speed up the saturation, a DC beam current from gun is increased smoothly and slowly from zero to the full value at the first 10-20 RF cycles.

Figures 2 (a) and (b) show spatial distributions of beam in the input+gain cavity section and in the bunching cavity section of the XB72K No.10 buncher, respectively. The strong bunching of beam (RF current/DC current ≈ 1.7) is created toward the end of the buncher section.



(a) (b)

Figure 2: Spatial distribution of beam (a) in the input+gain cavity section and (b) in the bunching cavity section of the XB72K No.10 buncher.

3.3 Traveling-Wave (TW) Output Structure

Simulation of TW output structure is quite straightforward as any other cavity. In order to simulate effects of a non-axis-symmetrical output coupler by the 2.5-D version of MAGIC, we model it by a ring-shaped conductor which has the same complex S_{11}-matrix element (i.e., the reflection coefficient for amplitude and phase). This is illustrated in Fig. 3. There are three free parameters to fit the frequency dependent S_{11}-matrix element: the conductance, and the inner and the outer radii of the conductor. For details of the output coupler modeling, refer to Ref.[9]. As shown later, simulation results for many klystrons seem to verify the validity of this approximation.

Before inventing the above conductor approximation, we have considered a use of an axis-symmetrical radial transmission line to model a 3-D coupler. However, this method cuts the output structure into two disconnected parts, and thus an artificial DC voltage is induced by the DC component of beam at the output cell to which the output couplers are attached. This artificial DC voltage causes a non-negligible effect to the particle dynamics, and results in error. Figure 4 shows the simulation results for the output structure of XB72K No.10.

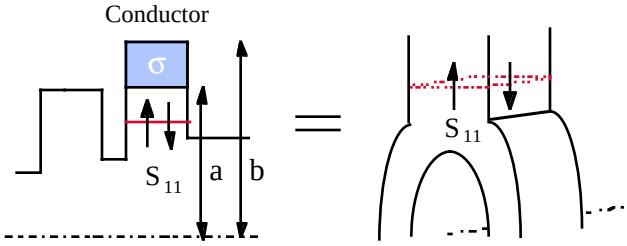


Figure 3: Illustration for 2.5-D modeling of 3-D output coupler using a conductor.

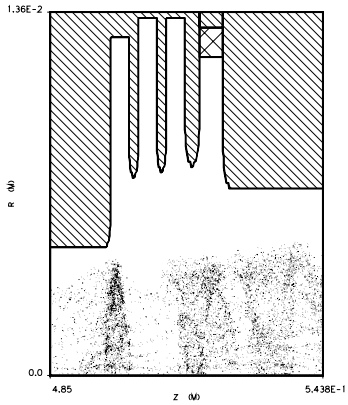

Figure 4: Simulation of XB72K No. 10 in the output structure.

5 SIMULATION RESULTS AND MEASUREMENTS

Figure 5 shows the simulation results of MAGIC and the experimental data for the saturated output power vs. beam voltage for XB72K No.8 klystron. Excellent agreements can be seen. The closed triangles in Fig. 5 are DISKLY simulations. It reveals the accuracy limitation of the 1-D disk model code.

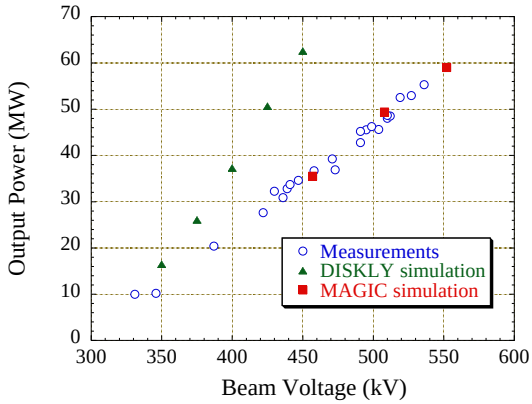

Figure 5: Simulation results of MAGIC and DISKLY and the measurement data for XB72K No.8 klystron.

Let us move to the simulation of SLAC XL-4 klystron. XL-4 klystron produced50 MW at 400 kV with

1.5 μs pulses at 120 pps. It attained 75MW at 450 kV, but the pulse length could go up only to 1.2 μs before the RF breakdown in the output cavity. The simulation results for the output power are compared with the measurements in Fig. 6. MAGIC simulations reproduce the measurement data quite well. The CONDOR prediction at 450 kV, denoted by the closed triangle, was at 10% too high. Figure 7 shows the output power vs. the input power for XL-4. It is clear that the simulation reproduces the measured gain curve well.

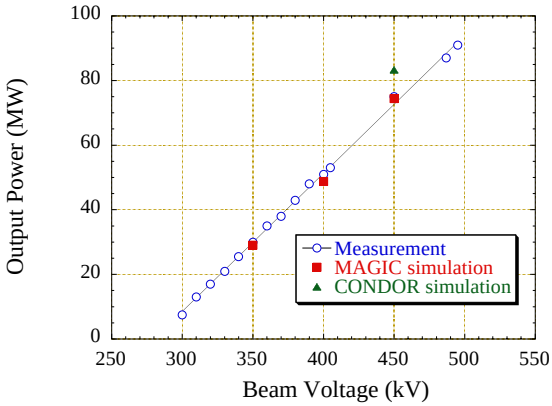

Figure 6: Simulation results of MAGIC and CONDOR and the measurement data for the SLAC XL-4 klystron.

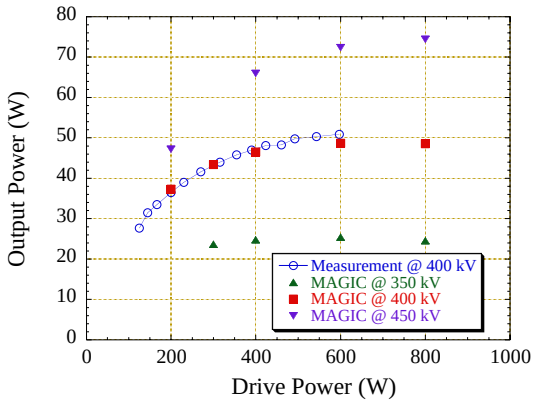

Figure 7: Simulations and measurement data of the output power vs. the input power for the SLAC XL-4 klystron.

Our simulation method can also make an accurate prediction of performance for a PPM klystron. Figure 8 shows the simulation results and the measured values of output power for the BINP PPM klystron. The evolution of DC and RF beam current as a function of distance from the gun is plotted in Fig. 9. The sudden drop of the DC current is due to the particle interception at the final cell of the output cavity. The interception is caused by lack of focusing for particles that drop to the stop-band voltage after losing energy to the traveling-wave. This simulation result explains the experimental observation of significant particle loss described in Section 1.

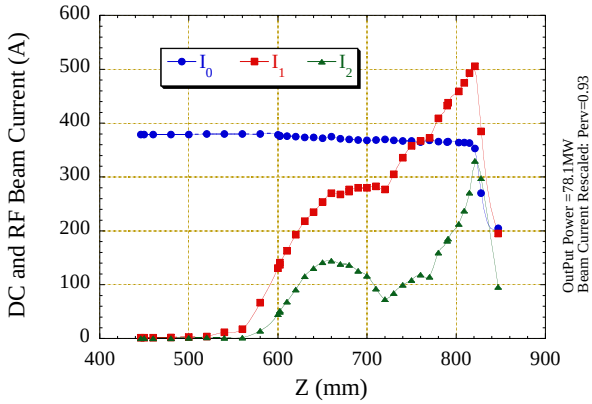

Figure 9: Evolution of the DC and RF beam current in the BINP PPM klystron.

3 XB72K NO.10 DESIGN

XB72K No.10 is the last solenoid-focused klystron in the XB72K series. Main changes from the previous XB72K klystrons are the buncher section and the TW output structure. The operational experience with the previous klystrons proved that the gun portion of XB72K has sufficient performance (1.2 microperveance at 2μs pulse length) and no interception of particles has been observed. The old buncher has two gain cavities and only one bunching cavity. It has a poor RF power generation capability: the RF current /DC current is only 1.2 at the entrance of the output structure. In XB72K No.10, one more bunching cavity was added and the drift space was lengthened to 16cm. The stagger tuning of gain cavities was also adopted to increase the band-width to the current specification of 100 MHz.

The most challenging part of XB72K No. 10 design is a high efficiency and low gradient TW output structure. MAGIC is quite useful for getting an accurate estimate of klystron performance, but the design of an effective TW structure is another matter. A systematic design method was needed to avoid getting lost in the freedom of too many parameters.

For this end, we have developed a simple-minded theory of a constant group/phase velocity TW structure. The idea

is to let the power flow with a constant group velocity throughout the structure, while evolving due to merge of the extracted power from a beam. The Q-value at the output port is matched to this group velocity so that the power exits at the same speed as it flows in the structure. This smooth flow of power prevents congestion at local spots and thus the electromagnetic energy density is more equally distributed in the structure

It is also better to keep the phase velocity constant (approximately equal to the average beam velocity) from the first to the last cell, rather than being matched with the declining beam velocity. When the perfect synchronization of traveling-wave and the beam is tried, the beam loses energy too quickly to the wave, and its velocity becomes too slow to be matched with the wave after a few cells (XB72K No. 10 has four cells). The beam then moves to the acceleration phase of the wave and starts to get energy back. The energy extraction efficiency of each cell does not have to be too good. Only the total efficiency of all cells matters. It is more important to keep the beam in the deceleration phase of the wave all the time. In our method, the traveling-wave travels behind the beam at first, and catches it up with in the middle of the structure. It then moves ahead of the beam, but exits from the output port before the beam slips into the acceleration phase of the wave.

We also demand that each cell is operated in $2/3\pi$ mode at 11.424 GHz. The cell length is also constant except the last cell (slightly longer to reduce the field gradient). As the result, the cells become almost identical. We then tapered up the iris aperture slightly to equalize the field gradient among the cells. In this method, once the group and the phase velocities are chosen, the geometry of the structure are almost uniquely determined. The structure of output port can be adjusted to control the reflection of power to maximize the output power.

The predicted output power vs. the beam voltage is plotted in Fig. 10:

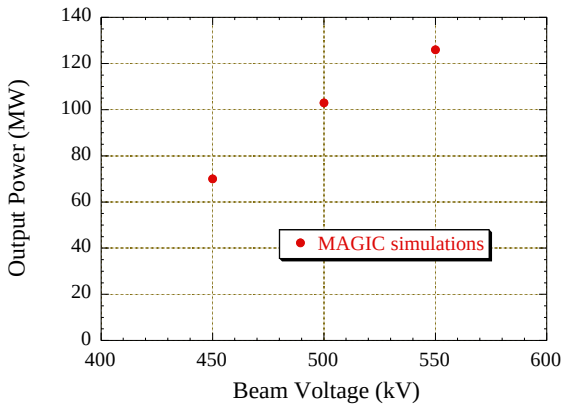

Figure 10: Predictedoutput power vs. beam voltage for the XB72K No.10.

The predicted performance is summarized in Table 4. Figure 11 shows comparison between XB72K No.10 and SLAC XL-4 for the saturated power vs. the maximum field gradient in the output structure. Both have similar efficiencies of about 48%, but the maximum gradient of XB72K No.10 is about 20% lower than that of XL-4, though the power is 67% larger. In XB72K No.10, the fairly constant gradient is achievedin the output structure. This comparison indicates that the XB72K TW output structure can attain 120 MW power at a longer pulse than XL-4 at 75 MW without cavity breakdown. At 75MW, XB72K can tolerate an even longer pulse. It is now in manufacturing and testing will begin in November 1998.

Table 4: Predicted performance of XB72K No. 10.

Peak output power	126 MW
Beam voltage	550 kV
Efficiency	48.5%
Maximum field gradient in TW	77 MV/m
Pulse length	1.5 μs or longer
Band-width	100 MHz
Gain	53 dB

Abstract

An unstable electrostatic mode has been observed in particle-in-cell simulations that, for unbunched ion beams with sufficient intensity and thermal anisotropy, transfers thermal energy from the transverse ($\perp$) to the longitudinal ($\|$) directions[1-4]. This instability can be important and appears to be insensitive to the details of the initial distribution as well as the nature of the applied focusing. The unstable mode is characterized by an axial wavelength comparable to the beam radius and growth rates comparable to the frequency of $\perp$ particle betatron oscillations. We present a theory of this instability based on the work of Wang and Smith[5]. This theory employs a continuous focusing model in the limit of strong thermal anisotropy with a warm, $\perp$ KV distribution and a cold, $\|$ distribution. The predicted mode structure is found to compare favorably with simulations carried out over a range of space-charge strength.

1 INTRODUCTION

In a continuous focusing (CF) channel, a thermal equilibrium (TE) beam distribution represents a stable, maximum entropy state that an arbitrary initial distribution will relax to under the influence of collisions[6]. Although collective processes and phase mixing can enhance the rate of relaxation, the beam lifetime in the machine is often insufficient to allow significant relaxation. Moreover, in real accelerators, the focusing is usually periodic, and in this situation there is no known TE distribution. Nevertheless, distributions that more closely resemble a CF TE distribution are expected to have less free energy to drive instabilities. This renders thermodynamic concepts like beam temperature useful for non TE distributions.

Although temperature is, strictly speaking, a thermodynamic quantity, one can define local kinetic temperatures (energy units) by $T_i/2 = \langle (p_i - \langle p_i \rangle)^2 \rangle / 2m = m v_{th,i}^2/2$, where m is the particle mass, p_i is the $i = x, y, z$ particle momentum, $v_{th,i}$ is the ith local thermal velocity component, and $\langle \cdots \rangle$ denotes an average over the momentum space degrees of freedom in the particle distribution. Here and henceforth, we have adopted a nonrelativistic model for simplicity in presentation. Differences in these kinetic temperatures (or equivalently momentum spreads) provide a measure of deviations from an isotropic TE, and such differences can provide free energy for so-called "equipartitioning" instabilities that drive the beam closer to TE[7].

$\perp$-$\|$ temperature anisotropies tend to naturally develop in accelerators[6,8]. For example, consider an ion diode with particle energy $\mathcal{E}_b$ (~ 50 keV typical) and source temperature T (~ 0.1 eV typical). In the absence of $\perp$-$\|$ coupling, one would expect the final axial (z-direction) temperature to be strongly cooled with $T_z = T^2/2\mathcal{E}_b$. On the other hand, one would expect little accelerative change in $\perp$ temperatures with $T_x = T_y \sim T$, consistent with any $\perp$ beam compression, $\perp$ instabilities, etc. These effects suggest a strongly anisotropic beam emerging from the diode. Further $\perp$-$\|$ anisotropy can develop in the transport following the diode. Neglecting $\perp$-$\|$ coupling, $T_z \tau \simeq const$, where τ is the beam pulse duration, and T_z will evolve consistently with any $\|$ beam expansion or compression during acceleration. Some change in T_z can also be caused by the thermalization of $\|$ space-charge waves launched by acceleration errors. On the other hand, nonlinear forces associated with focusing aberrations and nonuniform space charge (from instabilities, various beam manipulations, etc.), can lead to increased $\perp$ normalized beam emittance ($\propto r_b \sqrt{T_x}$, where r_b is the beam radius) while only producing small changes in T_z.

In high intensity applications such as Heavy-Ion Fusion (HIF), the need for a small focal spot radius r_s leads to interrelated constraints on the beam $\perp$ emittance, space-charge strength, and $\|$ momentum spread, as well as machine misalignments and abberations in the final focus optic[9]. For a final magnetic optic, dispersion results in a limit of allowable $\|$ momentum spread that can be estimated as $\Delta p/p < r_s/8\theta d$. Here $p = \langle p_z \rangle$ and $\Delta p = \sqrt{2\langle (p_z - p)^2 \rangle}$ are the axial momentum and momentum spread, d is the distance from the final optic to the focal spot, and θ is the beam convergence angle to the spot. This typically results in spread limits of less than $\Delta p/p \sim 1\%$. If the $\perp$ and $\|$ beam temperatures must remain similar, this will introduce an additional constraint that must be considered. Moreover, if any bends are present, dispersion can result in further momentum spread limits that $\perp$-$\|$ equilibration can influence[8].

In most accelerators, particle collision times are generally much longer than the beam lifetime in the machine. Hence collision induced equipartitioning is usually negligible. On the other hand, rapid kinetic instabilities can result in significant equipartitioning. Thus it is prudent to understand any such instabilities so they can be properly

* This research was performed under the auspices of the US DOE by LLNL, NRL, and LANL under contracts W-7405-ENG-48, DE-AI02-93ER40799, and DE-AI02-94ER54232.

accounted for in machine design.

In this paper, we present simulation (Sec. 2) and theory (Sec. 3) on an intense-beam collective mode that produces a rapid transfer of thermal energy from the $\perp$ to the $\parallel$ degrees of freedom for sufficient $\perp$-$\parallel$ thermal anisotropy. The beam is unbunched, and nonlinear space-charge forces associated with the unstable electrostatic mode produce this energy exchange rather than $\perp$-$\parallel$ coupling induced by the shape of the beam ends. For simplicity, all analysis is carried out for an axisymmetric ($\partial/\partial\theta = 0$) beam propagating without acceleration in a continuous focusing channel with a linear radial focusing force. This focusing arrangement can represent the average effects of a lattice of alternating gradient electric or magnetic quadrupoles, or a periodic solenoidal magnetic field for a beam with zero total canonical angular momentum[10].

2 PIC SIMULATIONS

Particle-in-cell (PIC) simulations were carried out with the electrostatic WARP code[2,8]. An axisymmetric (rz) package of the WARP code suite that neglects self-magnetic field effects was employed with periodic boundary conditions axially, and a grounded, perfectly conducting cylindrical beam pipe transversely. Simulations employed 100 k to 1 M particles, and typical grid dimensions consisted of 32 radial and 256 axial zones. When T_z was sufficiently cold, Gaussian smoothing was employed in the axial direction to suppress a $\parallel$ numerical grid instability. The initial $\perp$ distribution of beam particles had zero canonical angular momentum and was either KV [uniform density and a parabolically decreasing temperature profile in the radial coordinate $r = \sqrt{x^2 + y^2}$, see Ref. 6 and Sec. 3] or semi-Gaussian (SG) [uniform density and a uniform temperature Gaussian in $\perp$ momentum space]. The initial $\parallel$ distribution had uniform density and Gaussian momentum spread. The instability is seeded from noise associated with the finite particle statistics.

Typical runs employed: K^+ ion at $\mathcal{E}_b = \langle p_z \rangle^2/2m = 10$ MeV axial kinetic energy, equilibrium beam radius $r_b = 2.5$ cm, beam current $I = 5$ A, and conducting pipe radius $r_p \geq 2r_b = 5$ cm. The spatial average $\perp$ beam temperature $\hat{T}_x = \hat{T}_y = (2\pi \int_0^{r_b} dr\ r T_x\ )/\pi r_b^2$ was then consistently set as follows (in an rms equivalent beam sense[6] for an initial SG distribution). Denote the angular frequency of $\perp$ particle oscillations in the equilibrium fields in the absence (i.e., $I = 0$) and presence (specified I) of space charge by ν_0 and ν, respectively. Using the equilibrium envelope equation, these so-called "betatron" frequencies can be expressed as[10]

$$\begin{aligned} \nu_0^2 &= 4\hat{T}_x/mr_b^2 + \hat{\omega}_p^2/2, \\ \nu^2 &= \nu_0^2 - \hat{\omega}_p^2/2 = 4\hat{T}_x/mr_b^2, \end{aligned} \qquad (1)$$

where $\hat{\omega}_p$ is the beam plasma frequency. Then $\hat{T}_x$ was set to achieve a specified tune depression ν/ν_0 satisfying $0 \leq \nu/\nu_0 \leq 1$, where $\nu/\nu_0 \to 1$ and $\nu/\nu_0 \to 0$ correspond to the warm- and cold-beam limits, respectively. With $\hat{T}_x$ fixed, ν_0 (i.e., the external focusing) was then set consistently with Eq. (1). For $\nu/\nu_0 \sim 0.1$ to 0.4, these parameters are representative of those in the low energy end of linear induction accelerators for Heavy Ion Fusion[9]. The $\parallel$ temperature T_z was set as a fraction of $\hat{T}_x$. Axial grid lengths were chosen sufficiently short for the $\parallel$ variations of the unstable mode to be well resolved, but sufficiently long where 5 or more wavelengths of variation were simulated to reduce the influence of the periodic boundary conditions. This resulted in grid lengths of 10 to 25 cm. Timesteps for the particle advance were chosen such that $dt < 0.01/\nu_0$.

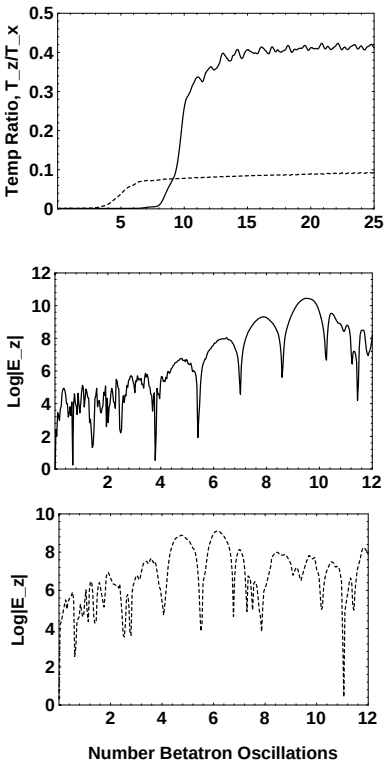

Figure 1: Temperature anisotropy $T_z/\hat{T}_x$ (top, SG and KV) and the log of the absolute value of the axial electric field $\ln|E_z|$ (middle for KV, and bottom for SG) verses the number of undepressed betatron oscillations $\nu_0 t/2\pi$.

Results of simulations illustrating properties of a space-charge mode that transfers thermal energy from the $\perp$ to the $\parallel$ directions are presented in Figs. 1 and 2. The simulations are for initial $\nu/\nu_0 = 0.45$, $T_z = 0.01\hat{T}_x$, a 13.4 cm axial beam length, and $r_p = 2r_b$. Results are shown for both initial KV (solid curves) and SG (dashed curves) $\perp$ distributions. In Fig. 1, the anisotropy ratio $T_z/\hat{T}_x$ is plotted as a function of the number of undepressed betatron oscillations of an equilibrium particle, $\nu_0 t/2\pi$, where t is the time. Evidently, in the initial quiescent period the growth in $T_z/\hat{T}_x$ starts from the noise, followed by a period of exponential growth, and then saturation with $T_z/\hat{T}_x \sim 0.4[0.1]$ (results given for initial KV with SG values in "[]" brackets). This instability leads to increased T_z and decreased $\hat{T}_x$ as energy is exchanged. Phase space plots of the mode have been presented elsewhere[3,4]. Also in Fig. 1, the log of the abso-

lute value of the axial electric field, $\ln|E_z|$, is plotted (arbitrary units) for a fixed location moving with the equilibrium beam as a function of $\nu_0 t/2\pi$. Little variation in structure is observed with the choice of location, suggesting an absolute instability. These plots suggest that a single unstable mode is dominating the evolution with an oscillation period and e-fold time of approximately 3.2[2.8] and 0.82[1.1] undepressed betatron oscillations, respectively. The radial and axial structure of the perturbed electrostatic potential $\delta\phi$ describing this mode was extracted with a discrete Fourier transform diagnostic. The dominant axial wavelength λ of $\delta\phi$ was well expressed with $\lambda/r_b = 1.3[1.1]$ and the radial mode structure of this harmonic component is shown in Fig. 2 for $\nu_0 t/2\pi = 9.2[3.9]$. Note that $\delta\phi$ is peaked at the center with one radial node within the beam ($r < r_b = 2.5$cm) and has small amplitude outside the beam ($r_b < r \leq r_p = 5$cm).

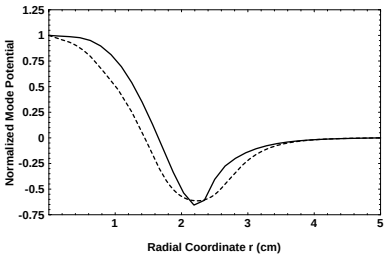

Figure 2: Normalized electrostatic potential of the unstable mode $\delta\phi/\delta\phi(r=0)$ verses radial coordinate r.

The simulations indicate that the essential features of this instability are similar for both initial KV and SG $\perp$ distributions. However, since the SG is not a real equilibrium, the lack of detailed radial force balance influences the initial evolution of the mode, complicating the interpretation of the onset of instability (note the shift in Fig. 1). Moreover, details of the saturation are different for the KV and SG $\perp$ distributions, with wave breaking in the KV distribution leading to a trapped particle phase-space that may represent an intermediate state on a longer timescale evolution. The KV and SG initializations also have differing numerical collision properties, further complicating interpretations. Preliminary data is presented in Table 1 on the space-charge threshold (ν/ν_0 less than indicated values leads to instability) and the saturation level (in $T_z/\hat{T}_x$) of the instability. Data is tabulated for both initial KV and SG $\perp$ distributions for several values of initial temperature anisotropy ($T_z/\hat{T}_x$). Note that the threshold is a strong function of the initial anisotropy and depends weakly on the type of initial distribution. Saturation occurs when T_z is a fraction of $\hat{T}_x$, with the value depending on the initial anisotropy, space-charge strength, and distribution type. Growth rates of the unstable mode are larger for strong initial anisotropy and space-charge strength. Smaller growth rates can render simulations difficult due to the noise associated with the finite particle statistics.

Finally, previous studies[1,4] suggest that the instability only transfers $\perp$ thermal energy to the $\parallel$ direction and not vice-versa when $T_z > \hat{T}_x$. Full 3D simulations have also been carried out with both alternating gradient and CF channels and the results are similar those presented here.

Table 1: Instability threshold and saturation properties.

3 THEORY

Neglecting particle correlations and collisions, the beams simulated in Sec. 2 are described in terms of a single-particle distribution function f that is a function of the coordinate $\mathbf{x}$, momentum $\mathbf{p}$, and time t, and evolves according to the Vlasov equation

$$\left\{\frac{\partial}{\partial t} + \frac{\partial H}{\partial \mathbf{p}}\cdot\frac{\partial}{\partial \mathbf{x}} - \frac{\partial H}{\partial \mathbf{x}}\cdot\frac{\partial}{\partial \mathbf{p}}\right\} f(\mathbf{x},\mathbf{p},t) = 0. \qquad (2)$$

Here, $H = \mathbf{p}^2/2m + m\nu_0^2 r^2/2 + q\phi$ is the Hamiltonian, q is the particle charge, and ϕ satisfies the Poisson equation $\nabla^2\phi = 4\pi q\int d^3p\, f$ subject to the boundary condition $\phi(r = r_p) = const.$ To perform a conventional equilibrium/stability analysis, we expand

$$\begin{aligned} \phi &= \phi^0(r) + \delta\phi(r,\omega,k_z)e^{-i(\omega t - k_z z)}, \\ f &= f^0(\mathbf{x},\mathbf{p}) + \delta f(r,\mathbf{p},\omega,k_z)e^{-i(\omega t - k_z z)}, \end{aligned} \qquad (3)$$

where equilibrium quantities (superscript zero) correspond to $\partial/\partial t = 0$ solutions to Eq. (2) with $\delta\phi = 0 = \delta f$ and $\delta\phi$ and δf are normal mode perturbations with angular frequency ω and wavenumber $k_z = 2\pi/\lambda$. We assume a $\perp$ KV and $\parallel$ Gaussian f^0 defined by[6,10]

$$f^0 = \frac{\hat{n}}{2\pi m}\delta\left(H_\perp^0 - 2\hat{T}_x\right)\frac{\exp\left[-\frac{(p_z - m v_b)^2}{2mT_z}\right]}{(2\pi m T_z)^{1/2}}. \qquad (4)$$

Here, $v_b = \langle p_z\rangle/m$ is the axial beam velocity, $\delta(x)$ is the Dirac delta-function, and $H_\perp^0 = \mathbf{p}_\perp^2/2m + m\nu_0^2 r^2/2 + q\phi^0$ with $\mathbf{p}_\perp = p_x\hat{\mathbf{x}} + p_y\hat{\mathbf{y}}$. The form of f^0 is consistent with undepressed and depressed $\perp$ particle oscillations with frequencies ν_0 and ν given by Eq. (1) with $\hat{\omega}_p^2 = 4\pi q^2\hat{n}/m$ and beam edge radius r_b. For $0 \leq r < r_b$, Eq. (4) also corresponds to uniform density, $\int d^3p\, f^0 = \hat{n} = const$, and a parabolic $\perp$ temperature profile, $\int d^3p\, (\mathbf{p}_\perp^2/2m) f^0 = 2\hat{n}\hat{T}_x(1 - r^2/r_b^2)$.

The linear eigenvalue equation for the perturbed potential $\delta\phi$ can be derived by linearizing the Vlasov equation (2) and inverting the resulting equation for δf with the method of characteristics and inserting the result in Poisson's equation. After some algebraic manipulation, this results in

$$\left\{\frac{1}{r}\frac{\partial}{\partial r}r\frac{\partial}{\partial r}-k_z^2\right\}\delta\phi=\frac{\hat{\omega}_p^2 r_b}{4\hat{T}_x/m}\delta(r-r_b)\;[\delta\phi+\kappa_1]\big|_{p_\perp=0} + \hat{\omega}_p^2\Theta(r_b-r)\left[\frac{m^2}{p_\perp}\frac{\partial}{\partial p_\perp}\kappa_1+ik_z^2\kappa_2\right]\Bigg|_{p_\perp^2/2m=T_x}, \quad (5)$$

where $\Theta(x)$ is the Heaviside step-function, and κ_1 and κ_2 are equilibrium orbit integrals defined by

$$\kappa_1 = i\int\frac{d\psi}{2\pi}\int_{-\infty}^{0}d\tau\;\left(\Omega-i\frac{k_z^2T_z}{m}\tau\right) \times \delta\phi[\tilde{r}(\tau)]\exp\left[-\frac{k_z^2T_z}{2m}\tau^2-i\Omega\tau\right], \quad (6)$$

$$\kappa_2 = i\int\frac{d\psi}{2\pi}\int_{-\infty}^{0}d\tau\;\tau\delta\phi[\tilde{r}(\tau)]\;\exp\left[-\frac{k_z^2T_z}{2m}\tau^2-i\Omega\tau\right].$$

Here, $T_x\equiv 2\hat{T}_x(1-r^2/r_b^2)$, $\Omega\equiv\omega-k_zv_b$, and the equilibrium characteristics are defined by $\tilde{r}^2(\tau)\equiv r^2\cos^2(\nu\tau)+(rp_\perp/m\nu)\cos(\;\;)\sin(2\nu\tau)+(p_\perp/m\nu)^2\sin^2(\nu\tau)$.

Equation (5) is a difficult integro-differential equation that must be solved for Ω and $\delta\phi$ simultaneously. Wang and Smith[5] derived the dispersion relation corresponding to Eq. (5) in the limit of infinite thermal anisotropy ($T_z/\hat{T}_x\to 0$ by coupling together earlier transverse solutions ($T_z=0$ and $k_z=0$) by Gluckstern[11] for $k_z\neq 0$. In this procedure $\delta\phi$ is expanded within the beam ($0\le r\le r_b$) as

$$\delta\phi(r)=\delta\phi(r=r_b)+\sum_{n=1}^{\infty}A_n\delta\phi_n(r), \quad (7)$$

where $\delta\phi_n(r)=(1/2)[P_{n-1}(1-2r^2/r_b^2)+P_n(1-2r^2/r_b^2)]$ is an nth order $\perp$ Gluckstern eigenfunction, $P_n(x)$ is a nth order Legendre Polynomial, and $\delta\phi(r=r_b)$ is the potential at the beam edge (generally nonzero). The expansion coefficients A_n generally depend on k_z and Ω and satisfy recursion relations, which together with an interface ($r=r_b$) jump condition on $\delta\phi$, yields a dispersion relation expressible in terms of an infinite determinant.

Approximate numerical solutions to this dispersion relation can be found by truncating the series [$n<n_{max}$ in Eq. (7)] to obtain a finite determinant dispersion relation[5]. Solutions for $\Omega/\nu_0=(\omega-k_zr_b)/\nu_0$ are parameterized by ν/ν_0, k_zr_b, and r_b/r_p. The number of distinct mode branches found is $n_{max}(n_{max}+2)$ or $(n_{max}+1)^2$ for n_{max} even or odd. The branches are characterized according to their limiting properties. For $k_zr_b\to 0$, $n_{max}(n_{max}+1)$ branches corresponding to nth order $\perp$ Gluckstern modes[11] are found (labeled T_n) with $\delta\phi\propto\delta\phi_n$ for $r\le r_b$ and $\delta\phi=0$ for $r\ge r_b$. Properties of this $\perp$ limit dispersion relation have been described elsewhere[10,11]. For long wavelength perturbations with $k_zr_b\ll 1$ and $\hat{T}_x\to 0$ ($\nu\to 0$), a single branch (labeled L_1) corresponding to an "ordinary" cold-beam $\parallel$ mode is found. This limiting form mode has $\delta\phi\propto I_0(k_zr)$ for $r\le r_b$ with $I_0(x)$ a 0th order modified Bessel Function and $\Omega^2=(\hat{\omega}_p^2/2)(k_zr_b)^2\ln(r_p/r_b)$. Other branches (labeled L_n with $n=2,4,\cdots,n_{max}-1$ or n_{max}) are found to reduce for long wavelengths ($k_zr_b\ll 1$) and weak space-charge ($\nu\to\nu_0$) to a little known class of $\perp$ coupled $\parallel$ modes. These modes have $\delta\phi\propto\delta\phi_n$ within the beam and

$$\Omega^2=\frac{\hat{\omega}_p^2}{8n(n+1)}(k_zr_b)^2\int_0^{2\pi}\frac{dx}{2\pi}\;P_n(\cos x).$$

In general, a large n_{max} truncation will result a high-order polynomial dispersion relation with many branches; some of which describe low-order modes and others, high-order modes. One takes n_{max} sufficiently large to accurately represent modes of interest, but small enough to reduce the number of branches and facilitate mode identification. Instabilities arise in parameter regimes where two or more branches of Ω "collide" and coalesce. Unfortunately, many of these instabilities, particularly higher-order ones, are associated with unphysical features of the KV model[10]. Nevertheless, we believe that a low-order confluent branch where the T_2 and L_2 branches coalesce describes the instabilities observed in Sec. 2. This low-order T_2-L_2 confluent branch may also represent a non-pathological KV instability that persists for more realistic (non-singular) equilibrium distribution functions.

Comparisons between the confluent T_2-L_2 mode branch and simulations are presented in Figs. 3 and 4. All simulations were seeded from noise and it is assumed that a single unstable mode dominates the evolution. In the theory, an $n_{max}=4$ truncation was employed. In Fig. 3, the radial eigenfunction $\delta\phi$ of the T_2-L_2 mode (k_z selected for maximum growth rate) is compared with simulation and $\perp$ ($k_z\to 0$) theory for $\nu/\nu_0=0.45$ and $r_p/r_b=2$. Note that the T_2-L_2 has similar structure to the $\perp$ T_2 mode, but has finite amplitude at the beam edge ($r=r_b$) and is unstable, in contrast to the $\perp$ mode. Also in contrast to the $\perp$ T_2 mode, where $\delta\phi_2$ is independent of ω, the radial structure of $\delta\phi$ varies with Ω and k_z for the T_2-L_2 mode. In Fig. 4 the normalized axial wavenumber, oscillation frequency, and growth rate of the T_2-L_2 mode is compared to the simulation results over the range of space-charge strength $0.3\le\nu/\nu_0\le 0.5$. The theory curves were generated employing the wavenumber k_zr_b with maximum $\mathrm{Im}\,\Omega/\nu_0$ growth rate at specified ν/ν_0. The spreads about the simulation points indicate measurement uncertainties. For $\nu/\nu_0\ge 0.4$ the theory agrees reasonably well with the simulations outside of a slightly lower simulated growth rate that is likely due to the finite axial temperature employed in the simulations (initial $T_z<0.01\hat{T}_x$). For $\nu/\nu_0<0.4$, low-order KV instabilities of the T_2, T_3, and T_4 $\perp$ Gluckstern modes[10] may produce the systematic deviations observed from the results predicted by the T_2-L_2

branch. Extension into this strong space-charge regime will likely require systematic mode seeding to avoid exciting such unphysical $\perp$ KV instabilities. Approximate expressions for the mode density, temperature, and flow velocity perturbations have been derived from a fluid theory[10] (using the kinetic theory dispersion relation) for use in future mode seeding studies.

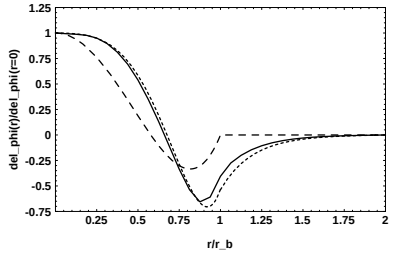

Figure 3: Eigenfunction comparisons for simulation (solid), 3D T_2-L_2 confluent mode theory (dotted), and $\perp$ T_2 mode theory (dashed).

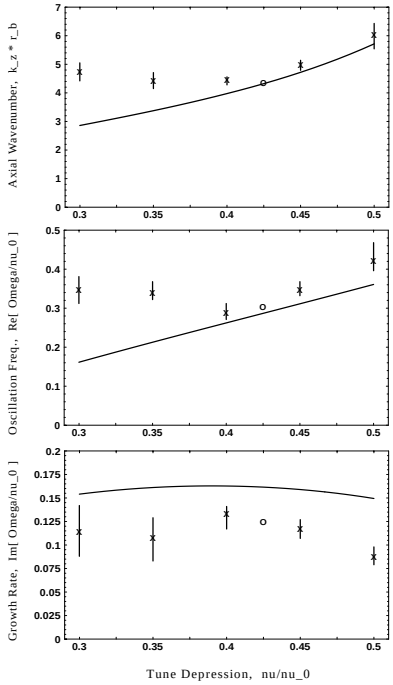

Figure 4: Normalized mode axial wavenumber ($k_z r_b$), oscillation frequency ($\mathrm{Re}\,\Omega/\nu_0$), and growth rate ($\mathrm{Im}\,\Omega/\nu_0$) verses tune depression (ν/ν_0) from theory and simulation.

4 CONCLUSIONS

Simulation and theory have been presented characterizing an electrostatic instability that can transfer thermal energy from the $\perp$ to the $\parallel$ directions for an intense, unbunched beam with sufficient thermal anisotropy ($T_z/\hat{T}_x < 1$). General features of this instability are insensitive to the specific form of the applied focusing and initial distribution, and therefore, a $\perp$ KV model was used to explore the idealized mode structure. The instability has short axial wavelength ($\lambda \sim r_b$) with growth rates and oscillation frequencies comparable to the depressed betatron frequency ($\mathrm{Re}\,\Omega \sim \mathrm{Im}\,\Omega \sim \nu$). The unstable mode has an anisotropy (initial value of $T_z/\hat{T}_x$) dependent threshold in space-charge strength (ν/ν_0) and saturates when the $\parallel$ temperature (T_z) is a fraction of the $\perp$ temperature ($\hat{T}_x$). Since $\parallel$ accelerative cooling and $\perp$ emittance increases can contribute to the anisotropy that drives the instability, the mode needs to be better understood to access impact on machine design. The energy exchange associated with the instability leads to decreased $\perp$ emittance with increased $\parallel$ momentum spread. Whether this effect is beneficial or harmful will depend on the details of a particular application. Possible consequences of the instability can be estimated by assuming that T_z remains saturated during transport at a set fraction of $\hat{T}_x$ if significant $\perp$-$\parallel$ anisotropy would have developed in the absence of the unstable mode. Equipartitioned design concepts have also been applied to bunched beams in rf linacs[12], where the $\perp$ and $\parallel$ focusing can be adjusted to maintain equilibration. Proper modeling this instability also has implications for simulations, since it requires the resolution of short axial wavelengths in simulations of long, "unbunched" beams.

DECELERATING AND ACCELERATING RFQS

A.M. Lombardi
PS Division, CERN, 1211 Geneva 23, Switzerland

Abstract

This paper presents an overview of RFQ working principles, highlights the relevant parameters and summarises the different design approaches for the high, medium and low intensity cases. Attention is then focussed on the beam dynamics design in decelerating RFQs and, in particular, on how to cope with the intrinsic problems of deceleration (e.g. physical emittance increase and reduction of the longitudinal stable area). Fields of application for decelerating RFQs and their advantages with respect to conventional decelerating techniques will also be highlighted. The beam dynamics of the RFQD, the post decelerator for the CERN Antiproton Decelerator (AD) ring, will be presented in detail. This RFQ is intended to decelerate the 5.3 MeV antiproton beam coming from the AD down to an energy of virtually zero. Several decelerating schemes have been studied to fit the experimenters' need for a high quality beam with the final energy varying in the range 0 to 100 keV. Various potential solutions will be presented and discussed, with particular attention given to the intended approach.

1 INTRODUCTION

The idea of a Radio Frequency Quadrupole Accelerator (RFQ) was born in 1970 in Russia [1,2]. Its highlights are: an alternating-gradient velocity-independent focusing and a remarkable efficiency in bunching and accelerating a continuous low energy ion beam while preserving the transverse beam quality. The efficiency of an RFQ for injection into a Drift Tube Linac can reach values as high as 90% - making it extremely attractive when compared to the 50% attainable with standard quadrupoles-and-bunchers transfer lines. It has become the key machine for attaining high-current low-emittance beams. Nowadays there are more than 100 RFQ accelerators in operation, mainly as H+,H- and heavy ion injectors but also in medical facilities, material research and material production facilities. Recently the physicist community manifested an interest [3] in using an RFQ to post-decelerate a beam coming from a ring to energies of some ten keV. This could potentially broaden the range of application of such a machine, as the theoretical deceleration efficiency is one to two orders of magnitude higher than the more widespread degrader foil technique.

2 (ACCELERATING) RFQS

The RFQ is a linear accelerator that focuses, bunches, and accelerates a continuous beam of charged particles: all three functions are performed by the electrical radio-frequency (RF) field. The RFQ consists of a cylindrical cavity resonating in the TE21 mode with four electrodes placed along the direction of propagation of the beam, which present a longitudinal modulation. The four-fold symmetry provides an alternating focussing channel, and the longitudinal modulation produces a field in the direction of propagation, which bunches and accelerates the beam. A sketch of an RFQ is reported in Fig. 1, with characteristic parameters indicated. The ratio between the focusing and the acceleration, the bunching and accelerating rates and the synchronicity between the longitudinal field and the beam are determined by the geometry of the electrodes, i.e. the aperture, the modulation and the distance between peaks and troughs on the electrode surface. Once the electrodes are machined, the RFQ is a “one-button” machine, as only the power going into the cavity can be varied. This feature, while making the RFQ easy to operate, necessitates a rigorous design phase and has given rise to the development of powerful computer codes to simulate the beam dynamics [4].

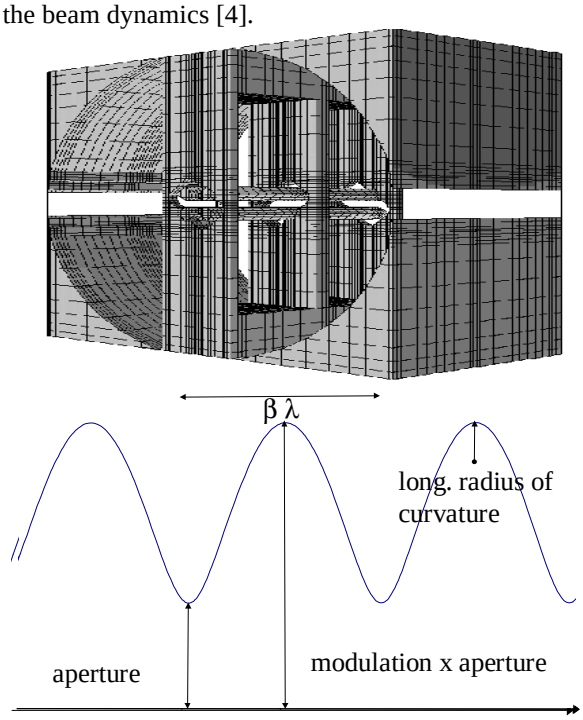

Figure 1: Sketch of an RFQ structure (top) and electrode microstructure (bottom).

2.1 Basic parameters and initial choices

For sake of completeness a list of the RFQ basic parameters [5,6,7] used throughout this paper is reported in the following.

- The focussing parameter:

$$B = \left(\frac{q}{m_0 f^2} \right) \left(\frac{V}{a^2} \right) \left(\frac{I_o(ka) + I_o(mka)}{m^2 I_o(ka) + I_o(mka)} \right)$$

linked to the phase advance per focussing period:

$$\sigma = \sqrt{\frac{B^2}{8\pi^2} - \frac{\pi q E_0 T \sin(\varphi)\lambda}{m_o c^2 \beta \gamma^3} - \frac{3 Z_0 q I \lambda^3 (1 - f(p))}{8\pi m_o c^2 \gamma^3 r^2 b}}$$

- The accelerating efficiency:

$$A = \frac{m^2 - 1}{m^2 I_o(ka) + I_o(mka)}$$

linked to the effective accelerating field:

$$E_0 T = AV\left(\frac{2}{\beta \cdot \lambda}\right)\frac{\pi}{4}$$

- The longitudinal radius of curvature

$$\rho_l = -\frac{A \cdot k \cdot r_o^2 \cdot I_1(mka) - 2 \cdot m \cdot a}{A k^2 r_o^2 I_o(mka)}$$

which determines the maximum dimension of the cutting tool.

In the above: *a*=bore radius, *b*=the average beam length, β,γ=relativistic parameters, *c*=speed of light, *f*= rf frequency, *I*=beam current, *I0,1*=zero,first order Bessel function, *k*=wave number, λ=wavelength, *m*=electrode modulation, *m0*=rest mass, *f(p)*= geometrical factor, *p*=ratio of the transverse beam dimensions, *q*=charge, *r*= average transverse beam dimension, *r0*=average bore, *V*=vane voltage, *Z0*=free-space impedance (376.73 Ohm).

There are several factors that influence the choice of the basic parameters of an RFQ and each RFQ is a "special" case.

The beam-dynamics quality factors are mainly the beam output quality (transverse and longitudinal emittance, intensity), the current limit and the sensitivity to input condition, mechanical alignment and to the RF field quality (flatness, frequency stability,..). Several other "external" factor can influence the RFQ design as e.g. budget, availability of RF power and frequency of the downstream accelerator. Additionally, the structure length is always an issue, not only because of cost but also because of machining and alignment concerns.

Frequency is a fundamental design consideration as it strongly influences the focussing power and the length of the RFQ. Due to the strong frequency dependence of the focussing parameter frequencies lower than 200 MHz are more indicated for ions or very-high-current proton beams while higher frequency (300-400MHz) are more suitable for protons.

The maximum field on the vane-tip (and the maximum voltage between the electrodes) influences the acceleration rate (and consequently the length of the RFQ) and the probability of breakdown. The Kilpatrick field [8] gives a guideline: values up to 2 Kilpatrick are commonly used for low-duty-cycle machines but require a careful surface cleaning and RF conditioning.

The minimum and maximum modulation, which define the minimum and maximum acceleration rate, are determined by machining limitation. For standard machining ρ*l* should be bigger than some 5 mm.

The phase advance per focussing period is a measure of the transverse stability [5] and it should be set at a value between 20 and 40 degrees.

2.2 Design recipes

Designing an RFQ co-ordinates three aspects: the mechanic design, the RF design and electrode profile design. The field pattern in the beam region is given by the electrode micro-structure; the beam dynamics depend mainly on the electrode design, which is the only aspect this paper deals with.

An RFQ is conceptually divided into four sections [9]: the Radial Matching Section (R.M.S.), the shaper, the gentle buncher, and the accelerator. In the R.M.S. (4-6 cells) the focussing parameter is tapered up to its final value in order to adapt the beam to a time-dependent focussing system. In the shaper the longitudinal field is slowly increased in order to form the beam longitudinal structure. The shaper determines the final value of the longitudinal emittance: a smooth shaping (over several cells, up to 20-40) guarantees a small output longitudinal emittance. In the gentle buncher the synchronous phase is adiabatically changed towards a stable accelerating phase, the beam is bunched and its energy gradually increased. The end of the gentle buncher, where the modulation is maximum and the aperture minimum, defines the transverse acceptance. Finally, in the accelerator the phase, aperture, and modulation are kept constant while the beam is brought to the final energy. An exit matching section can then be added to adapt the beam to the downstream user needs. The laws of change of the defining parameters (aperture, modulation and phase) determine the transition between the different sections in the RFQ. The smoother the transition the better the output beam quality but also the longer the RFQ.

A fundamental issue when choosing an RFQ design "recipe" arises from space charge effects. These are difficult to address in the design phase as they strongly couple the longitudinal and the transverse dynamics. As a consequence it is not possible to separate bunching and acceleration because the space-charge force increase, due to bunching, must be compensated by acceleration. This imposes an extremely smooth transition both between the

"shaping" and the "bunching" as well as between the "bunching" and the "acceleration". The result is that for the same beam energy increase the high-intensity RFQs turn out to be longer than the corresponding low-intensity one and that an emittance increase is unavoidable (due to bunching in the presence of space charge). During the design phase a careful trade-off between RFQ length and emittance increase has to be chosen. For low-intensity RFQs it is possible to have a fast pre-bunching section, and a boosting section (before acceleration) where the synchronous phase and modulation are varied very rapidly. Typical designs for a high and for a low intensity RFQ are shown in Fig. 2. Both these RFQs are currently operating at CERN and their nominal performances have been attained [10,11].

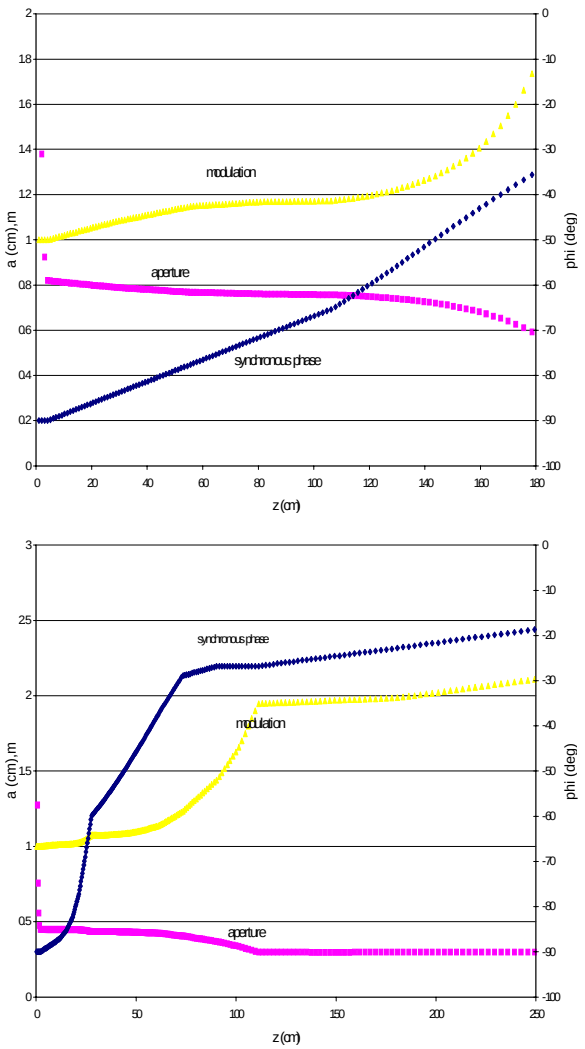

Figure 2: Evolution of modulation, aperture and synchronous phase along the axis for (top) CERN RFQ2 (200 mA protons, 90-750 keV, 200 MHz) and (bottom) for CERN LEAD ION RFQ (100 μA lead ions, 2.5-250 keV/u, 100 MHz)

3 DECELERATING RFQS

The concept of a decelerating RFQ is fundamentally different than that of a "reversed" accelerator. The main difference lies in the fact that the process of shaping and bunching the incoming beam can not just simply be done in reverse. This is not only for the inconvenience of generating an unreasonably long structure but also because of the fact that the longitudinal critical point (minimum bucket stable area) is located at the last cell of the machine. Therefore a completely different longitudinal approach needs to be applied to a decelerator RFQ.

3.1 Longitudinal dynamics and the need for a matcher

The stable motion in the longitudinal phase space in any linear accelerator can be described as an oscillation around the synchronous phase and energy along a characteristic pattern. Stable patterns lie within a separatrix [7]. In the case of an RFQ the maximum energy excursion of a particle moving along the separatrix can be expressed as:

$$\Delta W = \sqrt{2 \cdot W_s \cdot V \cdot A \cdot (\varphi_s \cdot \cos(\varphi_s) - \sin(\varphi_s))}$$

and the phase excursion (φ) follows

$$tg(\varphi_s) = \frac{\sin(\varphi) - \varphi}{1 - \cos(\varphi)}$$

where *W*s is the synchronous energy, and the rest has the same meaning as in Section 2.1

Due to the energy dependence, the stable area shrinks during the deceleration process and the separatrix of the last decelerating cell defines the acceptance of the machine. Hence the first design criterion for an RFQ decelerator is to maximise the expression above at the last cell by 1) choosing the highest vane voltage that the sparking limit allows and 2) keeping the accelerating factor (A) as high as machining limits allow. The phase should be kept as close as possible to -180°. This first criterion determines the vane voltage and the aperture and modulation of the last cell. The design of the RFQ starts then from the high-energy end: the modulation of the first cell is set to a high value (between 2 and 3) and the aperture to a value that gives the desired transverse phase advance per focussing period. From here the RFQ is generated cell-by-cell with the following procedure: with a fixed minimum acceptable longitudinal radius of curvature (ρ*l*), the maximum allowable modulation is chosen. The aperture is tentatively set to keep the focussing constant, although it can be changed to allow for a higher accelerating efficiency. With this method a rough design for the RFQ is generated. This is then

refined by tuning the parameters of each individual cell to optimise locally: 1) the transverse phase advance per focussing period; 2) the maximum field on the vane-tip, and; 3) the smoothing of abrupt changes in aperture and/or modulation.

Once the design of the decelerating part is complete, the next step is to determine the longitudinal matched condition: the separatrix at the last cell is traced backwards to the input of the RFQ. This assumes that the points of the boundary rotate counter-clockwise around the synchronous phase and synchronous energy with a cell-by-cell angular velocity given by the longitudinal phase advance. The backtracked stable area defines the "decelerating acceptance": only the particles falling in this area are successfully decelerated. It should be stressed that the decelerating acceptance is only a small fraction of the separatrix at the high-energy end and is not necessarily upright. The RFQ decelerator system therefore needs a front-end longitudinal matching section. This task can be accomplished by an adiabatic buncher system (for example a special shaping section of an RFQ) or by a discrete buncher system (conventional RF cavity). In general it is more convenient to use a discrete bunching system - the long RFQ cell length that goes with the high energy and the number of such cells typically required for smooth shaping would result in an unreasonably long machine.

The efficiency of an RFQ decelerator is determined by its front-end longitudinal matching system. The longitudinal output-beam quality depends instead on the decelerating rate at the lower energies: the faster the deceleration rate the better. This can be explained by the fact that the beam, towards the lower energies, gets closer and closer to the separatrix line and moves along an unstable path with the characteristic shape of a golf club (reversed in this case, see Fig. 3).

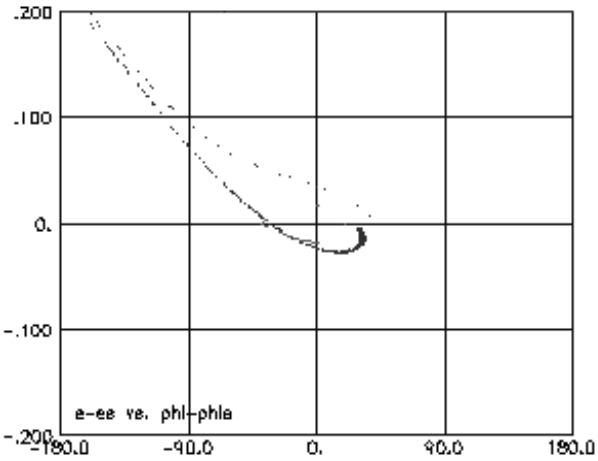

Figure 3: Characteristic path followed by particles at the boundary of the decelerating acceptance (stable particles have been removed from the plot for sake of clarity). PARMULT [4] simulation result.

3.2 Transverse dynamics

The transverse dynamics in a decelerator RFQ poses fewer problems than the longitudinal one as the process can be reversed. A standard R.M.S. can be employed at the beginning. The physical emittance increases during deceleration, and the focussing period is shortened proportionally to the beam velocity. The phase advance per focussing period (σt) is tentatively kept constant so that the beam envelope is constant along the decelerator. Conversely the divergence of the decelerated beam increases. In the critical points where σt can not be kept constant due to the more stringent longitudinal constraint, some extra cells are inserted to provide a smooth transition. This fix has been proved sufficient, in absence of space charge, for avoiding emittance increase due to mismatch.

Due to the strong beam divergence at low energy an exit matcher, to make the beam round as it exits the RFQ, facilitates the transport from the RFQ.

The RFQ is an effective focussing channel also for particles outside the longitudinal acceptance, which exit from the machine un-decelerated.

4 THE RFQD

The ASACUSA collaboration [3] is planning to use the antiproton beam coming from the CERN AD ring [12] for gas target and trap experiments. The 5.3 MeV beam coming from the ring should be post-decelerated with as-wide-as-possible energy variability around 50keV. The acceptable output energy spread is ±5 keV and the beam dimensions, a few mm.

4.1 Proposed decelerating schemes

The energy deceleration from 5.3 MeV to 50 keV is quite large: the longitudinal decelerating acceptance is 10 times smaller than the separatrix at the high energy. The possible frequencies (availability and expertise at CERN) are 200 or 100 MHz: 100 MHz makes the designing easier but would also result in an extremely long machine.

Optimisation following the criteria of Section 3 has led to the conclusion that, for a frequency of 200 MHz, the minimum energy attainable with acceptable beam quality is 50 keV. The decelerator length is about 4 meters; the equivalent structure at 100 MHz would be double this length, making it unattractive. A RF cavity performs the front-end longitudinal matching.

Some extra device must provide the energy variability, as the RFQ itself does not have this capability. Several set-ups have been considered [13], amongst which the most representative are:

- A 200 MHz RFQ decelerator to 80 keV followed by a double gap RF cavity. Energy variability: 30-130keV. The design of the double gap buncher is

quite challenging due to the poor efficiency for a 200 MHz cavity at low energies.

- Use two frequencies: a high-energy section (till 400 keV) at 200 MHz, a low-energy section at 100 MHz. Energy variability: 10-140,300-500 keV. This is the best-performing solution but requires a longer drift length between the pre-buncher and the RFQ.
- The RFQ tank would be divided in two sections independently powered and phased, the second one with flat electrodes. The first part of the RFQ would decelerate the antiproton down to 100 keV, the potential drop between the wall of the second cavity and the electrodes would provide energy variability in the range 80-120 keV.
- An RFQ decelerator to 60 keV, whose inner structure, mounted on a ceramic insulator, can be raised to a DC voltage of ± 60 keV. This solution gives energy variability in the range 10-110 keV with excellent beam quality for all the output energies.

The beam quality and the cost are comparable for all the solutions; the variation in the energy range, however, is quite different. The last solution was eventually chosen based on its simplicity and the advantage of bringing the beam to an energy of virtually zero. It will be described in more detail in the next section.

4.2 The chosen solution

Particles coming from the ring at 5.3 MeV and with an energy spread of 0.2% and an overall physical emittance of 10π mm mrad are bunched by a coaxial TEM resonator loaded with double gap with an effective voltage of 47 keV. The drift (6.15 m) to the RFQ contains magnetic elements to match the beam to the RFQ transverse acceptance. The voltage and the length of the drift are optimised to maximise the number of particles in the RFQ decelerating acceptance. The RFQ, a four-rod structure, is 3.44 m long and it decelerates the beam to 63 keV. The structure holding the electrodes can be raised to a potential (± 60 keV) to further accelerate/decelerate the beam as it exits the RFQ. A corrector cavity, identical to the one at the beginning of the line, placed at the RFQ entrance, counteracts the unwanted electrostatic effect at the input. This cavity can also correct for small variations in the input beam energy.

The normalised transverse emittance is constant along the RFQ, and 46% of the incoming particles are decelerated within ± 5 keV of the nominal energy. The RFQ defining parameters are given in Fig. 4.

5 ACKNOWLEDGEMENTS

I would like to acknowledge the constant guidance and support of the RFQ-section leader W. Pirkl, and the invaluable contributions of B. Couturier and F. Grandclaude.

A LOW-CHARGE-STATE CW RFQ

K. W. Shepard, M. Kedzie, and R. A. Kaye
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

A two-meter long, 12 MHz RFQ has operated cw at an intervane voltage above 100 kV, the voltage required to accelerate singly-charged ions of mass 132. The prototype unit is the first of three that will be required to provide for efficient injection of exotic beams into the existing ATLAS heavy-ion linac, while maintaining the high beam quality characteristic of ATLAS beams. The room-temperature, normal conducting RFQ utilizes indium gasketed joints, originally developed for the superconducting resonators of ATLAS, to maintain good vacuum, thermal, and rf properties while permitting a highly modular design. Another unusual feature of the design was the use of aluminum for the main structure, which was electroplated with 100 microns of silver to minimize rf losses in critical areas. Preparations are currently underway for beam tests to be performed later this year.

1 INTRODUCTION

The superconducting heavy-ion accelerator ATLAS can provide ion beams of any mass, including uranium, with state-of-the-art beam quality, particularly with respect to longitudinal emittance [1]. A related characteristic of ATLAS is very large transverse acceptance. Because of these characteristics, ATLAS is highly suitable for the task of accelerating radioactive ion beams [2,3]. ATLAS is presently injected by an electron cyclotron resonant (ECR) ion source capable of producing high charge-state ions, for example uranium 26+ [1]. For hard-to-produce exotic species, however, we require the use of more efficient ion sources, which produce singly-charged ions. For such charge states obtaining sufficient transverse focussing to maintain good beam quality becomes problematic, particularly for the heavier ions. Adapting ATLAS to radioactive beams requires development of a low-charge-state injector capable of maintaining the good features of ATLAS. The design of the entire injector system has been discussed elsewhere [2,3]. This paper discusses the design and development of the entrance section [4].

For heavy ions of charge state 1+ and energies of a few hundred keV, an electric quadrupole provides the strongest possible transverse focusing, and thus the greatest possible transverse acceptance. This consideration dictates the choice of an RFQ structure for the entrance section. The primary technical challenge arises from the requirement of maintaining substantially smaller longitudinal emittance than is typical for an RFQ.

Table 1: RFQ Design Parameters

Parameter	Value
Frequency	12.125 MHz
Structure	Split-coaxial
Voltage (vane-vane)	100 kV
Peak Electric Field	12.8 MV/m
Minimum Aperture	8 mm radius
Modulation Factor	1.5
Benchmark Beam	$^{132}Sn^{1+}$
Entrance Energy	378 keV
Exit Energy	1508 keV
Number of cells	44
Length	222 cm
Synchronous phase	-30 degrees

2 DESIGN FEATURES AND PARAMETERS

The RFQ design parameters are shown in Table 1. These parameters provide for our initial development goal of producing high-quality beams of singly-charged ions as heavy as mass 132. Ions of less mass can then be accommodated by turning down the RFQ operating voltage.

The split-coaxial geometry was chosen since it has already been shown to be suitable for very low frequencies [5], and to maximize the aperture of the device, we want the RFQ to operate at as low a frequency as practicable. In this way we both maximize the transverse acceptance and also minimize longitudinal emittance growth.

The primary reason we chose to inject the RFQ with a pre-bunched beam was to maintain a smaller longitudinal emittance than results from bunching within the RFQ

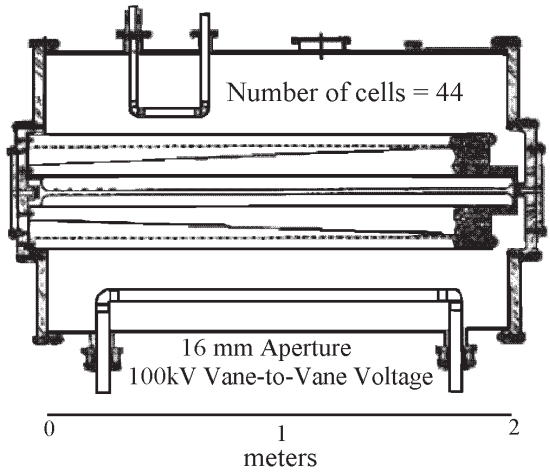

Figure 1: Section of 12 MHz split-coaxial RFQ

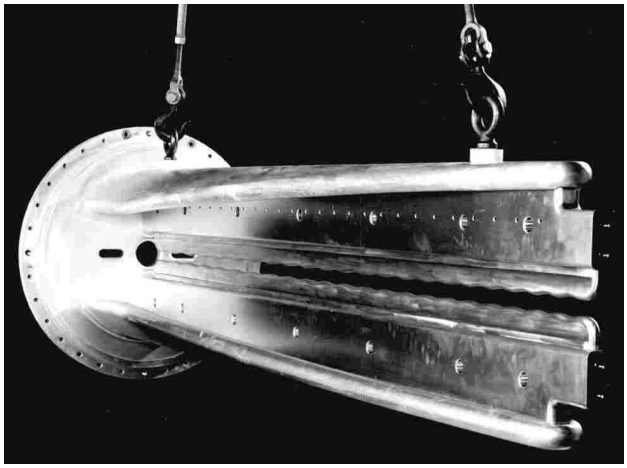

Figure 2: Two-meter long vertical vane pair.

structure [6]. There are several additional benefits from pre-bunching. By separating out the bunching function, the entire length of the RFQ can be used for acceleration, providing more voltage gain. A less obvious benefit results from the fact that the split-coaxial structure is characterized by a voltage offset at entrance and exit of half the vane-vane voltage. With a pre-bunched beam, we are able to make use of the voltage offset by attaching a drift tube to the high-voltage vane pair at both the entrance and the exit of the RFQ. The two drift tubes provide appreciable accelerating field, and increase the voltage gain through the structure by more than 20%.

3 MECHANICAL CONSTRUCTION

Figure 1 shows a section of the cavity. The structure is fabricated as several elements which are demountably joined using an indium-gasket seal described in more detail below. All elements are of 6061 aluminum, except for the RFQ vane tips which are formed of copper. Assembling the cavity from several elements greatly simplifies the machining and forming of the structure. Mechanical tolerances are effectively relaxed, since the structure can be assembled and examined, then disassembled and critical surfaces re-machined to correct mechanical misalignments or errors in rf tuning or field distribution.

A major sub-assembly, the vertical vane pair, is shown in Figure 2. The two-meter long vanes are cantilevered from the end flange which mounts at one end of the cylindrical outer housing. The low density of aluminum permits massive, monolithic structural elements providing good thermal and mechanical stability, while keeping mechanical resonant modes at high frequency. This helps minimize the effects of ambient vibration on the rf eigenfrequency.

Using a demountable joint to attach the vane tips provides several advantages. It is relatively inexpensive to completely replace the vane tips, and by so doing modify virtually any RFQ beam parameter. Also, we can then use copper in the high electric field region of the cavity, where the use of aluminum would possibly increase sparking and reduce the maximum attainable voltage.

Aluminum is appreciably inferior to copper or silver as an rf conductor. To reduce rf losses, those areas of the RFQ supporting high rf currents were electroplated with a 100 micron thick layer of silver.

3.1 Demountable Indium Gasket Joint

The demountable joint used was developed more than two decades ago: several thousand such seals have been used in the superconducting cavities and cryogenic plumbing of the ATLAS accelerator. The design has been found to provide a highly reliable seal with good vacuum and thermal properties. The rf losses in metal to metal joints formed in this way are known to be small from direct measurement in superconducting cavities.

A section of a typical gasketed joint is shown in Figure 3. The gasket is 1.6 mm diameter, high-purity indium wire. One surface of the joint is planar. The opposing surface is grooved to hold the indium wire, the groove having a cross-sectional area typically 65% of the wire cross-section. A key feature of the seal design is that the region to either side of the indium groove is relieved. The relief provides that when the mating surfaces are clamped together, excess indium is extruded into the relief volume. In this way, the compressed area is well-defined and limited in size. The loading on the seal is uniform, and the flow of indium when the seal is made up proceeds rapidly, with a short relaxation time.

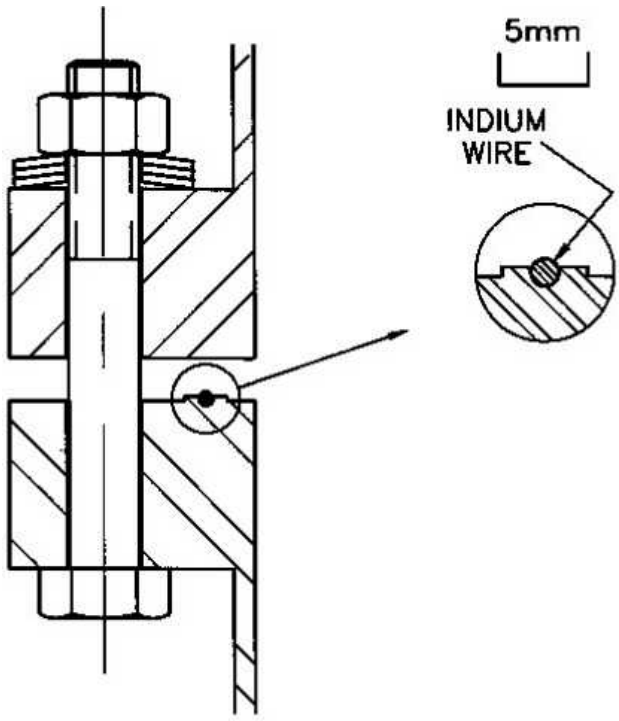

Figure 3: Details of the indium gasket seal used to make a joint with good RF, thermal, and vacuum characteristics.

4 EXPERIMENTAL RESULTS AND DISCUSSION

Optical measurements following initial assembly indicate that the errors in transverse position of the vane tips are everywhere less than 0.8 mm and the rms error is 0.5 mm. Note that the mean aperture is 20 mm, as is the vane thickness. The observed level of error is expected to be tolerable both for tuning and for the beam interaction. The definitive test, however, will be the planned measurements with beam.

When assembled, the rf eigenfrequency was found to be 11.6 MHz. The loop-coupled tuner can bring the frequency up to 11.9 MHz, still slightly below the design value of 12.125 MHz. For initial testing, and even testing with beam, this discrepancy is of no consequence. For eventual use with the ATLAS linac, a slight change in the vane tips will be required to tune to the design frequency.

The measured intrinsic Q of the RFQ resonant cavity is 8863, a result that indicates the rf losses to be appreciably less than were expected from earlier tests of a (nominally) half-scale model [4]. This result implies that the rf loss properties of the silver plating are excellent, as is discussed further below. To operate at a vane to vane voltage of 100 kV, the RFQ requires 16.6 kW of rf input.

Because of the high Q, the 3 dB bandwidth is slightly more than 1 kHz. In designing the RFQ, there was some concern that the effects of ambient acoustic noise might induce troublesome fluctuations in the rf eigenfrequency. Measured microphonic frequency jitter was less than 100 Hz peak to peak, a small fraction of the intrinsic bandwidth and too small to present any operational problems.

Water cooling to the cavity was configured in nine separate loops to enable calorimetric measurement of the detailed distribution of rf power. The distribution, shown in Table 2, was determined by measuring the flow rate and temperature rise (typically 2 C) in each loop separately. The summed total of calorimetric power agrees quite well with the measured rf input power of 17.4 kW. Of particular interest is the fact that one vane exhibits 40% higher rf loss than the other three. This result indicates the critical nature of the plating process in obtaining good rf performance.

Table 2: Calorimetrically measured RF heating

RFQ Element	Calorimetric Power
Top Vane	2.75 kW
Right Vane	2.72 kW
Bottom Vane	2.86 kW
Left Vane	3.90 kW
Entrance End Flange	1.40 kW
Exit End Flange	1.61 kW
Housing	2.19 kW
Drive Loop	0.07 kW
Tuner Loop	0.87 kW
TOTAL	18.37 kW

The cavity vacuum is maintained by two 500 l/sec turbopumps. With no baking, the vacuum in the cavity reached $6.4 \cdot 10^{-7}$ torr in 72 hours. On initial application of rf power, sparking was first encountered at a vane-vane voltage of approximately 60 kV and the input power was limited by outgassing. The cavity quickly conditioned up in voltage. After a few hours of conditioning the vacuum outgassing diminished and the RFQ could be operated above 100 kV. During initial tests, the RFQ was operated continuously for some 90 minutes with the vane voltage between 100 and 108 kV and vacuum in the low 10^{-6} torr range. Thermal stability of the RFQ during these tests was excellent.

In the design phase, the performance of the RFQ was projected using the Kilpatrick model. Figure 4 shows the frequency and gap dependent voltage limit (parallel-plate) as originally put forward by Kilpatrick [7]. It should be noted that the often quoted value for the Kilpatrick limit is the asymptotic limit for large gaps from the model shown in Figure 4. For most RFQ implementations, the frequency is sufficiently high that typical vane spacing is in the asymptotic region, where the gap dependence of the voltage limit can be ignored. As we have shown both in the earlier in the half-scale model pulsed rf tests [4] and also in the present 12 MHz cw result, the gap dependence is important in establishing the voltage limits for very low frequency RFQ's.

5 CONCLUSIONS AND FUTURE PLANS

The basic design concepts, i.e., indium rf joints, silver-plated aluminum rf surfaces, demountable copper tips, etc. have proven feasible as evidenced by the voltages achieved in initial tests of the low-charge-state RFQ.

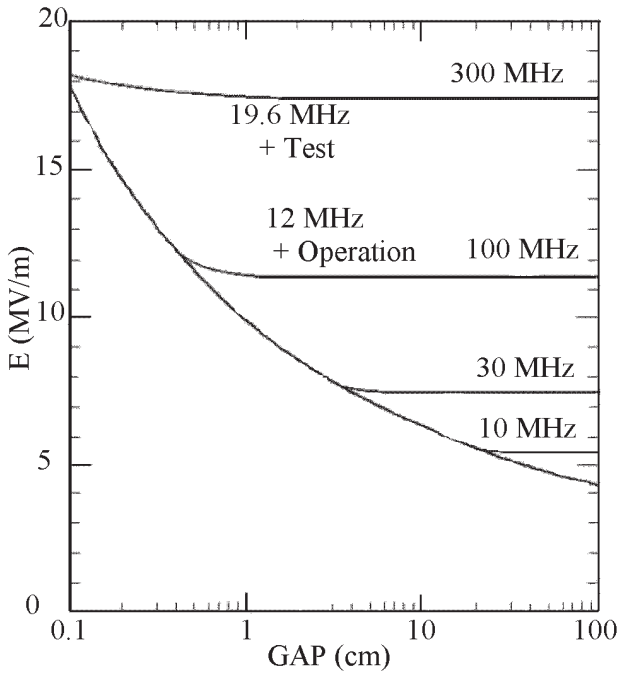

Figure 4: Sparking electric field limits in the Kilpatrick model, including electrode gap dependence.

The vane voltages achieved are sufficient to permit high-quality beams as heavy as uranium to be injected into ATLAS. Although our initial design was for Sn^{132} beam with a transverse acceptance of 0.25 π·mm-mrad, numerical simulation indicates that acceleration of uranium with a transverse acceptance of 0.16 π·mm-mrad while maintaining longitudinal emittance of a few keV-nsec is possible with the voltages achieved.

A remaining development task is demonstration of the expected transverse acceptance and longitudinal beam quality by beam tests. Preparation for such tests are currently underway.

6 ACKNOWLEDGEMENTS

The authors gratefully acknowledge the help of John Vincent in design of the 25 kW drive amplifier. Many helpful discussions of RFQ design were held with Rolf Muller, John Staples, and Alvin Schempp.

We are indebted to Pete Smith of Norbet Plating, Chicago for electroplating the silver films that exhibited such excellent properties. Also, Ed Bonnema and others at Meyer Tool and Manufacturing were most helpful in fabrication of the prototype.

DESIGN OF THE 200-MEV PROTON LINAC FOR THE JAPAN HADRON FACILITY

T. Kato and Y. Yamazaki
KEK, High Energy Accelerator Research Organization
1-1 Oho, Tsukuba-shi, Ibaraki-ken, 305-0801, Japan

Abstract

A 200-MeV proton linear accelerator for the JHF has been designed [1][2]. A peak current of 30 mA with a 500 μsec pulse duration will be accelerated at a repetition rate of 25 Hz. The designed average current will be 200 μA at the beginning, and nearly 1 mA in the future. The linac consists of a 3-MeV radio-frequency quadrupole linac (RFQ), a 50-MeV drift tube linac (DTL) and a 200-MeV separated-type drift tube linac (SDTL) [3]. A frequency of 324 MHz has been chosen for all of the rf structures. A future upgrade plan of up to 400 MeV is also being considered, in which annular-coupled structures (ACS) of 972 MHz are to be used over an energy range of above 150 or 200 MeV. The balanced beam quality in both the transverse and longitudinal motions is one of the main features of the design. It can be achieved both by using an equipartitioning focusing scheme and by adopting an SDTL structure for the medium-energy range.

1 REQUIREMENTS

The required main parameters for the JHF proton linac are listed in Table 1. The construction plan of the linac consists of two stages. An output energy of 200 MeV and a peak current of 30 mA with a pulse length of 500 μsec at a repetition rate of 25 Hz are required in the first stage of construction. The required momentum spread of the output beam is ±0.1%. In order to reduce any beam losses after injection into the ring and to achieve high-intensity operation in the ring, a fast beam chopper in the low-energy region is required. It is crucial for the fast chopping system that the fraction of particles during the rising and falling times of the chopping pulse is very small.

Tabel 1: Required main parameters of the linac

1-1 Oho, Tsukuba-shi, Ibaraki-ken, 305-0801, Japan	Initial stage	Final stage	
Particles	H^-	H^-

Momentum spread	±0.1	±0.1	%

2 DESIGN OF THE LINAC

2.1 Design features

The design is summarized in Table 2. The features of the design are as follows: (1) a frequency of 324 MHz has been chosen for all of the rf structures up to 200 MeV, resulting in no longitudinal transition; (2) an SDTL has been chosen in the energy range from 50 to 200 MeV, resulting in a higher effective shunt impedance and a separation of the transverse transition at 50 MeV from the longitudinal one at 200 MeV; (3) a 3-MeV RFQ has been chosen, resulting in the adoption of quadrupole magnets for the following DTL with sufficient focusing forces; (4) a transition energy of 150 or 200 MeV from the SDTL to the ACS has been selected in the upgrade plan; (5) the equipartitioning focusing method is applied; and (6) klystrons are used for all of the accelerating structures.

2.2 Ion source and RFQ

A promising experimental result (a peak injection current of 13.2 mA with a 90% emittance of 0.55 πmm-mrad was accelerated in the RFQ with a transmission efficiency of 83%) was achieved in the preinjector system

Table 2: Parameters of the JHF 200-MeV proton linac (DTL and SDTL).

	DTL	SDTL

(a volume production negative-hydrogen ion source and a 432-MHz RFQ) at KEK [4]. Therefore, a peak current of more than 30 mA from the ion source will be realized if some increases in the transverse emittance are allowed. A four-vane type 324-MHz RFQ has been designed [5]. It accelerates ions from 50 keV to 3 MeV. The detailed design is under development.

2.3 DTL

A 324-MHz DTL accelerates beams from 3 to 50 MeV. It consists of three post-stabilized tanks [6]. An accelerating field of 2.5 MV/m is determined from the viewpoints of satisfying the equipartitioning condition and being sufficiently low for avoiding any discharge problem. All drift tubes contain quadrupole magnets. Model magnets of the hollow-conductor type with a magnetic-field gradient of 117 T/m were designed and successfully fabricated [7]. The parameters of the DTL are listed in Table 3.

2.4 SDTL

A 324-MHz SDTL is adopted for medium-energy acceleration from 50 to 200 MeV. Each tank consists of five unit cells. Since the focusing magnets (doublet) are placed between two adjacent SDTL tanks, the shunt impedance can be freely optimized without any geometrical restriction from the quadrupole magnets, which are placed in the drift tubes in the conventional DTL system. There are many other advantages in the SDTL system: the number of required focusing magnets has been reduced, fabrication of drift tubes has become easier, stabilizing devices are not necessary, and the required alignment accuracy of the drift tubes and each tank has been reduced. The parameters of the SDTL are listed in Table 4.

2.5 ACS

An extensive beam-dynamics calculation regarding an upgrade of the output energy up to 400 MeV by using the CCL-type structure was performed [1]. It was concluded that an accelerator complex of DTL, SDTL and the ACS is a good choice from the viewpoints of both the output

Table 4: Parameters of the SDTL.

Length of unit tank	1.48 - 2.61	m
Number of tank	31	
Number of cell	155	
Rf driving power	0.34 - 0.71	MW
Total rf power (30 mA)	0.46 - 0.86	MW
Accelerating field	3.75	MV/m
Stable phase	-26	degree
Bore diameter	30	mm

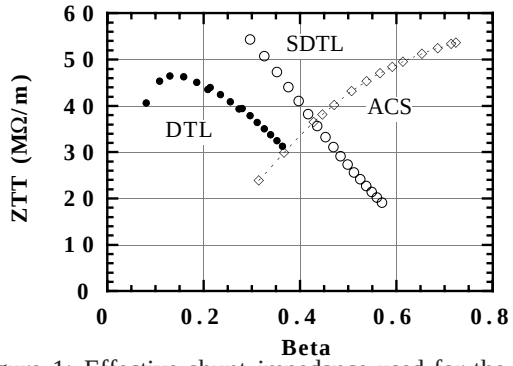

Figure 1: Effective shunt impedance used for the JHF proton linac.

beam quality and the accelerating efficiency. Also, it was pointed out that the ACS has more balanced characteristics concerning both the shunt impedance and the field symmetry [8]. A frequency of 972 MHz, three-times as high as the fundamental frequency, and a transition energy of above 150 or 200 MeV were selected. The fundamental RF issues concerning the ACS have already been solved, and a number of high-power RF tests using the 1296-MHz prototype cavities were successfully performed [9]. Therefore, a future extension using a 972-MHz ACS will be possible with some modification efforts.

The effective shunt impedance for the three kinds of rf structures mentioned above is plotted in Fig. 1.

3 BEAM DYNAMICS

A beam simulation was performed using the code LINSAC [10]: the code includes an accurate field distribution in an accelerating gap, and takes into account any space-charge effects by the particle-particle method. It includes all space harmonics into the calculation. Both the emittance growth and halo formation during acceleration were carefully studied, since they are one of the main issues in designing the high-intensity JHF proton linac.

3.1 DTL and SDTL

Both the transverse and longitudinal focusing parameters were determined based on equipartitioning theory combined with coupled envelope equations for the bunched beam [11][12][13]. The equipartitioning condition is approximately satisfied during acceleration in the design. Figure 2 shows both the transverse and longitudinal phase

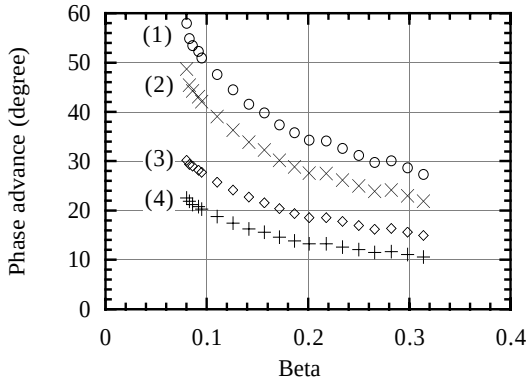

Figure 2: Phase advance in both the transverse ((1) 0 mA and (2) 30 mA) and longitudinal ((3) 0 mA and (4) 30 mA) phase spaces along the DTL vs. beta (v/c).

advances in the DTL. Two sets of normalized rms emittances at the entrance of the DTL were used in the simulation through the DTL and the SDTL (Type A: 0.187 πmm-mrad and 0.133 πMeV-deg and Type B: 0.375 πmm-mrad and 0.266 πMeV-deg). Compared with the transverse-focusing design with a constant phase advance of 60 degrees, the calculated results with the equipartitioning focusing design show better beam qualities totally, especially in both the emittance growth and halo formation in longitudinal phase space [2]. For the type-A beam, the ratios of the emittance growth between two focusing methods (the equipartitioning focusing and the constant phase advance one) are 1.22 and 0.62 in the transverse and longitudinal rms emittances, respectively. It has been found that the ratio of halo-like particles is about on the order of 10^{-3} ~10^{-4} in a simulation with 48000 particles. The ratios of halo formation between these two focusing methods are nearly equal in the transverse motion and 0.52 in the longitudinal motion. Here, halo-like particles in the transverse motion are defined by those outside 6.5 times as far as the standard deviation of the radial distribution of the output beam, while halo-like particles in the longitudinal motion are defined by those outside 12.5 times as far as the longitudinal output rms emittance.

3.2 MEBT

A beam-transport line, 2.7 m long between the RFQ and the DTL (MEBT), has three purposes: achieving both transverse and longitudinal beam-matching, chopping the beam for reducing beam losses after injection into the ring and measuring the beam properties before injection into the DTL [14][15]. It consists of eight quadrupole magnets, two bunchers and two rf-chopping cavities (referred to as RFD) [16]. Detailed simulation results show that high performance in the chopping operation can be achieved by using the RFD: the number of unstable particles at the DTL exit (50 MeV) during the transient times is less than 0.08% of the total injection particles [14][15].

Table 5: Parameters of the RF power source.

Repetition rate	50	Hz
Pulse width	620	μsec
Number of klystrons	19	
Peak output power	2.0	MW

4 RF POWER SOURCE

A high-power rf system has been designed on the basis of accumulated knowledge and experience during the construction and operation of the JHP test stand [17]. The main parameters are listed in Table 5.

A LINAC FOR THE SPALLATION NEUTRON SOURCE*

Andrew J. Jason with the SNS Linac Team
Los Alamos National Laboratory, Los Alamos, NM 87545 USA

Abstract

The Spallation Neutron Source Project (SNS), to be constructed at Oak Ridge National Laboratory, accelerates H^- ions to an energy of 1.0 GeV with an average current of 1-mA for injection into an accumulator ring that produces the short intense burst of protons needed for the spallation-neutron source. The linac will be the most intense source of H^- ions and as such requires advanced design techniques to meet project technical goals. In particular, low beam loss is stressed for the chopped beam placing strong requirements on the beam dynamics and linac construction. Additionally, the linac is to be upgraded to the 2- and 4-MW beam-power levels with no increase in duty factor. We give an overview of the linac design parameters and design choices made.

1 OVERVIEW

The SNS project is described in depth elsewhere [1,2]. Los Alamos is responsible for the design and construction of a linac suitable to meet project specifications. H^- beam enters the linac at an energy of 2.5 MeV with a peak current of 27.7 mA and a normalized rms emittance of 0.23 π-cm-mrad. The linac input beam is produced by a "front-end" assembly that sequentially consists of an ion source, RFQ, and transport line that contains a chopper. The chopper provides a gap in the beam as required by the accumulator ring extraction scheme. Lawrence Berkeley Laboratory is responsible for the front end [2] except for the chopper system that is to be constructed by Los Alamos. The linac output energy is 1.0 GeV with little emittance growth or current loss and will maintain the nominal time structure of the input beam. Beam then enters a transport line and is conveyed to an accumulator ring, to be constructed by Brookhaven National Laboratory [3]. It is also a Los Alamos task to construct and power a bunch rotator in the transport line. The ring, at constant energy, accumulates the nominal 1-ms-long linac macropulses to an intense proton pulse of 590-ns duration for impingement on the spallation target. The average beam power on the target is 1.0 MW with a pulse rate of 60 Hz. The beam-power is upgradeable to up to 4 MW by increasing the peak linac current.

* Work supported by the U.S. Department of Energy, Office of Energy Research, Office of Basic Energy Sciences.

2 BASIS OF DESIGN

Requirements on the linac included cost effectiveness, high operational availability, low beam loss, upgradability, high beam quality, and insensitivity to chopping. We believe that the present design meets these criteria. A block diagram of the linac is shown in Figure 1.

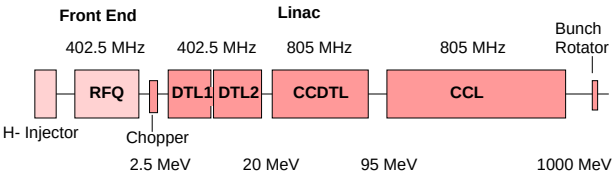

Figure 1. Block diagram of SNS linac

The linac consists of a drift-tube linac (DTL) up to 20 MeV, a coupled-cavity drift-tube linac (CCDTL) to nominally 95 MeV and a coupled-cavity linac (CCL) to the full energy. The DTL and the CCL are well known structures, appropriate to their energy ranges. The CCDTL, though a recent invention, has received cold-model testing and is considered a good intermediate structure between the DTL and CCL in terms of beam-dynamics matching and shunt impedance. This structure has other advantages and is believed to be the optimum choice in the given energy range.

In order to minimize cost, a tradeoff study was conducted early in the project that varied the linac gradient. On the basis of this study an average gradient (E_0T) of 2.7 MV/m was chosen. Later and more accurate costing showed this to be near the optimum value. The length arrived at was 493 m giving a real-estate energy gradient of 2.02 MeV/m. Although higher than many previous proton linacs, the peak field is everywhere less than 1.5 Kilpatrick, a safe value. Because of the high gradient, a relatively large amount rf power (slightly less than 100-MW peak delivered to the linac) is needed.

The linac rf frequency was similarly chosen; assessment of this and other design choices showed that frequencies near 800 MHz have best performance and lower cost. The exact frequency of 805 MHz was chosen because of our familiarity with the LANSCE linac and subsequent ease of technology transfer as well as an assessment of klystron cost and availability. The 402.5-MHz value for the structure frequency below

20 MeV was chosen to allow funneling in future upgrades.

Low beam loss and high availability are closely related. The linac structure must suffer only low levels of activation so that maintenance and upgrade can be done quickly. A spacious aperture and adequate steering are important in this regard and are part of the design. Furthermore, our calculations show that with good matching, halo formation will contribute negligibly to beam loss. However, it is expected that the predominant beam loss will occur by stripping of the negative hydrogen ions through collision with background gas. Calibration of the LANSCE-linac activation and loss-transport calculations are convincing that, at 1 GeV, a loss of 1 nA/m will cause activation of greater than 10 mrem/hr an hour after shutdown at a distance of 1 ft. To achieve this low-loss level at the 4 MW upgrade, a vacuum of $5x10^{-8}$ torr is required and, with proper design, is achievable.

A room-temperature structure was chosen over a superconducting structure largely to minimize technical and schedule risk. An assessment showed that if an R&D program were successful in addressing the issues of transient control and power coupling, the capital cost and schedule would be little affected and that the operating costs would be decreased by nearly 4 M$ per year. Nonetheless, if such an R&D program were to run into difficulties, the program schedule and cost would be strongly affected.

3 CHOPPING

A 35%-duty-factor chopping at 1.189 MHz (just slightly off the ring revolution frequency) is applied to the beam before entering the linac by a traveling-wave deflector. This decreases the average macropulse current to 18.8 mA for the 1-MW case. The chopper rise time should be under 2.5 ns to prevent partially chopped pulses from entering the linac and possibly creating additional loss downstream. R&D work [4] is in progress to define a deflecting structure and modulator that can provide the required 18-mrad deflection in a 0.5-m deflecting structure with such a challenging rise time. FET drivers with the required rise time are not commercially available; development work with a semiconductor manufacturer is scheduled. A device with 5-ns rise time is judged to be immediately feasible and construction of a prototype is underway. This decreased rise time may be adequate for the 1-MW scenario.

The chopper plays a secondary role in providing time-width modulation of the beam in order to maintain constant peak current during the 20-μs ramp up planned at the macropulse start.

Transient analysis has been done to evaluate the effect of chopping on the linac-cavity fields. Negligible excitation of high-order modes was found. The main effect predicted is a 3% field variation in the 4-MW case throughout the linac at the chopping frequency. The major effect is a broadening of the energy and phase width, small compared to the unperturbed parameters. The effect is inversely proportional to the accelerating field, thus further justifying the high linac gradient.

4 STRUCTURES

The 402.5-MHz DTL is 8.7-m long and uses a FOFODODO lattice with period 8 βλ (at 805 MHz). This was chosen over a FODO lattice to allow feasibility of permanent-magnet quads in the drift tubes. To achieve good field stabilization, the DTL is broken into two tanks at the 10-MeV point. The structure tune is maintained by regulating water temperature.

The 68.8-m long CCDTL uses a 12-βλ FODO lattice. Each of the 101 segments (structure between quads) contains two cells of length 3βλ/2, each with one drift tube. The space for quadrupole magnets, containing a coupling cavity is 6βλ/2, allowing sufficient room for quadrupole magnets and diagnostics but requiring a low acceleration gradient of 1.08 MeV/m. An adequate prototype quadrupole magnet has been made.

The CCL comprises the remaining 85% of the structure length and uses a 12-βλ FODO lattice. Up to 166 MeV the structure has eight cells per segment with 2-βλ quad spaces. The large intersegment spacing provides adequate space for quads and diagnostics. At higher energies, where βλ has increased sufficiently, a 10 cell segment is used with 1-βλ quad spaces.

The segments are joined by coupling cells to form isolated rf modules. Bridge couplers are not used; the modules are driven by from 1 to 3 klystrons in a symmetrical feed-point arrangement that minimizes field droop in a module. Partitioning of the modules has been chosen to facilitate upgrades. The choice of an even number of half βλ cells in the segments permits all segment couplers to remain on one side of the structure for simplified mounting, fabrication, and vacuum pumping. Structure tune is maintained by regulating the cooling water temperature for each module against cavity frequency offset.

5 BEAM DYNAMICS

The linac beam dynamics along with the physics design is discussed elsewhere [5]. We here note a few salient features. Variants of the code PARMILA were used to define and find a matched beam for each structure. The structures are joined and smooth matching done across structure transitions with appropriate phase and field ramping. There are no explicit matching sections; matching is done between structures by the quads and structure design. As well as matched beam studies, error studies and end-to-end

simulations have been done using 10,000-particle sets starting from the RFQ output. We plan to increase the size of this particle set by using massively parallel processing.

The aperture size is maintained at 10 times the beam rms size to promote low beam loss; predicted halo growth will not intercept the aperture even with alignment errors and can be readily scraped in the transport line to the ring. A plot of aperture versus energy is shown in Figure 2.

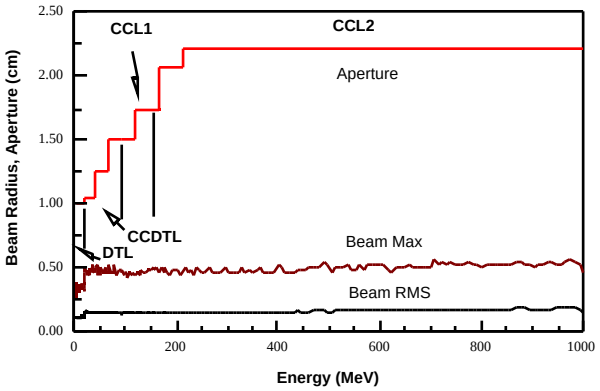

Figure 2. Aperture and beam size in the linac

6 RF SYSTEM

The rf system [6] will deliver approximately 99 MW peak power at 7.02% duty factor to the structure for an average power of 6.74 MW. The ac wall-plug power has been specified at 22 MW. Two 1.25-MW peak-power klystrons drive the DTL and a third klystron will be provided for the RFQ. The remainder of the structure uses 56 anode-modulated 805-MHz 2.5-MW klystrons in the baseline design. Allowing for control margin and system losses, 2-MW are available to the structures. Klystron size was determined from optimization of cost, technical feasibility, and relation to linac-structure. The anode modulation was judged to be the most technically feasible method of pulse switching. However, recent developments indicate that an IGBT switching system is likely feasible and will be substantially more cost effective; R&D work is planned for this approach. A two klystron modulator, developed in previous projects, is planned, also for economic reasons. The klystron modulators are located above and lateral to the linac tunnel in a gallery that contains the water systems, vacuum pump controls, low-level rf controls and beam-diagnostics electronics. The rf system will control the cavity fields to within ±1% and ±1° through a stable reference system and using sophisticated feedback techniques, including fast adaptive feed forward.

7 UPGRADES

The requirement that the SNS is to be readily upgradeable to beam powers up to 4 MW in a staged approach strongly affects the 1-MW design. An upgrade to 2-MW, with doubling of the ion-source current, could be accomplished by redefinition of the linac rf modules and the addition of rf power (14 klystrons). Upgrade to 4 MW requires beam funneling at 20 MeV because of likely ion-source limitations and the inability of the RFQ to accelerate the 108-mA current at 805 MHz. A second linac reconfiguration is then required along with addition of 14 more klystrons. The linac reconfiguration could be done without structure replacement by redefining the number of segments (half focusing periods) of the rf modules and terminating the module ends with special λ/10-cavity sections. Thus a module end could be defined by removing a CCDTL or CCL coupling cavity and terminating the two cells previously joined by the coupling cavity. Correspondingly a module could be extended by removing adjacent terminating cells and joining the terminating segments with a full coupling cell. Drive points and waveguide runs would have to be built into the design at initial construction. However, substantial effort would be required to effect the reconfiguration as well as in the initial design. A simpler scheme has recently been discussed that would use two klystrons for each of 26 rf modules and eliminate any structure reconfiguration in a direct upgrade from 1 to 4 MW. Here a third klystron would be added to the center of each module. and provision would be made for the appropriate (small) change in rf matching during the initial design.

Abstract

High intensity accelerator concepts for **H**eavy **I**on **I**nertial **F**usion (HIIF) injectors require small emittance, high current and high energy beams. The improvement of brightness in such a driver linac is done by several funneling stages at low energies, in which two identically bunched ion beams are combined into a single beam with twice the frequency, current and brightness. For the **H**eavy–**I**on **D**riven **I**gnition **F**acility (HIDIF) we have proposed the use of a two–beam accelerator structure which provides two beams within one cavity, and a single r.f. deflector structure which bends the two beams to one common axis. The progress of the experiment and first beam–test results will be presented.

1 INTRODUCTION

By the use of the two–beam RFQ the two beams are brought very close together while they are still radially and longitudinally focused. Additional discrete elements like quadrupole–doublets and –triplets, debunchers and bending magnets, as they have been proposed in first funneling studies [1, 2, 3], are not necessary. A short r.f. funneling deflector will be placed around the beam crossing position behind the RFQ. The layout of the proposed HIDIF–injector with two–beam RFQs in front of the first and second funneling sections is shown in Figure 1. The HIDIF linac starts with 16 times 3 ion sources for three different ion species to allow so–called "telescoping" at the final focus [4]. With four funneling stages the frequency has been increased from 12.5 MHz to 200 MHz accordingly.

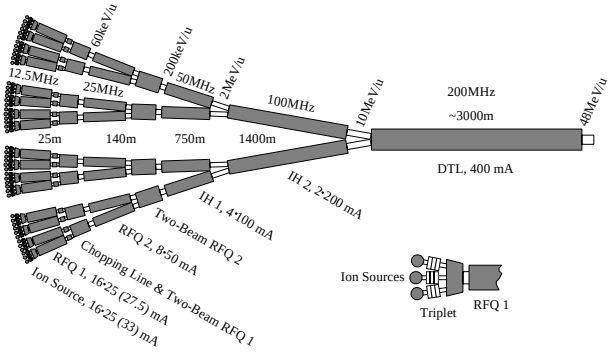

Figure 1: Layout of the 12.5. . .200 MHz HIDIF linac system for 400 mA of Bi^+.

* Work supported by the BMBF

For studies of the new two–beam RFQ structure and the r.f. deflector, the first two–beam funneling experiments will be carried out with He^+–ions at low energies to facilitate ion source operation and beam diagnostics. Two small multicusp ion sources and electrostatic lenses, built by LBNL (Lawrence Berkeley National Laboratory) [5, 6], are used. The ion sources and injection systems are attached directly on the front of the RFQ with an angle of 76 mrad, the angle of the beam axes of the two–beam RFQ. Figure 2 shows the experimental set–up of the two–beam funneling experiment. In Table 1 the main parameters of the experiment with He^+ and the design parameters of a first HIDIF funneling stage for Bi^+ are shown.

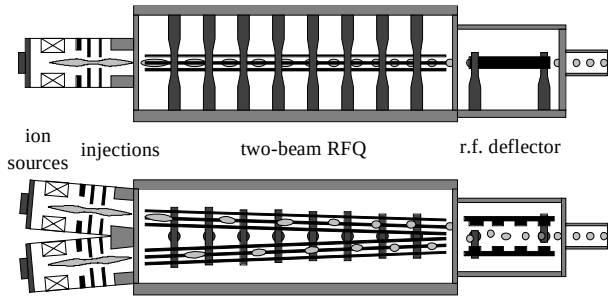

Figure 2: Experimental set–up of the two–beam funneling experiment.

Table 1: Main parameters of the experiment with He^+ and the design parameters of a first HIDIF funneling stage for Bi^+.

Two–beam RFQ	He^+	Bi^+
f_0 (MHz)	54.5	12.5
Voltage (kV)	10.5	180
R_p value (kΩ m)	80	250
Q_0 value	1800	5000
T_{in} (keV)	4	209
T_{out} (MeV)	0.16	12.54
Angle between beam axes (mrad)	76	76
Beam separation at output (mm)	40	40
Multigap funneling deflector		
f_0 (MHz)	54.5	12.5
Voltage (kV)	6	450
Length ($\frac{\beta\lambda}{2}$)	9	2

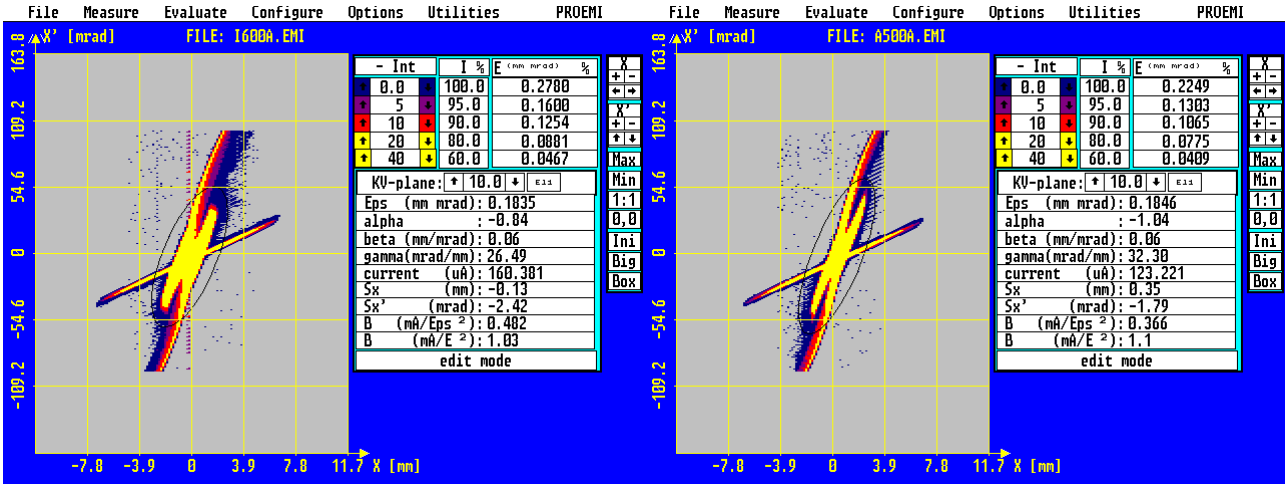

Figure 3: Comparison between the emittances of the extracted beams of the two ion sources at 0.8 mA. The ellipses correspond to the 90% normalized KV–emittances which are ϵ_{KV} =0.1835 π mm mrad for the first source and ϵ_{KV} =0.1846 π mm mrad for the second source.

2 ION SOURCES AND INJECTION SYSTEMS

To optimize the synchronous operation, both ion sources and injection systems have been tested on an emittance measurement device. Figure 3 shows the measured emittances of the extracted ion beams of the two ion sources at 0.8 mA, which scales to a beam current of 40 mA of Bi^+. The minimum difference of the two normalized 90% KV–emittances was 0.5%. The values are dependent on the included divergent neutral beam.

3 THE TWO–BEAM RFQ

The two–beam RFQ consists of two sets of quadrupole electrodes, where the beams are bunched and accelerated with a phase shift of 180° between each bunch, driven by one resonant structure. With the use of identical RFQ electrode designs for both beam lines, the electrodes of one beam line are installed with a longitudinal shift of 2.55 cm (i.e. $\frac{\beta\lambda}{2}$) to achieve the 180° phase shift between the beam bunches of each beam line. In Figure 4 a photograph of the two–beam RFQ, with the first section of the electrodes mounted, is shown.

The RFQ electrodes are divided into two sections with different functions. While the first section, 140 cm long, bunches and accelerates the ions to the final energy of 160 keV, the second 60 cm long section consists of a drift and a matching section. So an x, y focus is at the funneling deflector position, while the axial focus will be behind the deflector for a matching into the next accelerator stage [7].

In Figure 5 the measured energy spectra behind the RFQ are shown. The final beam–energy of 166 keV is reached at an electrode voltage of 10 kV. Up to 4 kV electrode voltage the He^+ beam is only transported.

At the beam crossing position behind the two–beam RFQ emittance measurements have been done. In Figure 6

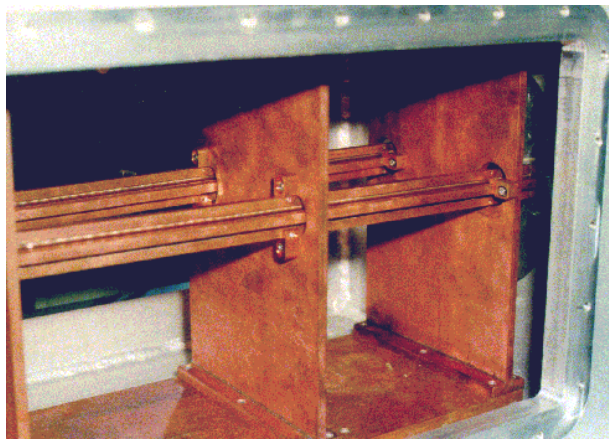

Figure 4: Photograph of the two–beam RFQ with the first section of the electrodes mounted.

the 2D– and 3D–view of the two emittances at an electrode voltage of 11.5 kV is shown. The difference between the two emittances is mainly dependent on the parameters of the injection systems.

4 THE FUNNELING DEFLECTOR STRUCTURE

The electrode geometry of the multigap deflector consists of several deflector plates divided by sections with larger aperture with equal length. In this geometry, the particles will see the deflecting field in one direction several times but the deflection in the opposite direction is always less. The length of the sections have to be proportional to the particle velocity and to the inverse frequency of the deflector system. For beam funneling, the frequency of the deflector has to be the same as the accelerator frequency, so that the bunches from different beam axes will see opposite

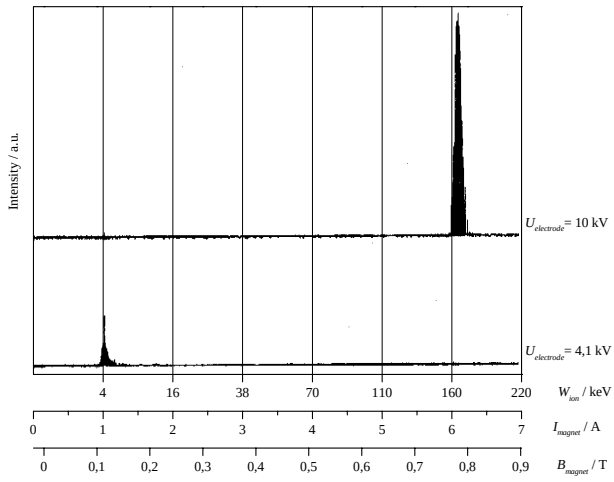

Figure 5: Energy spectra behind the RFQ. With the design voltage of 10 kV the final beam–energy of 166 keV is reached.

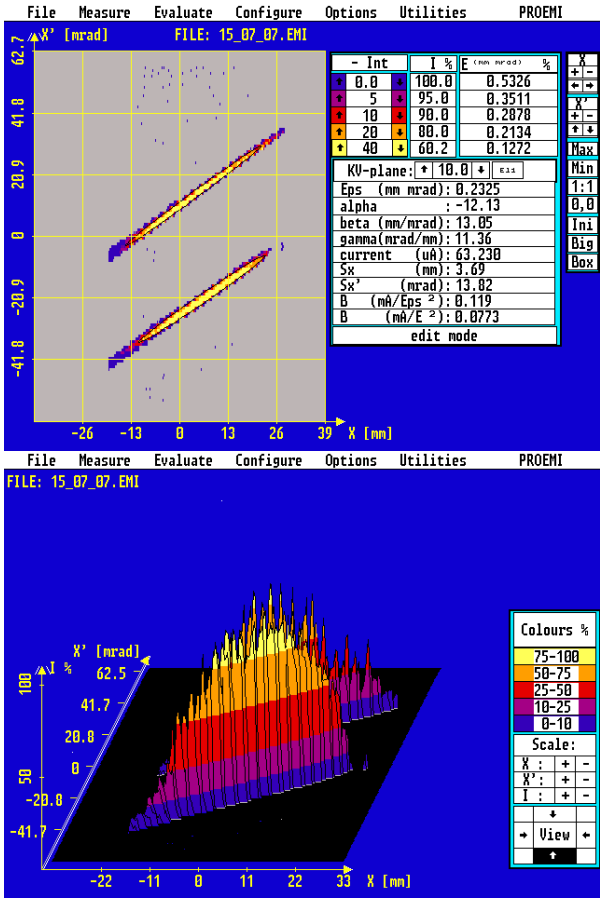

Figure 6: 2D– and 3D–view of the measured emittances behind the RFQ at the place of beam crossing. The ellipses correspond to the 90% normalized KV–emittances which is about ϵ_{KV} =0.25 π mm mrad for each beam.

field directions because of the phase shift of 180° between each bunch. Figure 7 shows a schematic drawing of the 9–gap funneling deflector which will be used.

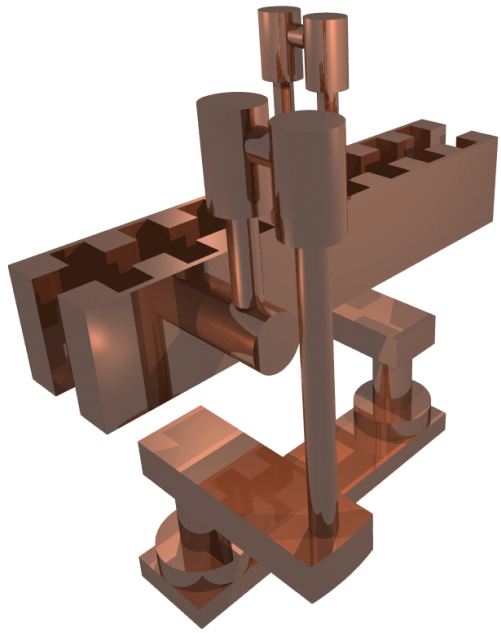

Figure 7: View of the multi–gap funneling deflector.

5 CONCLUSION

The beam tests results of the injection systems and the two–beam RFQ have shown that the chosen set–up can deliver two nearly identical ion beams for the planned funneling experiment. Next step will be the installation of the r.f. funneling deflector behind the two–beam RFQ.

The experiment with He^+ is a scaled version for funneling of Bi^+ at 60 $\frac{\text{keV}}{\text{u}}$ as it is required in the first funneling section of HIDIF, but can also be scaled to higher energies for e.g. the second section at 200 $\frac{\text{keV}}{\text{u}}$ or other funneling applications like spallation source.

PRESENT PERFORMANCE OF THE CERN PROTON LINAC

C.E. Hill, A.M. Lombardi, E. Tanke, M. Vretenar
PS Division, CERN, 1211 Geneva 23, Switzerland

Abstract

The original 1973 design specification of the CERN 50 MeV Proton Linac was for a 150 mA beam but this intensity was rarely used. Preliminary tests for the high brightness beam required for LHC indicated that 170 mA could be produced for short pulses (30 μs). Since then further optimisation has enabled the 170 mA to be delivered reliably, within the nominal emittances and dispersion, in long pulses (120 μs) to the user, the PS Booster (PSB), about 80 m downstream of the linac. The improvements will be described along with the steps envisaged to attain a goal of more than 180 mA.

1 INTRODUCTION

Linac2 has now been the primary source of protons for the CERN accelerator complex for the last 20 years [1]. In spite of its age, the machine performance has been steadily improved over the past few years in anticipation of the demands that will be made on it in the LHC era. Table 1 indicates the evolution of the beam intensity delivered to the PS Booster (PSB) over recent years. Figure 1 shows the layout of the linac and PSB injection lines.

In the early years, there was no particular demand for high intensities from the linac as, usually, more than sufficient protons could be supplied to the users, and high intensity beams were only produced as an academic exercise or to supply special test beams. It was generally felt that 150 mA out of tank 3 of the linac was a limit defined by the RF power available. However, the anticipated requirements of LHC started investigations into the possibilities of accelerating higher currents. By limiting the beam pulse length to around 30 μs, it proved possible to accelerate around 170 mA. However, existing high intensity users required a beam pulse length of the order of 120 μs. The measures taken to attain the present performance for a long beam will now be described.

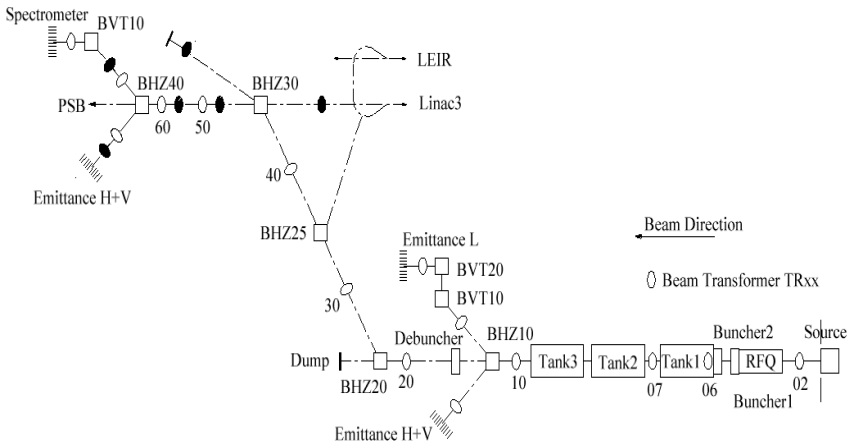

Figure 1: Schematic layout of Linac2 and its transfer lines.

Table 1. Evolution of operational beam intensity at transformer TR60 in Linac2 since 1992.

Date	Event	mA
up to1992	C-W injector operation	140
1993	RFQ2 installed	135
1994	Typical operation	135
1995	Realignment RFQ+LEBT	142
1996/I	Annual startup	140
1996/II	New high energy optic	145
1997/I	Annual startup	145
1997/II	New setting RFQ	160
1977/III	Source + LEBT adjustment	170
1998/I	Annual startup (reduced)	158
1998/II	Stable operation	173

2 INSTALLATION OF RFQ2

The high beam brightness required by the LHC requires some modifications to its injectors, and in particular an increase in the linac peak current. The consequent reduction in the number of turns needed in PSB injection leads to a smaller emittance at the end of the process. A major step towards a higher linac current was the replacement in 1993 of the old 750 kV Cockroft-Walton and Low Energy Beam Transport (LEBT) by a new 90 kV platform, a 750 keV RFQ (RFQ2) with compact (<1m long) beam transport lines between source and RFQ, and RFQ and linac [2]. After two months of installation work and one month of setting-up, the linac was able to provide 135 mA for the normal operation and 165 mA for high intensity studies.

3 RFQ2 ALIGNMENT

Whilst the RFQ was still on the test stand, it was found that the beam at its output was mis-steered. After installation on Linac2, the high-energy end of the RFQ had to be positioned off axis to get a good transmission through the linac. On

the stand, the beam emittance measured directly behind the source showed that the beam was off axis in position and angle. Although the source anode hole had been centred to better than 0.1 mm, it was not perpendicular to the beam axis. This same error was also found on Linac2 and corrected [3].

The line between the source and the RFQ contains two solenoids. Due to coupling, a beam passing through a solenoid off axis in, say, the horizontal plane can cause errors in beam position and angle in both transverse planes at the output. Originally, the solenoids had been aligned on their mechanical, not on their magnetic axes. Moving the solenoids whilst checking the beam centre (position and angle in both transverse planes) enabled the beam to be brought onto axis into the RFQ. As a result the overall performance of the RFQ improved with a reduction of RF breakdowns, which were often induced by ions hitting the electrodes, and the RFQ could be realigned mechanically to the theoretical axis.

4 RFQ2 CONDITIONING

The RFQ was designed to accelerate a space charge dominated beam of 200 mA. For this reason the design vane voltage had to be relatively high (178 kV) [4] which corresponds to surface electric fields of more than 2 times Kilpatrick on a large fraction of the electrodes and locally as high as 2.5. Conditioning on the test bench was only partially successful; only about 95% of the nominal voltage was attained before heavy sparking started. Once installed at the linac, the RFQ was operated at 92% of the design voltage to avoid excessive breakdowns that would have perturbed the whole CERN proton acceleration chain. This resulted in a 10% reduction in beam transmission.

It turned out that a defective drag pump in the RFQ vacuum system used to pump the large amount of hydrogen coming from the source, was backstreaming oil vapours into the cavity. The hydrocarbon deposit on the vane surface enhanced field emission (dark current) that finally resulted in RF breakdown.

Steady operation at high field level in the following years slowly eliminated the hydrocarbon from the electrodes. Figure 2 shows Fowler-Nordheim, ($ln(I/V^{2.5})$ vs. $1/V$), plots of dark current, derived from the excess power going to the electrons [5], as function of vane voltage at different moments of the RFQ2 history. The derived field enhancement factor β is a figure of merit for electrode roughness and cleanliness. Between 1993 and 1997 the dark current in the RFQ (operating at 92% of the nominal level) went down from about 70 mA to virtually zero. A comparison of the beta-factors deduced from Figure 2 shows that the cavity after delivery from the workshop (1990) was already somewhat polluted (β=220), while at the installation at the linac (1993) pollution was extremely high (β=920), It went down drastically (β=67 in 1997) after removing the source of pollution and slow RF conditioning. The present value is reasonable for the standard of surface finish used in the RFQ.

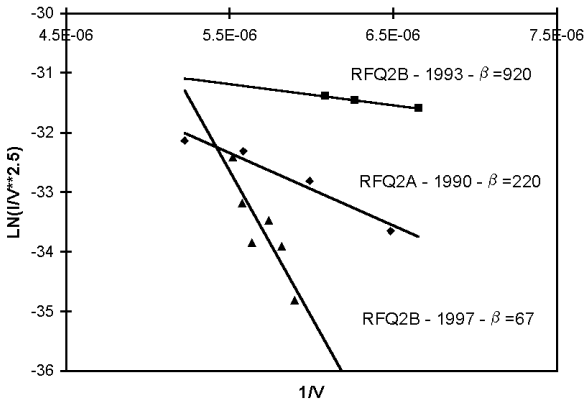

Figure 2: Fowler-Nordheim plots for the RFQs.

Following the discovery of the reduced β, the RFQ was reconditioned from 92% up to 100% of the nominal level during normal operation. The level was increased in small steps, taking care to limit the breakdowns so as not to perturb the users. As a result, the current delivered by the linac went up from 145 to 160 mA.

5 RF IMPROVEMENTS

The RF power needed for the design current of 150mA (cavity plus beam loading) is about 2.1 MW for each of the 5 final amplifiers, well within the capabilities (2.5MW) of the amplifiers [6]. For LHC, allowing for 5% beam losses, the 180 mA at the PSB correspond to 190 mA in the linac. For this, the final amplifiers will have to provide about 2.5 MW. With a 10% margin for phase and amplitude control, tuning precision and amplifier balancing, at least 2.7 MW per final amplifier will be needed

Some upgrades were gradually applied to the RF chains to increase their output power. The final amplifier tubes (TH170R) are rated for 2.5 MW power at a duty cycle greater than that used at Linac2, but they can deliver more power provided that enough drive power is available. Initially an additional amplifier stage was added in the Tank 1 chain which experiences the heaviest beam loading. Then modern 4.5 kW solid state amplifiers were installed in all the chains to replace aging tube units which generally had a lower power output. These more reliable transistor amplifiers have also contributed to a decrease in the linac fault rate.

Great attention was also given to the correct adjustment of the feedback loops which have not only to compensate for an increased beam loading but also have to stabilize amplifiers which are often working in the non-linear region close to saturation.

6 HIGH ENERGY OPTICS

The 80 metre 50 MeV proton beam line from the linac to the PSB is composed of 20 quadrupoles, 2 bending magnets, 8 steering magnets, and a debuncher cavity and is also equipped with eight position pick-ups and two emittance measurement lines. The optics of the line has been studied and optimised for the high current.

The space charge force varies considerably along this line as the beam comes out of the linac with a very marked longitudinal microstructure that is gradually lost. The beam is strongly space charge dominated at the beginning of the line and becomes emittance dominated after about 50 metres. The focusing of the line has been set-up in such a way so as to provide a "quasi" FODO system with constant phase advance per focusing period: this arrangement turned out to be the most convenient for optimising transmission and beam qualities, and minimising the sensitivity to steering. This last parameter is particularly critical, as the stray field of the PS machine penetrates the transfer line and sensitivity to steering has been considerably reduced with this configuration. Figure 3 shows the measured beam centre displacement before and after the change.

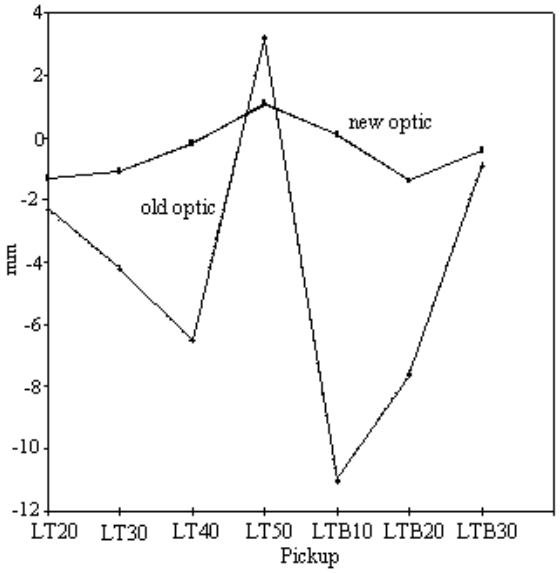

Figure 3: Measured beam centre displacement for 0.25 mrad variation in steering after the linac.

7 SOURCE OPTIMISATION

Normally, the total beam out of the duoplasmatron source is around 275 mA with a hydrogen consumption of about 7 std.ml/min. This results in a N_2 equivalent pressure of approximately $3.5*10^{-5}$ mbar in the preinjector housing falling to the high 10^{-7}s in the RFQ. With this relatively high pressure in the LEBT, neutralisation is very high. Thus, the effective focusing of the solenoids is highly dependent on the gas flow from the source. Gains in intensity of around 10% were obtained by iterative re-optimisation of source parameters and solenoid focusing strengths. Naturally, as source parameters and the injector vacuum quality change with time, this optimisation process must be repeated at regular intervals.

8 LINAC OPTIMISATION

In parallel to these major changes to the linac, a major long term effort was initiated to reduce the losses in the machine and transfer lines. A consequence of the new optics, and its inherent stability against perturbations, was that it became much simpler to control losses in the high energy transport line. Equally it is also easier to optimise both transverse and longitudinal parameters in the linac itself. Computer programmes are being developed to try to optimise the linac on-line using hill climbing techniques to find the optimum combinations of these parameters.

9 THE FUTURE

During one short study period in 1997, a peak current of 176 mA in 120 μs was passed to the PSB. This demonstrated that there is still potential for further improvements in intensity. The goal is to try to pass the 180 mA barrier in the near future. However, it is also known that there are serious bottlenecks at the beginning of the linac that will require ingenuity to overcome . It is also appreciated that this higher performance will place new demands on the linac with attendant consequences on reliability.

ACHIEVING 800 KW CW BEAM POWER AND CONTINUING ENERGY IMPROVEMENTS IN CEBAF*

C. E. Reece
Thomas Jefferson National Accelerator Facility, Newport News, Virginia 23606 USA

Abstract

During the past year, CEBAF at Jefferson Lab has demonstrated its full capacity of sustained 800 kW beam power. All systems performed as intended. The energy stability at the design parameters of 4.0 GeV, 200 μA CW beam was measured to be better than 3×10^{-5} rms. During the fall of 1997, physics experiments were conducted using 4.4 GeV beam. Having demonstrated the benefits of *in situ* helium/rf processing of SRF cavities for increasing the energy reach of CEBAF, we began a program of processing all installed cryomodules. This processing has proven effective against the principal gradient limitation of the SRF cavities in CEBAF: discharges at the cold rf waveguide window, induced by electron field emission in the cavities. Such effects limit approximately half of the cavities. Regular operation at 5.0 GeV is just beginning, and preparations are underway to support 5.5 GeV in early 1999.

1 CEBAF DESIGN

CEBAF was designed and constructed as a 4.0 GeV, 200 μA CW recirculating electron linac. [1] The acceleration system employs 330 superconducting radiofrequency (SRF) cavities operating at 1497 MHz and 2.0 K. Each cavity is individually regulated and powered by a 5 kW klystron. Beam may be recirculated through the split linac up to five passes before delivery to the three experimental halls.

2 OPERATING EXPERIENCE

The accelerator has been supporting physics experiments since October 1995. Routine multi-hall operation has proceeded for the past two years. Tolerable CW beam currents are typically either limited to very low currents (100 pA–100 nA) by event discrimination constraints—for example, in the Hall B Large Acceptance Spectrometer—or to ~130 μA by heating of cryogenic targets in Halls A and C.

The first physics run above 4 GeV took place during November 1997. One experiment took 4.4 GeV beam while another received four-pass 3.5 GeV beam.

*Work supported by the U.S. Department of Energy, contract DE-AC05-84ER40150.

The SRF cavities in CEBAF as well as the rest of the acceleration system have been quite stable and reliable. By August 1998, over 4,000,000 cavity-beam hours had been accumulated.

3 FULL POWER TEST

On September 16, 1997, a test was performed on the CEBAF accelerator to demonstrate its full design capability of 200 μA CW beam at 4.0 GeV. This beam was delivered to the Hall C dump with minimal difficulties and with stability characteristics consistent with normal operations. Since no physics target was available that could handle 200 μA, the test was performed without a target in place. Rastered beam went directly to the dump. One clear indicator of the robustness of the integrated accelerator system was the ability to place 200 μA on the injector Faraday cup, retract that cup, and immediately transport lossless, full-power beam to the Hall C dump and maintain this current for at least tens of minutes with all orbit locks off. The duration of the full test was 10 h.

As illustrated in Figure 1, the test demonstrated the economy of exploiting SRF technology. A typical cavity operating at 6.5 MV/m fully matches the input 3.8 kW rf to the beam.

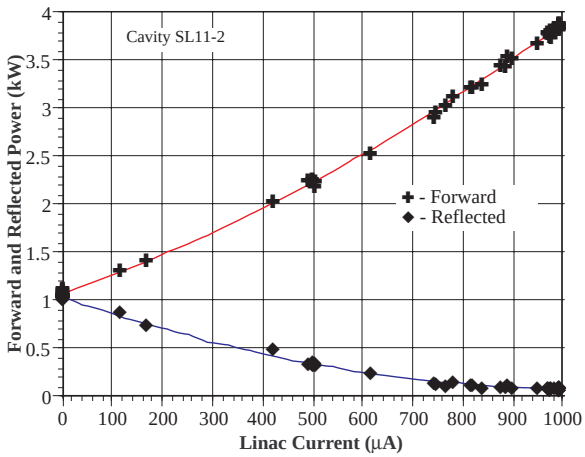

Figure 1. Matched rf load at full current.

During delivery of 200 μA to Hall C, measurements were made of the stability of beam position and energy. The dominant features observed were at 60 Hz. Beam motion in high dispersion and zero dispersion regions was comparable with comparable beta functions, so it's unlikely to be due to energy variation which, based on

a set of BPM measurements, had a fractional peak-to-peak amplitude of 4×10^{-5}.

There was no problem with input waveguide vacuum pressures as the input rf power increased and shifted to full travelling-wave conditions. An increase in the 2 K heat load was observed, increasing quadratically with total linac current, with an additional 200 W from the maximum 1 mA circulating current. The source of this heat has yet to be fully explored.

The beam dump cooling systems had no problem handling the 800 kW of beam power. The high-power beam dumps were designed to accept well over 1 MW. The test also challenged the beam current monitoring system used as part of the safety interlock system. We were able to approach the administrative limits with absolute beam accounting to better than 1%.

4 ENERGY IMPROVEMENTS

4.1 Limitations

The CEBAF cavities, though performing substantially better than initial specifications, are primarily limited in performance by internal electron field emission. Periodic arcs at the cold ceramic rf window are strongly correlated with field emission in the associated cavity.[2] Over a third of the 330 SRF cavities are now limited in usable gradient by this arcing phenomenon. Post-production tests have demonstrated that this arcing may be eliminated by moving the ceramic window away from the beamline and adding a dogleg in the cold waveguide section. All future rework will implement at least this change.

The other effects of field emission are x-ray production and spoilage of the cavity Q. Because it is more easily measured, we use the radiation as an indicator of decreasing Q and presently tolerate 2 R/h outside the cryostat from each cavity.

4.2 Helium Processing

The most economical route for incremental extension of the CEBAF energy reach has been through *in situ* conditioning of the SRF cavities, seeking to reduce the internal field emission and thus also the periodic arcing. Helium/rf processing, first attempted on an installed CEBAF cryomodule in September of 1996, has proven to be an effective method of improving cavity performance.[3]

Because of CEBAF's very full run schedule, we have continued to upgrade the processing methods in order to minimize any impact on run time. Beginning in 1998, the normal rf control system was used during processing rather than one of three stand-alone systems. A local ~70 MHz VCO was substituted for the fixed-frequency 70 MHz IF line. Including this VCO in a phase-locked loop then enabled dealing with the low-level multipacting barrier, as previously described.[4]

Also, to maximize the yield from helium processing, it is now preceded by a thermal cycle up to 40 K in order to desorb and remove any accumulated He and H. This is followed by several hours of detuned pulsed rf conditioning of the input cold waveguide region.

The actual processing is accomplished with 10^{-4} torr He on the beamline while driving the cavity at its highest sustainable field level for ~1 h. A subsequent thermal cycle to 40 K is used to remove the He. Following this procedure there have been no difficulties immediately resuming normal operation. The markers for effective processing are reduced arcing and reduced generation of x-rays by field-emitted electrons.

This upgraded processing scheme was commissioned on two cryomodules in February 1998. Using staggered crews, 16 additional cryomodules were processed during seven days allocated in July. The number of cryomodules processed was limited only by the capacity of the cryogenic system to handle the thermal cycles.

In addition to direct processing gains, other cavity gradient limitations are revisited during the processing work, and in many cases additional voltage has been found through reducing margin based on accumulated operating experience.

4.3 Results

To date, we have applied helium-rf processing at 2 K to 224 cavities in 29 of the 41 installed CEBAF cryomodules. Figure 2 shows the shift of limits after processing.

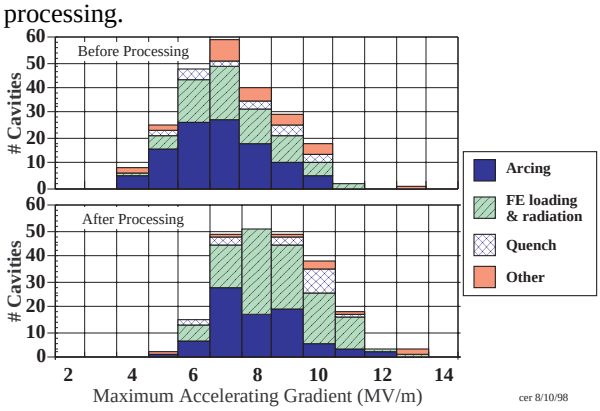

Figure 2. Change of limitations with processing.

Helium processing and requalification of cavities have increased the available installed CEBAF voltage by 155 MV, corresponding to an added 775 MeV for five-pass beam. At this rate we project an additional 55 MV gain from processing the balance of the machine, which would be adequate for extending the energy reach of CEBAF above 6 GeV. Figure 3 presents the present voltage capacities of the 41 CEBAF cryomodules.

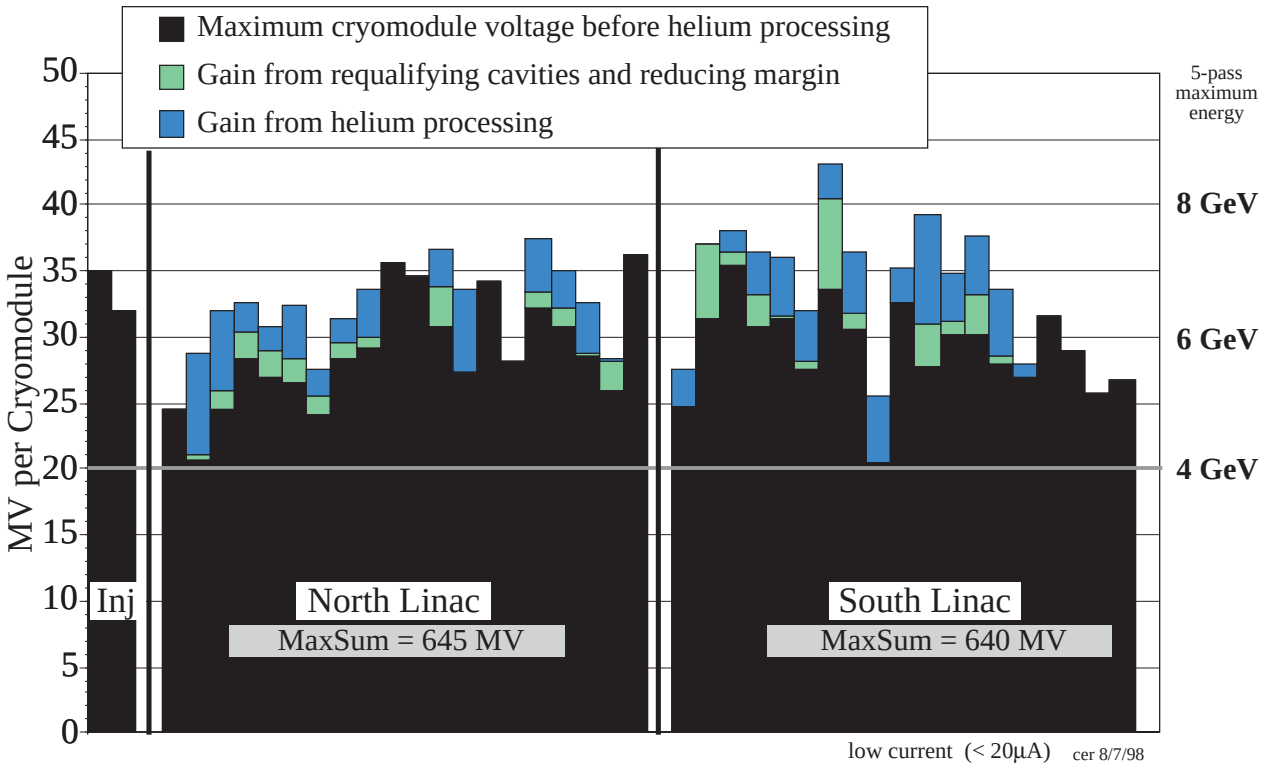

Figure 3. Maximum SRF Cavity Voltage per Cryomodule in CEBAF.

The distribution of present cavity performance limits is discussed in another contribution to this conference.[5]

5 UPGRADE PLANS

Beyond the virtually complete improvement to 5.5 GeV, upgrades to several arc dipole power supplies are being implemented in order to handle 6 GeV beam. Realization of this energy is planned for 1999.

Plans are presently being developed for a possible upgrade of CEBAF to 12 GeV. The most economical route includes the construction of new 80 MV cryomodules to populate the ten slots left empty by the early design switch for CEBAF from a four- to five-pass machine. Such new cryomodules will have improved filling factor by incorporating seven-cell rather than five-cell cavities, and take advantage of the process improvements in SRF technology of the last decade.[6]

6 ACKNOWLEDGEMENTS

J. Bisognano, J-C. Denard, L. Doolittle, V. Lebedev, B. Dunham, M. Spata, M. Tiefenback, and M. Wiseman all made important contributions to the success of the full-power demonstration test. A large number of Jefferson Lab staff have participated in the helium processing improvement work. Particular credit goes to G. Myneni, V. Nguyen, E. Strong, D. Dotson, T. Powers, G. Marble, G. Lahti, and C. Hovater for their creative efforts. All of this work has been solidly supported by the Operations and AES groups.

CONTROLLING BACKSTREAMING IONS FROM X-RAY CONVERTER TARGETS WITH TIME VARYING FINAL FOCUSING SOLENOIDAL LENS AND BEAM ENERGY VARIATION

Yu-Jiuan Chen, George J. Caporaso, Arthur C. Paul
Lawrence Livermore National Laboratory, Livermore, California 94550 USA

Abstract

Backstreaming ions emitted from an x-ray converter hit by a tightly focused intense electron beam can form an ion focusing channel and over-focus the electron beam. As the ions move upstream in time, the net focusing strength increases. The final beam spot size on the target would then change in time and typically be larger than intended. We have developed a model to estimate the backstreaming ions' neutralization factor in a potential sheath near the target surface and away from the sheath. Performance of high resolution x-ray radiography facilities requires high current electron beams to be focused to a millimeter spot size on an x-ray converter through out the entire current pulse. We have studied the possibility of maintaining a constant final spot size for the entire pulse by using either a time varying final focusing solenoid field or beam energy variation to compensate the time varying ion focusing effects.

1 INTRODUCTION

Performance of high resolution x-ray radiography facilities requires several kiloamperes of electron beams to be focused to a millimeter spot size on an x-ray converter target through out the entire current pulse. D. Welch claimed that it would be difficult to maintain the tight focus of electron beams on a converter during the entire pulse length because of the existence of backstreaming ions[1]. He stated that a high density electron beam can heat the target surface up to 400°C and lead to rapid desorption of surface contaminants within a few nanoseconds. These desorbed gases form a plasma layer on the converter surface. Meanwhile, the charge redistribution on the target after the electron beam hits the surface creates a large potential drop and an ion diode on the target surface. The space charge field of the electron beam would pull ions out of the plasma layer into the beam. These ions trapped by the electron beam move upstream, form an ion focusing channel and over-focus the electron beam. As the ions move upstream in time, the net focusing strength increases. The final beam spot size on the target would then change in time and typically be larger than intended. The potential backstreaming ions are protons and oxygen from the water vapor on the target surface, carbon and tantalum or tungsten from the target itself. The lighter ions have a greater potential to destroy electron beam's final focus since they would travel upstream at a higher speed and form a longer ion channel. The ions from the target material itself are usually too heavy to have a large effect on the beam spot size during the beam pulse time. On the other hand, the backstreaming protons would have the worst effects on the electron beam's final focusing if these backstreaming protons do exist. Single-pulse experiments at various radiography facilities and laboratories [2-4] (except at CESTA's PIVAIR linac [5]) have not yet been able to provide a strong evidence of existence of backstreaming protons. However, The simulated double-pulse experiments on ETA-II indicated a different backstreaming ion emission mechanism [4]. The space charge field of the electron beam would pull ions out of a pre-existing target plasma generated by the preceeding pulse. The ETA-II results also indicated that the backstreaming ion emission follow a the Child-Langmuir law. In this paper, we study the possibility of maintaining a constant final spot size for an entire current pulse by using either a time varying final focusing solenoidal field or beam energy variation to compensate the time varying ion focusing effects. We have found that the required time varying rates for both the solenoidal field and the energy variation are too large to be feasible.

2 MODEL

To model the backstreaming ion effects consistently with the beam and target geometry, we should study this problem with particle simulations. Typically, the electron beam size at a converter target is about 1 mm, and the beampipe wall radius is about several centimeters. The backstreaming ion channel can vary from a few millimeters at the beginning of an electron beam pulse to a meter at the tail of a pulse. The simulation volume has to be large enough to include the pipe wall and the entire ion channel in order to model the space charge potential and the backstreaming ion focusing effect properly. At the same time, the simulation mesh size has be small enough to model the backstreaming ion emission in a millimeter size A-K gap. These requirements make examining time varying focusing field and energy with particle simulations very time consuming. Therefore, we study the feasibility of controlling the electron beam's spot size with a time varying final focusing solenoidal field or beam energy variation by solving the envelope equation given as

$$R'' + \frac{k_{co}^2}{4\gamma^2\beta^2} R - \frac{2I}{\gamma\beta^3 I_o R}\left\{1 - f_i(z) - f_T(z) - \beta^2\right\} - \frac{E^2}{R^3} = 0 \quad (1)$$

where R and E are the beam's edge radius and edge emittance, f_i is the backstreaming ions' charge neutralization factor, and f_T is the foil focusing effect provided by the x-ray converter. In our model, all backstreaming ions are trapped within the electron beam.

Both the electron density and the ion density are constant in radial positions within the beam radius.

2.1 Beam Potential near a Target

Let the x-ray converter target locates at $z = z_T$. At a location far away from the converter surface ($z_T - z >> a$), the radial scale length of the beam is much less the longitudinal scale length, where a is the beam radius at the z location. Let the wall potential be zero. The space charge suppressed potential inside the beam at this location is well known and given by

$$\phi(r, z_T - z >> a) = \phi_o + \frac{I}{\beta c a^2} r^2 \quad , \tag{2}$$

where

$$\phi_o = -\frac{I}{\beta c}\left(1 + 2\ln\frac{b}{a}\right) \quad , \tag{3}$$

and b is the wall radius. Let's assume that the beam potential is separable in r and z such that

$$\Phi(r, z) \approx \phi(r, z_T - z >> a)\psi(z) \quad . \tag{4}$$

Substituting Eqs. (2) and (4) into Poison equation, we find that the beam potential is given in the form

$$\phi(r, z) \approx \phi(r, z_T - z >> a)(1 - e^{-(z_T - z)/\lambda}) \quad , \tag{5}$$

where

$$\lambda = \frac{a}{2}\sqrt{1 + 2\ln\frac{b}{a}} \tag{6}$$

is the scale length of the potential sheath at the target. Note that the sheath thickness is always about several times of the beam radius regardless of the wall radius since λ varies from $0.5a$ to $1.49a$ as the b/a value varies from 1 to 50. The radial, electrostatic space-charge field is given by

$$E_r(r, z) = -\frac{2I}{\beta c r}(1 - e^{-(z_T - z)/\lambda}) \quad . \tag{7}$$

Comparing Eq. (1) with Eq. (7), it is obvious that the focusing effect provided by the x-ray converter is given by

$$f_T(z) = e^{-(z_T - z)/\lambda} \quad . \tag{8}$$

By integrate Eq. (8) over z, we find that the target's effective focusing length is λ, and the effective foil focusing factor is 1. For the case that the wall radius is 5 cm and the beam radius is 0.5 mm, the effective foil focusing length is 0.8 mm. For simplicity, we ignore the target's focusing effects.

2.2 Backstreaming Ions

According to Eq. (5), the potential drop over the distance $d = 3\lambda$ from the target is 95% of ϕ_o. An ion diode is formed across this potential drop. To estimate the amount of an ion current could be extracted from this diode, we assume that the ion emission is space charge limited. We further assume the extracted ion current follows the planar Child-Langmuir law,

$$J_i = \frac{1}{9\pi}\sqrt{\frac{2q}{M}}\frac{|\phi_o|^{3/2}}{d^2} \quad , \tag{9}$$

where q and M is ion's charge and mass, respectively. After leaving the A-K gap, i.e., $z < z_T - d$, ions move backstream with a velocity $v_i = \sqrt{2q|\phi_o|/M}$. From Eq. (3), it is obvious that the length of the ion channel would depend on beam current, spot size, wall radius and ion species. We find that the backstreaming ions' charge neutralization factor outside the A-K gap is given by

$$f_i \approx \frac{4}{9}\left(\frac{\lambda}{d}\right)^2 \approx 5\% \tag{10}$$

as $z > z_T - v_i t$. A 5% charge neutralization factor has been observed in the PIC simulations for the backstreaming protons [6]. Note that the backstreaming ions' charge neutralization factor within an ion channel is independent of beam parameters, wall radius and ion types. A re-entry (beer-can) target configuration would help to reduce the spot size blow-up rate by reducing the beam space-charge potential, hence the length of the ion channel. However, the ion charge neutralization factor remain the same. Caporaso has shown that the backstreaming ions' charge neutralization factor is 6.4% in a beer-can model that both the electron beam and the ion beam fill a beampipe [7].

The ions' neutralization factor varies along the z location within the A-K gap region and approaches infinity. The neutralization factor averaged over the gap is

$$f_i \approx \frac{4}{3}\left(\frac{\lambda}{d}\right)^2 \approx 14.8\% \quad . \tag{11}$$

For the case that the wall radius is 5 cm and the beam radius is 0.5 mm, the A-K gap distance d is only 2.4 mm. For a 6 kA beam, backstreaming protons would travel 1.9 cm, that is much longer than the A-K gap distance, within 1 ns. For simplicity, we assume the ion neutralization factor constant (5%) for the entire ion channel.

3 TIME VARYING SOLENOID FIELD

A potential way to compensate for the increasing backstreaming ions' focusing strength is to reduce the final focal lens strength in time. For the Advanced Hydrotest Facility's (AHF) [8] 6 kA, 20 MeV beams with 1200π mm-mr normalized edge emittance, we use a solenoid focusing field of 6350G to focus beams at a waist with a radius of 0.5 mm. Figure 1(a) shows that we need at lease to reduce the focusing field at the rate of 30 G/ns to compensate the backstreaming protons' focusing effects. We have found that varying the focusing lens' strength is not effective once the protons have traveled upstream and passed the final lens (t > 35 ns). Figure 1(b) indicates that at least 14 G/ns is needed to maintain the spot size for backstreaming carbon. For both cases, the required reduction rate in the final lens' strength would be hard to achieve due to the pulse power limitation.

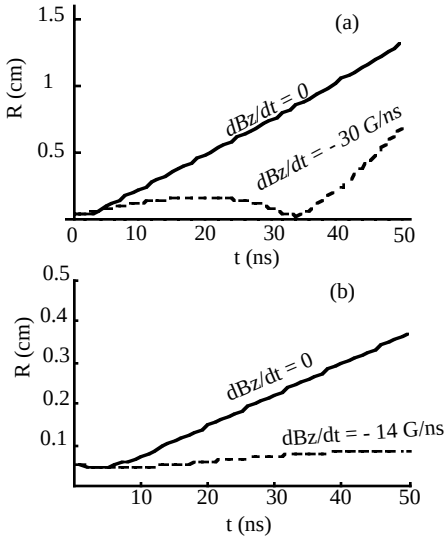

Fig.1 The time varying beam radius on a target with backstreaming (a) protons and (b) carbons and a constant (solid) and time reducing (dashed) focusing field.

4 TIME VARYING BEAM ENERGY

We now examine the feasibility of maintaining the beam spot size on a target by varying the beam energy. For simplicity, we assume that the beam energy increases linearly within a pulse, and there is no envelope variation in the pulse. For the same AHF beam, Fig. 3(a) and (b) show the compensation results for the focusing effects of backstreaming protons and carbons, respectively. Even with 150 kV/ns of energy variation rate, we can only maintain the beam spot size to a small value for about 35 ns for the backstreaming proton case (see Fig. 2(a)). For the backstreaming carbons, by varying beam energy at the rate of 40 kV/ns, we can successfully maintain the beam spot size constant (see Fig. 2(b)). For a 50 ns long, 20 MeV beam, this would require a 10% energy variation through a pulse. It would be difficult to transport a beam with such a large energy variation to the final focus region without any envelope variation.

5 CONCLUSIONS

We have developed a model to estimate the neutralization factor of backstreaming ions emitted from an x-ray converter hit by a tightly focused intense electron beam. We have found that the neutralization factor is always 5% regardless of the ion mass and charge, the electron current, beam radius and the wall radius. We have also studied two schemes, reducing the final focus lens' strength in time and increasing beam energy in time, to compensate for the increase in focusing produced by these ions. We have found that neither methods are effective in maintaining a small beam spot size if the backstreaming ions are protons. In the case of backstreaming carbons, both methods can maintain a small beam spot size. However, the required solenoid field variation rate and the energy variation rate are quite large.

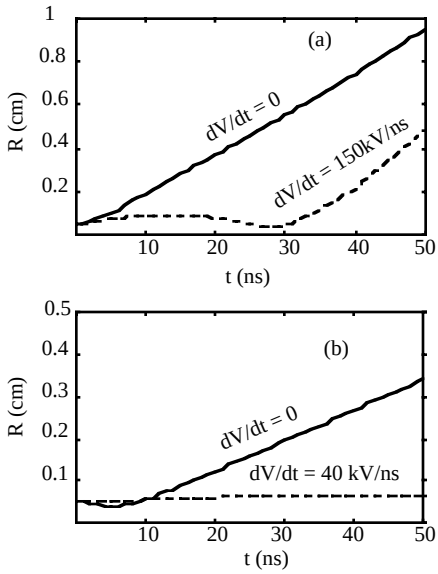

Fig. 2 The time varying beam radius on a target with backstreaming (a) protons and (b) carbons for a constant (solid) and for a time varying beam energy (dashed).

ACKNOWLEDGMENTS

We would like to thank J. McCarrick for numerous discussions. The work was performed under the auspices of the U.S. Department of Energy by LLNL under contract W-7405-ENG-48.

ELECTRON GUN SIMULATION USING MAGIC

S. Michizono, H.Tsutsui, S. Matsumoto, Y. H. Chin and S. Fukuda
High Energy Accelerator Research Organization (KEK), Tsukuba, Ibaraki 305-0801 Japan

Abstract

The electron gun plays an important role concerning klystron performance, especially for X-band klystrons with a small drift-tube diameter. This paper describes a new method for an electron-gun simulation by using MAGIC. MAGIC solves the Maxwell equations in the presence of charged particles on a time-domain. The results simulated by MAGIC are compared with those by EGUN and measured values. It reveals that the perveance is almost the same as the measured values, and that the current-density distribution and beam angle are almost the same as those of EGUN. Although it takes half days to simulate the gun, the simulation has the potential that a single code can enable one to simulate the whole structure of a klystron.

1 INTRODUCTION

It is important to design the electron gun precisely when we design klystrons. In a future linear collider, such as Japan Linear Collider (JLC) and SLAC NLC, high-power klystrons at the X-band (11.424 GHz) will be used. In these klystrons, the beam (>350A) should be compressed to around a radius of 3 mm and the area-convergence ratio of the beam should be more than 100.

In order to simulate a whole structure of a klystron precisely by a single code, we started to use a 2.5D particle-in-cell (PIC) program, called "MAGIC"[1], which is used in plasma-physics problems. In MAGIC, neither a port approximation nor an equivalent-circuit model is used, and only the geometry of the structure is necessary to be input. By using a general program ("MAGIC"), one can modify and develop a simulation system by oneself, even if a new idea for klystrons occurs.

In the klystron, the gun and all rf components are electromagnetically divided from each other, and the simulation is executed at three parts (gun, buncher and output) [2-4]. We report on the results of some klystron-guns (S- and X-band) simulated by MAGIC.

2 BOUNDARY PREPARATION

2.1 Spatial geometry of "large" and "small" area

In MAGIC, arbitrary rectangular grids are used and the spatial grid is the primary determinant of accuracy. It is especially necessary to define fine grids in a spherical cathode and the small aperture of the drift tube radius. Since the electrons emitted due to the electric-field strength on every grid of the cathode, a careful configuration of the cathode surface is important to avoid edge emission. In order to construct the boundary condition easily, we made a program similar to the boundary-definition-program POLYGON [5] used for EGUN [6]. Figure 1 shows a schematic of the electron-gun boundary. The grid dimensions, such as Δr and Δz, must be defined in the program. Since the grids should be located on the drift tube wall, the number of grids existing in the r-direction of the drift tube is necessary as an input. There are restrictions in the number of grids (r- and z-directions and total numbers), and the grid sizes depend on the geometry size.

It is possible to simulate a "small area" (divided by "GAP" line in Figure 1) after the simulation of a "large area" (total area of Figure 1). In a small-area simulation, the electric-field (Ez) distribution on "GAP" obtained by a "large-area" simulation is used for the voltage input. Although a "small-area" simulation is possible only when the "GAP" can be treated as a Neumann boundary, this is convenient to reduce the number of cells or to make a precise simulation.

By using this boundary program, it becomes easy to compare the data obtained by EGUN.

2.2 Time step of "rough" and "fine" simulation

The data of particles and electromagnetic fields are repeatedly imported at the next buncher and output region, and the time step should be a divisor of the period of the operation frequency. When we simulate the entire structure of a klystron, it is selected as 0.24315 ps ("fine" simulation) in an X-band klystron (XB-72k [7]), which corresponds to 1/360 of the period (1 degree). The default time step with 0.5 mm grids is about 0.8 ps, which reduces the simulation time ("rough" simulation). This is convenient when we simulate only the electron-gun

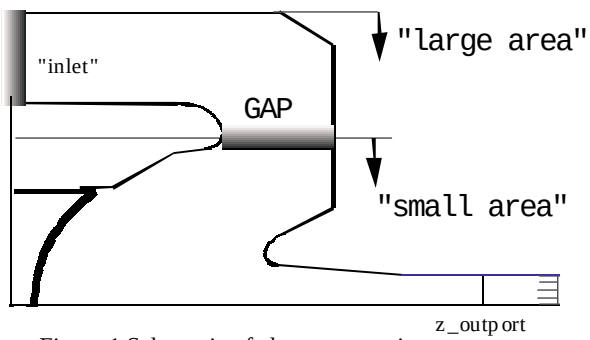

Figure 1 Schematic of electron gun giometry.

region. Both “rough” and “fine” simulations gave the same results in the gun region.

2.3 Magnetic fields

The magnetic fields used for electron-beam convergence can be introduced from the output of the LANL POISSON/PANDIRA codes [8].

2.4 Cathode voltage

In MAGIC, the voltage is applied at “inlet” in Figure 1 is a “large-area” simulation and at “GAP” in Figure 1 in a “small-area” simulation.

Since MAGIC is a time-domain code, the applied voltage should gradually be increased so as to avoid any numerical oscillations: we set 0.8 ns for the rise time.

3 PERFORMANCE OF MAGIC

3.1 Execution procedure

The execution of a MAGIC simulation is done as follows:

(1) “Large-area” simulation with a “rough” time step

If the “GAP” (in Figure 1) can be treated as a Neumann boundary, then

(2) Input the electric-field distribution on “GAP”

(3) Make a “small-area” simulation with a “fine” time step

After the simulation, the particle and field data can be exported to the next buncher and the output region of the klystron.

3.2 Output data

Since MAGIC is a general code for plasma problems, we can specify the output of the simulations. (1) A phase plot (particle trajectory) is obtained by MAGIC. Figure 2 shows the trajectories of XB-72k with an applied voltage

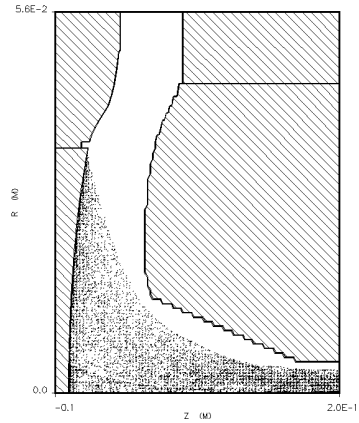

Figure 2 Particle trajectories of XB-72k with “small-area” and “fine” time step. The applied voltage and beam current are 550 kV and 490 A respectively.

of 550 kV. Due to a careful grid configuration, edge emission is not observed. (2) The transition of the beam current and voltage between a wehnelt and an anode are monitored in order to evaluate the machine time necessary to be stable. A simulation of the XB-72K with 0.5 mm grids requires 15 ns (about 60,000 time steps with “fine” simulation) to be stable.

By using exported particle data, (3) the current density distribution and (4) beam angle (v_R/v_z) are also obtained.

We can compare results (1), (3) and (4) with those of EGUN. Figure 3 shows the current-density profile of XB-72K by MAGIC together with that obtained by EGUN. The results obtained by MAGIC agree well with that by EGUN. Figure 4 shows the radial distribution of the beam angle obtaiend by MAGIC and by EGUN. Since the position of the beam waist was different between EGUN and MAGIC, probably caused by a difference in the total beam current (450 A in EGUN and 490 A in MAGIC), the beam angle by MAGIC is about half that obtained by EGUN.

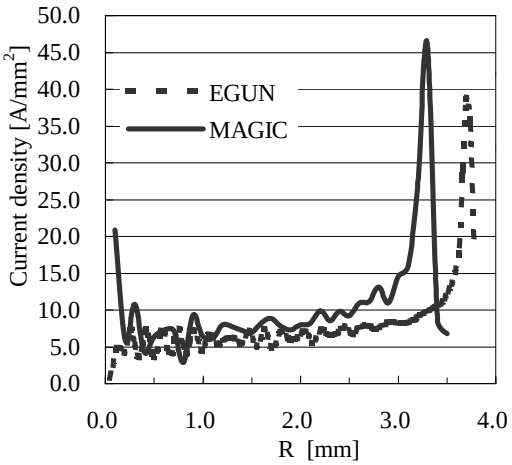

Figure 3 Current-density distribution of the electron gun (XB-72k) at 175 mm in the Z-direction.

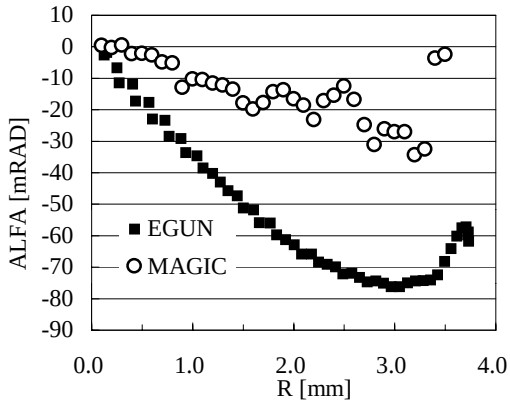

Figure 4 Electron-beam angle (vr/vz) of the electron gun (XB-72k) at 175 mm in the Z-direction. About half the value of MAGIC is due to the difference in the beam oscillation position (see Figure 5).

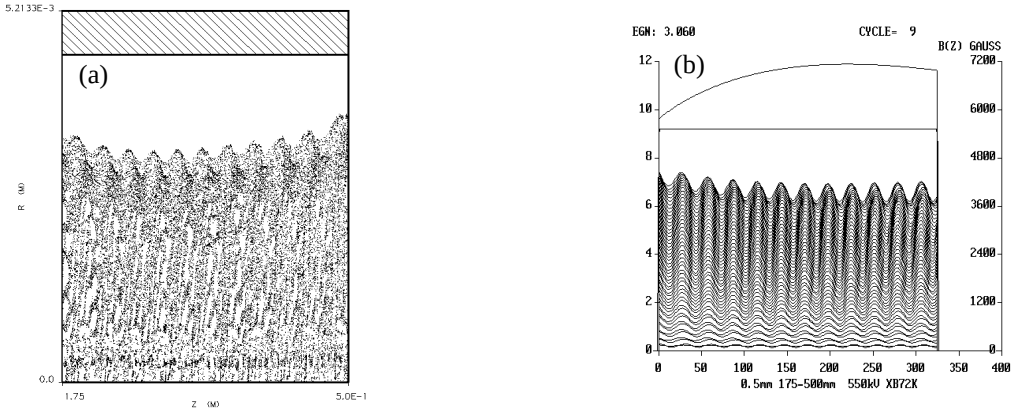

Figure 5 Beam trajectories obtained by MAGIC (a) and EGUN (b) from z=175 mm to 500 mm of XB-72k. The oscillation is almost the same, but the phase is different, probably due to a difference in the total current.

3.3 Diode simulation

By importing particle data from electron-gun region, we can simulate the drift-tube region. Figure 5 shows the particle trajectories of the diode together with that by EGUN. The trajectories obtained by MAGIC are almost the same as those obtained by EGUN.

3.4 Performance and machine time

The performance and machine time are summarized in Table.1. Simulations by MAGIC are carried out not only for an X-band klystron, but also for the S-band klystrons used in the KEK(PV3030A2)[9] and SLAC(5045)[10,11]. The perveances are almost the same as the measured values and 5-10% larger than those obtained by EGUN.

The machine time depends on the grid size and time step; it takes about 15 hours to simulate "15 ns" with a "small-area" and "fine" time step by PentiumPro-200MHz PC. Now, the pentiumII-300MHz PC is used, which reduces the simulation time by half.

Table 1 Performance of a MAGIC simulation.

Klystron	PV3030A2	5045	XB-72K
Frequency	2,856 MHz	2,856 MHz	11,424 MHz
Voltage	300 kV	315 kV	550 kV
Experimental			
μperveance	2.05	2.0	1.2
EGUN			
Grid size	0.5 mm	0.5 mm	0.5 mm
μperveance	1.89	1.78	1.10
machine-time*	2 min.	2 min.	6 min.
MAGIC			
Grid size	0.5 mm	0.5 mm	0.5 mm
Time step	0.9726 ps	0.9726 ps	0.24315 ps
μperveance	2.03	1.99	1.19
machine-time*	5 hours	5 hours	15 hours

*The time simulated by PentiumPro200MHz PC.

4 SUMMARY

An electron-gun simulation was successfully carried out by MAGIC. A boundary-formation program was developed which makes it convenient for comparisons with EGUN. (1) The particle trajectories, (2) transitions of the voltage and beam current, (3) current-density distribution, and (4) beam angle were obtained; the results agree well with those obtained by EGUN. The obtained perveances were almost the same as the measured values for the S- and X-band klystrons. Although it takes more than a half day to simulate with a fine time-step used for a whole-structure calculation, the machine time can be reduced by using a faster PC. Since the whole-structure simulation reveals good agreements with the measured values, this simulation method is useful for the final stage of klystron design.

Abstract

A spectrometer/Optical Multi-channel Analyzer has been used to measure the proton fraction of the cw proton injector developed for the Accelerator Production of Tritium (APT)[1] and the Low Energy Demonstration Accelerator (LEDA) at Los Alamos. This technique, pioneered by the Lawrence Berkeley National Laboratory (LBNL), was subsequently adopted by the international fusion community as the standard for determining the extracted ion fractions of neutral beam injectors. Proton fractions up to 95 ± 3% have been measured on the LEDA injector. These values are in good agreement with results obtained by magnetically sweeping the ion beam, collimated by a slit, across a Faraday cup. Since the velocity distribution of each beam species is measured, it also can be used to determine beam divergence. While divergence has not yet been ascertained due to the wide slit widths in use, non-Gaussian distributions have been observed during operation above the design-matched perveance. An additional feature is that the presence of extracted water ions can be observed. During ion source conditioning at 75 kV, an extracted water fraction >30% was briefly observed.

1 INTRODUCTION

A diagnostic developed by the magnetic fusion energy community has been successfully utilized on the LEDA injector test facility[2] at Los Alamos. The technique was developed in the late 1970s at LBNL[3] as a means of determining the composition of neutral beams used to heat magnetic fusion plasmas. Extracted H^+, H_2^+, and H_3^+ interact with background gas to produce fast, excited hydrogen atoms with energies of E, E/2, and E/3, where E is the ion source extraction potential. By observing the beam at an angle relative to the direction of propagation, the Doppler-shift separates the light from the three species. The wavelength of the Doppler-shifted light is $\lambda = \lambda_0 (1 - \beta \cos \theta)$, where λ_0 is the unshifted wavelength, β = v/c, and θ is the angle between the viewing line of sight and the beam's direction of propagation. Beam composition is determined from the quantity of light associated with each Doppler-shifted line. Cross sections for Balmer-α (Hα) production from H^+, H_2^+, and H_3^+ incident on hydrogen gas have been measured[4], permitting a quantitative measure of the beam composition. In addition to the Doppler shift due to the differing β's, the light from each species is broadened due to cos θ. For small beam divergence, and neglecting broadening due to the instrument, the line shape is a direct measure of the velocity distribution. In principle, a quantitative measure of the divergence can be made[5]. Collisions of extracted water ions with the background gas produce excited hydrogen atoms with energy E/18, where E is the extraction potential. Water contamination becomes apparent at a level of <1%

Experiments carried out at Los Alamos have been a successful proof-of-principle test on a proton injector, even though photon fluences from the injector are orders of magnitude below that of large fusion ion sources. The photon production rate is proportional to the beam current, the background gas density, and the Hα production cross sections. While the current densities of fusion and APT ion sources are similar, fusion ion sources have much larger extraction areas. Fusion ion source currents are of order 100 A versus 100 mA for the LEDA/APT injector. Another significant difference is the background gas density. In neutral beam injectors, the goal is to convert the extracted ions into neutrals by collisions with background gas. For a proton injector, it is important to avoid proton loss via charge exchange to H^0. Near the ion source, the background gas density is ~10 times lower than in a fusion neutral beam injector. The net result is that the Hα production rate in a proton injector is ~10^4 times less than in a fusion neutral beam injector.

Several factors favor the proton injector. The APT ion source is cw compared to pulse-lengths of a few seconds for fusion ion sources; long integrations are therefore possible. Another advantage is that the neutralization and dissociation of the extracted ion beam, that takes place in the neutral beam injector before the beam reaches the observation point, occurs to a much smaller degree in a proton injector. The problem created by changing the state of the beam is that the Hα production cross sections are different for the daughters than for their parents. Therefore, the composition of the beam at the observation point must be known to deduce the composition at the extraction plane. Due to the low gas pressure between the ion source and observation point in a proton injector, a beam composed of H^+, H_2^+, and H_3^+ can be assumed.

Initial data collection occurred at 50 kV, during experiments supporting a 1.25 MeV cw radio-frequency quadrupole (RFQ)[6]. The RFQ for LEDA and APT has been designed to accept a 75 keV proton beam. A small amount of data was obtained after the ion source was regapped for operation at 75 keV.

2 DESCRIPTION OF THE HARDWARE

A complete Doppler-shift spectroscopy system[7] was borrowed from the Princeton Plasma Physics Laboratory (PPPL). It consists of a 135-mm Canon lens to focus collimated light onto a 600-μm glass fiber; an Instruments S.A. 640-mm Czerny-Turner spectrometer; a Princeton Applied Research Corp. vidicon detector; a detector controller; and a computer control console.

The beam was observed 34 cm downstream from the extractor as it exits the cone that follows the accelerator. The 7-cm exit diameter of the cone equals the 7-cm diameter of the light collection cylinder. At this location the 4-rms beam diameter is 2.2 cm. Since light is collected from the entire horizontal extent of the beam, all of x phase space is observed.

Each pixel in the 500x500 square detector is 25 μm. When integrating light from a 43-cm tall PPPL neutral beam injector, the slits of the spectrometer were set at 3 μm. In the present case, they were opened to 50 μm, providing additional light. Opening the slits beyond the 50-μm size of the pixels caused broadening of the lines and merging of the two molecular lines. 50 μm is a compromise between signal and resolution.

3 DATA AND ANALYSIS

Figure 1 is a spectrum obtained at 50 kV with 120 mA of ions measured at the first DC current toroid. (All quoted beam currents were measured with this toroid.) The viewing angle, θ, was 60°, the entrance slit of the spectrometer was 50 μm, and light was integrated for 16 s. Since the beam came towards the line of sight, the Doppler shift was in the blue direction. Left to right, the first three lines are the Doppler-shifted lines from incident H^+, H_2^+, and H_3^+. The rightmost, and tallest, line is unshifted Hα (656.3 nm).

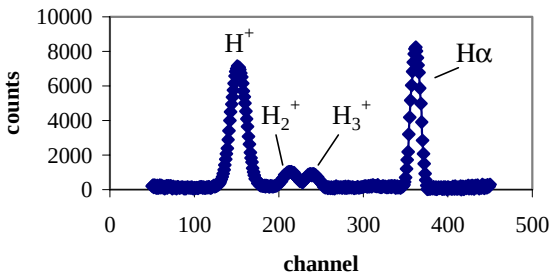

Figure 1. Spectrum at 50 kV and 120 mA with 50 mm slits.

Light falls on a portion of the height of the detector corresponding to the diameter of the fiber. Each channel was defined to be one pixel wide by 60 pixels tall (sufficient to include all pixels illuminated by the fiber). The wavelength corresponding to a particular channel can be determined by assigning 656.2 nm to channel 362 and using a dispersion of 0.016 nm/channel. The ordinate represents the number of counts detected in each channel.

Proton fractions were obtained by fitting the three Doppler-shifted lines to Gaussians. Error bars of ±3% for the proton fraction, 17% for H_2^+, and ±20% for H_3^+ are based on uncertainties of ±10% in calculating the line areas, ~±5% in cross sections[4], and assuming that the gas line density between the ion source and observation point could be as high as 1.5×10^{14} cm^{-2}.

4 RESULTS

Proton fractions have been measured for scans of the ion source microwave power and gas throughput. In both cases, the spectrometer and detector were operated in the as in figure 1. Figure 2 shows the results of scanning the 2.45 GHz microwave power to the source over the range of 500 to 1500 W while the beam energy and gas throughput were fixed at 50 keV and 2.22 standard cubic centimeters per minute (sccm). Beam current varied from 36 mA to 140 mA. Due to the wide range over which the beam current changed, the currents to the two electron cyclotron resonance (ECR) solenoids needed to be varied to maintain stable operation.

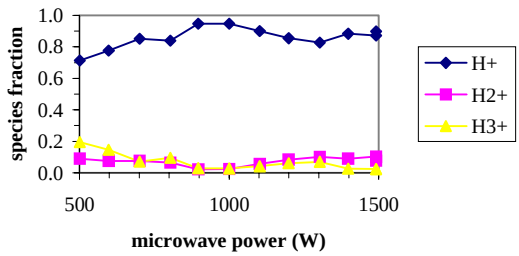

Figure 2. Beam composition as a function of microwave power.

Proton fractions of 0.95 ± 0.03 were found at 900 and 1000 W. These values agree with measurements made using an emittance measuring unit modified with a deflection magnet preceding the Faraday cup[2].

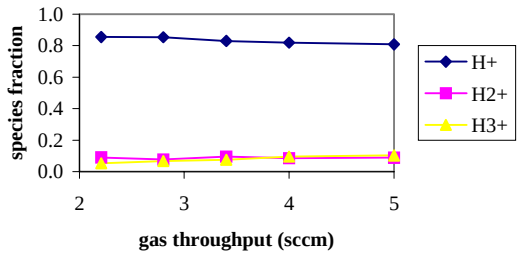

Figure 3. Beam composition as a function of gas throughput.

Figure 3 is the result of a scan where the gas throughput was varied from 2.2 to 5 sccm, at a constant

microwave power of 1000 W. As the throughput increased from 2.2 to 5 sccm, beam current decreased from 92 mA to 71 mA. As above, the currents to the two ECR solenoids were adjusted to maintain stable source operation.

It is important to note that the proton fraction corresponding to the 2.2-sccm data point in figure 3 (85%) does not agree with the 1000 W data point in figure 2 (95%). Source microwave power and throughput were the same in these two cases, but the proton fractions differ by 10%. Inspection of the raw data supports the measured difference. ECR solenoid settings were slightly different. This observation, together with the variations in figure 2, indicates that the proton fraction is sensitive to minor variations in ion source setpoints.

Figure 4 is a spectrum from 50 kV, 132 mA source operation. The source is operating above its design-matched perveance (110 mA at 50 kV). An important difference between the way this spectrum was acquired and all of those discussed so far is that the slit width was reduced to 20 μm.

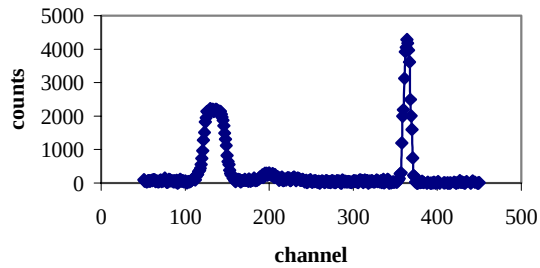

Figure 4. Spectrum taken at 132 mA with 20 μm slit width showing a non-gaussian proton peak.

Note the non-Gaussian shape of the proton line. Such a distribution is indicative of poor beam optics. In this case, it can be attributed to overdense beam extraction. Other data taken with 20-μm slits show a return to Gaussian shape as the current was reduced to 110 mA. The data taken with 50-μm slits is more Gaussian because the natural line width is convolved with a wider instrument function.

Data were also taken during several hours of ion source operation at 75 keV. Immediately prior to when this data was taken, the ion source was exposed to air for accelerator maintenance. The spectrometer slit width was back to 50 μm.

An interesting spectrum was noted and is shown in figure 5. Situated at channel 300 is a line due to hydrogen atoms extracted as water ions. The presence of significant water in the beam is attributed to the fact that the ion source was just beginning to be conditioned and that water became absorbed on the source walls during its exposure to air.

Cross sections for the production of Hα from water incident on hydrogen have not been measured. To estimate the water fraction, the required cross sections were estimated from cross sections for the production of Hα for hydrogen atoms incident on water[8].

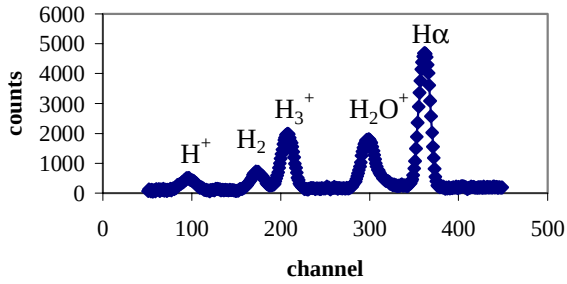

Figure 5. Spectrum at 75 kV, just after the ion source was open to air.

The proton fraction is estimated to be in the range of 30 to 40% while water is 40 to 25%, respectively. There is a large uncertainty in the beam fractions in this case due to the facts that protons are no longer the dominant line and that estimates of the water cross sections differ by a factor of two.

After approximately 10 minutes of cw operation, the water level in the beam decreased by over an order of magnitude. However, the proton fraction was still poor due to the low source power. Residual gas analysis of the injector vacuum always indicates the presence of water contamination for several days after exposure to air. Water in the ion source cleans up at a more rapid rate due to its active removal by the plasma and the beam.

ACKNOWLEDGMENTS

This work has been supported by the US Department of Energy contract DE-AC04-96AL89607. We would also like to thank the neutral beam operations group at the Princeton Plasma Physics Laboratory for the loan of the Optical Multi-channel Analysis system.

M. C. Scott, Continental Electronics Corporation, Dallas TX

Abstract

The 1700 MeV, 100 mA Accelerator Production of Tritium (APT) Proton Linac will require 244 1 MW, continuous wave RF systems. 1 MW continuous wave klystrons are used as the RF source and each klystron requires 95 kV, 17 A of beam voltage and current. The cost of the DC power supplies is the single largest percentage of the total RF system cost. Power supply reliability is crucial to overall RF system availability and AC to DC conversion efficiency affects the operating cost. The Low Energy Demonstration Accelerator (LEDA) being constructed at Los Alamos National Laboratory (LANL) will serve as the prototype and test bed for APT. The design of the RF systems used in LEDA is driven by the need to field test high efficiency systems with extremely high reliability before APT is built. We present a detailed description and test results of one type of advanced high voltage power supply system using Insulated Gate Bipolar Transistors (IGBTs) that has been used with the LEDA High Power RF systems. We also present some of the distinctive features offered by this power supply topology, including crowbarless tube protection and modular construction which allows graceful degradation of power supply operation.

1 POWER SUPPLY REQUIREMENTS

The High Voltage Power Supplies are required to convert standard AC distribution voltages to regulated HV DC power. The efficiency of this power supply was required to be greater than that of proven power supply technologies. The large number of power supplies required by APT implies that each power supply must be extremely reliable. Protection of the personnel who will service the power supply systems in the APT plant is of primary importance. Protection of the klystron from damage during a klystron arc is secondary to safety but still a crucial requirement. The humidity and temperature of the environment around the APT plant at Savanna River Site impose additional requirements on the power supply.

1.1 Performance

While over 100 of the klystrons in the APT plant will require a maximum of 17 A of current at 95 kV, the three klystrons which drive the RFQ of the accelerator will require up to 21 A at 95 kV. In contrast, the RFQ klystrons will make up approximately half of the klystrons in the LEDA RF systems. The function and reliability of all candidate power supply designs must first be proven out in the LEDA accelerator before they can be considered for the APT plant. In order for candidate power supply designs to gain significant testing time on LEDA, all candidate power supply designs must be capable of providing currents of up to 21 A at 95 kV.

The output voltage regulation was required to be within ±400 V around the setpoint and the ripple was required to be ≤1100 Vpp while the input line voltage varied ±5% and the input voltage phase unbalance was ≤3.8%.

The input voltage of this power supply design was required to be 4160 V three phase service. The power supplies were required to have a power factor ≥0.98 for all output voltage levels between -60 kV and full power and all current levels between 10 and 21 amps. The harmonic distortion of the current drawn from the input lines was required to meet IEEE Std 519-1992 specifications.

When operating at -95 kV and currents between 17 and 21 amps, the efficiency was required to be ≥97%. When operating between -80 kV and -95 kV and currents between 12 and 21 amps, the efficiency was required to be ≥96%. When operating at or between -60 kV and -80 kV and currents between 10 and 21 amps, the efficiency was required to be ≥95%. The requirements on efficiency are summarized in Figure 1.

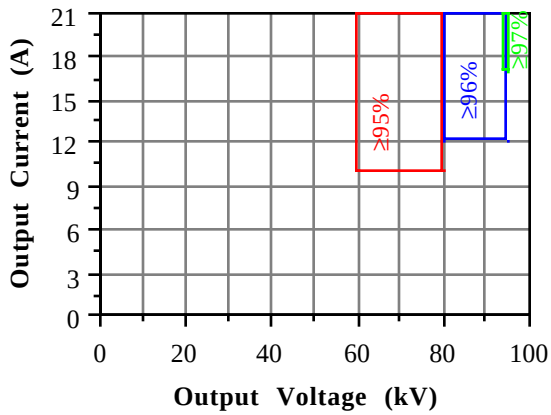

Figure 1: The efficiency requirements were specified over a range of currents and voltages.

1.3 Reliability and Maintenance

The goal for power supply Mean Time Between Failure (MTBF) was 25,000 hours. This goal was driven by the combination of the MTBF for all other components in each RF system and the large number of high power RF systems that will be required in the APT plant.

Serviceability was given consideration from the beginning the power supply design. The goal for the Mean Time To Repair (MTTR) of the supply was one hour or less to minimize the cost of maintaining the APT accelerator.

1.4 Safety and Klystron Protection

The Kirk® Key locks on the power supplies were required to integrate with the existing Kirk® Key lock system used in the existing LEDA High Power RF systems.

The power supplies were also required to meet all existing safety requirements at LANL including the requirement that debugging the low level power supply control circuits could be done without exposure to voltages in excess of 24 V.

The power supply was required to NOT use a crowbar but still limit the energy deposited in a klystron arc to less than 40 Joules and have a backup means of shutting off the power in the event that the principal system failed.

1.5 Environment

The environmental requirements were specified such that they covered both the expected environmental conditions at the Savanna River Site and the environmental conditions at LANL. The power supply was required to function over an ambient temperature range of 10°C to 32°C (50° F to 90° F) which was determined by the indoor location of the power supply. The power supply was required to function over a humidity range of up to 85% non-condensing which was chosen based on the environment at Savanna River Site. Finally, the power supply was required to function at an altitude of up to 2438 m (8000 feet) to allow it to be tested at LANL.

2 POWER SUPPLY DESCRIPTION

The design of the IGBT controlled Solid State Modulator High Voltage Power supply is based on the design of Solid State Modulators sold by Continental Electronics. Over 100 of these modulators are now in use and offer impressive AC to DC conversion efficiency.

2.1 Electrical Design.

The power supplies utilize 96 separate rectifying modules stacked in series. Each module is fed from an isolated secondary winding on one of four transformers as shown in Figure 1. The primary windings of each transformer are extended by different amounts to produce 24 pulse rectification at the power supply output.

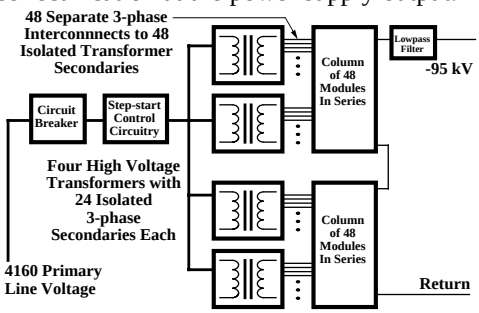

Figure 1: Two transformers serve each power column.

Each module uses an IGBT for current control as shown in Figure 2, eliminating the need for a crowbar. Each module also contains independent control circuitry to monitor the module output and inhibit the SCRs in the six pulse bridge in the event that an IGBT fails closed. Failed modules are bypassed by the control system to provide graceful degradation of operation. If more than five modules have failed, then the maximum voltage the supply can produce under the condition of 5% input voltage droop is reduced by roughly 1 kV per failed module after the first five.

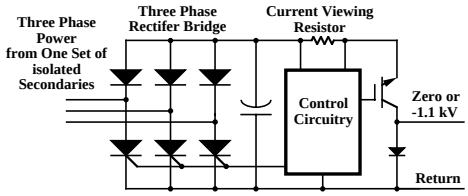

Figure 2: Each module contains independent control circuitry to disable the module in the event of module control failure.

2.2 Physical Structure.

The whole power supply is located behind a 6.1 by 5.5 m fence. Each module is contained on a removable circuit card. The circuit cards are arranged in the two power columns in four rows of twelve. This arrangement allows cooling air from fans at the bottom of the columns to be blown across each module. The columns support corona rings on each row to hide sharp edges on the modules from high electric fields and to grade the electric field as the potential increases toward the top of each column.

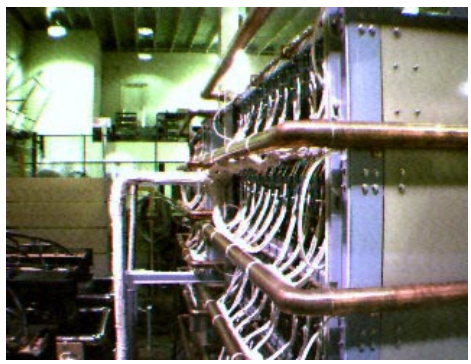

Figure 3: Each module is connected to a unique isolated 3-phase secondary on one of the four transformers.

The backplanes of the power columns contain connections to the 24 isolated 3-phase secondaries on each of the four transformers as shown in Figure 3. The backplanes also contain the shorting mechanisms that insure that all modules are shorted out before the fence is opened when the power supply is to be serviced.

2.3 Mean Time Between Failure and Mean Time To Repair

The MTBF was calculated after the design was finalized. The power supply was designed such that up to five modules could fail before the supply's ability to produce 95 kV under the conditions of a 5% input voltage droop was impaired. A block diagram of the method used to calculate the MTBF is shown in Figure 4.

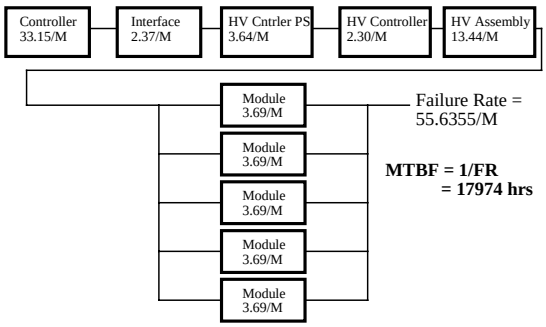

Figure 4: The total MTBF for the supply was calculated from published MTBF data for each component in the power supply.

The power supply was designed with serviceability in mind. A 44 minute MTTR was achieved in part by designing the power columns such that it possible to remove and replace any modules in the power columns without the use of tools once the Kirk® Key locked fence has been opened and the columns have been grounded.

3 ACCEPTANCE TEST RESULTS

Acceptance testing of the power supply is done in two parts. Almost all required functions of the power supply (including output power quality, safety systems and klystron protection systems) are tested at the vendor's facility before the power supply is shipped. The testing of power supply efficiency and a full power heat run is done at LANL due to the availability of a 95 kV, 2 MW resistive load at the LEDA facility.

Three of these power supplies are on order from Continental Electronics. The first has passed its factory acceptance tests and is being shipped to LANL.

3.1 Factory Acceptance Test Results

All methods of triggering the Fast Shut Down Mode (FSDM or the equivalent of a "crowbar") were tested successfully. The power supply shut down quickly enough to prevent a 0.614 meter long 35 gauge copper wire (40 Joules) from melting placed across the high voltage output. This test was performed 192 times at full voltage over a period of 48 hours. Calculations made of the energy deposited in the wire indicate that the energy that will deposited into a klystron arc will be less than 10 Joules when the power supply is operating at full voltage and current.

The power supply was tested into a 640 Ω load at 21 A for 48 consecutive hours. During this test a heat wave combined with an air conditioning failure at the vendor's facility caused the ambient temperature and humidity rise above the maximum specified levels. Despite the extreme temperature, the full current test was passed without failure. Figure 5 shows the core temperature of the first transformer during this run. The time required to reach a relatively constant core temperature was approximately ten hours, significantly less than the length of the 48 hour test..

The harmonic content of the input current during the 21 A output current tests showed magnitudes that were all below 20 dB down from the 60 Hz fundamental. While all of these values are significantly below the maximum allowed values of IEEE Std 519-1992, these measurements will be taken again at LANL where the test can be repeated with loads in the MW level. The utility connections at LANL are also expected to provide a more realistic source impedance to the supply.

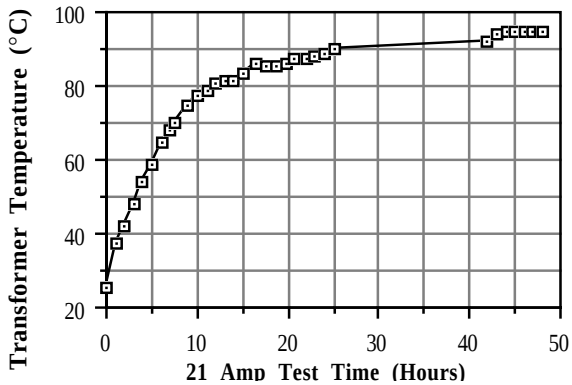

Figure 5: Transformer core temperature while running at 21 Amps in an ambient temperature of greater than 38° C.

3.2 Final Acceptance Tests

The final acceptance tests will be performed at LANL where a 2 MW, 95 kV resistive load is available. The power supply is being shipped to LANL for installation. Final acceptance tests will take place in September, 1998.

4 CONCLUSIONS

The first IGBT Controlled SSM High Voltage Power Supply has successfully passed the factory acceptance tests. This power supply is being shipped to LANL for final acceptance tests. Final acceptance tests will include measurement of efficiency at output power levels in the MW range and more detailed measurements of the input current harmonic content.

THE COLD MODEL OF THE CDS STRUCTURE

V.V. Paramonov, L.V. Kravchuk, V.A. Puntus
Institute for Nuclear Research, 117312, Moscow, Russia

Abstract

The Cut Disk Structure (CDS) was proposed as the compensated accelerating structure for high energy linacs. Cold rf model was manufactured to examine CDS parameters, partially for S-band electron linacs. In agreement with design parameters, coupling coefficient near 22% was obtained together with high shunt impedance. Results of experiments are presented.

1 INTRODUCTION

The Cut Disk Structure (Fig. 1) was proposed [1] as the result of investigations for coupling coefficient k_c increasing in compensated accelerating structures. Results of numerical simulations [1], [2] have shown attractive features of the structure - high k_c value together with high effective shunt impedance Z_e. Nine cell $\beta = 1$ cold model with operating frequency $f_0 = 2450$ MHz was produced to proof CDS design parameters for high β region.
This paper describes CDS design parameters, rf model, tuning procedure and results of experiments.

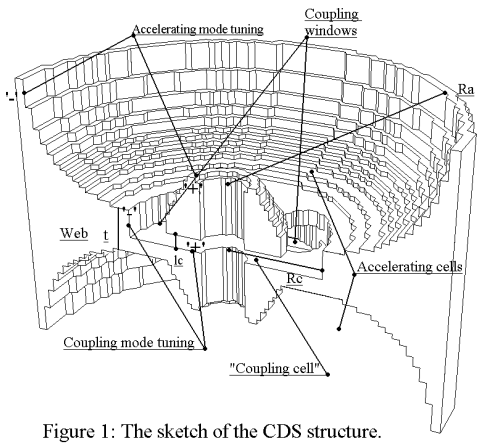

Figure 1: The sketch of the CDS structure.

2 THE CDS PARTICULARITIES

Instead of CDS is very similar outwardly (Fig. 1) to On-axis Coupled Structure with coupling slots, it realise another idea. In CDS accelerating mode is distributed in accelerating cell of usual Ω-shape with distributed electric and magnetic fields. For coupling mode electric field is concentrated in the short space between half tubes (in "coupling cell", Fig. 1), but main part of magnetic field is distributed in the volume of accelerating cell. It results in strong overlapping for magnetic fields of coupling and accelerating modes and high k_c [2],[3] value. In CDS coupling windows serve as real 'window' trough which main part of magnetic field for coupling mode penetrates in the volume of accelerating cells and some conclusions, based on extensive experience with coupling slots, are not correct for CDS. For example, k_c is practically not sensitive to the thickness of window. For $\beta = 1$, $f_0 = 2450$ MHz increasing of the window thickness from 3.5 mm to 6 mm (and total increasing of the web between accelerating cells from 10 mm to 15 mm) k_c reduces only from 22% to 19%. The frequency shift for accelerating mode due to coupling windows is also smaller than for slot coupled structures.
May be several (2,3,4...) coupling windows at one side of the cell. The dependencies k_c on total windows opening are shown in (Fig. 2a) together with plots for calculated Z_e (Fig. 2b). At (Fig. 2b) Z_0 is the effective shunt impedance of solid accelerating cell without any windows. For small k_c values $Z_e > Z_0$ [2] and for every β there exists such k_c^0 value when calculated $Z_e = Z_0$. Due to increasing of the volume for accelerating cell with β increasing, k_c^0 decreases from $\approx 30\%$ at $\beta = 0.4$ to $\approx 22\%$ at $\beta = 1$.

3 CDS MODEL

3.1 Design parameters

As in all Coupled Cells (CCL) structures with Ω-shaped accelerating cells, Z_e value for CDS decreases with increasing of the web thickness t between accelerating cells. As an example, at (Fig. 3a) 2D calculated plots of Z_e are shown for "electron" CCL option (aperture diameter 10 mm, nose cone radius 2.0 mm). At (Fig. 3b) plots for normalised (to Z_{emax} at zero web thickness) are shown. (For "proton" CCL option Z_e reduction at low β with t increasing is

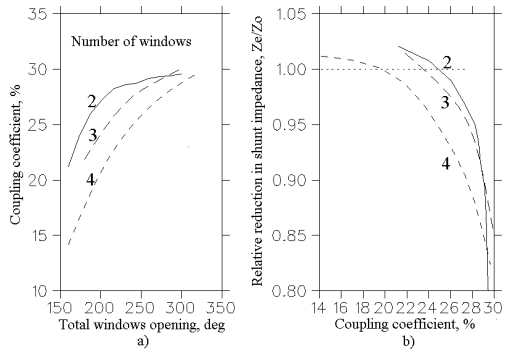

Figure 2: Parameters of the CDS structure

not so drastic.) In the CDS design we allow Z_e reduction due to increased web thickness hoping this reduction be compensated with CDS particularities (Fig. 2) and resulting Z_e value will be not less than for another CCL structures, which loose Z_e with k_c increasing. The shape of accelerating cells was 2D optimised for accelerating gradient $E_0T = 10.0$ MV/m to have $Z_{e2D} = 89.7$ MOhm/m, $Q_{2D} = 17900$. The web thickness $t = 10$ mm.

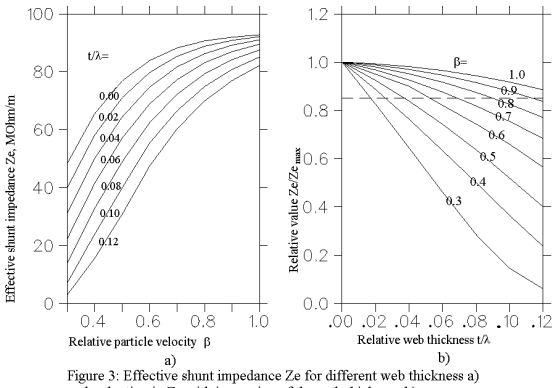

Figure 3: Effective shunt impedance Ze for different web thickness a) and reduction in Ze with increasing of the web thickness b).

3.2 The model description

The cold CDS model was manufactured from aluminum alloy to simplify the manufacturing procedure. The units of the model have been manufactured in INR with using reliable, but usual (not numerically controlled) equipment. Enough soft tolerances (not stronger than $\pm 50\mu$) were accepted for essential dimensions of the structure - dimensions of "coupling cell", coupling windows and accelerating cell. The radius of accelerating cell R_a and the length of "coupling cell" l_c (see Fig. 1) were reduced with respect to design values to have ≈ 50 MHz reserve for rf tuning.

The model contains nine periods of the structure. The termination of the model is with two plates in the middle of end accelerating cells. In each period of the structure there are two caps. Joint between caps (the place of rf contact) are in middle-planes of accelerating and "coupling cells". To reduce quadruple perturbation of accelerating field by coupling windows, at opposite sides of accelerating cell windows are placed face-to-face. Because rf properties of material are not known well, to have information about quality factor Q, special reference cylindrical cavity was manufactured from the same material, at the same equipment, with the same requirements, with the same length $\beta\lambda/2$, with the same number of rf joints.

The usual equipment was used to provide rf and bead-pool measurements. As the bead-pool the aluminium sphere 3 mm in diameter was used.

3.3 Tuning procedure

As usual, tuning of compensated accelerating structure should have three procedures:
- tuning of the accelerating mode frequency f_a to f_0 one;
- tuning of the coupling mode frequency f_c to confine with f_a (closing of the stop-band);
- tuning of the accelerating field distribution (if needed).

During the mode frequencies tuning there were no tuning of individual cells. Both for accelerating mode tuning and coupling one the change in dimensions was the same for all cell in the section. But after each step of the frequencies tuning the frequencies of accelerating mode and coupling one were determined by measuring frequencies of two 0 type and one π type modes in the assembly from two caps terminated with end plates. It was just for purpose of investigation.

The accelerating mode frequency tuning in CDS do not differs from the same procedure in another CCL and may be performed by R_a increasing (decreasing of f_a) or drift tube shortening (increasing of f_a) (Fig. 1). Starting f_a value was 2598 MHz and f_a tuning has been performed in three steps. Two steps (draft) were done by increasing of R_a value to achieve $f_a = 2451$ MHz. Because this kind of f_a tuning is soft enough ($df_a/dR_a \approx 45$ MHz/mm), there were no problems. Last step of f_a tuning was done after f_c tuning by providing narrow circular ditch at the spherical surface of accelerating cavity.

Due to big k_c value, direct determination of the coupling mode frequency both for each cell and for total section, which is reasonable in usual CCL structures, provides big error $\Delta f_c \approx f_c k_c^2/2$. The coupling mode frequency f_c tuning is based on our experience in the tuning of Disk and Washer accelerating structure. In all compensated sturcures the stop-band width $\delta f = f_a - f_c$ may be determined [4] as:

$$\delta f = \frac{\Delta F_m - \Delta F_n}{m^2 - n^2}, \Delta F_m = f_m^+ + f_m^- - 2f_0, \qquad (1)$$

where f_m^+ is the mode frequency of $\frac{(N-m)\pi}{N}$ type at the top branch of dispersion curve (Fig. 4), and f_m^- - at the bottom one.

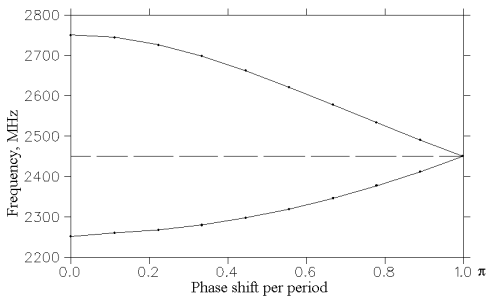

Figure 4: Dispersion curves for operating passband (experiment).

The coupling mode frequency tuning in CDS may be performed by R_c increasing (decreasing of $f_c, df_c/dR_c \sim$ 30MHz/mm) or by increasing the gap between half drift tubes l_c (increasing of $f_c, df_c/dl_c \approx 285$ MHz/mm) (Fig. 1). Starting f_c value was 2413 MHz and f_c tuning has been performed in two steps. The first step (draft) to achieve $f_c = 2447$ MHz was done by increasing of l_c value at total area of "coupling cell". Because this kind of f_c tuning is not soft, the second step has been performed by providing washer-type ditch in the space between half drift tubes. For coupling mode in CDS the tuning procedure should be under special attention.

In this study no efforts have been performed to tune accelerating field distribution, because coupling windows in this model should be identical. The mutual orientation of caps, to fix mutual orientation of windows, has been controlled with maximum deviation not more 0.25^o.

4 RESULTS OF EXPERIMENTS

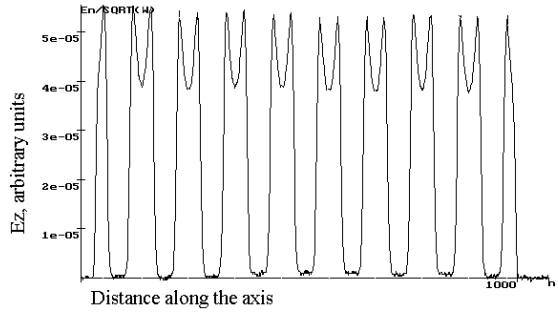

Figure 5: Electric field distribution along the axis of the model

After the model tuning, operating frequency $f_0 = 2450.1$ MHz, the stop-band width $\delta f = 400$ kHz (relative value $\delta f/f_0 = 1.9 * 10^{-4}$) were obtained. The relative values for standard deviation for frequencies of accelerating cells σ_{fa}/f_0 and "coupling cells" σ_{fc}/f_0 are $1.63 * 10^{-4}$ and $1.42 * 10^{-3}$ respectively. This σ_{fc} value is due to only soft tolerances for "coupling cell" dimensions. The measured dispersion curve is shown at Fig. 4 and calculated with this curve the coupling coefficient value $k_c = 22\%$ confirmed the designed one. In spite of one can look through the structure (there is overlapping of windows), the CDS has practically "ideal" shape of the dispersion curve. The fitting with the standard five parameters lumped circuit model shows neighbour coupling coefficients k_1 and k_2 being practically zero. Nearest high order modes of TE_{11n}-like type are placed at frequencies ≈ 3670 MHz with the passband width ≈ 160 MHz. The experimental results for spectral parameters of the CDS model confirm fine the design values.

The electric field distribution as the result of bead-pool measurements is shown at Fig.5. and exhibits the standard deviation value $\sigma_E = 1.05\%$. The main part in σ_E contribute deviations of k_c, because contribution due to deviations in frequencies of cells σ_{ef} is estimated as $\sigma_{ef} \approx 0.12\%$ for k_c, σ_{fa}, σ_{fc} and δ_f given. The measured value of the quality factor for aluminium model $Q_{eCDS} = 7880$, and for cylindrical reference cavity $Q_{eref} = 9850$. Taking into account additional rf losses in two end walls (42% from rf losses in one CDS period) and assuming 2D calculated Q factor for the solid copper reference cavity $Q_{cref} = 19400$, we are expecting Q for solid regular copper CDS structure as $Q_{CDS} \approx 16240$. The calculated from bead-pool measurements R/Q value is $(R/Q)_e = (3.6 \pm 0.07)$ kOm/m, in good agreement with calculated by using 3D MAFIA $(R/Q)_c = 3.625$ kOm/m. Together with transit time factor $T = 0.861$ for solid regular copper CDS we obtain $Z_e \approx 85.5$ MOm/m, 95% from 2D calculated one. This value do not takes into account the surface imperfectness and possible rf contacts, but is not less in comparison with another CCL structures (with low coupling) and confirm that CDS practically do not lose in shunt impedance due to strong coupling.

5 CONCLUSION

The results of experiments with 9-period $\beta = 1$ cold model of the CDS structure confirm parameters as high coupling ($k_c \approx 22\%$) and high effective shunt impedance. Another attractive CDS features are in simple design, manufacturing and tuning procedures, small transverse dimensions.

As the results of experiments, recommendation for CDS design and manufacturing procedure improvements are developed. The treatment of "coupling cells" and windows regions should be careful.

With the combinations of these parameters, CDS looks as very attractive structure for electron and high energy proton linacs. The study of the structure continues for medium β in investigation of the structure cooling, possibility of multipactoring, accelerating field "quality".

Abstract

In the design of JHF linac, the beam needs to be chopped for the injection into the following rapid-cycling ring. The chopper has been decided to locate in the 3-MeV medium-energy transport line between the RFQ and the DTL. A 324-MHz RF deflector (RFD) is adopted as a fast beam-chopper for its various merits, such as compactness and high deflecting field, which benefit for an efficient deflection of the beam within a short beam line. In the application of an RF deflector for an intense-beam linac, the beam loss in the transient time is a major concerned issue. The shunt impedance should be as large as possible to make the cavity to be powered by a commercially available solid RF source. An RFD cavity is designed by the HFSS code to have a very low loaded-Q value of about 10 by means of two large coupling loops, and meanwhile to keep the higher order modes sufficiently far away from the deflecting mode. An aluminum cold- model cavity was made for a test. In this paper, the design, simulation and the test results are described in detail.

1 INTRODUCTION

The JHF 200-MeV linac provides a H^- beam of 30 mA–60 mA peak current for injection into the following 3-GeV rapid-cycling ring[1]. A beam chopper must be used in the linac in order to produce a pulsed beam with a pulse length of 278 nsec and a pulse separation of 222 nsec. This chopper is located in the 3-MeV medium-energy beam-transport line (MEBT) between the 324-MHz RFQ and DTL[2]. As a high-current linac, beam-quality preservation and beam-loss control are of superior importance in the design. The MEBT should be short so as to avoid emittance growth, since the beam energy is low. An RF deflector (RFD)[3] was chosen as the chopper cavity owing to its compactness and high deflecting field. A fast rise/fall time is a fundamental requirement for the RFD to minimize the beam losses due to partial deflection to the beam during the transient time. This can be achieved in an RF cavity with a very low loaded Q value. On the other hand, a high transverse shunt impedance is pursued in the design in order to keep the RF power demand from a solid RF source within a reasonable range.

In this paper, a design study of the RF deflector cavity is presented. We first give the cavity simulations by MAFIA[4] and HFSS[5] codes in order to show the detailed design investigation in the geometry needed to meet the requirements mentioned above. Then the measurements of a cold model cavity are presented and shown to have a good agreement with the code simulation and a satisfactory result for our purpose.

2 CAVITY DESIGN STUDY

The RF deflector cavity is operated in a TE_{11}-like mode with two electrodes, as shown in Fig.1. A transverse electric field oscillating at 324 MHz between the two electrodes deflects the beam bunches away from the beam axis to a beam dump downstream during the beam-cutoff time of 222 nsec.

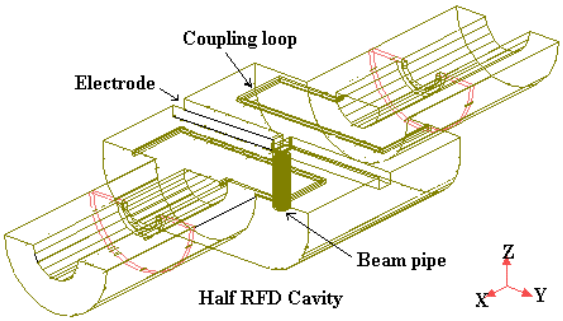

Fig.1 RF deflector cavity with large coupling loops.

One of the design target of the cavity is a high value of Z/Q_0, while keeping in mind the beam dynamics limitation. Here, Z is the transverse shunt impedance and Q_0 the unloaded Q value. In order to achieve a very short rise/fall time, the cavity will be heavily loaded by two coupling ports. In this case, the power demand from a solid RF source for operating the cavity becomes very high. To minimize the power demand P, a large value of Z/Q_0 should be pursued according to the approximate relation

$$P \cong \frac{V^2}{\omega_0 \tau (Z / Q_0)} \quad , \qquad (1)$$

where V is the deflecting voltage, ω_0 the oscillation frequency and τ the rise time.

2.1 Geometry of the electrode region

The ratio Z/Q_0 is determined by the equivalent capacitance C according to the relation

$$Z/Q_0 = \frac{1}{\omega_0 C} \quad . \qquad (2)$$

* On leave from China Institute of Atomic Energy

The C for the mode is mainly dependent on the geometry of the electrode gap region. Therefore, the parameter choice around this region must be carefully made.

The fringe fields of the electrode along the beam axis should be taken into account in the beam dynamics to calculate the effective deflection. To avoid an inverse deflecting effect of the high fringe field, the length of the electrode along the beam axis should not be equal to, but less than $\beta\lambda/2$, with β being the relative speed of a particle (v/c) and λ the free-space RF wavelength. To determine the length, MAFIA runs were conducted and the electromagnetic field distribution from MAFIA was used in a modified TRACE3-D[6] for beam-deflection tracking. The result showed that the length of the electrode should be slightly less than $\beta\lambda/2$. In this way, Z/Q_0 is larger (due to smaller C) and the high fringe field beside the electrodes can work in phase with the field in the central part of the electrodes, while keeping the effective deflecting length long. It was concluded that the electrode length along the beam axis should be 29 mm. Furthermore, the fringe field between the electrodes and the cavity wall needs to be sheltered so as to minimize its inverse effect. A beam-deflection simulation of a cavity without beam pipes showed that the net deflection is less than half that in a cavity with beam pipes. Therefore, two beam pipes are added beside the electrodes with 5.5 mm gaps between the pipes and the electrodes.

Of course, the two electrodes should be as close as possible to generate high deflecting field between them. This gap is, however, limited by the full beam size. The beam envelope from TRACE3-D suggests that the gap should be around 10 mm in order to guarantee no particle losses on the electrodes.

Also, the size of the electrode in non-deflection direction should be small in order to obtain a large Z/Q_0 value. Again, the beam envelope sets the minimum limit. The necessary size is 20 mm according to TRACE3-D simulation on beam size and the MAFIA result concerning the field distribution.

2.2 Cavity shape optimization

After the electrode size has been decided, the other dimensions of the cavity is then further optimized for the value of Z/Q_0 to be as high as possible. Since two RFD cavities will be cascaded in the beam line, the cavity should not be too long along the beam axis, due to a lack of focusing to the beam in this space, which may result in a beam emittance increase. Taking all of these factors into account, MAFIA runs suggested a cavity of 324 MHz with Z/Q_0= 437 Ω. It can be estimated from Eq.(1) that the demanded power from an RF source is reasonably about 27 kW (more accurately, HFSS gives the power of 22 kW in the next subsection) to generate a necessary deflecting field of 1.6 MV/m if a rise time of 10 nsec is assumed. Such a fast rise time indicates that the loaded Q of the cavity should be decreased down to about 10.

2.3 Cavity design with a very low loaded Q

The use of two large input/output loops is an easy option to realize a low loaded Q. A loop-coupled cavity was redesigned using the HFSS code on the basis of the previous design by MAFIA, provided that the electrode region maintains the same geometry. A modification to the cavity shape is necessary because of the introduction of large loops into the cavity, which shift the cavity resonant frequency due to the additional inductive reactance.

Two large loops with the same size are inserted into the cavity. The loops are connected to a coaxial transmission line of 50 Ω. To reach such a low loaded Q value, the size of the loop is 75×218 mm in the surface with the maximum flux. An HFSS simulation gives the S parameters, S_{21} and S_{11}, versus the frequency, as shown in Fig.2. From the figure, it can be found that the resulting Q_L is about 10, assuming it is given by the whole frequency width, Δf (31 MHz), at 70% maximum value.

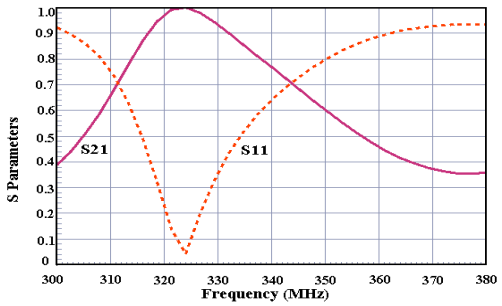

Fig.2 S-parameters from the HFSS for the cavity with Q_L=10.

The two loops of the same size are placed asymmetrically with respect to the middle plane. This induces a spectrum asymmetric with respect to the central frequency: the high-frequency side is wider than the other side, as depicted in Fig.2. It thus helps to reach a larger Δf. On the other hand, it also makes the fundamental mode to be close to and mix with the higher mode. To avoid such a problem, the loop should not be too deeply inserted into the cavity. It must keep a sufficient distance between the loop and the electrode in order to insure that the electric field between them remains extremely low. We thus increase the other dimension of the loop to a very large value (i.e. 218 mm) so as to guarantee a sufficient coupling as well as a wide mode separation.

HFSS simulations also showed the dependence of the large coupling on the diameter of the coaxial transmission line. A large coaxial line of WX-152D was adopted for the input/output of the cavity, resulting in a

loaded Q of 10. However, the loaded Q became 17 if a coaxial line of WX-77D was used.

The variation of the deflecting field (Ey) in three directions calculated with HFSS is plotted in Fig.3. The original point corresponds to the center of the cavity. The beam radii in x and y directions are both less than 5 mm according to the TRACE3-D result. It can be observed from the figure that the field has no obvious variation within the beam-size region, and hence that the beam can be deflected by a field having the same magnitude. HFSS gives Ey=1.6 MV/m in the deflecting gap when the input power is 22 kW.

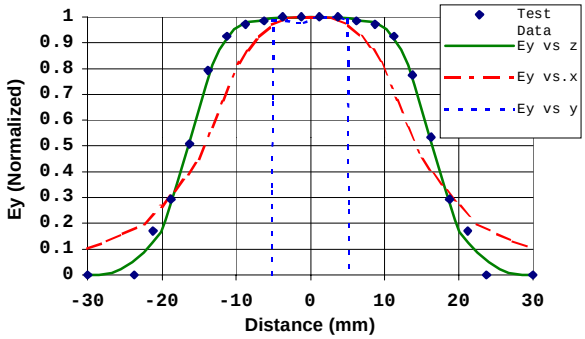

Fig. 3 Ey field distribution in three directions (test data is in the z-direction).

3 COLD MODEL TEST

An aluminum cold-model cavity was manufactured according to the design by HFSS. A series of measurements were conducted to check the applicability of the design.

A direct measurement of the rise time was performed by means of a digitizing oscilloscope with the result shown in Fig.4. It indicates that the rise time (Delta T) is 18.3 nsec, which includes about a 9 nsec contribution from the pulsed RF signal source. The effect of the transient time on the beam dynamics is discussed in Ref. [2], in which an improved method is proposed for the cavity, and the unstable particles are estimated.

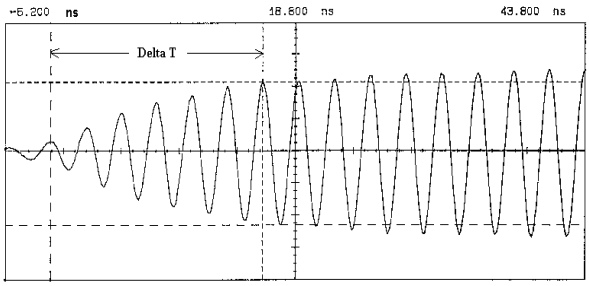

Fig.4 Measured rise time (Delta T) of the RFD cavity.

Network Analyzer depicted the scattering parameter S_{21} versus frequency in Fig.5. It gave a loaded Q of 9.7 and a resonance frequency of 324 MHz. The results are well concordant with the HFSS simulation. Some small coupling loops were prepared for a test of the dependence of the loaded Q on the size of the loops. For example, when the loops size became 65×218 mm, the loaded Q increased to 23. With two very small coupling loops, the loaded Q equaled 1463 and S_{21} was –2.18 dB. The unloaded Q was deduced to be 6580.

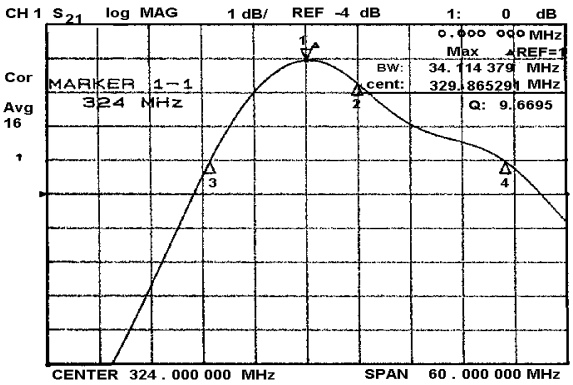

Fig.5 Spectrum of S_{21} showing the Q_L=9.7.

The field pattern in the deflecting gap was measured with a pulling bead of 5 mm in diameter. In Fig.3 the measured deflecting field (Ey) along the beam axis (z direction) is dotted. It shows a good agreement with the calculation result from HFSS.

Since the cavity is heavily loaded with a very wide spectrum, it is possible to operate it without a tuning device. To verify the temperature dependence of the resonance frequency, the cavity was heated. It was found that the cavity has a frequency shift of 60 KHz when the temperature rises up to 10°C.

CONCLUSIONS

A 324-MHz RF deflection cavity used for JHF linac was designed and a cold model was tested with satisfactory results. The measurement gives a loaded Q of about 10, which is necessary for a fast rise/fall time. The test results are in good agreement with the design calculations with MAFIA and HFSS. To meet the deflection requirement, the cavity with a loaded Q of 10 requires an input power of 22 kW according to HFSS.

DESIGN OF AN OGIVE-SHAPED BEAMSTOP

Los Alamos National Laboratory, New Mexico

Abstract

This paper addresses the evolution, design, and development of a novel approach for stopping cw (continuous-wave), non-rastered proton beams. Capturing the beam *in vacuo* within a long, axisymmetric surface of revolution has the advantages of spreading the deposited energy over a large area while minimizing prompt neutron backstreaming and reducing shield size and mass. Evolving from a cylinder/cone concept, the ogive shape avoids abrupt changes in geometry that produce sharp thermal transitions, allowing the beam energy to be deposited gracefully along its surface. Thermal management at modest temperature levels is provided with a simple, one-pass countercurrent forced-convection water passage outside the ogive. Hydrophone boiling sensors provide overtemperature protection. The concept has been demonstrated under beam conditions in the CRITS (Chalk River Injector Test Stand) facility at Los Alamos.

1 INTRODUCTION

The Accelerator Production of Tritium (APT) program [1] requires several commissioning beamstops [2]. This paper discusses the first of these, which will be used to commission the Radio Frequency Quadripole (RFQ) and the first Coupled-Cavity Drift Tube Linac (CCDTL sections in the Low Energy Demonstration Accelerator (LEDA) presently being built at LANL (Los Alamos National Laboratory) [3]. The first LEDA beamstop must accommodate a 0.1 A proton beam in cw operation at energy levels of up to 6.7 MeV. Early studies showed that conventional beamstop approaches (e.g., plate-type with beam rastering to distribute the heat) would result in a large, costly, immobile installation with significant radiation back-streaming issues—attributes which would severely complicate the job of developing and maintaining the Linac. These issues are addressable with an approach that minimizes the projected area (footprint) presented by the beamstop normal to the beam.

Eliminating rastering reduces this footprint to that of the beam spot size, but requires management of sharply higher energy fluxes imposed by the Gaussian beam. The circular spot shape of the beam suggests a conical impact surface for the beamstop, a concept which has been successfully used on other Linac applications.

Even smaller orthogonal footprints result when the conical geometry is combined with an upstream cylindrical scraper section that exploits the divergent qualities of the beam to spread the heat distribution. The conical end section then would capture the central portion of the beam while the wings of the Gaussian distribution are deposited in the cylindrical section. The cone/cylinder beamstop proportions are governed by the practical combination of radius and length that captures the beam within a minimum radius without spillage. This typically results in a long, thin structure, with a re-entrant configuration that inherently minimizes both the back-streaming potential and the radial shield thickness requirement. The circular cross-section also minimizes edge effects which could produce hot spots. However, the abrupt cone/cylinder intersection creates a sharp thermal gradient that needs to be smoothed out. The graceful, continuous inflection obtained by replacing the cone/cylinder with an ogive shape is a logical solution to this problem.

The ogive shape addressed here is generated by revolving a circular arc about a centerline to produce a surface of revolution, as shown in Figure 1. The ogive

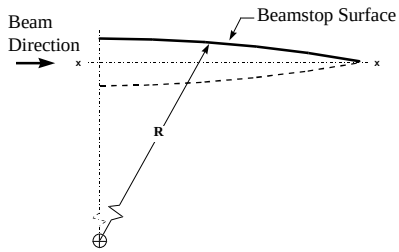

Figure 1: Ogive Shape

contour adjusts the angle of incidence as needed to accommodate the variable power density of the diverging beam: the greatest angles occur where the power density is lowest, and vice versa, resulting in a smooth, relatively mild heat flux profile on the beamstop surface.

2 DESIGN CONSIDERATIONS

Table 1 summarizes the LEDA beamstop design, which is based on the ogive concept.

Table 1: LEDA Beamstop Design

BEAM CHARACTERISTICS	
Energy x Current	6.7 MeV x 0.1 A, Gaussian
Operation	1 Hz to cw (~ 6 mos. At cw)
PHYSICAL FEATURES	
Overall Dimensions	~ 109-in Height x 133-in Length
Beam Centerline Height	72-in
Target Geometry	Axisymmetric; Tangent Ogive
Target Dimensions	6-in ID x 92-in L x 0.1-in Thick
Target Material	Electroformed Nickel
Coolant	Water outside (vacuum inside)
Coolant Flow Arrangement	1-Pass Forced Convection, Counterflow to Beam Direction
Neutron Shield	Water
Neutron Shield Tank Material	Aluminum
Gamma Shield	1-in Lead Wall on Upstream Face
THERMAL MANAGEMENT	
Heat Removal	670 kW
Peak Heat Flux	212 W/cm^2 incident to surface
Peak Wall Temperatures	275 F water; 430 F beam
Water Conditions	305 gpm, 60 F/75psig in; 35 psid

The ogive beamstop is integrated into a simple, replaceable water-cooled cartridge that connects directly to the upstream beam pipe. In the arrangement shown in Figure 2, a flow shroud around the ogive creates an annular passage for once-through, forced-convection water cooling.

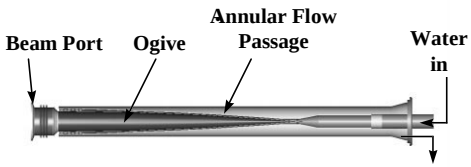

Figure 2: Ogive Beamstop Cartridge

The shielding advantages of the ogive approach are evident in Figure 3, which presents a cutaway view of

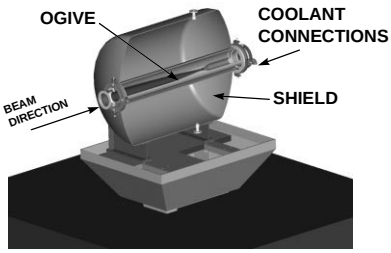

Figure 3: Integrated Beamstop Arrangement

the integrated beamstop assembly. The deposition of the beam energy deep within the small-diameter ogive makes it possible to have a near-4-pi, minimum-size neutron shield. The gamma shield wall is not shown.

2.1 Thermal Management

The thermal design is based on the quasi-Gaussian beam characteristics predicted for the LEDA linac, including the location and severity of hot spots produced by beam focus and steering errors. Figure 4 shows the mild axial heat flux and waterside temperature profiles predicted for the 6.7 MeV LEDA ogive at the nominal operating condition. The beam direction is from left to right.

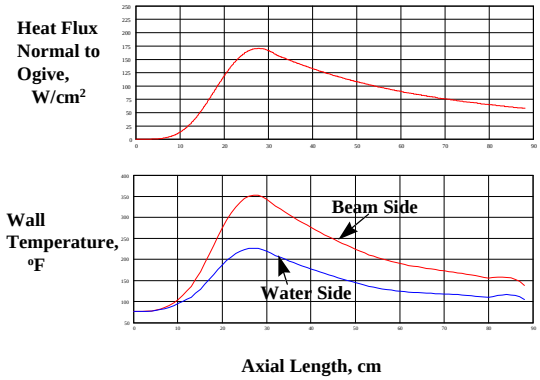

Figure 4: The heat flux normal to the ogive surface is about 1/30th of that normal to the beam cross-section, resulting in modest temperatures.

The thermal design is based on cooling with high-velocity water flow under sufficient static pressure to suppress boiling. Since the flow passage near the tip of the ogive is a venturi, care must be taken to ensure that the static pressure in this region will remain above the boiling limit.

2.2 Structural Design

The ogive structural analysis considered buckling, flow-induced vibration, thermal stress due to heat flux, thermal bowing due to misaligned beam, and the potential for thermal/flow feedback instability. Figure 5 is an example of the analytical sophistication needed to confirm structural adequacy.

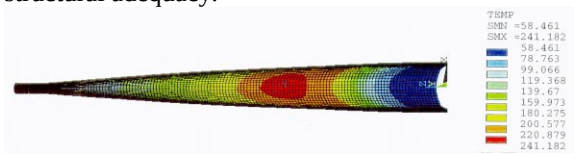

Figure 5 : Temperature Distribution of Ogive Coolant for One Case of Beam Misalignment

3 DEVELOPMENT

Although the LEDA beamstop has not yet gone into service, valuable experience has already been obtained on the fabricability and performance of the ogive concept.

3.1 CRITS BeamstopTesting

By happy coincidence, an adjunct proton Linac program at LANL urgently needed a new beamstop just as the LEDA design was being finalized, affording the opportunity to test out the ogive concept under actual cw, beam-on conditions similar to those of LEDA, but at reduced power levels. The water-cooled copper 6.5-in ID x 42-in long ogive, shown in Figure 6, was designed to accommodate a 1.25 MeV proton beam at 75 mA. With a proton energy well below the

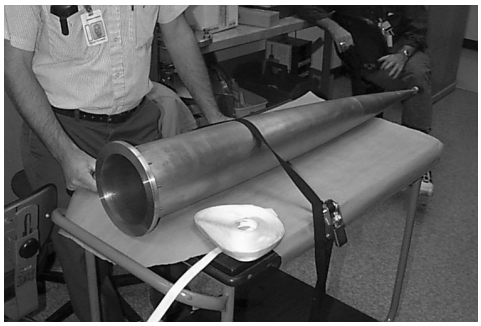

Figure 6: CRITS Ogive

2.2 MeV neutron activation threshold for copper, neutron shielding was not required. The ogive easily met design performance, permitting the CRITS linac to reach the highest cw 1.25 MeV beam power ever demonstrated [4]. During this testing, calorimetry performed on the ogive cooling water circuit helped verify the beam power measurements. The excess cooling capacity in the beamstop design defeated attempts to confirm the functionality of the hydrophone boiling sensors installed on the ogive flow shroud.

3.2 *LEDA Beamstop Fabrication*

Unlike its CRITS predecessor, which was spun from a copper cylinder, the nickel ogive for LEDA was produced by electroforming. This plating method produced a robust, one-piece, seamless, near-net shape ogive section to which a machined nose was added, using an electroformed cold-weld process. Figure 7 shows the completed LEDA ogive beamstop before it was inserted into its cartridge (see Figure 2).

Figure 7: Electroformed Ogive for LEDA

The 6.7 MeV LEDA beamstop has been installed at LANL and is now undergoing precommissioning checkouts. Testing should begin later this year.

4 CONCLUSIONS

The CRITS and LEDA experience gained to date have validated the ogive approach, which is now being applied to the design of the beamstops needed to commission the low to intermediate energy sections of the APT.

5 ACKNOWLEDGMENTS

This joint GA/LANL project was sponsored by the Department of Energy under Contract No. DE-AC04-96AL8907. Key members of the GA/LANL team included Ken Redler, Paul Wegner, Chuck Charman, Hank Brodnick, Ralph Senior, Herb Newman, Denise Pelowitz, Ross Meyer, Jr, and Dave Hodgkins. The support of Joe Sherman and the CRITS project team is particularly appreciated.

UPGRADING OF LINEAR INDUCTION ACCELERATOR X-RAY FACILITY (LIAXF)

J.J.Deng, B.N.Ding, J.S.Shi, Y. He, J.Li, Q.Li, G.G.Cao, L. Wen, G.S.Dai
LAPA, Institute of Fluid Physics, CAEP

Abstract

Linear Induction Accelerator X-ray Facility(LIAXF) is a pulsed X-ray machine at Institute of Fluid Physics which produced X-ray by impacting an electron beam on target with beam parameters of 10MeV, 2kA with 90ns pulse width(FWHM). The machine was upgraded to LIAXFU by increasing energy and current and reducing its spot size in 1996 in order to increase the capability of penetration. Description of the LIAXF and upgrades to LIAXF are presented. Simulation on the redesigned drift and focusing section is also given. Experimental results of 12MeV, 2.6kA with 90ns pulse width, about 4mm spot size have been obtained.

1. INTRODUCTION

Linear Induction Accelerators are powered by causing a large, pulsed, time-varying current to once circle a ferrite annulus. This results in a large, time-varying, azimuthal magnetic field to be imbedded in the ferrite annulus. A particle beam threading the center of the annulus acts as the secondary of this 1:1 pulsed transformer and is accelerated by the induced electromotive force. Stacking many such transformers in series and having the particle beam be the secondary common to all modules enables high beam energy to be obtained.

Induction Linac has many application in the fields such as free electron laser[1], high power microwave, flash X-ray radiography[2], heavy ion fusion[3], and so on due to its distinct advantage of high peak power, capacity of producing high current, high energy beams with pulse durations ranging from tens of nanoseconds to microseconds. LIAXF is a linear induction accelerator designed to produce X-ray by impacting the electron beams onto a tantalum target with the nominal beam parameters of 10MeV, 2kA with 90ns pulse width, which was developed by scientists at Institute of Fluid Physics, CAEP, in the early 1990s'. LIAXF was assembled with a four-induction-cell injector and 28 accelerator cells. The first 12 induction modules were used as driver for SG-1 free electron laser[4].To improve the capability of the LIAXF, the upgrades to the LIAXF centered on improving beam quality and increasing beam energy and current.

2. DESCRIPTION OF THE LIAXF

2.1 Injector

The injector is composed of four induction cells and a field emission diode, each cell of the injector is applied to 250kV, for a 90ns(FWHM) high voltage pulse. The voltage contribution of the four cells is summed along the hollow stainless steel stem to drive the diode. The surface of the cathode is covered by the velvet cloth, the anode aperture is closed off with fine tungsten mesh. The emitting current is collimated and matched into the accelerating section by axial magnetic field.

2.2 Accelerating Section

There are total 28 accelerating cells that are arranged in four-cell blocks in the LIAXF. Each accelerating cell contributes about 320keV energy to the beam. The electron beam from the injector is guided by a near-continuous array of solenoids that are positioned both internal and external to the accelerating cell. The current view resistor(CVR) between the four-cell blocks give the beam current and position information for machine tuning. The capacitor probe at each cell measures the accelerating voltage of each cell.

2.3 The Ferrite Toroids Used in LIAXF

The characteristics of the ferrite are very important to the accelerating cells. In order to obtain a non-distorted high voltage pulse, Large saturated and residual fluxes are expected. The ferrite toroids used in the LIAXF were developed by ourselves. It worked very well. The characteristics of the ferrite toroids are as follows:

B_S:	3.9kG
B_r:	3.0kG
μ:	350
ρ:	10(6)Ohm-cm

Dimensions:

OD:	508mm
ID:	230mm
Ht:	25mm

2.3 Beam Drift and Focusing Section

The beam drift and focusing section of the LIAXF is composed of five solenoids and three thin magnetic

lenses, and a tantalum target. The total length of this section is about 4.5m.

2.4 The Pulsed Power System

The pulsed power system can be divided into charging system and triggering subsystem. There are five Marx Generators in charging subsystem. Each charges six or seven Blumlein pulse forming lines through inductors.

There are three stages of triggering switches. One first stage switch triggers five second stage switches that then trigger 32 Blumlein switch in turn. Therefore the output voltage of each Blumlein was synchronized with the beam and applied to the induction cell to accelerate the electron beam.

3. UPGRADES TO LIAXF

The first task was to add four induction cells to the end of LIAXF, then increase the working voltage of each accelerating module from original 320kV to 350kV. The total beam energy can be more than 12MeV.

The next tasks in improving LIAXF beam quality were to realign the mechanical axis of the whole machine for reducing the corkscrew motion and improve the synchronization of the accelerating voltage with the beam for reducing the beam energy sweep.

The injected beam current into accelerating section was also increased to about 3kA.

The drift and focusing section was redesigned to achieve smaller spot size. The length of this section was shortened to about 2cm. Only two solenoids and two thin magnetic lenses were employed. Simulation showed that 4mm spot size can be achieved.

4. CONCLUSION

With the completion of these upgrades, LIAXFU produced the electron beam with parameters of 12MeV, 2.6kA with 90ns pulse width. The spot size was reduced from 6mm of LIAXF to about 4mm. LIAXFU has stronger capability of penetration and smaller spot size.

Abstract

The AIRIX flash X-Ray Radiographic facility will consist of a 3.5kA/4.0MeV/60ns injector and 64 induction cells powered by 32 H.V. generators (250 kV per cell). The induction cells studies made on the PIVAIR accelerator [1], which is the prototype of AIRIX, have allowed to design specific vacuum technology cells (ferrite are under vacuum). In this paper, we will present the technical features of the injector, and particularly the time-resolved energy measurement, the pepper-pot emittance measurement and the results of the three gradient method experiment which has been made by optical transition radiation and Cerenkov radiation observation. In a second part, we will present the design of the induction cells and their HV performances. We will see also the different tests and characterizations we make on each cell, and how we install the accelerator. Finally, we will expose the intermediate experiment we plan to do with the electron beam, after the first 16 cells, that are just installed. Those experiments will be a comparison between PIVAIR and AIRIX accelerators. They will allow to characterize the electron beam, and to optimize beam transport and beam centering procedures, before continuing the installation.

1 INTRODUCTION

The AIRIX induction accelerator has been designed to generate an intense bremsstrahlung X-ray pulse of 500 rads @ 1m using a 3.5kA/20MeV/60ns electron beam. It is made up by an injector that delivers a 3.5kA/4MeV/60ns electron beam, and 64 induction cells powered by 32 H.V. generators (250 kV per cell).

The PIVAIR prototype at CESTA, that is a validation step of AIRIX up to 8MeV, has allowed to test two different technologies for induction cells [1] and to improve beam transport and centering procedures [2].

The AIRIX installation at PEM has begun in 1997 with the reception of the injector. The accelerator part (H.V. generators and induction cells) is now under construction and partly installed.

We present in the first section the experimental results obtained with the injector. In the following paragraphs we expose the different tests made on the H.V. generators and induction cells before their installation. We will see, in particular, the magnetic alignment constraints for the cells. Finally, we expose the beam characterization experiments we plan to do at the end of this year in order to validate industrial production.

2 INJECTOR

The AIRIX injector is a reproduction of the PIVAIR one, and has been made by PSI corporation [3]. The association of a 4 MV pulsed generator and a vacuum diode create a 4MeV,3.5kA,60ns electron beam. The time-resolved energy spectrometer that we use [4], has shown that the energy spread is very low: $\Delta E/E = 1\%$ over 60ns (figure 1).

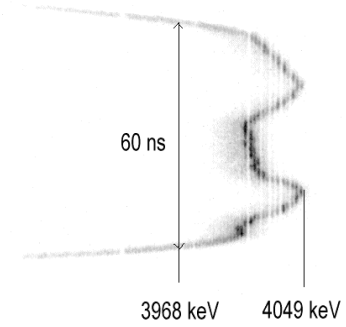

Figure 1: energy spectrum of the AIRIX injector

The next table gathers the results of the acceptance test of the AIRIX and PIVAIR injectors. The essential difference is the cathode configuration.

Table 1: injectors acceptance test results

Injector	**PIVAIR**	**AIRIX**
Diode voltage (spectrometry)	4029keV± 4 keV	4027keV± 4 keV
Voltage flatness	< ± 1% over 60ns	< ± 1% over 60ns
Voltage reproducibility	1%	1%
jitter	< 1 ns	< 1 ns
Cathode diam.	76 mm	89 mm
Velvet recess	2.8 mm	6.1 mm
Beam current	3.5 kA	3.5 kA
Normalized RMS emittance	1650 Π.mm.mrad	1900 Π.mm.mrad

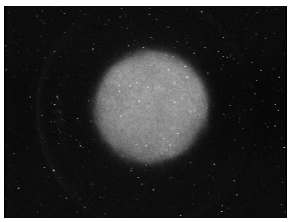
We have been obliged to increase the cathode diameter and the velvet recess in order to hold the 3.5kA current value and to have the smaller emittance value as possible. The beam normalized RMS emittance has been measured

with the Pepper-pot method [5]. Nevertheless, the differences we observe (table 2) in the measurement of this parameter, for similar cathode configuration between the two injectors aren't yet explained.

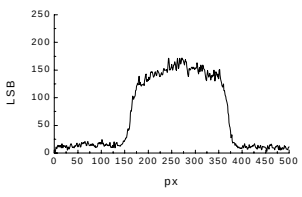
Table 2: RMS emittance comparison between AIRIX and PIVAIR with: cathode diameter=76mm, recess=2.8mm

	ε rms (π mm mrad)
PIVAIR	1600 ± 100
AIRIX	2100 ± 100

The determination of the initial parameters of the beam, (Ro=beam diameter, R'o=beam envelope slope at the origin) is made with the three gradient method [5]. Images of the beam are made by an intensified and gated camera, observing Cerenkov radiation (CR) or Optical Transition Radiation (OTR) created when the beam passes through a 5µm thin aluminized mylar foil. The analysis of the beam profile, with a 5ns gate placed at different temporal position of the pulse, has shown important differences. More precisely, at the end of the pulse, we observe an abnormal and centered peak (figures 2-5).



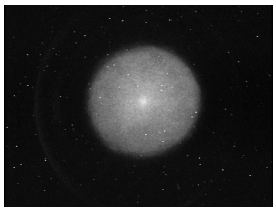
2



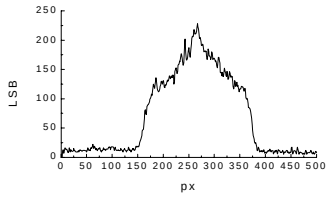
3

Figure 2: image of the beam observed with a gate of 5ns placed in the firts 10 ns of the flat-top of the pulse

Figure 3: the associated and centered beam profile



4



5

Figure 4: image of the beam observed with a gate of 5ns in the last 10 ns of the flat-top of the pulse

Figure 5: the associated and centered beam profile

Those images have been made when we used the 89mm diameter and 5.7mm recess cathode. We have obtained equivalent results with the 76mm diameter cathode and a recess of 4, 5 and 6mm by observing in the same way OTR or CR. We have experimentally demonstrated that the importance of the phenomenon is coupled to the value of the recess. When we use the 76mm diameter cathode, and a recess of 2.8 or 3.2 mm, the beam profiles are quiet different to those obtained with big recess, and the peak seems to be less important but the emittance is higher. In that configuration, the beam profiles are very similar to those obtained on the PIVAIR injector with the same apparatus.

However, the peak apparition is perhaps produced by combined effects between cathode emission and the optical diagnostic that visualizes the beam. Future experiments for optical diagnostic studies will check if there is a diagnostic effect or no.

We are now continuing tests on the injector to find the best configuration of the cathode (lower emittance, stable beam profile during the pulse) before determining the initial parameters of the beam.

3 H.V. GENERATOR

The AIRIX high voltage pulsed generator have been designed to drive two induction cells with a 250 kV, 75 ns pulse (flat top deviation less than ± 1%).

Some improvements have been necessary in order to reach specifications and reliability:

- the spark gap geometry has been corrected and a polarization added;
- thyratron command unit: initially built by EEV, a new one designed by EUROPULSE has been successfully tested.
- minor modifications on magnetic switch reset circuit and H.V. delay line.

Table 3: H.V. pulsed generators characteristics

	PIVAIR gen.	**AIRIX gen.**
Blumlein operating range	100 to 270 kV	100 to 270 kV
Main switch polarization	none	V/3
SF6 nominal pressure	3 bars	1 bar
Thyratron command unit	EEV (gas switch)	EUROPULSE (solid state switch)
jitter peak-peak jitter rms (1 σ)	18. 9 ns 3 ns	12 ns 2,6 ns

4 INDUCTION CELLS

Each induction cell comprises:

- 13 ferrite cores (270 mm I.D., 500 mm O.D., 24 mm thick) housed in a non magnetic stainless steel body
- a guiding solenoid magnet
- two printed circuit dipoles coils for beam centering
- two quadrupoles to correct possible transverse beam dissymmetry.

The 19 mm width accelerating gap has been shaped in order to give good high voltage behavior and minimize the beam coupling with the gap cavity to reduce BBU instability.

Compare to PIVAIR cells, the ferrite section has been increased by 9% in order to delay ferrite saturation and to optimize the timing of the acceleration.

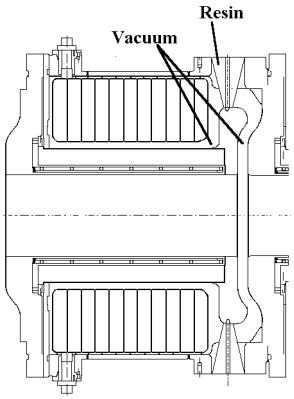


Figure 6: AIRIX induction cell

The H.V. test performed on the 16 first cells loaded with resistors confirmed the flux gain.

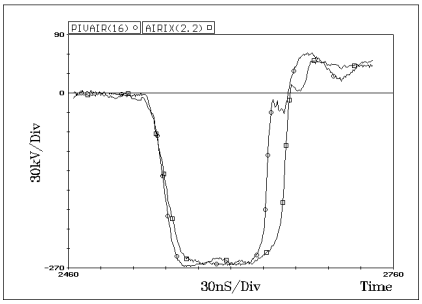

Figure 7: PIVAIR and AIRIX cells H.V. response on resistive loads

The next table shows the cell changes from PIVAIR to AIRIX design.

Table 4 : induction cells characteristics

	PIVAIR cell	**AIRIX cell**
ferrite length	12 x 25 mm	13 x 24 mm
available flux	24.4 mV.s	26 mV.s
gap spacing	19 mm	19 mm
flat top duration at 250 kV	65 ns	75 ns
Quadrupole coil	none	2

This should lead to a better behavior after beam loading, according to PSPICE calculations

5 CELLS ASSEMBLY

After vacuum and high voltage tests, the cells are aligned and assembled 4 by 4 [8]. We consider after this step only the block of four cells with his alignment references.

To minimize chromatic effects, the specific criteria impose that all the cell magnetic axes have to be enclosed in a 250 µm diameter cylinder with an angle spread lower than 500 µrad around the reference beam axis. In order to install only cells which have consistent magnetic axes with the criteria, we characterize magnetic defaults with the pulsed wire field technique.

6 ‘‘AIRIX 16 CELLS’’ EXPERIMENT

To make a comparison with PIVAIR, and to improve industrial realization, we are preparing different experiments with the electron beam accelerated by 16 cells. In a first step, we will characterize the acceleration with the time-resolved spectrometer. This diagnostic will confirm also the good machine timing [6].

We will measure the emittance with the Pepper-pot method. We will improve also the beam transport calculation code ENV [7] with CR beam imaging, and the beam centering procedure with the use of new Beam Position Monitors.

We plan to make experiments during 6 weeks at the end of this year to well characterize the electron beam and then validate the AIRIX technological choices.

7 CONCLUSION

Today 19 H.V. voltage generator have been assembled and tested at PEM. Three blocks of 4 cells have already been installed.

The accelerator will be completely assembled in march 99. After the final alignment of the machine with HLS and WPS technology [8], we will test the entire accelerator. The complete machine is planed to be operational for the radiographic experiments at the beginning of 2000.

EXPERIMENTAL RESULTS OF ELECTRON BEAM NEUTRALIZATION INDUCED BY A LIMITED SPACE-CHARGE EMISSION

C. Vermare, J. Labrouche, D. Villate, P. Le Taillandier
Commisariat à l'Energie Atomique, Centre d'Etudes Scientifiques et Techniques d'Aquitaine
Bp n°2, 33 114 Le barp - FRANCE

Abstract

At the exit of the flash X-ray photography accelerator AIRIX, an intense relativistic electron beam (4 kA, 16-20 MeV, 80 ns) impinges on a high-Z target. The quality of the radiograph obtained is directly tied to the properties of the electron beam (RMS size and position, energy and current).

In a study on the LELIA linac (1 to 2 MeV, 1 kA) to study optical diagnostics, a very strong time-dependent focusing effect near the target was observed. The size of the spot emitting Cerenkov light was found to vary with time during the beam pulse. This observation was confirmed on the last Optical Transition Radiation (OTR) studies with the PIVAIR linac (7.2 MeV, 4 kA, 80 ns).

After analysis of this experimental results, an explanation of the effect in terms of the emission of positive ions by the target, and their subsequent tendency to move upstream has been simulated using a PIC code. The results support the concept of backstreaming ions adding an additional time-dependent focusing force that acts on the electron beam.

1 THE EXPERIMENTS

After a short description of the experimental set-up, we present the observed phenomena. An hypothesis is proposed to explain this observation.

1.1 Description of the accelerators and the optical diagnostics

Two different induction linear accelerators have been used. The first, LELIA, delivers a 1 kA electron beam with an energy up to 2.2 MeV. Initially developed to perform microwave FEL experiments [1-2] it has also been used as a test bed for the AIRIX induction accelerator [3], in particular for beam transport studies and diagnostics development.

The second, PIVAIR, is the prototype of AIRIX. It operates at 3.5 kA with an energy from 3.5 MeV up to 7.3 MeV.

At low energy, as in the case of LELIA, the optical observation is based on the emission of Cerenkov light which occurs when the beam hits a transparent target. The analysis of a part of this light, collected by optical cameras, allows us to measure the e-beam transverse dimensions [4]. Above 3 MeV, as in the case of PIVAIR, our optical diagnostic is based on the OTR [5] process.

Figure 1 presents the two different configurations we have adopted.

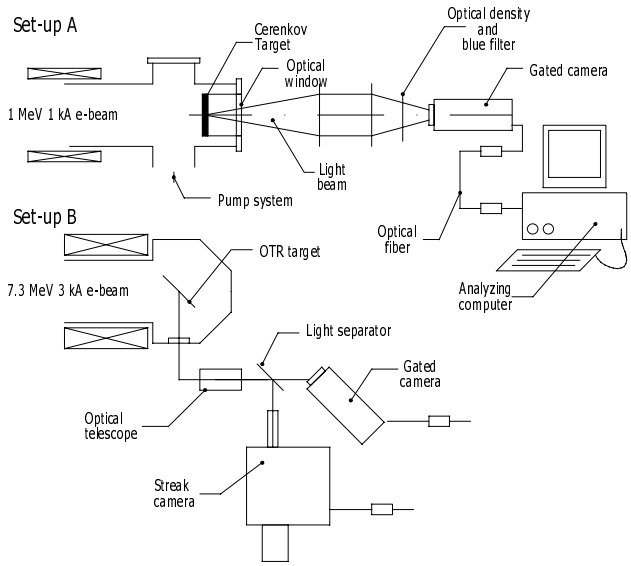

Figure 1: Schematic drawings of the two different set-up.

1.2 Results of the observation

During a "Cerenkov" measurement which used a 1 mm-thick fused silica foil (set-up A), we have observed a dependence of the beam radius as a function of time. Neither the beam current nor the beam energy exhibit a time variation fast enough to explain this behavior. An empirical solution has been found to reduce this effect by coating the target with aluminum to increase its conductivity. An example of the results obtained is given in Figure 2.

2 THE IONIC EMISSION HYPOTHESIS

2.1 General description

It is well-known that [6-7] the energy deposited in a target by an electron beam can produce free positive ions. In our case, their dynamic behavior is very interesting. The strong axial electric field generated near the target can accelerate and propagate upstream this ionic current to the primary beam. This mechanism is different from the one described in the references mentioned above. A neutralization of the strong electron beam current can appear and explain its focusing to small radii.

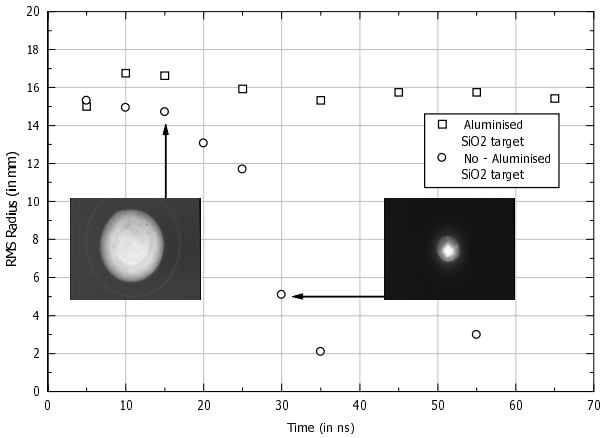

Figure 2: Behavior of the beam radius as a function of time. Two Cerenkov images of the beam at different times show its convergence.

2.2 Analytical approach

A simple model can be used to take into account the effects of the ions in the calculation of e-beam transport. We have computed the stationary longitudinal electric field generated by the e-beam itself [8]. By neglecting its transverse variations we have shown that close to the target, the electric field variations with z can be linearized. Then, the motion of the ions in this field can be calculated and the corresponding space charge-limited current is given by the following equation:

$$I_{ion} = \left(\frac{e}{M\varepsilon_0}\right)^{\frac{1}{2}} \left(\frac{I_e}{\pi c}\right)^{\frac{3}{2}} \qquad (1)$$

where M is the ion mass, e the elementary charge, I_e the e-beam current and c the light velocity. The ion energy becomes constant after a distance at which the electric field vanishes and is given by:

$$E_{ci} = \left(\frac{3e}{\pi^3 \varepsilon_0 c}\right) I_e \qquad (2)$$

If the e-beam current is 1 kA we find a proton current of 4 A and a maximum energy of 40 keV. These 2 values can be used to introduce a neutralization factor in the space charge term of the envelope equation in order to determine the influence of the ionic emission on the radius of the electron beam. The results of this calculation have shown a substantial focusing effect over in the pulse duration.

2.3 "PIC" simulations

We have developed a "Particle In Cell" code to simulate the experiment. It uses a 2D "Maxwell-Vlasov" algorithm in a cylindrical space. The electron beam initial conditions are determined thanks to the transport code ELECTRA [9]. Different species of ions are generated at the target position, the electromagnetic field and the particle dynamics are computed in order to obtain the effects of the ions on the electron beam radius.

3 COMPARISON BETWEEN NUMERICAL AND EXPERIMENTAL RESULTS

3.1 The parameters of the simulation

The main parameters are the mass and the charge of each kind of ion, their production rates and their initial energies. We have compared the experimental results by considering only protons. Their production rate is chosen to obtain the limited space charge ion current and they are emitted with a kinetic energy close to zero (10 eV).

3.2 Variations with the beam density

In the case of the experiment performed with the LELIA linac, we have varied the magnetic fields of the guiding coils in order to obtain, at a fixed total current, different values of the initial e-beam size, i.e. different beam densities. The current density has a strong influence on the evolution of the beam radius as a function of time. As shown in Figure 3, the higher the beam density the earlier the focalisation appears.

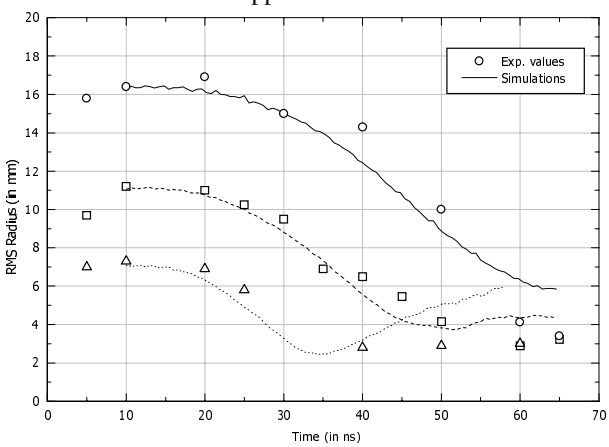

Figure 3: Numerical and experimental behavior of the beam radius versus time for three different initial beam densities.

4 OBSERVATIONS ON PIVAIR

The existence of this phenomenon, which has been observed with LELIA at CESTA as well as at LANL with ITS [10], has to be understood in order to evaluate its effects on the final focus of the AIRIX accelerator. Consequently, we have installed the experiment at the PIVAIR facility (Set-up B, figure 1).

4.1 OTR Time resolved measurement

The behavior of the e-beam size has been measured with an OTR diagnostic. The optical system was developed to obtain both the transverse dimensions of the

beam with a 5 ns gated camera and a time resolved 1D image with a streak camera. In this way, we are able to know the position of the slit of the streak camera in the transverse beam spot. Two images from the streak camera are displayed in Figure 4. They have been obtained for two distinct initial electron beam radii. As in the case of LELIA, we observe a variation of the radius during the beam pulse. It appears earlier for the small radius which corresponds to a higher beam density. The images from the gated camera exhibit the same behavior. Furthermore, these images reveal an unexpected bump in the beam transverse profile.

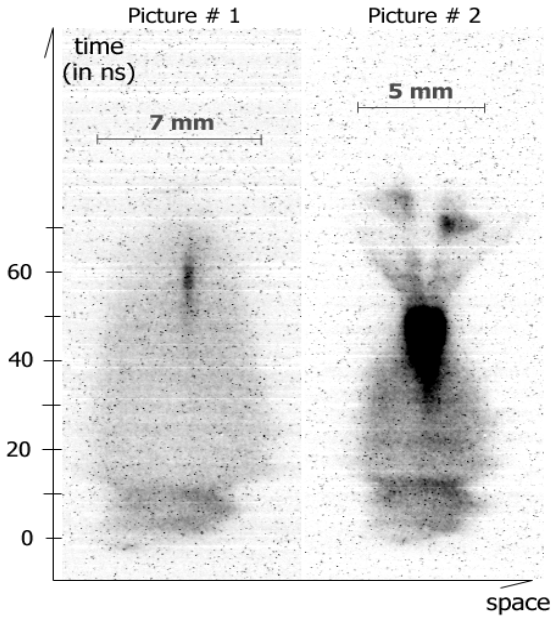

Figure 4: Examples of time resolved OTR images for 2 different beam radius at the target position.

4.1 Time behavior of the radial beam profile

The radial profile of the beam as a function of time has been studied and compared with the results of the PIC code. In Figure 5, we present the charge density of the electron beam at different times, both for LELIA and PIVAIR, the experiment shows a bump on the axis which blows up as the time increases. The numerical results reproduce this effect as indicated in the figure 5 for the LELIA case. We think this behavior, associated with the decrease in beam radius versus time, is the signature of the ionic focusing effect. It is present in the PIVAIR experiment though the beam parameters are very different. Consequently, the ionic focusing could be of prime importance in a higher energy accelerator like AIRIX.

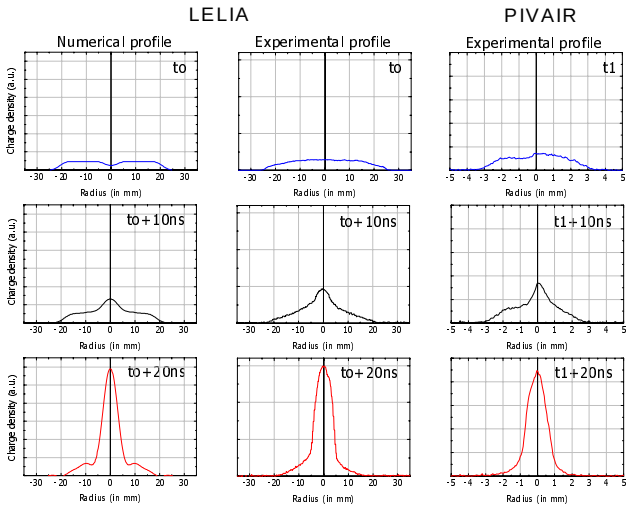

Figure 5: The structure of the e-beam radial profile versus time. The signature of the "ionic effect" appears with the two different accelerators.

5 ACKNOWLEDGEMENTS

The authors wish to acknowledge the valuable support and participation of the PIVAIR team.

We thank the CESTA/FEL team for their encouragement and support.

Abstract

We have built and are presently designing, photocathode-based accelerator systems for radiation chemistry applications. One of these accelerators is in operation at Brookhaven National Laboratory. All feature a photocathode electron gun and produce a short, intense electron pulse with a variable repetition rate. The designs range from 1 nC to 100 nC per pulse, with bunch lengths of 0.6 psec at lower charge levels to less than 50 psec at higher charge. A compact design which can deliver 10 nC of charge in less than 5 psec and a larger machine designed to deliver up to 100 nC of charge in less than 50 psec, are described. Data on the operating system is also presented.

1 INTRODUCTION

Linear accelerators based upon photocathode RF electron guns are ideally suited for a number of scientific applications. The unique properties of these systems include the ability to produce a single, intense pulse of electrons at a variable repetition rate whose timing can be precisely controlled. These electrons can be used directly, through a thin window, or to generate an intense burst of gamma rays.

For the past few years, we have been designing photocathode-based linacs for scientific research [1]. In particular, we have delivered one accelerator beamline to Brookhaven National Laboratory (BNL) for pulse radiolysis chemistry research, and have designed two others for similar applications. The installed accelerator has been operating successfully for almost two years, producing in excess of 10 nC per pulse. The design and performance of this accelerator follows. Thereafter, the other two designs with their differing performance and packaging, are described.

2 BNL SYSTEM PERFORMANCE

The machine presently in operation at Brookhaven includes two beamlines. The first is a beamline deflected 90 degrees from the straight path, and the other is a beamline along the straight path. Two further deflected path beamlines can be installed. The electrons are delivered to one beamline or the other through energization of the bend magnets.

The bent path fulfills several important functions. Firstly, when properly designed, it provides a certain amount of longitudinal bunch compression which leads to higher peak current and better time resolution. The bent path can also be used for energy analysis of the electrons, if desired, and provides excellent suppression of the dark current due to energy selectivity.

The electron source is a 3.5 cell S-band photocathode RF gun which can produce electron energies up to 9 MeV. The electrons are produced in a single microbunch through illumination of the photocathode with a picosecond laser pulse synchronized to the RF that drives the gun cavities. A variable laser pulse width can be used to tailor the electron bunches to suit the needs of the experiment. The system runs at a repetition rate of 10 Hz, but this is not a fundamental limit. Quadrupole, dipole steering, and dipole bending magnets transport the electron pulse to the desired target.

The system has achieved the design goals that correspond to the present photocathode drive laser performance. The deflected beamline was designed to produce 10 nC bunches with a pulse width of less than 5 psec on target. The straight beamline was specified to deliver greater than 20 nC with pulse lengths of less than 30 psec. The transverse spot size on both targets can be varied over a wide range. To date, up to 12 nC have been delivered to both target stations with laser energies of 180 μJ per pulse. The dark current on the deflected path is measured to be less than 0.1 nC summed over the entire 4 μsec RF pulse.

3 NEW DESIGNS

Two new but related designs, with very different performance parameters, have recently been developed. The first is a very compact machine with only two target stations. The second machine is much larger and presently envisages five target stations.

The compact design is very similar to the BNL machine. An S-band 3.5 cell gun produces the 9 MeV electron pulses. These pulses can be delivered to one of two target stations via either a straight path or a bent

* Funding for this work was provided by the Office of Basic Energy Sciences, United States Department of Energy, under Brookhaven National Laboratory Contract # 703171 and Argonne National Laboratory Contract # 972582401, and by the Northrop Grumman Corporation.

[a] Present address: General Instrument Corporation, 101 Tournament Drive, Horsham, PA 19044, USA.

path. The pulses contain over 10 nC in a FWHM length of less than 10 psec on the straight path, and less than 5 psec on the bent path. The entire beamline, from the gun to the target stations, fits onto an optical table with dimensions of 2 meters by 3 meters.

The final design is a significant departure from the two previously described systems. It was driven by two separate goals, namely, very high charge and very short bunch lengths.

Achieving much higher charge necessitated a switch to an L-band accelerator. Operation of the gun in L-band allows a longer laser pulse and a larger laser spot size before beam quality starts degrading significantly. The longer pulse and larger spot allow more charge to be extracted before charge shielding becomes a major issue. They also allow more laser energy to be incident upon the cathode without exceeding the maximum permissible intensity.

To make it possible to attain the shorter bunches, the design includes a four cell booster accelerator after the 2.5 cell photocathode electron gun. The booster's RF phase is used to adjust the electrons longitudinal phase space in order to achieve optimal compression in the subsequent magnetic pulse compressor. In addition, the gun has been designed to provide a nearly linear relationship in longitudinal phase space. Through careful matching of the gun and booster, compression ratios of around 15 between the output of the gun and the end of the beamline have been achieved.

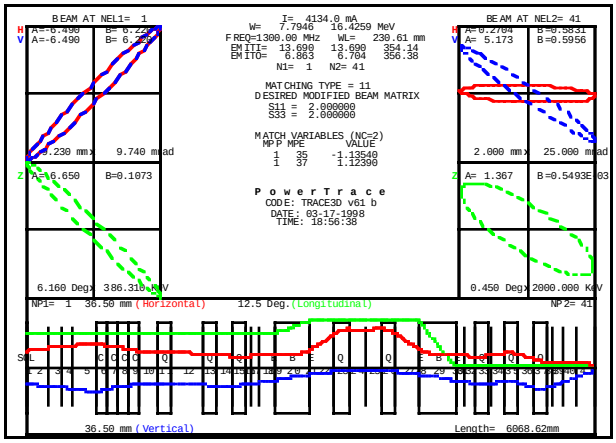

Figure 1. L-Band system beamline envelopes at 3.2 nC.

Figure 1 is a TRACE-3D [2] illustration of the beamline envelopes, showing the bunch compression. Nonlinear analysis of the beam on target using the TOPKARK [3] code yields, after aperturing, the transverse and longitudinal phase space plots of Figure 2.

The booster accelerator also assists in achieving the high charge operation. This is because, given a fixed amount of available RF power, the shorter gun can be operated at a higher gradient than would be possible with a longer gun. The gun and booster produce electron pulses up to an energy of 15 MeV while allowing the gun to be operated at maximum gradients. A higher gradient in the gun both raises the threshold for charge shielding considerations and raises the effective quantum efficiency of the cathode through the Schottky effect.

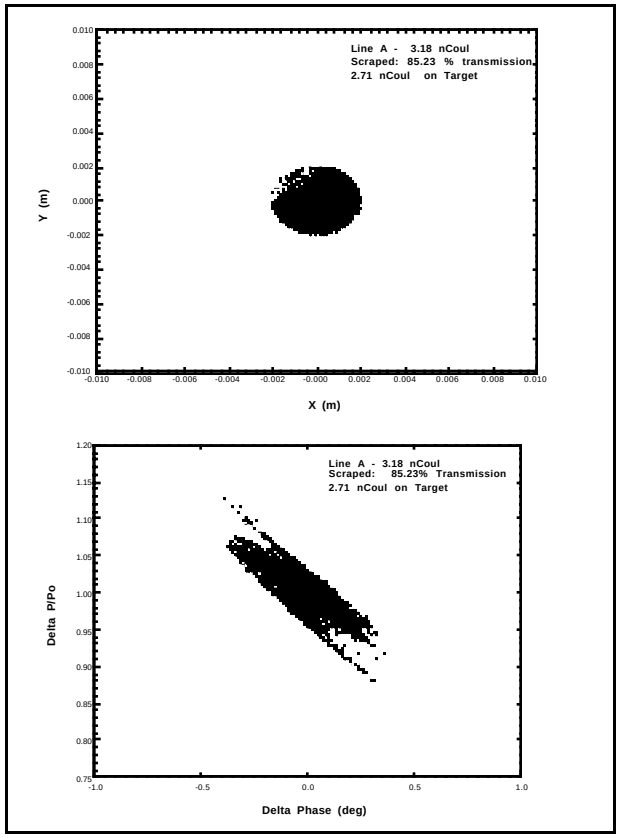

Figure 2. Transverse (upper) and longitudinal (lower) phase space plots for a 2 mm apertured, 2.7 nC, 0.67 psec FWHM bunch.

The beamline has multiple target stations, as shown in Figure 3, and the layout was designed to fit into an existing facility.

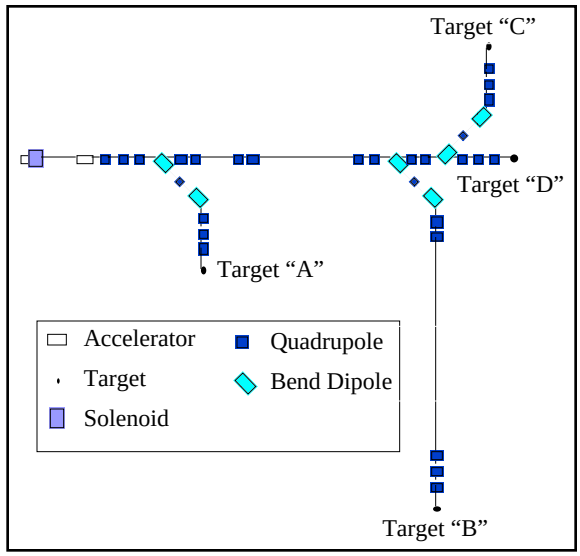

Figure 3. Four target L-band beamline layout.

The closest target to the accelerator, "A", is optimized for short pulse operation. Also, it is intended that the electron pulse at this target be synchronized with a sample of the photocathode drive laser to provide precise timing for pump-probe type experiments. At this target station, a pulse length of 0.67 psec FWHM has been achieved with 2.7 nC on target after aperturing a 3.2 nC beam and focusing the electrons to a transverse spot size of 2 mm radius. Lesser charge can be delivered in even shorter pulse lengths, while a 10 nC bunch can be compressed to less than 2 psec FWHM. At this target, we have achieved, in our non-linear simulations, peak currents in excess of 5 kA and peak densities in excess of 30 kA/cm^2.

The other two target stations on bent paths cannot match the performance of target "A" due to their distance away from the accelerator, smaller space for the achromat, and the necessity to have long sections of drift space. They were designed primarily to transport the high charge pulses.

The gun can produce up to 100 nC depending upon the available laser energy. After acceleration in the booster, this current can be delivered to either the first target station or any of the other targets. At target "A", the transport efficiency for the high charges approaches 100% and the pulse length can be compressed to less than 20 psec FWHM for 90 nC. The other two targets on bent paths have transport efficiencies of 81% and 89% with pulse lengths of around 25 psec FWHM. For comparison, the straight path target "D" has close to 100% transport with a pulse length of a little over 50 psec. A summary of the on-target performance at each of the four target stations is shown in Table 1.

4 SUMMARY

Northrop Grumman has built or designed three state-of-the-art electron accelerators. Although all three designs were driven by chemistry research applications, accelerators of this type have a much broader range of applications. These accelerators, based upon photocathode RF guns, can deliver very intense, very short (sub-picosecond) pulses of electrons or longer (20-30 psec), very high single bunch charge. The accelerator presently in use has met or exceeded all expectations.

DEVELOPMENT OF AN UPGRADE OF THE CEBAF ACCELERATION SYSTEM*

J. R. Delayen
Thomas Jefferson National Accelerator Facility, Newport News, Virginia 23606 USA

Abstract

Long-term plans for CEBAF at Jefferson Lab call for achieving 12 GeV in the middle of the next decade and 24 GeV after 2010. Such energies can be achieved within the existing footprint by fully populating the accelerator with cryomodules capable of providing 3 to 4 times as much voltage as the design value of the existing ones within the same length. In particular, this requires the development of superconducting cavities capable of operating at gradients above 12 MV/m and Q close to 10^{10}.

1 CEBAF DESIGN AND STATUS

CEBAF was designed and constructed to accelerate an electron beam to 4 GeV by recirculating five times through two 1497 MHz superconducting linacs, each providing 400 MeV per pass at the accelerating gradient of 5 MV/m. The two anti-parallel linacs are connected by 180 degree isochronous, achromatic recirculating arcs. The design maximum current is 200 μA cw, corresponding to a beam loading current of 1 mA [1].

The superconducting RF (SRF) system consists of 20 cryomodules in each of the two linacs and 2 ¼ cryomodules in the injector. Each cryomodule contains 8 accelerating cavities for a total of 338 cavities. The cavities, which are 50 cm long, were designed to operate at a gradient of 5 MV/m, which corresponds to an energy gain of 20 MV for each cryomodule. Each cavity is individually powered by a 5 kW klystron and controlled by a low-level rf control system to stabilize the phase and amplitude of the rf field. Having each cavity individually controlled allows for precise and careful optimization of the system and results in excellent phase and amplitude stability of the accelerating fields in the cavities.

The central helium refrigerator provides 2 K helium to the cavities with availability above 98%. The system, capable of providing 4800 W of refrigeration, presently operates with a constant heat load of 3100 W, of which 1500 W is the actual rf heat load.

From the beginning the performance of the acceleration system exceeded the design goal [2]. Early in 1996 a one-pass energy of 1 GeV was achieved, and in the spring of 1997 a 90 μA beam was accelerated to 1.16 GeV in a single pass (equivalent to a 5.6 GeV, 18 μA 5-pass beam). The average accelerating field in the active cavities was 7.8 MV/m, more than 50% above their design field. In the fall of 1997, the full capacity of CEBAF was demonstrated with the delivery of a 4 GeV, 200 μA beam [3]. Some of the arc dipole power supplies are being upgraded in order to deliver high-energy multipass beams, and physics experiments at 5.6 GeV are being scheduled for the first half of 1999.

The initial performance of the CEBAF cavities corresponded to a 5-pass energy of about 5 GeV. The performance was predominantly limited by electron field emission that can manifest itself in additional cryogenic losses, x-ray production, and periodic arcs at the cold window which is located close to the beam line [4].

In order to reduce field emission and increase the operational energy of CEBAF, a program to perform *in situ* helium processing of the cavities was initiated in the fall of 1996. To date 224 cavities in 29 of the 40 installed cryomodules have been processed [3]. This has increased the installed voltage by 155 MV, which corresponds to an added energy of 775 MeV for a 5-pass beam. The *in situ* processing program will be completed in February 1999 and it is expected that the additional gain will allow operation close to 6 GeV.

2 UPGRADE OPTIONS FOR THE ACCELERATION SYSTEM

CEBAF's long-term institutional plan calls for an energy upgrade to 12 GeV in the middle of the next decade, and to 24 GeV after 2010. The short-term goal is to have developed, installed in the accelerator, and demonstrated by 2002 prototypes of the key components of such an upgrade.

While the details of the upgrade path are still being developed, a top-level parameter list has been generated which guides the selection between the various options:

- The highest energy beam of 12 GeV needs to be delivered to only one experimental hall.
- CW operation must be preserved.
- The maximum circulating beam current will be 400 μA (corresponding to an 80 μA beam for a 5-pass design).
- The maximum installed refrigeration capacity will be 8.5 kW at 2 K.
- Cost and impact on accelerator operation during the upgrade must be kept to a minimum.
- Since the purpose of the 12 GeV electron beam is to generate an 8 GeV photon beam, the requirements on

*Supported by US DOE Contract No. DE-AC05-84ER40150

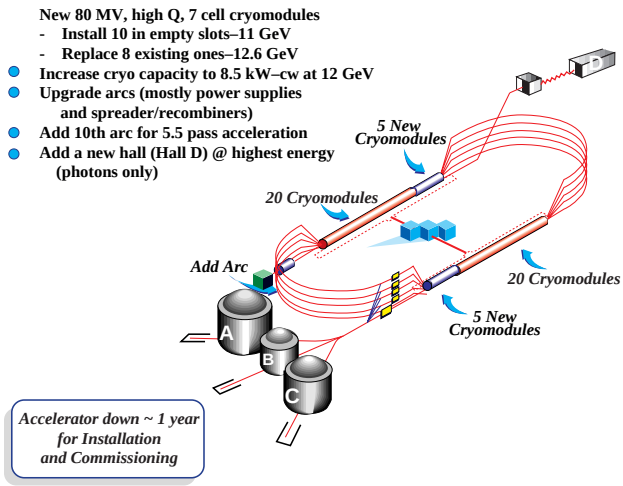
the electron beam quality can be relaxed from the existing requirements.

- Since the ultimate goal is an upgrade to 24 GeV, an upgrade path to 12 GeV that could be extended to higher energy would be preferable.

The original upgrade plan for CEBAF called for a maximum energy of about 9 GeV. The most attractive option to achieve this goal called for a systematic "reworking" of the cryomodules. This consisted of removing the cryomodules from the accelerator one at a time, reprocessing the superconducting cavities, and replacing or modifying some of the limiting components (for example relocating the cold windows and shielding them from field-emitted electrons). While this option seemed attractive to 9 GeV, it could not be easily extended beyond, either because it could not provide enough energy or because the cryogenic consumption would be excessive.

The most attractive option that has emerged from the studies that have been conducted during the last year consists of:

- addition of a fourth experimental Hall D at the end of the North Linac (turning CEBAF into a 5-pass machine for Halls A, B, and C, and a 5 1/2-pass machine for Hall D),
- development of high-voltage, high-Q cryomodules that would be installed in the 5 empty slots in each of the linacs,
- replacement of a limited number of existing cryomodules by the new ones (typically 3 in each of the linacs and 2 in the injector),
- upgrade of the refrigeration capability to 8.5 kW,
- addition of a 10th arc and upgrade of the existing ones.



3 DESIGN OF THE UPGRADE CRYOMODULE

The Upgrade Cryomodule is clearly the key component of the upgrade of the acceleration system. Its design is also somewhat insensitive to the details of the upgrade option that is ultimately chosen, once the top-level parameters have been defined, and it can be viewed as a building block that can be applied to a large number of upgrade options. For these reasons, most of the development efforts in support of the upgrade are directed toward the development and demonstration of prototype Upgrade Cryomodules.

3.1 Cavities

In order to increase the voltage that is provided by a cryomodule within a given length, one can either increase the gradient at which the cavities are operating, or increase the effective accelerating length, or both. While it may be argued that maximizing the accelerating length is the approach that presents the least technological risk, for cw accelerators such as CEBAF, maximizing the length instead of the gradient has the added advantage of lower dynamic load on the refrigeration system.

For this reason, it was decided early that the Upgrade Cryomodule would still include 8 cavities, but that these would be 7-cell cavities (70 cm) instead of the present 5-cell (50 cm). The option described in Section 2 calls for these cavities to provide a minimum voltage of 8.75 MV with a maximum power dissipation of 17.5 W, *i.e.* their Q must be at least 6.5×10^9 at 12.5 MV/m. Thus the greatest challenge is not so much in achieving a high gradient but in maintaining a high Q at high gradient. Given the constraint imposed by the available refrigeration, cw operation at 15 MV/m would be practical only if the Q at that field were at least 10^{10}.

While the CEBAF cavity cell design could have been improved, the potential benefits did not seem important enough at that time, and the first 7-cell cavity prototype was built using the existing cell design. The first prototype met the requirement of a Q of 6.5×10^9 at 12.5 MV/m. A redesign of the cells is still an option, although a low priority one.

3.2 Cryostat Concept and Cavity String Assembly

The existing CEBAF cryomodule is constructed from 4 cyounits, each containing a sealed cavity pair. These cyounits are then joined with bridging sections. In order to increase the number of cells from 5 to 7 while maintaining the same cryomodule length, this approach had to be abandoned. The Upgrade Cryomodule will include a continuous 8-cavity string assembly without isolation valves between the cavities. The present design calls for a 30 cm separation between cavities into which must fit the fundamental power coupler, the higher mode extraction system, the pick-up probe, connecting flanges and bellows, and connections to the helium tank and mechanical tuners.

Several cryostat concepts were explored:

- Cylindrical cryostat with radial penetrations for the power couplers,

- Cylindrical cryostat with axial (through the end plates) penetrations,
- Bathtub-type cryostat where all the innards are suspended from a top plate.

While all designs had advantages and disadvantages, a cost/benefit analysis did not reveal an obviously preferred option. The overriding consideration was the limited amount of time and resources expected to be available, and the radial design was chosen as it was deemed the one that would require the least amount of development given the on-site experience with the radial design.

3.3 Fundamental Power Coupler

Both coaxial and waveguide couplers were explored. The waveguide concept was retained because of its simplicity and flexibility at 1500 MHz. Unlike the present design, though, we have decided to completely separate the functions of fundamental power coupling and higher mode extraction. This produces a coupler design that, unlike the existing CEBAF design, is free of transverse kick imparted to the beam and allows a cryostat design where all the power couplers are on the same side [5].

3.4 Higher Order Modes Damping

The requirements for high order modes (HOM) damping for the 12 GeV Upgrade have been substantially relaxed from the original CEBAF design. Not only is the energy increased from 4 to 12 GeV but the maximum circulating current is being reduced from 1000 to 400 μA. Additionally, the experience acquired during CEBAF operation has led to a reduction of the "safety factor" for the stability threshold current. As a result an upper limit of 10^6 was adopted for the Q_{ext} of the HOMs.

The design of the HOM couplers is a departure from the existing design: we do not rely on any HOM being extracted from the fundamental power coupler, the 2 HOM couplers will be of a coaxial type as opposed to a waveguide type, the HOM couplers will be located outside the helium tank and the HOM power can be deposited at a temperature other than 2 K.

3.5 Frequency Tuning

The frequency tuners perform several functions: bring the cavities on resonance after installation, detune the cavities that are not operating, and track the changes in frequency due to Lorentz detuning, pressure and temperature fluctuations. For the Upgrade Cryomodule, the bandwidth will be small (~75 Hz), the Lorentz detuning large (~500 Hz), and we want to track the frequency accurately (~2 Hz) in order to minimize the rf power requirements. For this reason the baseline design incorporates two different tuning schemes: a coarse mechanical tuner with 400 kHz range and 100 Hz resolution that will be used infrequently, and a fine tuner, probably piezoelectric, with 1 kHz range and 1 Hz resolution that will provide the fine, frequent tracking.

3.6 Processes and Procedures

While the gradients required are modest compared to those for proposed linear colliders, a high Q is of primary importance. Furthermore, since rf power will be a hard constraint, "good" cavities cannot operate at higher gradient in order to compensate for "weaker" ones. For these reasons our main goal is to achieve consistent performance as opposed to the less frequent exceptional one. We have engaged in a complete review of all the processes and procedures involved in the fabrication and assembly of cavities and cryomodules. Modifications to the processing and assembly facilities, such as implementation of final chemistry and rinsing in the cleanroom, are under way.

3.7 Microphonics, RF Control, and RF Power

In order to contain the cost of the upgrade we have adopted as a goal only a modest increase of the rf power per cavity from 5.5 to 6 kW. This puts stringent requirements on microphonics and the control system. At 12.5 MV/m and 400 μA circulating current, the maximum allowable amount of detuning (including static and microphonics) is 25 Hz. The optimum Q_{ext} is $2x10^7$, and the Lorentz detuning is much larger than the loaded bandwidth; for this reason a new low-level rf control system will be required. The baseline concept is an agile digital system capable of implementing a self-excited loop on I/Q feedback.

Abstract

The FEL at the superconducting electron accelerator S-DALINAC has been operated at wavelengths between 6.6 and 7.8 µm corresponding to electron beam energies between 31.5 and 29.6 MeV respectively. In house developments like active stabilization of the optical cavity's length based on a laser interferometer and a fast 10 channel online-spectrometer for the near infrared laser radiation were incorporated and used for investigation of the properties of the FEL itself. In addition a simple focusing system produced power densities of 10^8 W/cm^2 and enabled us to perform first ablation experiments from different tissues. To optimize the complicated bunching process, the low energy part of the S-DALINAC was carefully studied by tracking calculations in order to achieve bunch length < 3 ps corresponding to peak currents > 1.5 A, necessary to operate the FEL reliably in the saturated regime. For operation at higher energies using two recirculations of the electron beam, longitudinal tracking simulations show that off crest acceleration together with nonisochronous recirculation introduce longitudinal stability resulting in significant improvement in energy spread.

1 S-DALINAC

The S-DALINAC operating since 1991 is a recirculating electron linac using superconducting (sc) accelerating cavities allowing for a continuous wave (cw) electron beam [1]. The machine provides beam to serve a variety of nuclear and radiation physics experiments and is since 1996 also used as a driver of a Free-Electron-Laser in the mid infrared wavelength region. A layout of the accelerator and the FEL is shown in Fig.1.

The electron beam is generated by a thermionic cathode, on a high voltage terminal providing a 250 kV electrostatic preacceleration. The beam gets its time structure in a chopper/prebuncher section at room temperature (see Sec. 3.) and is then accelerated up to 10 MeV in the sc injector linac consisting of a 2-cell (β=0.85) and a 5-cell (β=1) capture cavity and two 20-cell (β=1) accelerating cavities. Each of them is made of bulk niobium and operates at 2 K in a liquid helium bath at a resonant frequency of 3 GHz. Behind the injector the beam can be used in a low energy experimental area or bent 180° by a magnetic arc to be injected into the 40 MeV main linac consisting of eight 20-cell cavities. For nuclear physics experiments with electron energies up to 130 MeV the beam can be recirculated twice passing through dedicated beam transport systems.

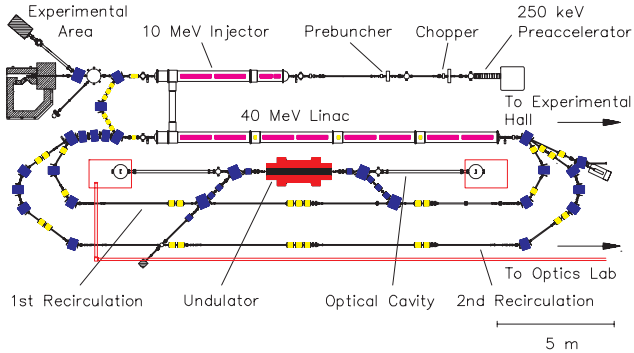

Figure 1. Layout of the S-DALINAC and its Free-Electron-Laser

The FEL is driven by transporting the beam from the first recirculation into the undulator through a magnetic bypass system. The infrared radiation generated and amplified in the 80 periods hybrid undulator is accumulated in a 15 m long optical cavity formed by two dielectric mirrors. For experiments part of the stimulated radiation is coupled through the downstream mirror and guided through an evacuated transfer to an optical laboratory.

Since its commissioning the S-DALINAC delivered some 16000 hours of beam time for experiments covering a wide range of beam parameters. Energies ranging from 2.5 MeV up to 120 MeV and currents from a few nA to 50 µA could be realized in a 3 GHz mode. The FEL is driven in a 10 MHz cw mode using a subharmonic injection scheme leading to peak currents of about 2 A at energies between 30 and 38 MeV.

2 FREE-ELECTRON-LASER

The FEL at Darmstadt benefits from the superconducting drive linac enabling time structures of the laser ranging from 100 µs long macro pulses to 10 MHz cw operation. The FEL has been operated so far at wavelength between 6.6 and 7.8 µm corresponding to electron energies between 31.5 and 29.6 MeV respectively. The wavelength could be tuned continuously in this range determined by the bandwidth of the dielectric

* Supported by BMBF under contract number 06 DA 820 and by DFG under contract number Ri 242/12-1 and through the Graduiertenkolleg "Physik und Technik von Beschleunigern"

mirrors by changing either the magnetic gap of the undulator or the electron energy. During the commissioning [4] of the FEL using an electron beam with an energy of 30.4 MeV and a measured bunch length of 3 ps corresponding to a peak current > 1.5 A, we were able to extract an average cw laser power of 3 W at a wavelength of 7.4 µm through a mirror with 99 % reflectivity. The net gain of the arrangement was measured to 3-5 %.

The laser output power turned out to be very sensitive to length variations of the optical cavity in the micrometer range. These perturbations are caused by vibrations on the optical tables due to cryogenic pumps and the heavy machinery of the helium liquifier as well as long time drifts caused by air pressure and room temperature changes. Therefore it was essential to develop an active feedback system to stabilize the length of the optical cavity. A commercial michelson interferometer (HP 5527A Laser Position Transducer) measures the length variations and generates a drive signal for the piezo transducers holding the mirrors. The control parameters can be software adjusted. The remaining length variation due to vibrations was measured to be a gaussian distribution with 232 nm FWHM, as shown in Fig.2., while the long time drifts were eliminated completely. Without feedback the position error is about 500 nm FWHM with drifts of 20 µm within 24 hours preventing stable laser operation.

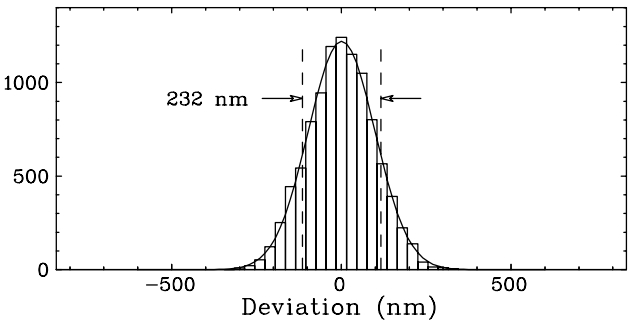

Figure 2. Length variation of the optical cavity with interferometric feedback active.

In order to control and optimize the laser performance an online- spectrometer was developed with a typical Czerny Turner setup for the spectral splitting and a ten element pyroelectric strip detector. The detector output is monitored online on a LED display or connected to ADC's for further analysis. The resolution of this device is 20 nm per element. Drifts and changes in the electron beam steering through the undulator leading mostly to longer wavelengths could be easily corrected with this device. The laser beam stabilized and monitored in such an way could be used for first ablation experiments on different tissues performed in cooperation with J. F. Bille and his group from the university of Heidelberg. The laser beam was focused by a single CaF_2 lens with a focal length of 350 mm to a spot size of 160 µm providing a power density of some 10^8 W/cm^2. The resulting ablation depths were measured with a scanning electron microscope and the ablation mechanism was described by an analytical model. It turned out that the ablation was due to thermal interaction. The measured ablation depths could be explained by a model assuming the tissue as water, being heated and vaporized by the radiation pulses. Ablation sufficient for medical purposes demands at least a 10^3 times higher power density in order to avoid too much thermal damage for nearby tissue. We are sure to reach this goal by means of more sophisticated focusing optics and by optimizing the optical transfer system. The use of regenerative amplifiers for the laser beam is also envisaged to reach even higher power densities in the future.

3 TRACKING CALCULATIONS OF THE INJECTOR LINAC

The quality of the laser output depends on the parameters of the electron beam entering the undulator, especially the longitudinal properties energy spread and bunch length are critical for the shape of the spectrum and the output power. These properties are almost fixed after the injector, therefore the beam dynamics in the low energy part of the accelerator was studied intensively by tracking calculations. For driving the FEL the thermionic cathode is pulsed with a repetition rate of 10 MHz. Pulses with a duration of 1 ns are extracted from the gun at 250 keV. The subharmonic chopper/prebuncher section working at the 5th subharmonic cuts out 370 ps corresponding to a charge of 6 pC and compresses these bunches to a length of 5 ps at the entrance of the capture cavity. For FEL operation we so far used only the 5-cell capture cavity followed by two 20-cell standard accelerating cavities.

The tracking simulations of this part of the machine are performed using the code GPT [5] including space charge forces and electromagnetic fields of the rf-resonators calculated by MAFIA [6]. The simulations are performed to find an optimized parameter set for the injector as well as to compare empirically found parameter sets and measured beam properties with the simulation results. The gauging relation between the tracking code parameters and the machine parameters like rf-phases and amplitudes were determined from separate calibration measurements. The nice agreement between measured beam properties from a previous FEL beam time and the simulation results confirmed this calibration method. Searching for an optimized setting with respect to bunch length and energy spread revealed an enormous sensitivity concerning the choice of rf-phases and amplitudes for the first two accelerating cavities due to non relativistic behavior in this section. In contrast to the common feeling (accelerate as fast as possible) the simulations suggested to reduce the field amplitude of the first 20-cell cavity. Since the longitudinal phase space is found to be correlated at the exit of the injector we can benefit from magnetic

bunching in the 180° bending arc towards the main linac. According to the tracking results a bunch length of 2 ps (FWHM) with sufficient energy spread of ± 33 keV (rms) at an energy of 8 MeV can be achieved at the entrance of the main linac as shown in Fig.3. below.

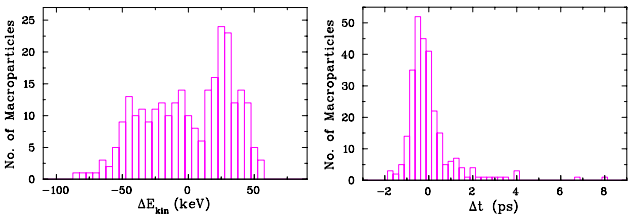

Figure 3. Distributions of particle energy and arrival time at the main linac for an optimized injector setting.

For the next beam time it is envisaged to verify this calculated parameter set hopefully leading to an increased small signal gain and higher peak power of the laser because of the shorter electron bunch. The simulations also showed that even at a quite modest bunch charge of 6 pC space charge effects influence the beam dynamics in our injector.

4 NONISOCHRONOUS RECIRCULATION

The principle of phase focusing is well known and used in circular machines like synchrotrons and microtrons. Recirculating linacs with only a few separate recirculations however, like the S-DALINAC, are usually operated with an isochronous beam transport system and on crest acceleration. The energy spread is then determined by the bunch length and the stability of the rf field in the accelerating cavities. But as pointed out by [7] the choice of an off crest synchronous phase together with a nonisochronous beam transport system offers a welcome longitudinal stability, thus reducing the effects of amplitude and phase jitter in the linac.

We simulated the situation at the S-DALINAC with two recirculations and 3 passes through the linac by simple tracking of the longitudinal phase space. We assumed a relativistic electron beam coming out of the injector uniformly distributed in longitudinal phase space with an energy spread of ± 0.1 % and a bunch length of 2° with respect to the rf-period. The eight cavities of the main linac are assumed to have an uncorrelated field amplitude jitter of 10^{-3} and a phase jitter of ± 1°. The longitudinal phase space distribution was calculated at the exit of the linac after 3 passes as a function of the synchronous phase ϕ_s and the longitudinal dispersion of the recirculating beam transport system. The simulations showed that at a working point of ϕ_s = -9.7° and r_{56} = 5.3° / % we can gain a factor of four in energy spread compared to isochronous recirculation. The remaining energy spread is mainly caused by the injected beam, while the contribution of amplitude and phase jitter in the linac becomes almost negligible. In Fig.4. the tracking calculations are summarized in a two parameter plot of the resulting energy spread. These concepts, highly relevant for improving the beam quality for nuclear physics experiments, could be verified already qualitatively and will be measured quantitatively soon.

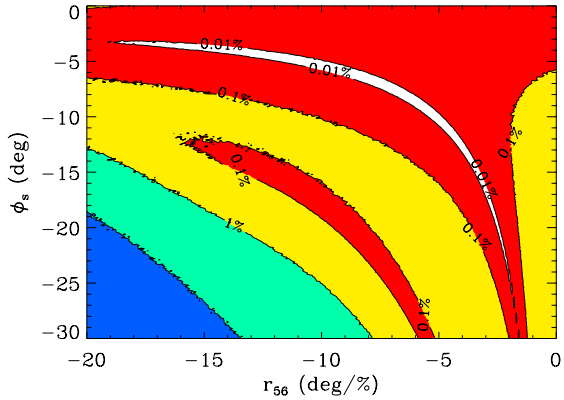

Figure 4 Energy spread after three linac passes as function of the synchronous phase ϕ_s and the r_{56}-matrix element of the recirculating beam transport system.

5 CONCLUSION

The successful operation of the FEL at the S-DALINAC has opened a wide new field of research possibilities. Therefore from now on besides the nuclear and radiation physics activities, both, user oriented experiments with the infrared light from the laser as well as investigations of basic FEL properties will be carried out. Improvement of the accelerator itself is focused on a better understanding and an optimization of its low energy part. To assure that the influence of space charge effects is taken into account correctly, we have already started to investigate the pulsed emission in the gun and electrostatic preacceleration using the time dependent Particle in Cell module of the MAFIA code.

1-GeV LINAC UPGRADE STUDY AT FERMILAB*

M. Popović, A. Moretti, R. Noble and C.W. Schmidt
Fermilab, Batavia, Illinois, USA

Abstract

A linac injector for a new proton source complex at Fermilab is assumed to have a kinetic energy of 1 GeV. This linac would be sized to accelerate 100 mA of H^- beam in a 200 microsecond pulse at a 15 Hz repetition rate. This would be adequate to produce $\sim 10^{14}$ protons per pulse allowing for future improvements of the new proton source complex. An alternate proposal is to add 600 MeV of side coupled cavity linac at 805 MHz to the existing 400 MeV Linac. This addition may either be in a new location or use the present Booster tunnel. A discussion of these possibilities will be given.

1 INTRODUCTION

This study investigates a possible upgrade of the Fermilab Linac to meet hypothetical muon collider needs, increased antiproton production and higher neutrino fluxes. Muon collider is the most demanding and anticipates 1.25×10^{14} protons per pulse at 15-Hz rate and an energy of 1 GeV. Presently, the Linac can deliver 45-50 mA peak current at 15 Hz with a pulse length of 35 to 57 μs for high energy physics or cancer therapy respectively[1]. With a small effort it is likely that pulses of 60 mA and 90 μs can be achieved at 400 MeV[2]. This represents a beam of 3.4×10^{13} protons per pulse at 15 Hz. Producing 20000 μs - mA, 1.25×10^{14} protons per pulse, is significantly more difficult and would require modifications at every stage of acceleration. For 1 GeV as a final energy, an additional accelerating structure is needed. Two options have been considered. Moving the operating Linac to a new location and extending the present side-coupled accelerating structure to 1 GeV. The other is to leave the operating Linac where it is, extend the side- coupled structure through part of the Booster tunnel and use existing tunnels to transfer the 1-GeV beam to a new booster[3].

2 1-GEV EXTENSION

To have a 1 GeV linac at Fermilab site which will satisfy the muon collider needs, there are three possible options, (Figure 1);

- Build a completely new Linac based on designs adopted for spallation neutron sources,
- Build a new Linac tunnel near the Main Injector which will house the whole linac and a new Booster. Move the existing linac into the new tunnel, make necessary modifications needed for higher beam peak current and longer pulse length, and add-additional accelerating structures to reach 1 GeV as the final kinetic energy.
- Leave the existing linac at its present location, make necessary modifications needed for higher beam peak current and longer pulse length, and use the existing Booster tunnel and galleries to house accelerating structure for acceleration from 400 MeV to 1 GeV.

The first option is the least controversial but may be the most expensive. The second option assumes increasing the linac energy in a conventional way, simply adding new structure to the existing Linac in the new tunnel to achieve 1 GeV. The additional 600 MeV structure is assumed to be an extension of the recent Linac Upgrade using the same side coupled cavity modules. A preliminary design requires 11 modules for acceleration and a "half" module for controlling the energy spread of the exiting linac beam. The total physical length of the structure is 131.3 meters. The design is based on the following assumptions:

- Values for transit time, Emax/Eo and ZTT are extrapolated from the fits calculated with SUPERFISH for the values of β from 0.46 to 0.72.
- Maximum allowed electric field is 1.55 Kilpatrick which for 804.96 MHz is equal to 40.3MV/m.
- Maximum power for a four section module should be less than 9 MW. This power limit includes power to the copper and power needed to accelerate 75 mA of beam.

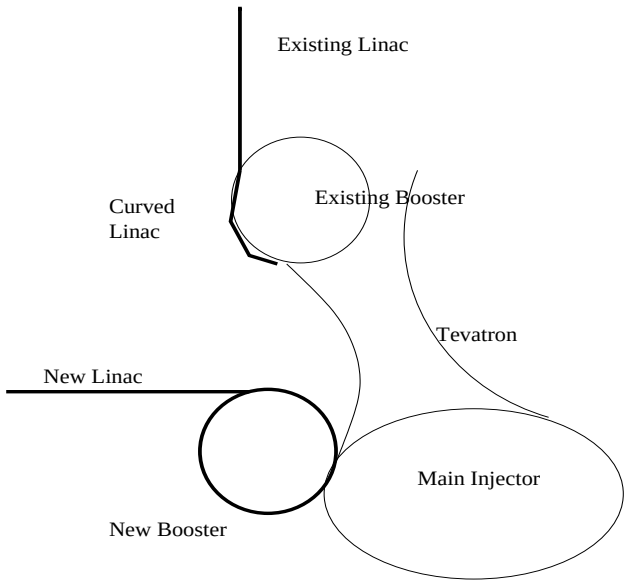

Figure 1: Location(s) of extended Linac and new Booster

* Operated by the Universities Research Association under contract with the U. S. Department of Energy

- ZTT used in the calculations is 85% of the value extrapolated from SUPEFISH calculations.
- Each module is made of four sections. The sections are made of 16 cavities of equal β. The value of β is equal to the beam's β at the mid point of the section. The sections are connected with bridge couplers and spaced for $3/2\lambda\beta$.
- Acceleration phase is -32 degrees.
- A FODO lattice is assumed using quads between each section with a phase advance of 90 degrees.

The third option, a 1-GeV linac extension in the present Booster tunnel, could prove to be economically and operationally viable. The H- beam from the 400 MeV Linac would be transported with the present 400 MeV transfer line to the Booster tunnel. To preserve the bunched beam we will use a buncher cavity at the entrance to the chute and/or retune the phase of the last module of the 400 MeV Linac. Recent experiments show that bunch length can be preserved for injection into the side coupled cavity. In this experiment linac pulses with pulse lengths less than a full Booster turn were injected in the Booster. The wall current monitor which is 334.3 meters from the injection point to the Booster was used to observe changes in the bunch length as a function of the debuncher phase and/or phase of the last accelerating module. The debuncher is located in the transfer line 33.2 meters from the exit of the Linac. The total length of 400 MeV transfer line is 62.2 meters, and by design it is dispersion free in both planes. Figure 2, shows the signal from the wall current monitor. The upper trace is a

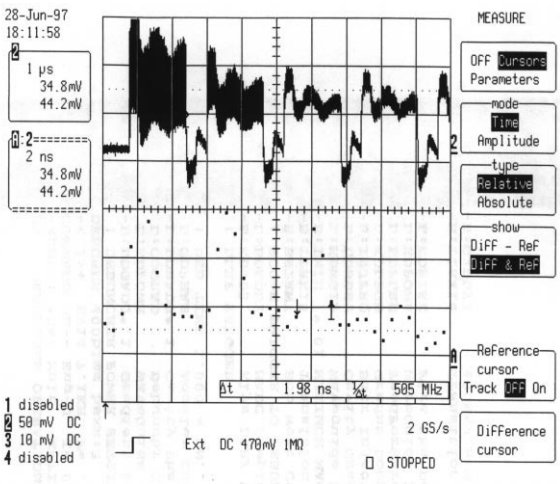

Figure 2: Bunch lenght at injection in the Booster

record of a little more than four Booster turns. The width of the trace is a measure of the strength of the 200-MHz signal. The lower trace is an expansion of the last three 200-MHz bunches seen by a detector on the first turn, after injection. The full width measured at this point is 1.98ns and this is at a location which is 396.6 meters away from the exit of the linac. On the second turn (474 meters away) the full width of the same bunch was measured to be 3.52ns. In the Booster tunnel the new linac will start 30 meters from the exit of the 400 MeV linac and will have two horizontal bends. The first bend is after three modules at a beam energy of 557 MeV. The bend consists of one FODO cell with two 11 degrees bend magnets. The next bend is at 703 MeV with the same type of bending magnets. The magnets are two meters long with a field of $\sim 3kG$. The H^- stripping probability is less than 4×10^{-12} at 557 MeV and less then 5×10^{-8} at 704 MeV. Each bend will introduce horizontal dispersion. TRACE3D calculations show an "increase" in horizontal emittance. Figure 3 shows the output

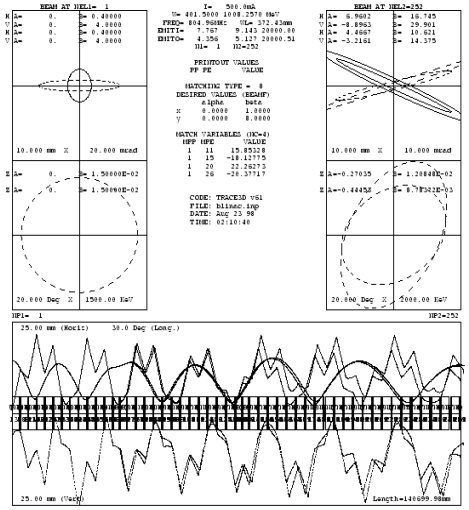

Figure 3: 1GeV Linac with bends

of TRACE3D where the beam was traced for two different cases. Input to the calculations is the linac as describe above, 13 accelerating modules and four bending magnets. The first trace simulates a "no bend" situation. In these calculations the bending angles were set to be 0.1 degree and the radius of curvature was adjusted to have the length of the "magnet" 2 meters. The second trace is for the case of four 11 degree bends. The output emittance printed by TRACE3D in this case is about two times bigger than for the "no bend" situation. In these calculations there was no attempt to adjust dispersion trough the linac after the first bend. The three quadrupoles around each bend can be tuned to minimum dispersion. The phase advance to the second bend can be arranged to supress if not cancel the dispersion.

3 PRESENT LINAC

To achieve 1.25×10^{14} protons per pulse will require considerable upgrading of the operating Fermilab Linac at the source, preaccelerator, low-energy linac and the high- energy linac. The maximum current the Linac is likely to achieve is 80-100 mA. This is limited by many constraints, most strongly by the ion source, RF power of the low-energy linac and the lattice design of the high-energy linac. Extending the pulse length is the other option, given that the

repetition rate is fixed at 15 Hz. The lower limit of 80 mA beam current sets the pulse length at 250 μs. These parameters set the conditions to which the present Linac must be capable.

3.1 Ion Source

The magnetron H^- ion source currently in use delivers a current of 65-75 mA with a pulse length of 90 μs[4]. Of this $\sim 5\%$ is lost in transport and 70% is captured in Tank 1 for a linac current of ∼45 mA through the Linac. To achieve the desired current of 80 mA an H^- ion source of ∼120 mA is necessary. BNL achieves 90 mA from a slightly modified magnetron source at an extraction voltage of 35 kV with a pulse length of 500 μs at 7.5 Hz[5]. The Fermilab source extracts at 18 kV. It is expected that a higher extraction voltage could give the desired current. A RF-driven H^- volume source may be another possibility having long lifetime. Such a source is undergoing R&D for other accelerator projects to produce 60 mA, 6% duty factor and a normalized emittance of 0.2 π mm- mr[6].

3.2 Preaccelerator and low energy transport

Two 750-kV Cockcroft-Walton generators are used as injectors to the Linac. Since neither has a bouncer, a voltage drop of ∼7 kV occurs for present beam pulses. At higher currents and pulse lengths a bouncer or other correction will be required. If the Linac were to be moved, one could consider a new tank 1 from 2 or 2.5 to 10.25 MeV, the energy of tank 2, and a set of RFQ's replacing the preaccelerators. This could also significantly improve the emittance[7].

3.3 Low-energy linac

The Fermilab Linac was designed for 75 mA and four turns of beam to the Booster (12 μs plus RF stabilizing time)[8]. At 90 mA the 5-MW RF power tubes will limit the beam current. However they can handle longer pulse lengths as shown by other U.S. accelerator facilities in table 1.

Table 1: US Proton Linacs

Beam	**BNL**	**FNAL**	**LAMPF**
Peak Current(mA)	37	48	18
Pulse Length(μsec)	500	57	900
Repetition rate(Hz)	7.5	15	120

Thus pulse lengths of 250 μs are possible with only a modest modification of the RF systems. To achieve longer pulses the quadrupole system for the drift tube linac will need modification. The pulsed power supplies will need to incorporate a second harmonic to give a relatively flat 250 μs pulse.

3.4 High-energy linac

The upgraded high-energy linac had a design goal[9] for the side-coupled accelerating cavities of 50 mA. The bridge couplers connecting the cavities were cut for a power level corresponding to 35 mA of beam, the traditional beam current when the upgrade was built. The cavities and couplers have handled up to 50 mA of beam. Whether they can handle 80-90 mA is questionable, and this is probably an upper limit. It may require rebuilding the bridge couplers. For 90 mA the 12 MW klystrons would need to be increased to 14.5 MW. The modulators, cooling systems, pulse transformers, oil tanks and low level rf systems would need to be redesigned for the higher power and pulse length.

3.5 Shielding and Losses

At the 1.0×10^{14} protons per pulse and 15Hz, the enclosure shielding, extrapolated from our present running, appears adequate except for a few areas that can be corrected. The radiation at the exterior high energy berm may exceed the permissible limit for an open unmarked area but could be corrected with a fence and signs or by adding soil. The door at the 400 MeV labyrinth into the Linac tunnel and the 400 MeV cable penetrations may exceed their allowed limits. This may require closing off the labyrinth and sealing the cable penetrations. The worst possible loss is the case of a spark in the last accelerating module if the extended structure for 1 GeV is located in the Booster tunnel. In this case about 2 μs of the beam located between the end of the 400 MeV Linac and the end of the 1 GeV linac will be lost in the Booster tunnel. This is less than the present losses in the Booster during normal operations. The beam in the 400 MeV part of the Linac will be dumped in the present Linac dump.

Abstract

The Accelerator Production of Tritium (APT) facility [1,2] is based on a linac which incorporates both normal-conducting and superconducting RF technology and accelerates a 100-mA cw proton beam to an energy of 1030 MeV or higher, depending on the desired production rate. Commissioning plans to achieve full power operation with minimum beam-induced activation of components have been evolving [3]. This paper presents the main issues and the basic approaches that are now being discussed.

1 COMMISSIONING OBJECTIVES

By commissioning of the accelerator, we refer to the process whereby the components are brought into operation with beam for the first time as a functioning integrated accelerator system. Commissioning need not await the complete installation and alignment of all the accelerator components, but may be done in stages. Two main activities make up the commissioning process. First is the initial setting of parameters, which includes the focusing and steering fields, and cavity-field amplitudes and phases, to values determined by the physics and engineering design. Second are the measurements to characterize the functioning of the integrated system, especially the beam and the RF system. These data will be compared with the predictions of simulation code. Discrepancies that are outside of error tolerances must be understood and, if appropriate, used to update the codes. The commissioning process is the time to detect and resolve any unanticipated performance problems that might arise. Also needed for evaluation of the overall performance are tests of different operating modes. For APT this includes operation with some superconducting cavities turned off, simulating fault conditions, where the rest of the linac is reset to continue beam operation.

2 SPECIAL CONSIDERATIONS FOR COMMISSIONING APT

The experience gained from operating and restarting the LANSCE proton linac, a pulsed machine with multiple beam operation that includes a 6%-duty-factor, 1-mA average current, and 800-MeV final energy, will be our reference point. LANSCE experience has shown that minimizing beam loss during normal operation is important, because beam loss produces radioactivity that restricts hands-on maintenance, and can cause equipment damage. Beam loss could be a concern during commissioning because the parameters are adjusted over a wide range and at times can deviate substantially from the design values. Many steps, including alignment, polarity setting, and calibration of focusing quadrupoles and steering dipoles, alignment and calibration of beam-diagnostic components, and relative phasing of multiple power feeds should be carried out prior to the start of beam tests. Also, commissioning operations that require beam should be done using pulsed beam with as small a beam duty factor and as small a peak current as is practicable, consistent with the capabilities of the beam diagnostics and the ion source. Beam-pulse lengths should be long compared with the transients in the low-energy beam transport and the RF system. We anticipate using cw RF power and pulsed beams with approximately 200-μs pulse length and a repetition rate from 1 to 10 Hz. Depending on the beam current, an RF-system settling time of 30 to 100-μs is expected before steady state is reached. The choice of peak current depends on the procedure. We expect a peak current of about 1 mA to be adequate for measuring the transverse beam-centroid alignment and setting the transverse beam steering. The 1-mA peak current, for which the space-charge forces are small, is suitable for phase scans used to set the phases and amplitudes of the cavity fields. After the 1-mA procedures are completed, the peak current will be increased to 100 mA to evaluate beam and system performance at full space charge and with full beam loading. To limit the beam losses during the commissioning, LANSCE experience suggests that the commissioning procedures should be as simple as possible, and should be done one section at a time, where each section to be commissioned consists of one of more accelerating modules.

After all the parameters have been set, beam measurements will be made to characterize the output beam from that section, using a commissioning beam-diagnostic package placed at the output. After the diagnostic package, a beam stop is installed, which prevents the commissioning beam from inducing radioactivity downstream of the section being commissioned. The beam stops must have sufficient cooling capability to absorb the beam power at 100-mA peak current with materials chosen to minimize long-lifetime activation. After the commissioning of a given section is completed, the diagnostic package and the commissioning beam stop are removed, making room for installation of the next section.

Although dividing the linac into sections helps to locate and fix problems, to keep the commissioning time within reasonable bounds, it is desirable to commission the linac in no more separate sections than is necessary, consistent

with the requirement that simple operational procedures be used. For practicality and simplicity, LANSCE experience suggests that all the commissioning steps, including the cavity phase scans, during which the beam energy varies over a large fractional range, be carried out with fixed quadrupole gradients. This requirement leads to a preliminary estimate of perhaps six commissioning-section final energies: 6.7, 10, 21, 54, 211 MeV, and 1030 MeV. A systematic study to determine the optimum number of sections and their final energies is now in progress.

3 SETTING THE PARAMETERS

Setting the parameters affecting the transverse beam dynamics, primarily quadrupole gradients and beam-steering fields should be straightforward except for outright mistakes or possible component failures. Quadrupole gradients can be set accurately to values determined from the physics design by using magnetic-field calibrations. Beam-profile measurements made near the major focusing-lattice transitions can be used to make adjustments in the quadrupole gradients if needed to improve the beam quality. As the beam energy increases, the apertures increase and good transmission can be expected over a wide range of the amplitudes and phases of the accelerating cavities.

The main task for the parameter-setting part of the commissioning process is expected to be setting the amplitudes and phases of the cavity fields. Beam measurements are required for this because direct RF field-measurement methods are not accurate enough. Cavity-field parameters can be set using a phase-scan method, in which the phase of each accelerating cavity relative to the input beam is varied, and for each phase, corresponding output beam parameters are measured. The beam measurements for commissioning can be made using both an interceptive method, such as the absorber/collector technique at low energies that measures the accelerated beam intensity above an energy threshold set by the thickness of a copper absorber, or a non-interceptive method based on beam-image-current probes in which signals are induced by the string of beam bunches. Advantages of the absorber/collector method for setting phase and amplitude at low energies are simplicity, and the ability to measure directly the phase width of the bunch from the shape of the curve of accelerated-beam intensity versus input phase.

The beam-probe method allows a measurement of beam arrival time or phase using a single probe, or beam-energy using a pair of probes separated by a drift distance. The non-interceptive beam-probe method allows more accurate measurements over the full range of beam energies and at full peak current. In the normal-conducting linac, plots of either the output-beam energy from a pair of probes or the output-beam phase from a single output probe, versus cavity phase are made as a function of the cavity amplitude. By comparing these curves with corresponding curves predicted by the simulation code, the RF parameters that produce the design values of the cavity amplitude and phase can be determined. The method based on a plot of output-beam phase versus cavity phase gives greatest accuracy when the longitudinal phase advance between the beginning of the cavity and the output probe is near an odd-integer multiple of 90°. The method involves plotting the curves for two amplitudes, one for the amplitude corresponding to 90° phase advance, and one for the design amplitude, which is known from simulation relative to the former amplitude. The two curves intersect at a known phase near the design phase. This method has the advantage that intertank spaces will generally be available allowing us to install an output probe near a location within the accelerating module corresponding to an odd-integer multiple of 90° phase advance. The other method based on a plot of output energy versus cavity phase is most accurate when the longitudinal phase advance is an integer multiple of 180°, a property that is not generally satisfied if the probes are installed in the drift space after the module.

A phase-scan procedure is also planned for the cavities in the high-energy superconducting linac. In this case the RF modules consist of either two or three independent superconducting cavities, driven by one klystron, and the longitudinal phase advance is small compared with 90°. Each cavity has an RF pickup probe that samples the field in the cavity, and whose amplitude can be calibrated in the laboratory using measurements of power and quality factor Q to an accuracy of about ±5%. After the cavities are installed in their cryostats in the tunnel, and before beam is injected into the linac, the cavity resonant frequencies are set by calculation to compensate for beam loading, the cavity fields are set to approximate values based on the laboratory calibrations, and relative phases of the cavities within the same module are set using low-power RF measurements and by adjusting mechanical phase shifters. This one-time setting of the mechanical phase shifters is determined by the design values of the cavity phases relative to the beam and the nominal value of the beam velocity at that location.

After presetting these parameters, we use the beam to determine the required RF drive phase that gives optimum phasing of the whole RF module relative to the beam, using a phase-scan measurement. In this case we obtain from the measurements a curve of output energy from a pair of beam probes versus RF drive phase. The curve is a skewed sinusoid, and using the phase locations of the peak and valley from the measured curve, we can set the RF drive phase to the design value. A complete analysis of tolerances has yet to be completed, but if uncertainties are limited to those from the beam diagnostics, the phase can be set to within a degree of the design value.

Because of the accuracy of the beam-energy measurement, the klystron amplitudes can be adjusted at each stage to minimize cumulative energy errors as we proceed down the linac. The beam energy from the pair of beam probes is obtained from the relation $\phi(\mathrm{deg})=360L/\beta\lambda$ and solving for β, where ϕ is the measured phase difference of the signals induced by the beam in the probes, L is the spacing of the two probes, β is the beam velocity relative to the speed of light, and λ is the wavelength at the bunch frequency of 350 MHz. For example, at 1 GeV (β = 0.875), L = 8.54 m (using the

spacing of two detectors separated by a lattice period), and λ = 0.857 m, we find that ϕ = 4102° or 142° (mod 360°). We are more interested in the energy uncertainty ΔW from the measurement. This can be calculated from

$$\Delta W = mc^2\gamma^3\beta^3\left(\frac{\lambda}{L}\right)\left(\frac{\Delta\phi(\text{deg})}{360}\right).$$

If we use mc^2=938.3MeV, L=8.54m, γ=2.066, β=0.8750, λ=0.857m, and $\Delta\phi$ =±3.1° (a conservative estimate of the "accuracy" from the beam diagnostics) we obtain a corresponding uncertainty in the beam-energy of ±4.8 MeV, which is only ±0.48%, sufficient to prevent a significant accumulation of an energy error.

4 CHARACTERIZATION OF THE ACCELERATOR SYSTEM

Experience from commissioning accelerators over the years has shown that as new parameter regimes are explored, new and unanticipated effects can appear. Especially because of the need to control beam loss to maintain high availability, carrying out a comprehensive set of measurements of the beam properties after setting the parameters of each stage is an important requirement. Such data taken at the end of each newly commissioned section will be compared with the predictions of the numerical simulation code. Discrepancies can be used to identify problems, which may include either component errors or physics effects that may not be included in the beam-dynamics model. Measurements made at the low-velocity end of the linac, where space-charge is important, are particularly important because discrepancies between measurements and simulation can provide an early warning of possible problems that could lead to beam loss at the high-energy end of the machine.

Measurements should be chosen so that, by comparison with the simulation code, we can answer three main questions. First, do we observe the expected low-peak-current beam characteristics, where space-charge effects are negligible? Second, do we observe the expected rms properties of the beam at the full peak current? These rms properties depend on the space-charge force, and should be compared with the numerical simulation code. Finally, do we understand the observed beam distribution including the beam halo, its density profile and its extent?

Using a commissioning beam-diagnostic package placed at the output of the section being commissioned, we plan to measure the beam current, beam loss, transverse beam profile, transverse rms emittance, transverse beam halo, final beam energy centroid, and bunch length at the output of each commissioning section [4]. Beam-loss measurements depend on the beam-halo characteristics, which depend on beam mismatches in either the longitudinal or transverse phase space [5]. Multiple transverse profile measurements using permanently installed beam-profile monitors will be compared directly with the simulations, and will also be used to determine the rms emittance during both commissioning and nominal operation. Because of its interceptive nature, a separate phase-space measurement using a conventional slit and collector device will provide beam-emittance measurements during low peak current operations. Comparison of the emittance measurements from the two methods will provide a calibration of the multiple profile measurements, which will be used to characterize beam operation after the commissioning process. Also, transverse beam-halo measurements will be obtained in which we acquire the transverse projected profiles of the beam from 3 to 5 rms-widths at multiple locations. Finally, for the longitudinal dynamics, we depend primarily on beam-centroid phase and energy measurements, and bunch length or phase spread measurements [4].

Prior to implementing supermodule RF systems in the normal conducting linac, klystron phase calibration measurements must be performed. These measurements are made to ensure that the RF phase of the klystrons have a unique and fixed relation to one another. In addition, the low-level RF (LLRF) control system has built in some on-line system-characterization capabilities [6]. These enable the operator to inject a signal of known frequency characteristics and measure the system response. After the RF parameters are set, measurements will be made to characterize the RF system performance under full beam-loaded conditions. These measurements will include the reflected power, and the errors signals associated with phases and amplitudes of the cavity fields, which are controlled by the LLRF system.

5 ACKNOWLEDGMENTS

We acknowledge support by the U.S. Department of Energy. We thank Jim Stovall for sharing with us his studies for setting the cavity parameters in the low energy linac, and Andrew Browman for helpful discussions.

STATUS UPDATE ON THE LOW-ENERGY DEMONSTRATION ACCELERATOR (LEDA)*

H. Vernon Smith, Jr. and J. David Schneider, APT Technical Project Office,
Los Alamos National Laboratory, Los Alamos, New Mexico, 87545

Abstract

As part of the linac design for the accelerator production of tritium (APT) project, we are assembling the first approximately 10-MeV portion of this cw, 100-mA proton accelerator. The primary objective of this low-energy demonstration accelerator (LEDA) is to verify the design codes, gain fabrication knowledge, understand beam operation, and improve prediction of costs and operational availability for the full 1000- to 1700-MeV APT accelerator. This paper provides an updated report on this past year's progress that includes extensive beam tests of the LEDA injector using the Chalk River Injector Test Stand (CRITS) radio-frequency quadrupole (RFQ) accelerator. The CRITS RFQ produces a cw, 100-mA, 1.25-MeV RFQ output beam. We also report on fabrication, assembly, tuning, and installation of the 6.7-MeV LEDA RFQ; installation and testing of the 350-MHz RF system; fabrication of the high-energy beam transport (HEBT); installation (as well as prototype testing) of the LEDA ogive beam stop; and upgrades to the facility. First tests with the 6.7-MeV, 100-mA, cw beam from the RFQ are scheduled for late fall, 1998. References are given to many detailed papers on LEDA at this conference.

1 INTRODUCTION

This overview paper summarizes activities completed and initiated on LEDA since the publication of ref. [1]. LEDA is designed as a prototype [2] of the first 10- to 20-MeV portion of the APT linac [3] that will be built at Savannah River. LEDA's beamline components now include a 75-keV proton injector, a 6.7-MeV RFQ, a HEBT, and a beamstop (Fig. 1). Initially, a 10 MeV CCDTL (coupled-cavity drift-tube linac, a hybrid between a standard DTL and a CCL structure) will be added after the RFQ tests are complete.

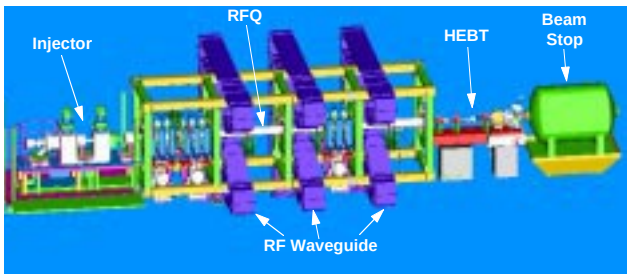

Fig. 1. Conceptual layout of the LEDA accelerator, showing the injector, RFQ (behind waveguides), HEBT, and beamstop.

* Work supported by the US Dept of Energy, Defense Programs.

Even though the output energy is low (10 MeV), the average beam power (1.0 MW) of LEDA will rank it with the LANSCE accelerator as the two highest power proton linacs in the world. Clearly, radiation shielding and power handling are important design issues. We summarize the LEDA status as of early August, 1998.

2 SUBSYSTEM DESCRIPTION

Injector:

The injector must match a dc proton beam of at least 110 mA at 75 keV into the RFQ. A 2.45-GHz microwave proton source, a single-gap extractor, and dual magnetic solenoids provide this beam. The ion source requires only 500-800 W to create a suitable plasma from which a beam having >90% proton fraction and >30% gas efficiency is extracted [4]. The single-gap, spherically convergent extractor provides a beam with emittance <0.2 π mm-mrad (normalized).

The low-energy beam transport (LEBT) uses two solenoids and two steering coils to ensure a proper match into the RFQ. A well-cooled variable-iris device is used to control injected current [5], and a microwave power modulator is used to provide beam pulsing [6] for commissioning and beam-tuning activities. Multiple extended beam runs with this injector have shown it capable of the required current, emittance, and stability. Measured erosion rates show a predicted maintenance-free lifetime exceeding 400 hours. The LEBT physics design [7, 8] is in good agreement with the mechanical design [9] and detailed measurements [10]. The LEDA injector is now installed in the beam tunnel (Fig. 2).

Fig. 2. LEDA injector installed in the beam tunnel.

The LEDA injector was used to inject a 50 keV proton beam into the CRITS RFQ. Beam operation with this 1.25-MeV cw RFQ is summarized in several papers at this conference [11, 12, 13]. Beam currents up to 100 mA

were accelerated by the CRITS RFQ [12]. A modification of the source-plasma 2.45-GHz microwave power feed lowers the rms noise on the output proton beam to < ±1% [14]. Also, an on-line method for measuring the proton fraction of the hydrogen beam confirms the previously-measured ~90% H^+ fractions [15].

RFQ:

LEDA's RFQ [16-18] is unique in terms of its long physical length (8 meters), high output energy (6.7 MeV), large beam power (670 kW), and cooling requirements (1.2 MW). It is constructed as an all-brazed, 100% copper (OFE) structure, assembled from eight separate 1-meter-long sections [17]. When in operation, its only active resonance control is by modulation of the input water temperature.

Of the eight separate sections, three are used for 350-MHz RF power feed [19] via four 250-kW coupling irises (12 total) and three sections provide vacuum pumping. Each section includes 16 static slug tuners, used only for tailoring the initial field distribution. Fabrication of the LEDA RFQ [20], the vacuum system [21, 22] and the resonance-control cooling system [23] is complete; this equipment is installed in the LEDA beam tunnel (Fig. 3); and the RFQ RF-field tuning procedure is complete [24].

Fig. 3. LEDA RFQ installed in the beam tunnel.

CCDTL:

This new 700-MHz structure [25] captures features of a DTL and a CCL, using either one or two simple drift tubes inside each π-mode cavity. Test results [26] for a CCDTL "cold model" confirms the 2-gap to 3-gap transition section for the LEDA CCDTL. A CCDTL 'hot model' has been fabricated to test structure cooling and response [27]. The LEDA CCDTL will be installed after the LEDA RFQ has been commissioned and tested.

RF Power Systems:

Three 1.2-MW, 350-MHz, cw RF-power systems are installed to power the RFQ [28-30]. The first of three 700-MHz, 1.0-MW systems that will be used to test the CCDTL have also been installed [29]. A 95-kV IGBT (insulated-gate, bi-polar) power supply that will drive the 700-MHz klystrons is being developed [31]. Each of sixteen 350-MHz RF vacuum windows have been tested at power levels >950 kW [32]. During operation, twelve of these windows will be run at power levels up to 250 kW each. The high-power RF system is ready for RF conditioning of the LEDA RFQ.

Low-Level RF Systems:

The LLRF controls system will perform a number of functions including: set and maintain the proper phase and amplitude of all accelerating cavities [33], distribute reference signals along the beam line, monitor cavity resonance condition, and provide many field signals from cavity pickup loops.

Controls:

LEDA is using a distributed control system based on EPICS [34, 35]. Many LEDA sub-systems have localized control with dedicated PLCs (programmable logic controllers), but all operational status and control commands can be accessed through the EPICS operator interfaces. An EPICS station and all peripherals have been controlling the LEDA injector for more than three years. An automated control routine provides prompt, hands-off, full-beam recovery from injector high-voltage sparkdowns. The safety and protection systems are monitored using EPICS - in the case of the fast-protect system the beam is shut down within 10-20 μsec of an interrupt and the first fault is recorded by EPICS.

HEBT and Beam Stop:

The HEBT safely transports and matches the RFQ output beam to the high-power beamstop. The HEBT (described in [36]) contains beam diagnostics that allow confirmatory measurement of the beam parameters.

For tests at 6.7 MeV, the beam will impinge on a nickel ogive beamstop [37] that is mounted inside an aluminum vessel that contains borated water (Fig. 4) to provide excellent shielding against prompt neutrons. Preliminary calculations indicate this ogive beamstop apparatus will be suitable for use at 8- and 10-MeV operation with the CCDTL sections.

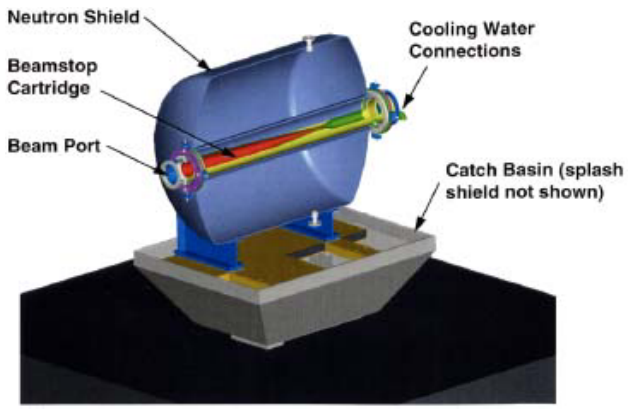

Fig. 4. LEDA ogive beamstop.

Beam Diagnostics:

The LEDA (mostly non-interceptive) diagnostics [38] measure and characterize the beam position [39] and the beam profile [40]: they also measure the beam current to obtain the RFQ transmission. This information will be used to operate the LEDA accelerator and to confirm the accelerator component designs.

Facility Modifications:

LEDA is installed in, and will be operated in, a pre-existing building that has a 140-m-long buried beam tunnel. The upgrades required to provide >10 MW of ac power and cooling water are nearly complete.

Safety Systems and Analysis:

A safety analysis document (SAD) has been prepared, reviewed, and approved. The LEDA accelerator readiness assessment is scheduled for this September. Operational run-permit is incorporated into the EPICS control system, with scores of interlocks to ensure that components and systems operate only when the risk of equipment damage is very low. A hard-wired fast-protect system ensures the near-immediate (10- to 20-μs) turnoff of the beam in event of beam spill as detected by fast ionization chambers. Totally separate from both these equipment safety systems, a personnel access control system (PACS) ensures that all personnel are excluded from the beam tunnel whenever beam or high rf power might be present. This PACS is very similar to the recently upgraded system in use at LANSCE.

3 SUMMARY

The LEDA project is on schedule to progressively assemble and test major components of a high-power, cw accelerator, first at 6.7 MeV, then 8 MeV, and then at 10 MeV. The possibility of testing the APT plant CCDTL at up to 20 MeV remains.

BEAM DYNAMICS DESIGN OF THE 211 MEV APT NORMAL CONDUCTING LINAC *

L. M. Young, J. H. Billen, H. Takeda, R. L. Wood
Los Alamos National Laboratory, MS H817, Los Alamos, NM 87545, USA

Abstract

This paper describes the normal conducting linac design that is part of the Accelerator for Production of Tritium (APT) project [1]. The new version of PARMILA [2] designed this linac. This linac accepts the beam from the 6.7-MeV radio-frequency quadrupole (RFQ) [3,4] without a separate matching section. At about 10 MeV, it has a smooth transition in the length of period from 8βλ to 9βλ in quadrupole focusing lattice. This adjustment of the period was needed to provide sufficient space for the quadrupole focusing magnets and beam diagnostic equipment. The linac consists of the coupled-cavity drift-tube linac (CCDTL) [5] up to 97 MeV and coupled-cavity linac (CCL) above 97 MeV.

1 INTRODUCTION

The first 211 MeV of the APT linac consists of the 700-MHz CCDTL and CCL. The CCDTL accepts the beam from the 350-MHz, 6.7-MeV RFQ without a separate matching section. The CCDTL accelerates the 100-mA beam to 97 MeV. The CCL accelerates the beam to 211 MeV. The CCDTL uses a transverse focusing period of 8βλ from 6.7 MeV to about 9.5 MeV. At this point the transverse focusing period is smoothly increased to 9βλ to make more room for the quadrupole focusing magnets. The 8βλ section of the CCDTL uses one accelerating cavity with 1 drift tube between each quadrupole magnet leaving plenty of space for the quadrupole. After the transition to 9βλ the CCDTL has one accelerating cavity with 2 drift tubes between each quadrupole. The rest of the CCDTL and CCL accelerator use the 9βλ focusing period. Figure 1 shows the particle coordinates versus cell number from a PARMILA simulation though the 211-MeV linac and the first 6 “Cryomodules” of the Superconducting linac. A “Cryomodule” is a cryostat with two or more accelerating cavities. Each accelerating gap and each quadrupole increments the cell number in this figure.

2 RFQ TO CCDTL MATCHING

We used no separate matching section to match the beam from the RFQ to the CCDTL. By adjusting the length of the fringe-field cell at the output of the RFQ, we matched the beam into the CCDTL quadrupole focusing channel. In addition, we adjusted the transverse focusing strength per cm of the RFQ to equal that of the CCDTL so that the match would be current independent. The longitudinal matching was a little more difficult because the longitudinal focusing goes to zero at the end of the final accelerating cell in the RFQ. Also, the beam drifts to the first cavity of the CCDTL before it sees any longitudinal focusing. Another complication is that the RFQ operates at 350 MHz and the CCDTL at 700 MHz. This problem was solved by setting the synchronous phase of the first accelerating cavity at -90° and increasing the RF fields in this cavity by a factor of 1.65. The second accelerating cavity was operated at -30° synchronous

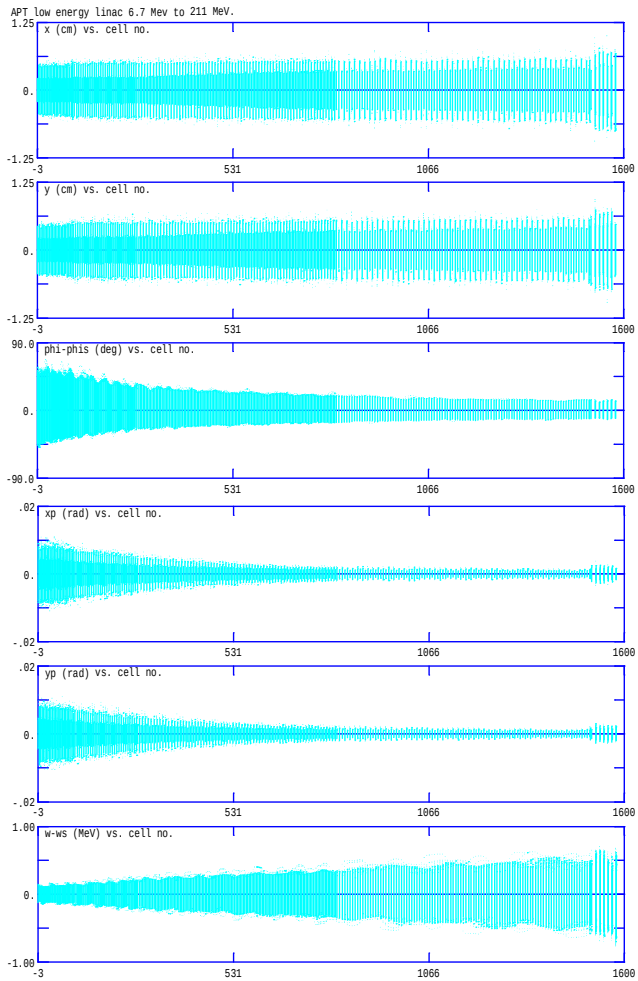

Figure 1. Beam size versus cell number of the 211-MeV APT Linac. Plotted versus cell number respectively from the top down are particle coordinates x, y, phi, xp, yp, and energy. The phase “phi” and the energy are plotted with respect to the phase and energy of the synchronous particle. Divergence coordinates are xp=dx/dz and yp=dy/dz. This data comes from a PARMILA simulation with 95405 particles.

*Work supported by the US Department of Energy.

phase and normal RF fields. The third and subsequent accelerating cavities operate at -60° synchronous phase to provide a large enough longitudinal acceptance to capture the beam bunches from the 350-MHz RFQ. We chose the RF amplitude at the beginning of the CCDTL to provide nearly the same longitudinal focusing strength per cm as provided by the RFQ near its exit. Figure 2 shows the longitudinal and transverse zero-current phase advance divided by the transverse-focusing-period length plotted versus energy from 1 MeV (in the RFQ) to 245 MeV (in the first part of the superconducting accelerator). The small discontinuities in the focusing strength in this figure at 6.7 MeV, show the match in the focusing between the RFQ and the CCDTL.

3 CCDTL

The RF amplitude slowly increasees and the synchronous phase approaches -30° as the energy increases. At 10 MeV, after the transition to the 9βλ focusing period, the real-estate accelerating field is too high for the 1-drift-tube CCDTL. The term real-estate refers to an average over a transverse focusing period. The CCDTL uses 2 drift tubes in each cavity from 10 MeV to 21.6 MeV. At 21.6 MeV the synchronous phase has progressed to -40° and the accelerating field to 1.863 MeV/m. The accelerating structure only occupies 5/9^{ths} of the real estate. Therefore the real-estate accelerating field is 1.035 MeV/m.

The CCDTL uses 2 cavities with 1 drift tube in each between each quadrupole magnet from 21.6 MeV to 96.7 MeV. The synchronous phase reaches its final value of -30° at 92 MeV. At that point the effective real-estate accelerating field, E_0T, is 1.12 MeV/m. We made the changes in the accelerating field and synchronous phase to keep the ratio of the longitudinal and transverse phase advance per cm nearly constant below 25 MeV. Below 25 MeV the transverse phase advance was keep constant at ~78° per period.

The effect of changing the period from 8βλ to 9βλ can be seen between 9.5 and 10 MeV in Figure 2. At energies above 25 MeV, we slowly decreased the quadrupole focusing strength as the energy increased. We reduced the quadrupole focusing strength at higher energies for two reasons. First, by keeping the ratio of the longitudinal focusing strength to the transverse focusing strength constant the bunch shape remained nearly constant. Also, as shown in Figure 3, the longitudinal tune depression did not fall to extremely low values as it would have without reducing the transverse focusing strength. Second, we had to reduce the transverse focusing strength at the end of the normal conducting linac to equal that available at the beginning of the superconducting linac.

4 CCL

The linac uses the CCL structure from 96.7 MeV to 211 MeV. The first segment in each module uses 6 accelerating cavities while the rest of the segments have 7 accelerating cavities. The accelerating structure occupies 7/9^{ths} of the real estate in this part of the linac. The first segment uses only 6 cavities to make room for a beam-line vacuum-isolation valve. The field in the first segment is increased to give the same energy gain as the 7 cavity segments. At the end of the normal conducting linac the real estate accelerating field is 1.427 MeV/m at 211 MeV. Figure 4 shows the transverse and longitudinal emittance in the normal conducting linac and the first part of the superconducting linac.

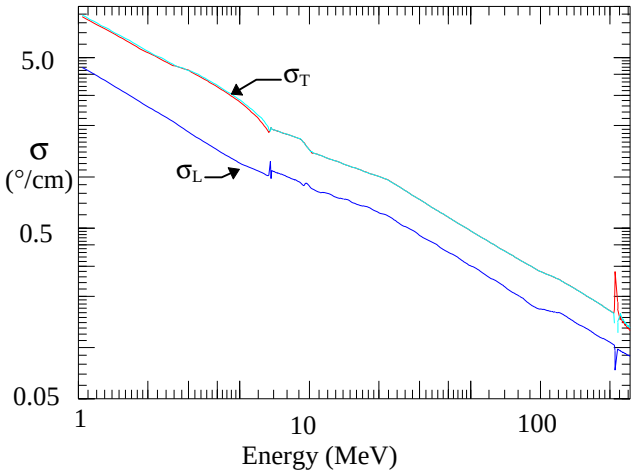

Figure 2. A log-log plot of the longitudinal (σ_L) and transverse (σ_T) zero-current phase advance divided by the transverse-focusing-period length. The transition from the quad-singlet focusing in the normal conducting linac to the quad-doublet focusing in the superconducting linac causes the spikes at 211 MeV.

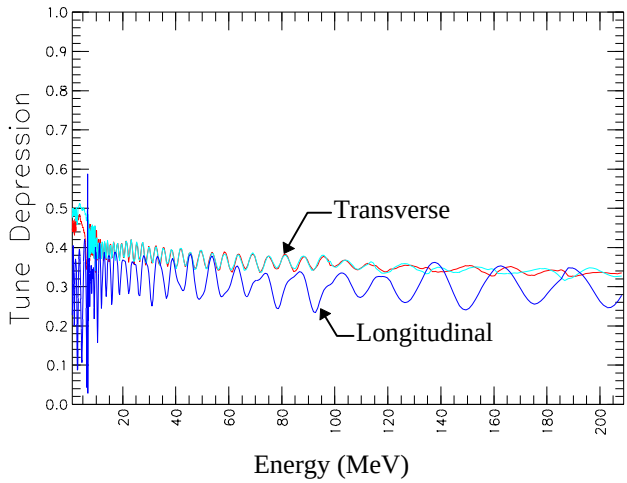

Figure 3. The longitudinal and transverse tune depression from 1.0 MeV to 211 MeV in the APT linac plotted versus energy. The tune depression is the ratio of the phase advance with 100 mA to the phase advance with "zero" current.

5 CURRENT INDEPENDENT MATCH

A current independent match means the beam match between two parts of the linac does not depend on the beam current. The APT linac must operate with a 100-mA

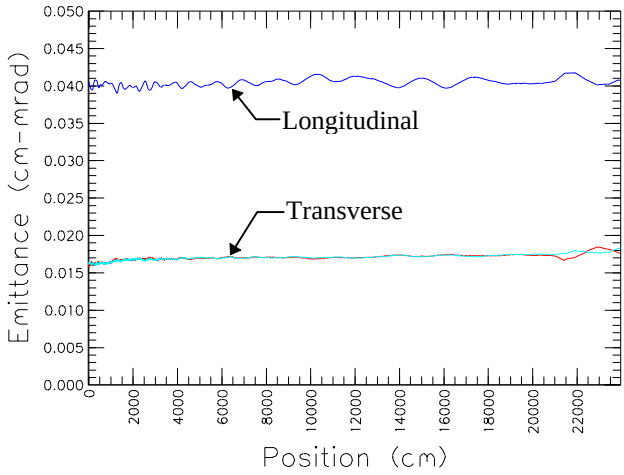

Figure 4. The transverse and longitudinal emittance versus position in the 6.7-MeV-to-211-MeV linac and the first 6 "Cryomodules" of the superconducting linac. The superconducting linac starts at ~21000 cm in this figure.

CW beam. We must keep the beam loss to a very small level even during commissioning. During commissioning we will use beam pulses of about 200 μsec duration and with low peak current at first. Under these conditions we can allow a larger fraction of the beam to be lost. Later in the commissioning process the pulsed beam will have a peak current of 100 mA and only a small fraction can be lost. During commissioning with a pulsed beam we will optimize the quadrupole magnet strengths and the RF amplitudes and phases for extremely small beam loss. We must not change these settings for the CW beam. Therefore, we need a current independent match so that we can operate the accelerator at any current up to 100 mA without readjusting the quadrupole focusing magnets or the RF settings. The current independent match between the RFQ and CCDTL has been checked by running PARMTEQ simulations of the RFQ with input beams with currents of 0, 40, 57, 103, and 110 mA. These output beam distributions from the PARMTEQ simulations were then used as the input beam distributions for PARMILA simulations of the beam through the CCDTL and CCL without changing any parameters. The PARMILA code uses the beam current contained in the input distribution file. The match in all cases was satisfactory.

We used the following philosophy throughout the design of the linac to ensure current independent matching between different parts of the linac. We kept the ratio of the longitudinal to the transverse focusing strength nearly constant and without steps in either the longitudinal or transverse focusing strengths. This philosophy results in a linac design with a beam that is nearly equipartitioned [6,7]. With a nearly equipartitioned beam there may be less beam in the halo for a well matched beam such as that shown in Figure 1. Reference [8] shows that a halo can develop even with a well matched beam if it is not equipartitioned. With a poorly matched beam, a halo will develop whether or not the beam is equipartitioned.

6 CONCLUSIONS

The PARMILA design of the normal conducting linac for APT is complete. The simulations show essentially no emittance growth in this linac. The match between the RFQ and the CCDTL is current independent. The match between the various sections of the CCDTL and the CCL is extremely good because there is no change in the transverse focusing period and the variation in the real-estate accelerating field is smooth.

The beam can be matched to the superconducting linac. Although we have not checked this match with a complete set of simulations (only with 0 and 100 mA) we expect the match to the superconducting linac to be current independent, because we kept the focusing strength per cm continuous across this transition.

FERMILAB LINAC 1997-98 OPERATIONS, STUDIES AND IMPROVEMENTS

L. J. Allen, C. W. Schmidt and M. Popovic
Fermi National Accelerator Laboratory*
Batavia, Illinois

Abstract

The Fermilab Linac operated as an injector for the Tevatron Fixed Target Program, booster studies and as a neutron source for cancer treatment during 1997 and 1998. Operational reliability was 98% of the scheduled operating time. Beam currents were generally in the 45 to 48 mA range with a high of 52 mA during studies. After completion of the Fixed Target Program, the Linac embarked on a series of studies. The studies were intended to verify visual survey data indicating a misalignment of the low energy linac, correct the misalignment, and install and use new wires for determining emittance. Operations data and studies results will be presented.

1 OVERVIEW

The Fermilab Linac operates at 400 MeV for linac studies and injection into the 8-GeV Booster for further studies and high energy physics (HEP). It also operates at 66 MeV as a neutron source for treating cancer in the Neutron Therapy Facility (NTF). There are two ion sources, feeding DC accelerating columns powered by Cockcroft-Walton generators at 745 kV. The Linac RF pulse repetition rate is 15 Hz, useable RF pulse length is 120 μsec and the maximum source beam pulse length is ~80μsec. The operating beam pulse length is dependent upon on its ultimate use and determined by choppers in the 750-keV line. Pulse lengths for HEP beam are determined by the Booster requirements, typically 15-25 μsec. NTF uses the unused 15-Hz pulses with a 57-μsec length. Linac studies use typically a 20 μsec pulse generally at 3 Hz.

2 FIXED TARGET RUN

In 1996 and 1997 Fermilab operated a Fixed Target Run providing 800-GeV beams to experimenters in the external beam-lines and 8 GeV antiproton beams to experimenters in the Accumulator Ring. The Linac provided 12 pulse bursts of beam for HEP and single pulses at 2.5 second repetition rates for antiproton production along with NTF. In September 1997 the Fixed Target program ended and the Linac embarked on a one year program of maintenance and studies with the Booster. Aside from the usual preventive maintenance a drift tube was replaced in tank two, a resurvey was done and scanning profile wires were added at the 400-MeV output of the Linac. Studies included the sampling of drift tube quadrupole placement to investigate a suggested vertical misalignment between tank 5 and the high-energy linac.

* This work supported by the U.S. Department of Energy through the Universities Research Association under contract DE-AC35-89ER40486.

Beam intensity, during the Fixed Target Run, averaged 45 to 48 mA as shown in Figure 1. Problems with the 2400 l/sec ion pumps used to maintain column vacuum on the preaccelerators, forced the use less efficient roughing turbo pumps. The resulting increase in pressure reduced the intensity slightly until they could be rebuilt. After the run was over and beam level safety permits were readjusted the Linac achieved 52 mA.

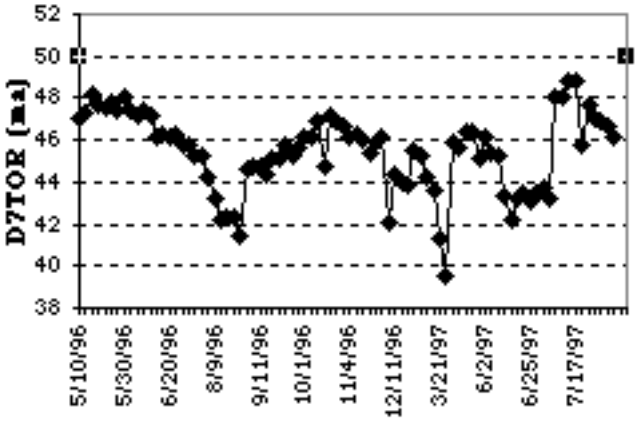

Figure 1. Linac intensity during fixed target run.

There are 35 loss monitors in the high-energy linac. They are of the Tevatron type [1] with Main Ring style amplifiers. They are not calibrated, but used as tuning aids and for comparison with previous data. The maximum value of the relative computer signal is 100 equivalent to 10V from the amplifier. By saving and averaging these values the tuning quality and level of losses in the Linac can be monitored. Reviewing this average since the high-energy linac was installed, Table 1, shows that the losses have decreased especially in the RF accelerating structures. Typical beam loss through the Linac from tank 2, after the beam has been captured, to the 400-MeV output is ~1% or less. Of the 65-70 mA of the preaccelerator beam 70% or more is captured in tank 1.

Table 1. Relative beam loss levels for each period for the total Linac structures and along the RF accelerating cavities.

Time	Whole Linac	RF Cav. Only
March, 1994	3.06	2.18
Beginning of run	2.82	1.43
End of run	2.61	0.95

Linac operated for 98% of the 10442 scheduled operating hours. As has historically been the case the vast majority of downtimes are very short. There were 1166 downtime entries, of which 80% are less than six

minutes and while 4% are one hour or longer they account for 66% of the 212 hours of downtime. Downtime by major system is shown in Fig. 2. The three major causes of downtime during the run were; the failure and replacement of klystron 3, replacing the power amplifier for low energy RF station 4 with an unconditioned spare and multiple failures of the SCR switches in klystron charging supplies and PFN's.

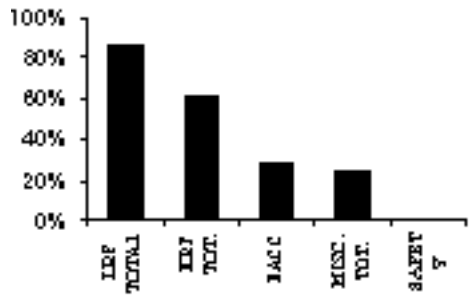

Figure 2. Linac downtime for fixed target run by major system

Klystron 3 was the first failure of a klystron and caused 7.8% of linac downtime. Being the first klystron to fail in use from aging, it had ~35,000 hours of operating time, the problem was at first unclear. Diagnosing the klystron emission failure, assembling the people and replacing the klystron assembly required a total of 16.5 hours over two days.

The power amplifier for RF station 4 was the last in an series of 7835 failures during a time when the test stand was unavailable for conditioning spares due to moving the test stand and an error by the manufacturer for a new dummy load. Total downtime for this failure was 7.4% of the linac downtime.

There have been repetitive problems with SCR switches and other components in the charging supplies and PFN's for the klystrons. This has caused 10.3% of the linac downtime. Solutions have been implemented and the failure rate has decreased dramatically.

3 STUDIES

In an effort to confirm survey data which showed a vertical misalignment between tank 5, the last tank of the low-energy linac, and the beginning of the high-energy linac, studies were done of the beam centering for each of the drift tube quadrupoles. This procedure was first used about ten years ago and now repeated where the current of each drift tube quadrupole pair (in the Fermilab Linac the DT quads are connected in FD pairs except for the two at the beginning and end of each tank) is individually changed by 10% up and/or down. The resulting beam motion at a downstream position detector (BPM or wire scanner) gives an indication of the beam centering at the changed DT quadrupole. If the beam center coincides with the magnetic center of the quadrupole, no motion of the beam center at the detector is observed. However, if the beam is off center relative to the quadrupole, when the current is changed a kick is given to the beam. This kick would then start an oscillation which continues down the Linac to be observed at an appropriate position detector. Usually two detectors, ~90^{O} apart in phase and at the farthest downstream position of the Linac are used so all DT quad positions could be observed relative to the same detectors. This is analogous to observing beam motion due to quadrupole misalignment in a transport line.

This procedure was used on the Linac in the late 1980's and predicted a large quadrupole misalignment in tank 2 by showing a cusp in the data. The drift tube was subsequently found to be off center by 1 mm. After correction the cusp was gone and the downstream beam oscillations reduced. It also indicated tank misalignments by showing increased errors from one tank to the next. Figure 3 shows a typical set of measurements for the old Fermilab Linac before tanks 6 through 9 were removed and replaced by the side-coupled cavities. The low errors in tanks 7, 8 and 9 are a result of steering magnets at the entrance and exit of tank 6 (~90% separated in phase) to remove beam errors and have the beam leave the Linac on axis of the 200-MeV beam line.

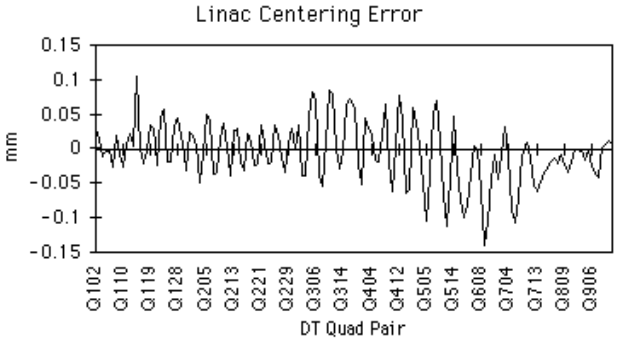

Figure 3. Detected beam motion for a 10% decrease in each Linac DT quad pair.

Recently similar measurements were made for the current Linac, figure 4, and consentrating on tank 5, figure 5. The mismatch in tank 5 is a result of beam leaving the tank off axis and at an angle for lowest losses in the high-energy linac. The steering magnets at the beginning of the high-energy linac were on hard to correct the angle. Moving the downstream end of tank 5 down 0.75 mm as indicated by the survey and beam, reduced the mismatch, allowed steering changes to reduce the errors in tank 5 (see figure 6), decreased the steering at the beginning of the high-energy linac, and reduced the losses significantly throughout the high-energy linac.

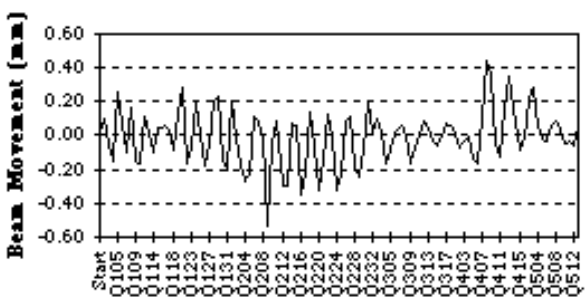

Figure 4. Recent detected beam motion for a 10% decrease in each Linac DT quad pair.

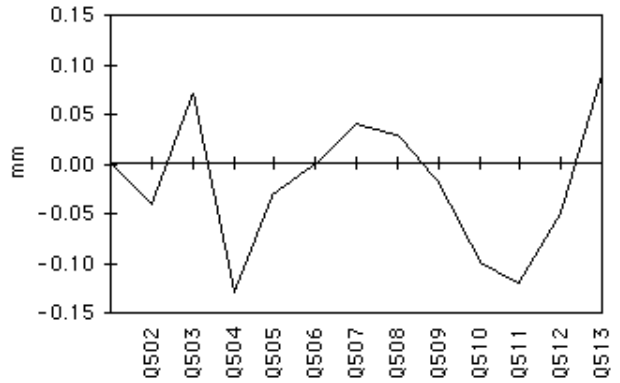

Figure 5. Error measurements before tank 5 change.

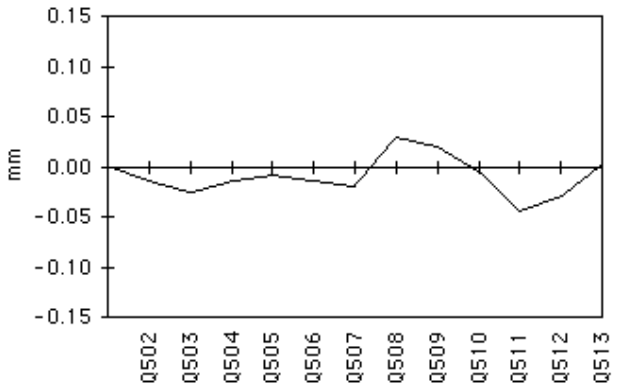

Figure 6. Repeat of figure 5 after lowering the downstream end of tank 5.

The condition of tank 5, indeed the complete Linac, depends on the tuning of earlier components. Tank 5 does not remain this good at all times, never-the-less the losses in the high-energy linac have remained very low. Table 2 shows current loss averages. Some loss monitors were moved to places where they are more sensitive to beam loss.

Table 2. Losses after moving tank 5.

Time	Whole Linac	RF Cav. Only
After studies	2.17	1.20

4 IMPROVEMENTS

During the recent shutdown, three wire scanners were installed in a drift space just beyond the 400-MeV output on the Linac. These wires will give better monitoring of the beam size, position and emittance leaving the Linac.

MOSCOW MESON FACTORY LINAC - OPERATION AND IMPROVEMENTS*

L.V. Kravchuk, Y.V. Bylinsky, S.K. Esin, P.N. Ostroumov, V.L. Serov
Institute for Nuclear Research RAS, 117312, Moscow

1 INTRODUCTION

Moscow Meson Factory Linac (MMFL) [1] has provided in 1997-1998, 4400 beam hours for physics, isotope production and machine development. The lack of adequate funding for machine operation (electricity etc.) has put severe limitation on the beam production time. Beam energy was limited by 305 MeV and in some production shifts even by 209 MeV. A significant part of the beam time has been devoted to isotope production for medical use at an energy of 160 MeV. The maximum average proton current during regular operation is 65 μA with a pulse duration of 85 μs and repetition rate of 50 Hz. In 1998 a proton beam has been delivered for the first time to the Pulsed Neutron Source. A number of improvements have been implemented, with a strong impact on the operation efficiency. One of the most important measures is the creation of a new control network (based on PCs) for the beam diagnostics data acquisition. The injection beam transport channel and RF power supply system are presently undergoing reconstruction. The aim of this reconstruction is to increase the beam pulse up to 140 μs and repetition rate up to 100 Hz which will result to the growth of average beam current to 200 μA.

2 LINAC OPERATION

The total scheduled time of the linac operation includes the beam delivery to users, the tuning of the linac and unexpected down time. On average for the last two years the beam delivery time to users was ~60%. About 30% of the time was spent for tuning and accelerator experiments and developments, the rest was down time. Essential development has been done on the linac RF system with the main aim of increasing the reliability and linac operation efficiency, as well as to prepare the RF system for operation at 100 Hz and a 140 μs beam pulse. Obtaining of 100 Hz repetition rate is simpler task than providing of the beam pulse length more than 100 μs, because of operation at 100 Hz is the design specification of all linac equipment. The design beam pulse duration of the linac is 100 μs. Therefore the modulators and preamplifiers have been revised. The automatic temperature control system of the accelerating cavities has been tuned in order to provide 100 Hz repetition rate of rf amplifiers.

Although the linac control system is based on old computer equipment, it is adequate for the linac operation. This system is mainly used for the support of RF and other technical equipment. Major profit from the control system has been obtained by development of software in order to support the RF system operation. In many cases the restoration of the RF system immediately after the malfunction has increased operational time. This is an important issue for the system with large electrical power consumption which is the case of the MMF linac. However the original control system has very restricted ability for the data processing and presentation. The existing beam monitors already produce large amount of information which is not fully available from the original control system. In addition, many beam diagnostic devices have been developed and installed on the linac, including:

- A new type of detector allowing the measurement of the transverse density distribution was installed in the 750 keV transport line.
- A new Bunch Length and Velocity Detector (BLVD) is installed in the 160 MeV transition line.
- Several beam profile harps.
- Non-interceptive beam position monitors.

Therefore the new control system was developed based on PCs which are connected to the local area network. The analogue and digital hardware is housed in CAMAC crates (up to 4 crates per sector). The system is based on MOON-Lab (Multi-tasking Object-Oriented Network Lab System) - a software run-time system and an application programming technology developed at INR [2].

The new control system serves different types of beam diagnostic monitors: beam current transformers, wire scanners, profile harps, BLVD, beam loss monitors, a monitor for the measurement of transverse beam density and neutron detectors. Fig. 1, 2 and 3, represent examples of graphical information obtained by new control system.

The beam delivery system to the isotope production area includes 27° bending magnet and ~12 m long transport channel [3]. The control of beam losses in the vicinity of the bending magnet is a problem of great importance due to high level of the average beam

* Work supported partly by the RFFI, grant 97-02-17475.

current. Discrepancy between the beam energy and the magnet current as well as the violation of the correcting element parameters can lead to instantaneous melting of the vacuum pipe during an extremely short time. To prevent such accidents, a number of protections measures have been undertaken.

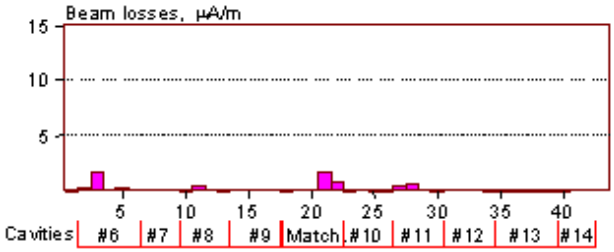

Figure 1: Scintillating beam loss counters (#1-40) along the 3rd sector of the MMFL. (Tanks #6-14)

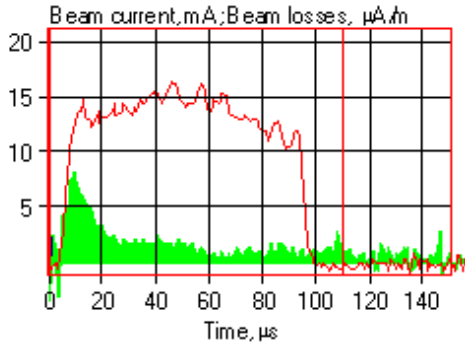

Figure 2: Beam current and particle losses along the macropulse. 3rd sector. Beam loss monitor # 21

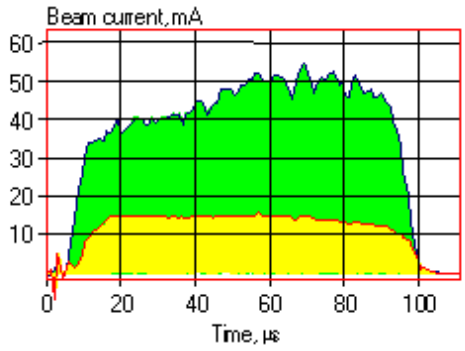

Figure 3: Capture coefficient control. Comparison of current transformer signals: at the input of the Tanks # 1 and at the output of the Tanks # 8.

The bending magnet in the 750 keV injection line is switched off and the 750 keV beam is deflected by a chopper, as well as the injector trigger being shifted with respect to the RF pulse if one of the following cases occurs: 1) Difference of the pulse charge in a given cycle registered with current transformers upstream and downstream of the bending magnet is in excess of the tolerance limit; 2) Beam loss monitor signal is in excess of the tolerance; 3) Phase and amplitude parameters of any RF system is out of tolerance; 4) Beam profile on the isotope production target moves too close to the edge of the target. Fig. 4 shows 2 signals from current transformers. The difference between the signals is well inside the tolerance. For initial accelerator tuning at the repetition rate of 1 Hz the protection is not used. At a repetition rate of 2 Hz and higher, the loss threshold may be reduced from 10% to 1%. As a result of careful tuning the total beam loss in the course of an isotope production shift does not exceed 0.5% and is usually kept near 0.1%.

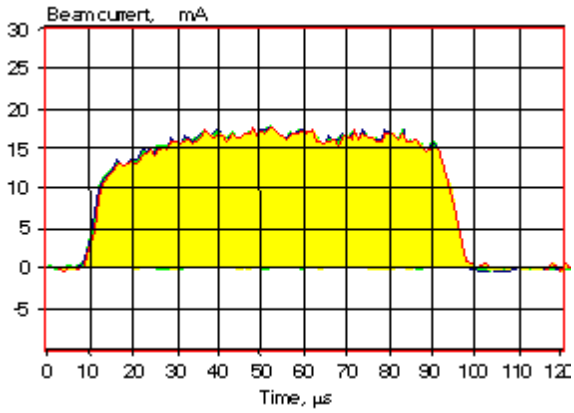

Figure 4: Two overlapped beam pulses: upstream of the bending magnet (almost invisible) and downstream of the bending magnet.

The MMFL contains two transition regions at 100 MeV and 160 MeV. It is important to verify the longitudinal bunch length in these regions. The bunch length measurement (BSM) system is well established at INR, and the most recently modified device, the Bunch Length and Velocity Detector (BLVD) has been installed in the 160 MeV area. The high resolution of the detectors, which is 14 ps, allows monitoring of the quality of the Linac beam during operation. The devices use a 100 μm wire which allows the measurements to be performed at up to 50 Hz repetition rate. After many years experience with the BSM and BLVD systems, we are able to detect the source of any deviation of the longitudinal profiles form the nominal state. Fig. 5 shows the bunch shape evolution along the macropulse at the energy of 160 MeV.

3 INJECTION CHANNEL UPGRADE

The essential reconstruction of the injection channel is under way. Fig. 6 a) shows the existing layout of the channel (equipment of 1st and 2nd parts of channel is not shown for simplicity). The channel is designed to inject 750 keV H^+ and H^- beam simultaneously into the Alvarez tank. However, the electrical strength of the 750 kV pulsed transformer is not sufficient for operation at 100 Hz repetition rate, hence the linac operates at 50 Hz

with half the average beam current of the maximum possible.

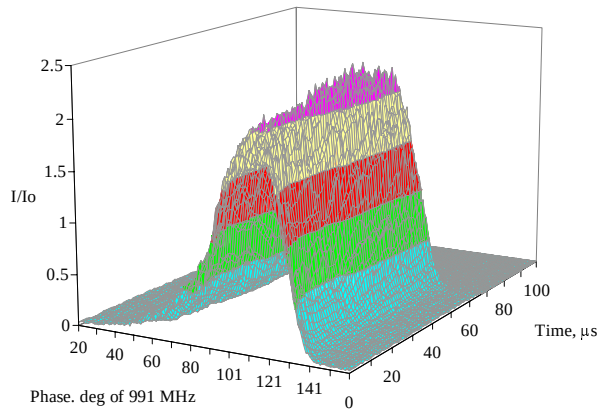

Figure 5: Bunch shape evolution along the macropulse at 160 MeV.

A decision was taken to insert the RFQ booster section into the 3rd part of the injection channel (Fig. 6 b)). The RFQ has been designed to accelerate hydrogen ions from 400 keV to 750 keV. The high voltage equipment of the injector works with good reliability up to the level of 400 kV. Moreover, the pulse length can be increased up to 140 μs without pulsed transformer saturation. It will allow the average beam current to beam increased up to 200 μA. The limited space does not permit to the realisation of adiabatic capture in the RFQ. To provide the longitudinal capture efficiency up to 80% at the peak current of 70 mA, the 400 keV prebuncher is placed upstream of the RFQ. A 750 keV buncher and four quadrupoles provide 3D beam matching between the RFQ and DTL tank. Fig. 7 shows the RFQ booster section which is now under high power test.

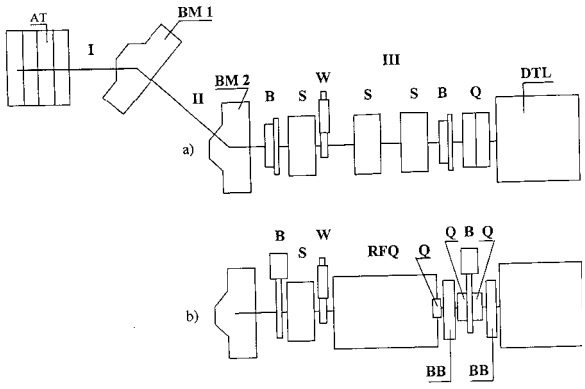

Figure 6: Injection channel layout.

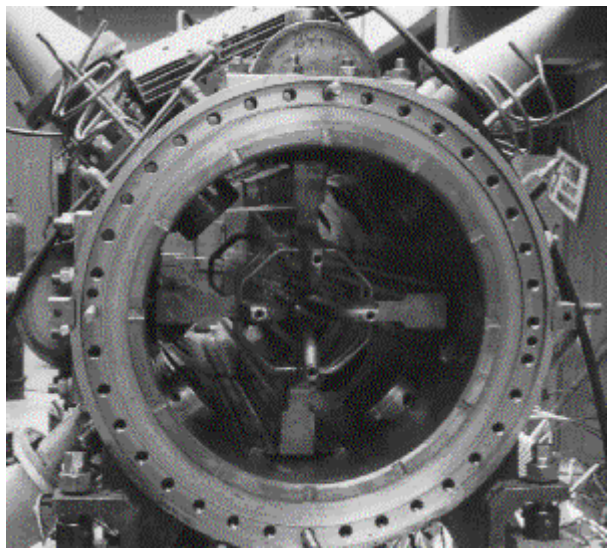

Figure 7: RFQ booster section.

High power modulators in the RF power supply permit to introduce moderate modification which will guarantee operation with longer rf pulses in order to accelerate 140 μs beam pulse.

Thus we hope increase the average beam current by up to a factor three over that presently attained.

4 ACKNOWLEDGEMENTS

In conclusion authors express their deep gratitude to the whole staff of the MMFL, who made the machine operational in recent times, which are not easy for scientific activity.

STATUS OF A NEW SWITCHYARD DESIGN FOR LANSCE*

R. W. Garnett, C. Rose, F. Shelley, and J. D. Zumbro**,
LANSCE Division, Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Abstract

Funding was recently received to study modifications of a section of the LANSCE beam switchyard. At present, the switchyard is used to deliver a proton beam to experimental Area A and an H^--ion beam down Line D. The total H^- repetition rate is 120 Hz. 100 Hz is transported to the Weapons Neutron Research (WNR) area. The remaining 20 Hz is injected into the Proton Storage Ring (PSR). In order to provide H^- beam to other experimental areas without interfering with the PSR operations, a new design of the switchyard is in progress. We are presently investigating a solution that would use pulsed kicker magnets to deflect a fraction of the WNR H^- beam down a separate existing beam-line at the demand of the experimenters.

1 INTRODUCTION

The Los Alamos Neutron Scattering Center (LANSCE) accelerator complex consists of an 800-MeV linear accelerator, a proton storage ring (PSR), and a number of experimental areas. Two beams are presently accelerated simultaneously on alternating cycles of the rf. The linear accelerator consists of two 0.75-MeV Cockroft-Walton injectors, one supplying protons and the other supplying H^- ions. A separate low-energy beam transport line exists for each beam species. A 0.75-MeV to 100-MeV drift-tube linac operating at 201.25 MHz, a 100-MeV transition region, and a 100 to 800-MeV side-coupled linac operating at 805 MHz is used to accelerate the two beams. Typically, peak beam currents as high as 18 mA are transmitted for variable duty factors to give a maximum average beam current of 1 mA for the H^+ beam and up to 100 μA for H^-.

A beam switchyard is used to direct beams from the linac to various experimental areas and for injection into the PSR. The 800-MeV proton beam is presently sent to an experimental area (Area A) via a separate beam-line where it presently interacts with a series of different targets for the Accelerator Production of Tritium program and for isotope production. Up to 3 μA of the 800-MeV H^- beam is sent to the Weapons Neutron Research Facility (WNR) where it strikes a target producing an intense white-neutron source. Since variable proton pulse widths are available, time-of-flight experiments for neutron energies ranging from a few MeV to 800 MeV are possible.

The PSR functions as a high-current accumulator or pulse compressor to provide intense pulses of 800-MeV protons to the Manual Lujan Jr. Neutron Scattering Center (Lujan) spallation neutron-production target. This target was upgraded for higher-average-current operation this year. The PSR operates at a repetition rate of 20 Hz. An entire linac macro-pulse is accumulated each turn around the ring with up to 2800 turns accumulated prior to single-turn extraction.

We recently received internal funding to study technical options that would greatly enhance our existing capabilities. We are presently performing simulation and conceptual design studies to determine the most cost-effective reconfiguration of a section of the beam switchyard. A diagram of the unmodified switchyard is shown in Fig. 1. The desired solution should allow simultaneous, uninterrupted beam delivery to Line D (PSR injection) and delivery of a "tailored" H^- beam-pulse to either Line B or Line C on the demand of the experimenters. The beam-pulse delivered on-demand will be diverted from the 100 Hz beam normally delivered to WNR.

Simultaneous beam delivery to Line B/C and Line D is not possible at present. A few hours are required to accomplish the required changes to allow the H^- beam to be directed from Line D to Line B/C. Delivery of beam to all users of this beam is interrupted during this transition period.

Immediate beneficiaries of this study will include the proton radiography program, neutron resonance spectroscopy studies, Lujan neutron scattering users, and WNR users at LANSCE. Other programs that may also benefit may include an ultra cold neutron facility and the future Dynamic Experimentation Laboratory. Implementation of a proposed solution will be contingent upon receiving additional project funding.

2 TECHNICAL REQUIREMENTS

Beam delivery for the present Line B/C users requires delivery of 800-MeV protons with ~2-3x10^8 protons per 5 ns (201.25 MHz) micro-pulse. The present ion-source and linac are capable of delivering this beam to the switchyard. The number and sequence of micro-pulses delivered, per macro-pulse, is determined by the accelerator master-timer and controls software. Modifications to this software will be required to fully

*Work supported by the U. S. Department of Energy Contract W-7405-ENG-36.
**Physics Division, Los Alamos National Laboratory.

implement any proposed solution and satisfy programmatic requirements.

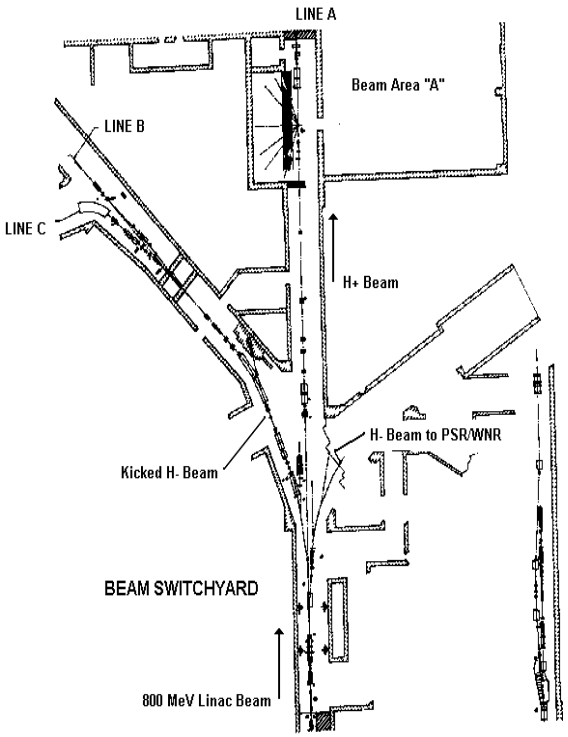

Figure 1 – LANSCE Beam Switchyard

Any proposed kicker solution must be capable of continuously delivering full-beam macro-pulses, for tuning, at a repetition rate of 1-20 Hz to Line B/C. The magnet response time requirement is 8 ms. This is the time between beam macro-pulses (120 Hz). Additionally, the capability to deliver a single macro-pulse on demand must be possible. Preserving the capability to operate in all the other existing facility modes is also a requirement. In particular, operation should not interfere with the 20 Hz H^- beam delivery for injection into the PSR. A desired feature, although not absolutely necessary, is that the solution be achromatic.

3 A TWO-KICKER SOLUTION

A schematic diagram of the unmodified H^- beam-line where the split between Line B/C and Line D occurs is shown in Fig. 2. The diagram is not to scale, but shows the general features of this area of the beam switchyard that we are proposing to modify.

3.1 TRANSPORT Results

We have modeled a two-kicker solution using TRANSPORT [1]. This solution requires the removal of the disabled kickers, the dipole bender, and the beam vacuum box just before the beam-line split (See Fig.2). These components would be replaced with two d.c. dipole magnets and two pulsed dipole kicker magnets. A new vacuum beam box design would also be required to match the new configuration to the existing beam-lines. Figure 3 shows a conceptual layout for this solution. The figure is not drawn to scale and only illustrates the relative positioning of the beam-line components.

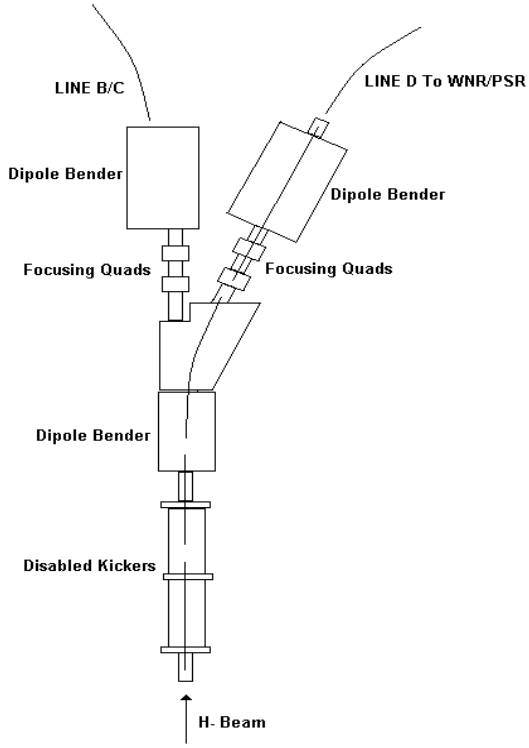

Figure 2 – Schematic of the Line B/C and Line D split in the LANSCE beam switchyard.

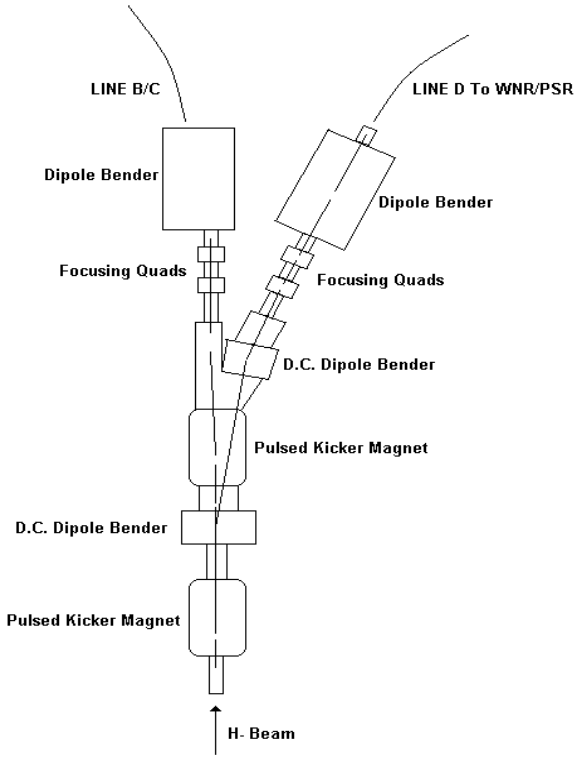

Figure 3 – Schematic of the proposed two-kicker solution

The two smaller d.c. dipole magnets will provide the same total bend angle of the single larger dipole magnet for the normal operation mode where beam is delivered down Line D. When the two kickers are fired, the beam is deflected in each kicker an amount equal to the bend of the first d.c. dipole, thus canceling out its effect. Beam is then delivered down Line B/C when the kickers are on.

The solution shown is also achromatic. This should help to preserve the relatively small linac energy spread. Table 1 gives the bend angle, field, and effective length requirements for the new magnets based on the simulation results.

Table 1 – New magnet parameters for the two-kicker solution.

Magnet	**Effective Length (m)**	**Field (KG)**	**Bend Angle (deg)**
Pulsed Kicker	1.016	1.26	1.5
DC Dipole	0.724	3.53	3.0
Pulsed Kicker	1.016	1.26	1.5
Dipole	0.656	3.53	2.7192

3.2 Kicker Magnet and Pulsed-Power System

The magnet requirements, as determined by the simulations, for this solution will allow use of a pulsed magnet and power-supply similar in design to that of the pulsed ring injection kicker magnet (RIKI) for the PSR at LANSCE [2].

The RIKI magnet is typically operated at 20 Hz. It can, however, also be operated in d.c. mode. This magnet is a laminated H-magnet with 20-turns/coil using hollow water-cooled conductor.

The pulsed-power system will provide a controlled current pulse to each kicker magnet. The RIKI pulsed-power system is capable of producing a current pulse with an amplitude that can be set in a range from 180 to 220 A with a flat-top width of up to 1.4 ms. Repetition rates ranging from 1 to 40 Hz have been tested with pulse regulation better than ± 0.5 %.

This system operates by resonantly discharging a capacitor of known voltage into a kicker magnet of known inductance through the following cycle. Initially, the current in the magnet builds resonantly. After the current has peaked, the circuit goes into "Freewheel" mode producing a settable flat-top of up to 1.4 ms width. Finally, the circuit goes into recovery mode where most of the stored energy in the magnet is recovered by returning it to the pulse capacitors. Implementing the firing of both kickers simultaneously and the potential problems that may be caused by timing errors have not yet been investigated.

3.3 Hardware Controls Requirements

We have estimated the approximate number and types of data channels that will be required for a flexible implementation scheme able to accommodate the final versions of the kicker power supplies. Our estimation is based on our past implementation of the RIKI magnet power-supply controls into the LANSCE control system. The RIKI power supply has control functions that use 9 binary input channels to indicate status and 5 binary command channels to provide on/off controls and reset functions. Two analog read-back channels are required to indicate voltage and current. One analog command channel is used to set the output current level. The modular design of the control system hardware provides the adaptability and flexibility required to implement the actual power supply controls.

One possible controls-hardware configuration is as follows. A VME crate using a Motorola processor module connected to the control system's Ethernet network can provide the foundation for the system and create an Experimental Physics and Industrial Control System (EPICS) input/output controller [3]. The use of the EPICS system allows existing operator interfaces to be used with a minimum of modifications, thereby reducing the cost of the system. The addition of VME Industry Pack carriers and Industry Packs, to provide the necessary signal conditioning, will complete the system. Industry Packs are small cards that perform specific I/O functions and are mounted on carrier boards for the bus system they are housed in. The interface between the Industry Pack and the carrier board is defined in the standard, ANSI/VITA 4-1995. Selection of Industry Packs similar to those already used in the control system can reduce the cost of software development. Local control for the power supply must be provided on each unit. This implementation has the advantage of providing isolation of the power supply control from the rest of the control system along with a modular design to increase maintainability and reduce system downtime.

4 SUMMARY

A solution for modification of the LANSCE switchyard has been described. In future studies, other solutions will be sought and compared to the two-kicker solution presented here.

UNDERSTANDING ACCELERATOR RELIABILITY

Abstract

The event data collected during operation of the LANSCE accelerator facility are being analyzed as part of an effort to understand accelerator reliability in support of current design activities for future large scale accelerator systems. In this paper, the sequence of failures and repairs of the system is represented as a composition of alternating stochastic failures and repairs processes and the process parameters are estimated. The derived estimates can also be used for practical maintenance planning.

1 PREAMBLE

Previous work [1] has identified the current state of the art as lacking in the area of reliability database information for components typically used in rf accelerator systems, such as rf stations, rf drives, rf transport, cooling, vacuum systems, magnets, and magnet power supplies. This led to intensive data collection efforts [2]. The data has already been used to derive initial estimates of failure and repair rates for typical individual accelerator components [3].

The present paper examines the data set of failure events for Cycle #71 for the complete LANSCE 800 MeV DTL/SCL accelerator facility. Instead of deriving failure and repair rates for individual components, we estimate here the parameters of the failures and repairs processes for the complete system [4].

2 ESTIMATING THE FAILURES/REPAIRS PROCESS

An accelerator is an example of a repairable system [5]. Reliability of a non-repairable system is determined by reliabilities of its individual components and the typical problem of interest for this kind of system is that of the first failure. For a repairable system, the analysis must also include the interactions between the system and the repair policies, maintenance procedures, spare parts policies, etc.

2.1 The Failures Process

We tend to think of a complex, repairable system such as an accelerator facility as a set of sockets, each carrying its corresponding part. The cycle of operation and repair of the component in each socket is described as a superposition of two alternating Poisson processes: one consisting of times between failures and the other consisting of down times. Each one is generally a nonhomogenous Poisson process (NHPP), with the number of failure events per unit time, typically called the rate of occurrence of failures (ROCOF), and the rate of "occurrence" of repairs (ROCOR), functions of time. The two processes are usually uncorrelated.

Thus, the analysis of data collected for a repairable system seeks to determine the type of the stochastic process represented by the data, rather than estimates of component population statistics. Of particular interest is the existence of any trends. If ROCOF is increasing, it is an indication of the system's deterioration and a potential basis for a significant action, such as a major improvement program (or abandonment: for example, by sending an old car to the junk yard). Decreasing ROCOF, on the other hand, is an indication of reliability growth.

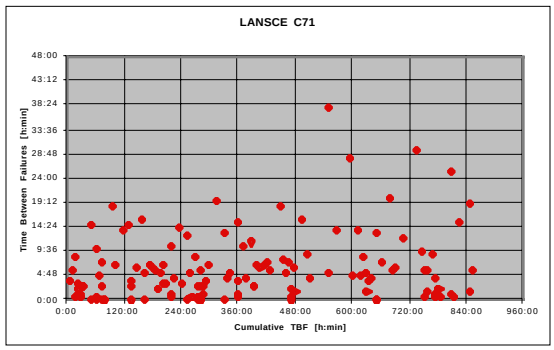

Figure 1. Times Between Failures

Application of this analysis procedure is illustrated here with the LANSCE Cycle 71 data. This data set was selected because it provides an example where the failures process is truly nonstationary. Over long periods of time stretching over many cycles, the observed tendencies are more balanced.

Raw data comes in the form of a sequence of times of occurrence of the failure events. One can extract from this data the sequence of times between failures shown in Figure 1.

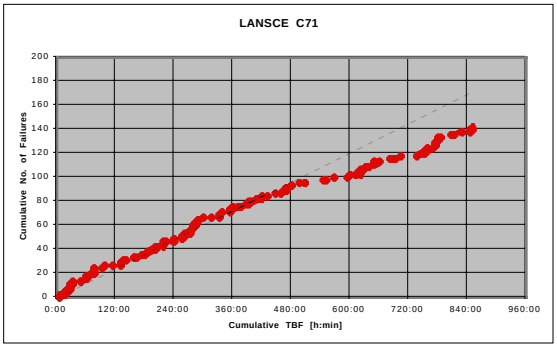

Figure 2. Cumulative Number of Failures

Figure 2 shows the cumulative number of failures as a function of cumulative operating time (sum of the times between failures). Comparison with the straight line fit indicates that the rate of occurrence of failures drops with time (after about 480 hours of operation).

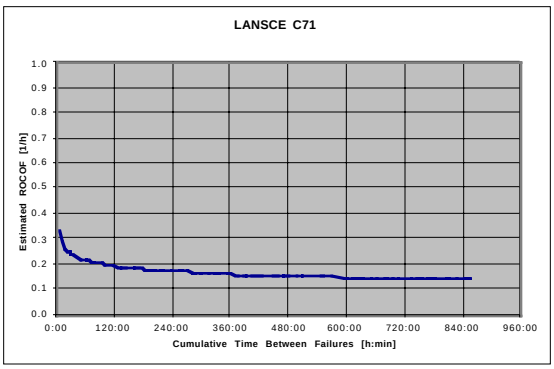

Figure 3. Estimated ROCOF

The Rate of Occurrence of Failures (ROCOF) is the limit of a series of discrete functions obtained by dividing the number of failures counted over a fixed delta interval when the length of the interval tends to zero.

Searching for ROCOF as a limit of the sequence of such discrete approximations is not practical. Direct statistical estimate of the parameters of the ROCOF assumed in the power form:

$$\lambda(t) = \alpha\beta t^{\beta}$$

results in $\alpha = 0.5036$, and $\beta = 0.8339$, which is shown in Figure 3.

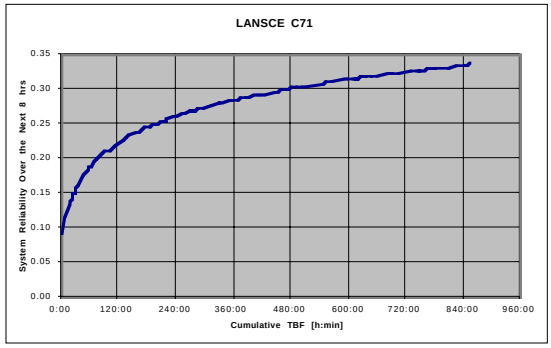

Figure 4. Expected Reliability over the Next 8 Hours

Once an estimate of ROCOF is obtained, we can use it to predict the system behavior, such as the expected number of failures in the next 8 hours or the expected system reliability in the next 8 hours for any desired instant of time shown in Figure 4 (since ROCOF is a function of time, both are functions of time as well).

Assuming a power relationship for MTBF(t) one can estimate the constants from the sample (resulting fit is shown in Figure 5):

$$MTBF(t) = 0.1056\, t^{0.2457}$$

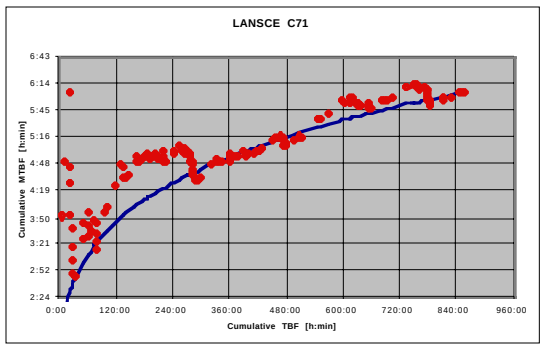

Figure 5. Estimating MTBF (t)

2.2 The Repairs Process

Figure 6 shows the cumulative number of repairs as a function of the cumulative down time (sum of the down times).

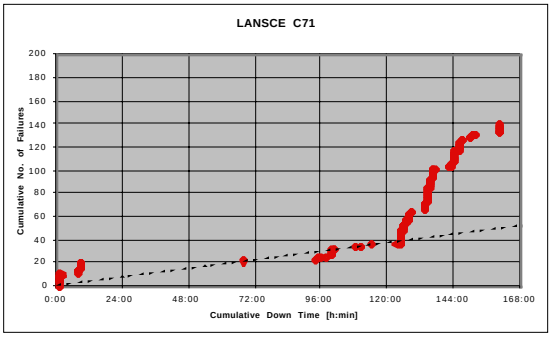

Figure 6. Cumulative Down Times

The down times are random just like the times between failures. However, in LANSCE Cycle 71, the down times history is dominated by a long 59 hour down time in the beginning of the cycle caused by the Magnet Power controller.

The ROCOR can still be assumed in the form of a power law. This time, this function is growing, indicating that the durations of the individual down times have a diminishing trend:

$$\mu(t) = 0.24114\ t^{1.3063}$$

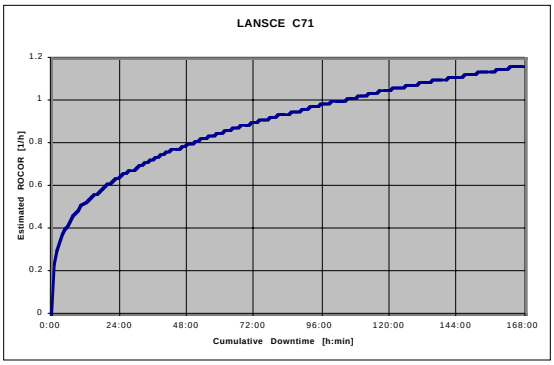

Figure 7. Estimated ROCOR - Rate of Occurrence of Repairs

A diminishing system MDT(t) can be fitted to the last part of the data (past 96 hours):

$$MDT(t) = 5.7302\ t^{-2.5186}$$

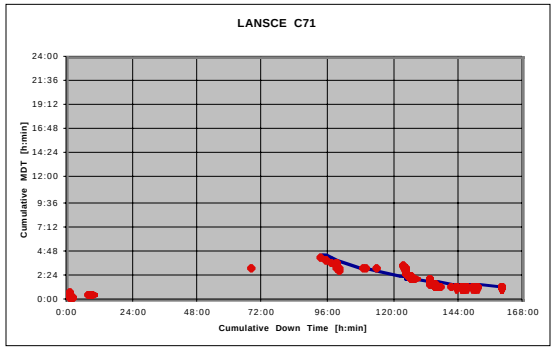

Figure 8. Estimated MDT(t)

3 CONCLUSIONS

The capability to predict the behavior of a repairable system is important for many reasons. Maintenance scheduling, advance spare parts procurement, and early detection of trends are essential in management and operation of the facility and planning for reliability improvement. The type of analysis presented in this paper may be used to gain such a capability from records of operational data.

Abstract

200 MeV Electron LINAC is an injector of HLS. The LINAC has been running well for ten years since 1987. A typical operation parameters are energy of 200 MeV, Current of 50 mA and energy spread of 0.8%. Some improvements are described in this paper, such as developing an energy stabilized system, developing a two mode combined pulser for the electron gun to meet single-bunch and multi-bunch mode running in the storage ring. Some applications are briefly described here also.

Keywords LINAC Synchrotron Radiation Gun Single bunch Isotope production

1 INTRODUCTION

200 MeV Electron LINAC is an injector of HLS(Hefei Synchrotron Radiation Light Source) [1], which layout is shown in Fig.1. The LINAC has been running well for ten years since 1987. A typical operation parameters energy of 200 MeV, Current of 50 mA and energy spread of 0.8%. Since 1991 some improvements were done, such as developing an energy stabilized system, adding a post-transport line in order to guide the beam into a nuclear physics experimental hall, developing a two mode combined pulser for the electron gun to meet single-bunch and multi-bunch mode running in the storage ring. The LINAC is also an electron beam source for some application users, such as detector crystal calibration, isotopes products using photonuclear reaction, and so on.

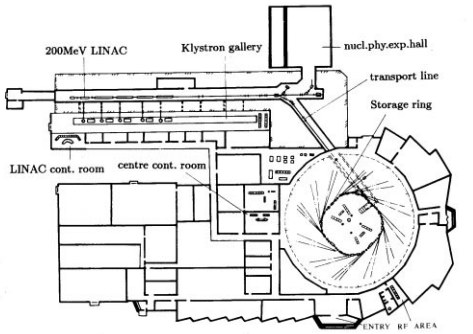

Figure 1. Plan of HLS

2 IMPROVEMENTS

2.1 Energy Stabilities

The 200 MeV LINAC has been run for 50,000 hours since 1987. The LINAC is running for both injecting the electron beam into HLS storage ring and providing the beam for producing some short lifetime isotopes, irradiation biology effects etc. The typical operation parameters are summarized in table 1.

Table 1. Operation Parameters of LINAC

Energy(MeV)	200.5
Current (mA)	70
Frequency (MHz)	2856.04
cavities' temperature ($^{\circ}$C)	42
output power of Klystron (MW)	
1# Klystron	9.7
2# Klystron	16.2
3# Klystron	15.7
4# Klystron	16.8
5# Klystron	9.3
beam pulse length(μs)	0.2~1.0
Energy spread (FWHM)	0.8%
Vacuum (mbar) (without beam)	$<1\times10^{-8}$
(with beam)	$<1\times10^{-7}$

In the beginning of the LINAC, its energy was not so stable that sometime it was difficult to inject the beam into the storage ring. After machine study, we adopted some measures. The energy stability has been improved. The main improvement was established an automatic energy stabilization system(AESS). Fig.2 showed a layout

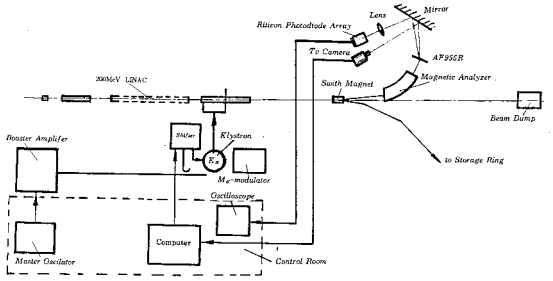

Figure 2. Layout of the automatic energy stabilizer

of the AESS. The energy stabilizing system was successful in stabilizing the energy. Typical running results are as following. When the AESS was not on, the central energy change rate $\Delta E_0/E_0$ was more than 0.8%. When the AESS was on, the $\Delta E_0/E_0$ was reduced down 0.4%. Now the LINAC has been running stably [2].

2.2 Combination pulser

The electron gun has been running for providing a pulse of μs beam for injection since 1989, so that there are multi-bunch running in the storage ring. Some users hope the ring running on a single bunch mode. This means that the beam pulse length from the LINAC must short than 4ns and the jitter time of the timing system is less than 0.5 ns. In order to meet the requirement, we need to improve the timing system, trigger system, beam diagnostic system and develop a ns pulser, and so on.

In order to produce a short pulse beam with width less than 3 ns, a grid pulser was developed and tested. The electronic circuit diagram is shown in Fig. 3. A key element of the circuit is employed a high frequency transistor 3DA87C with avalanche characteristics. The pulser can produce a short pulse of 2.5 ns (FWHM) and its amplitude is 120 volts. The waveform of the pulse is shown in Fig.4.

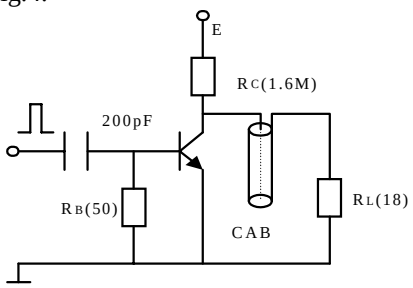

Figure 3. Circuit diagram of the ns pulser

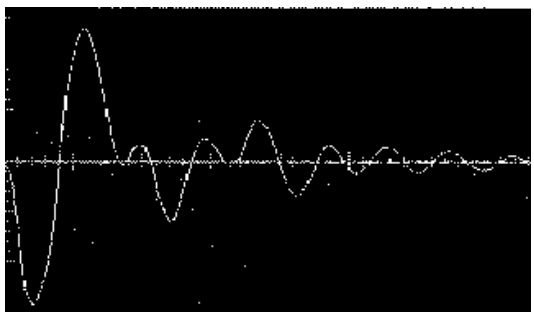

Figure 4. Waveform of the ns pulse

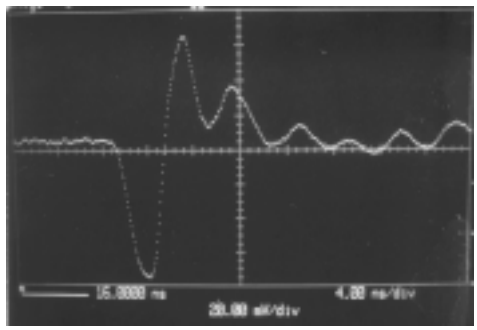
To transmit a trigger signal from the ground potential to a high potential, an optical fiber is most suited. The trigger signal transmission system consists of an electric-optical signal conversion circuit (E/O), and an optical- to -electric signal conversion (O/E). Time jitter including timing system, trigger system and pulser is less than 0.5 ns which is better enough for us.

Both grid pulser for long and short beam are assembled together in a circuit board, and employed a power splitter/combiners to transmit their signal respectively and isolate them each other. The trigger signals for the long and short beam are from a center control room and LINAC control room respectively.

Both long pulse and short pulse have been got and measured by means of Toroid monitors and wall current monitors which are installed in the LINAC and the transport line. The beam waveform are shown in Fig. 5(a),(b).

(a)



(b)

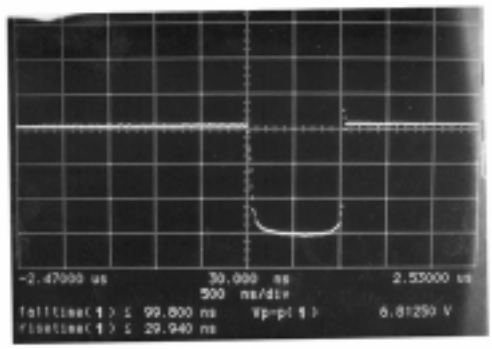


Figure 5. Waveform of output voltage of the combination pulser (a) ns waveform, (b) μs waveform

A single bunch mode running in the HLS storage ring has been successful using the combination pulser and a new timing system with jitter time less 100 ps (3σ) [3]. A waveform of the single bunch in the storage ring is shown in Fig. 6.

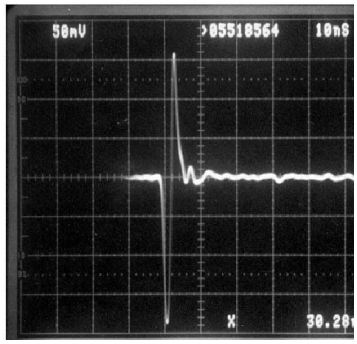

Figure 6. Waveform of a single bunch in the ring

3 APPLICATIONS

In the beginning the 200 MeV LINAC was designed for two purposes, one was as an injector of the HLS storage ring, another was to provide an electron beam of 200 MeV or less so that the machine can meet requirements from different scientific fields. Meanwhile the budget was shortage, a transport line for guiding the electron beam into a nuclear experimental hall and necessary experimental equipment were not constructed yet. last year a post-transport line for guiding the beam into the hall was added and an electron beam line was also established. The beam line will be used for studying the properties of single piece of P_bWO_4, such as light yield, decay time of the light and uniformity of the light output etc..

In order to utilize the electron beam from the LINAC fully, we established an equipment for photonuclear reaction at the end of the LINAC. As everyone knows, radioactive isotopes with short lifetime have been widely applied in medicine as tags or traces to study complex bodily processes and to diagnose some illness. Sequentially some new technologies , such as PET (positron emission tomography), SPECT (single photon emission computed tomograpgy), have developed. All of these have promoted a requirement of short-lived isotopes.

How do we get the radioactive short- lived isotopes? Neutron-capture reactions have long been used to induce them. By contrast, photon-induced nuclear reaction have been relatively neglected. But photonuclear reaction have great potential because they can results in medically important biological elements, such as carbon, nitrogen, oxygen and fluorine etc.

Since 1994, some researches on producing short-lived isotopes have been done in our LINAC. Some short lifetime isotopes, such as ^{18}F, ^{15}C, ^{11}C, ^{123}I, were got using the following photonuclear reaction ,

$$^{19}F(\gamma,n)\rightarrow{}^{18}F$$

$$^{16}O(\gamma,n)\rightarrow{}^{15}O$$

$$^{12}C(\gamma,n)\rightarrow{}^{11}C$$

$$^{124}X_e(\gamma,n)\rightarrow{}^{123}X_e\xrightarrow{\beta^+}{}^{123}I$$

Fig.7 showed a typical Gamma spectrum of the products of photonuclear reaction of natural Xenon which was irradiated by bremsstrahlung beam of 200 MeV, half hour generated via Tungsten convertor of 6 mm thick.

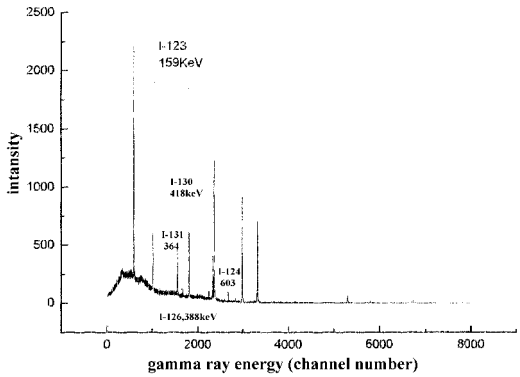

Figure 7. Gamma spectrum of products of photonuclear reaction of Xenon

Abstract

The 2 GeV electron linac at the Pohang accelerator laboratory (PAL) has been operated continuously as a full energy injector for the Pohang Light Source (PLS) since its completion on Dec. 7, 1994. There has been continuous effort to make the linac system more stable and reliable, such as the modifications of the klystron modulators, temperature stabilization of the main rf drive line, installation of one more klystron-modulator station with the addition of two sets of acceleration sections. The average high voltage operation time of the klystrons (E-3712, Toshiba) installed at the very beginning, 8 tubes are survived out of total 11 tubes, has been reached near 32,000 hours as of May 1998. Current overall system availability is well over 90%. In this paper, we report the major linac system upgrade for the nominal 2.5 GeV operation as well as the system performance and relevant machine statistics such as lifetime of klystrons and thyratrons, and overall system's availability, and others.

1 INTRODUCTION

PLS linac[1] has been injecting 2-GeV electron beams to PLS (Pohang Light Source) storage ring since September 1994. The linac klystron modulator system (K&M system[2]) has started its normal operation at the end of 1993, and the total accumulated high voltage run time of the oldest unit has reached beyond 37,000 hours. At the end of 1997 we have installed one more additional K&M module (total 12 modules with 44 accelerating structures), for the higher beam energy margin. The K&M system is normally operating in 70 to 80% of the rated peak power level to avoid the multipactoring phenomena occurring occasionally in random fashion in the waveguide networks and accelerating structures. The sum of all the high voltage run time of the K&M system is approximately 360,000 hours as of June 1998.

In this paper we have reviewed overall system performance statistics of the high power K&M system of the PLS linac for the period of September 1994 to June 1998. During this 4.5-year period the machine has been in operational mode for total 27,072 hours (counted only the scheduled run time).

2 K&M SYSTEM OVERVIEW

Key features of the K&M system design include 3-phase SCR controlled DCHV power supply, resonant charging of the PFN, resistive De-Q'ing, end-of-line clipping with thyrite disks, pulse transformer with 1:17 step-up turn ratio, and high power thyratron tube switching. The major operational parameters of the K&M system (PLS-200MW modulator) are listed in Table-1. The shot-to-shot beam voltage stability is controlled by the (1) the feedback of the DC high voltage to SCR primary input voltage control and (2) the resistive De-Q'ing. SCR DC feedback provides less than 0.5% fluctuation and additional De-Q'ing stabilizes the beam voltage better than 0.1% level. The details of the system design and performance characteristics are described elsewhere [2].

Table 1: K&M operation parameter summary.

Peak beam power	200MW*max.* (400kV @500A)
Beam vol. pulse width	ESW 7.5μs, 4.4μs flat-top
Pulse rep. rate	120pps *max.* (currently 30pps)
PFN impedance	2.64Ω (5% positive mismatch)
Voltage stabilization	SCR, DC feedback & 5% De-Q'ing
Pulse transformer	1:17(turn ratio), L_L:1.3μH, C_D:69nF
Thyratron switch	heating factor: 46.8x10^9VApps, 8.5kA peak anode current
Klystron tube	drive power:~300W, efficiency.:40%, gain:~53dB, peak power:80/65 MW (currently running at 50 to 65MW)

For the fault free stable operation of the system the thyratron tube is one of the most important active components which require continuous maintenance and adjustment. The thyratron tubes which meet the PLS-200MW K&M system specifications are listed in Table-2 together with their specifications, i.e. ITT/F-303, EEV/CX-1836A, and Litton/L-4888. We have all 3 types of tubes installed in our system, and the performance evaluations are underway. This effort is initiated to improve the system from the frequent occurring fault caused by the irregular recovery action of the thyratrons, which strongly depends upon the reservoir control.

There are three types of system's interlocks, namely dynamic, static, and personal protection interlocks. All the static fault activation is initiated by the relay logic circuit, and dynamic faults which require fast action response are activated using the electronic comparator circuit. When the system operation is interrupted by the static fault it can be recovered either by the automatic remote control computer or by the manual reset switch.

Table 2: Comparison of the thyratron tubes

ITEM	ITT F-303	Litton L-4888	EEV CX-1836A
Heater (Vac/A) *max*	6.6 / 80	6.7 / 90	6.6 / 90
Reservoir (Vac/A) *max*	6.0 / 20	5.5 / 40	6.6 / 7
Peak anode (kV/kA) *for*	50 / 15	50 / 10	50 / 10
Peak anode vol.(kV) *inv*	50	*n/c*	50
Avg. anode cur.(A) *max*	8	8	10
Min DC anode vol.(kV)	2	10	5
Heating factor ($x10^9$) *max*	300	400	*n/c*
dI/dt (kA/μs) *max*	50	16	10
Anode delay (μs) *max*	0.3	0.4	0.35
Trigger jitter (ns) *max*	2	10	10

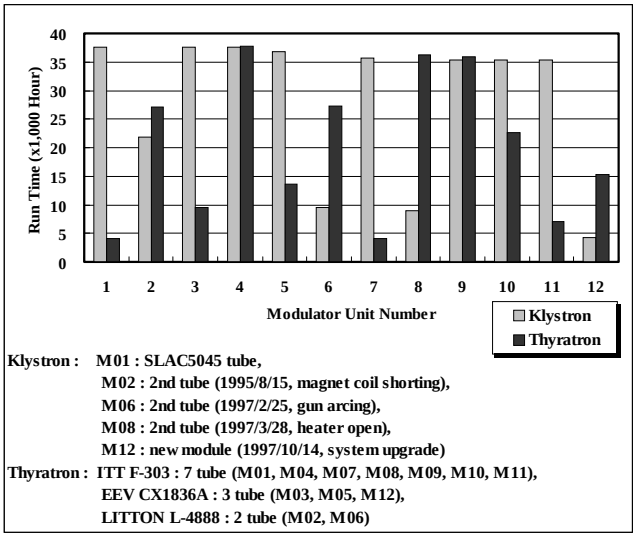

Figure 1: Run time statistics of all klystron and thyratron tubes (as of June 15, 1998).

3 SYSTEM AVAILABILITY STATISTICS

Since the completion of the PLS 2-GeV linac in December 1993 all the K&M systems have been operating continuously except scheduled short term and long term maintenance shut down. Fig-1 shows the accumulated run times of klystron and thyratron tubes as of June 15, 1998. As one can see in the figure rather shorter bars indicate that corresponding tubes have been replaced at least once or more. In fact we have replaced total 3 klystrons and 14 thyratrons during the total ~360,000-hr of operation time (run time sum of all 12 K&M modules). Table-3 & 4 show the calculated statistics of mean time to failure (MTTF) for the klystrons and thyratrons, respectively.

Machine availability analysis has been performed based on the data using the techniques described in detail in reference[4]. The results are summarized in Table-5. The MTBF (mean time between failure) is calculated by dividing the sum of the accumulated modulator run time with the total fault count (*MTBF = N*TO/FC*). The MTTR (mean time to repair) is equal to the total down time divided by total fault counts, *MTTR = TD/FC*.

During the early phase of the operation, from the late 1993 to early 1995, relatively low machine availability (*A = 1-MTTR*FC/TO*) has been obtained. This is due to the maintenance crew training as well as system debugging exercise. Most of time for the repair was spent for the extensive system diagnostics. The major changes that we implemented at the beginning of 1996 were the computer controlled automatic static fault reset and the modification of the circuit breaker (CB) trip interlock. They greatly contributed to the improved availability reaching over 90% as shown in the Table-5. Fig-2 shows the MTTF (mean time to failure) and the MTTR statistics of key component replacement works for the K&M system. For instance, the klystron replacement takes about 16 hours, and the thyratron tube replacement takes around 8 hours. Time estimation counted from the time of the fault to the time of complete recovery of the system.

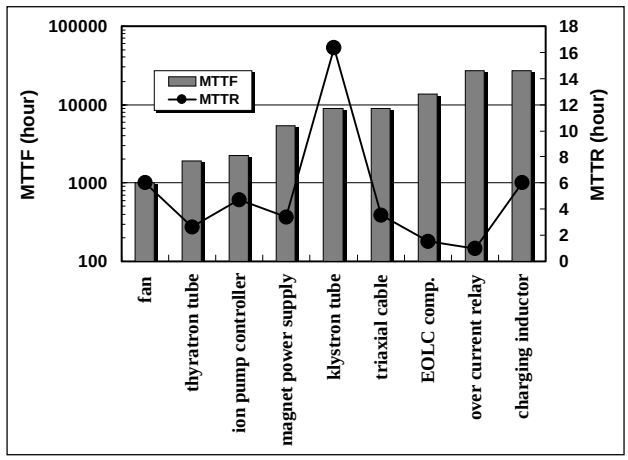

Figure 2: MTTF & MTTR for component replacement (data collection period: 94.9~98.6).

4 COMMENTS ON SYSTEM FAULTS
