It has been observed that the most frequent system fault is the circuit breaker (CB) trip. This is mainly due to the problems in thyratron recovery characteristics which depend on the elaborate reservoir ranging (hydrogen gas pressure control in the tube). Thyratron tubes of F-303 and L-4888 require ranging adjustment (see Table-2), and according to our experience they are very sensitive to the effects which may cause internal gas pressure change. Once out of normal operating point self-fire, firing miss, or slow recovery (causes shorting of the PFN charging power supply) can occur. The CX-1836A thyratron tubes require not so delicate ranging according to the manufacturer's specifications.

Other occasional troubles were corona discharges that are found to occur when there are bad contacts in high voltage components. It has been found also that even a small corona discharge disturbs the ground potential, which are configured to have a single point ground

connection inside the modulator, causing noise interference in digital displays as well as SCR phase controls.

5 SUMMARY

It has been approximately 5 years since the PLS 2-GeV linac has started its normal operation. We have analyzed the klystron modulator system's performance record for the period, which is the major source of the beam injection failure. It is observed that the average lifetime expectancy of the klystron is over 25,000-hr, and it is getting longer. Lifetime of the thyratron tube also appears to be reasonable except the occurrence of the infant failure, however the major improvement is necessary for the reservoir control which is the main source of the system trouble. The machine availability statistics of the K&M system for the beam operation mode is calculated to be over 90%. It appears to us that there are still lots of rooms for the improvement of the availability more than 95% with the smart design of the protection circuits and control schemes.

6 ACKNOWLEDGEMENTS

Authors gratefully acknowledge the sincere efforts performed by PAL linac division members to keep the PAL linac system at an excellent condition. This work was supported partly by POSCO and MOST, Korea.

THE DRIVE BEAM ACCELERATOR OF CLIC

D. Schulte, CERN, Geneva, Switzerland

Abstract

The drive beam of the Compact Linear Collider (CLIC) requires a current of several amperes. The time structure of this beam is discussed. First simulation results on longitudinal single bunch effects are presented and achievable bunch lengths and sensitivity to jitter of the gradient, initial energy and charge are analysed. The transverse stability of the beam is discussed based on the present structure model. Requirements on the damping and detuning of the cavities are given in detail. A beam-based alignment technique is presented and the stability with respect to jitter and ground motion is investigated.

1 INTRODUCTION

CLIC [1] is based on a two-beam scheme. The RF power used to accelerate the main beam (at $30\,\mathrm{GHz}$) is produced by a second beam (the drive beam) running parallel to the main one [2] through so-called "power extraction structures". This beam has a high current but low energy and is decelerated thus producing the RF power.

The drive beam is accelerated to a final energy of $1.2\,\mathrm{GeV}$ in a fully-loaded low-frequency linac ($937\,\mathrm{MHz}$), consisting of 99 $3.1\,\mathrm{m}$ long structures with a loaded gradient of $3.8\,\mathrm{MV/m}$. The beam is then separated into trains of bunches. In so-called "combiner rings", 16 of these trains are merged to form a single one. The length of the final train is the same as that of one of the inital ones, but the distance between bunches is reduced by a factor 16. These short pulses are then sent to the decelerator sectors.

The total length of the charge pulse to be accelerated is equal to twice the main linac length. Assuming a fill factor of $80\,\%$, the main linac will be $13.75\,\mathrm{km}$ long, and the pulse length will therefore be $92\,\mu\mathrm{s}$.

2 TIME STRUCTURE

At the combiner rings, the beam must consist of short trains of bunches, separated by gaps that are larger than the rise time of a kicker. In the drive beam accelerator these gaps would however lead to a significant variation in multi-bunch beam-loading, so it would be difficult to keep the bunch-to-bunch energy variation small, see Fig. 1a. On the other hand, the tolerance on the final energy is tight.

A solution to this problem is not to fill every bucket, but instead only every second one, increasing the train length by a factor of two. Each train is split into two half-trains,

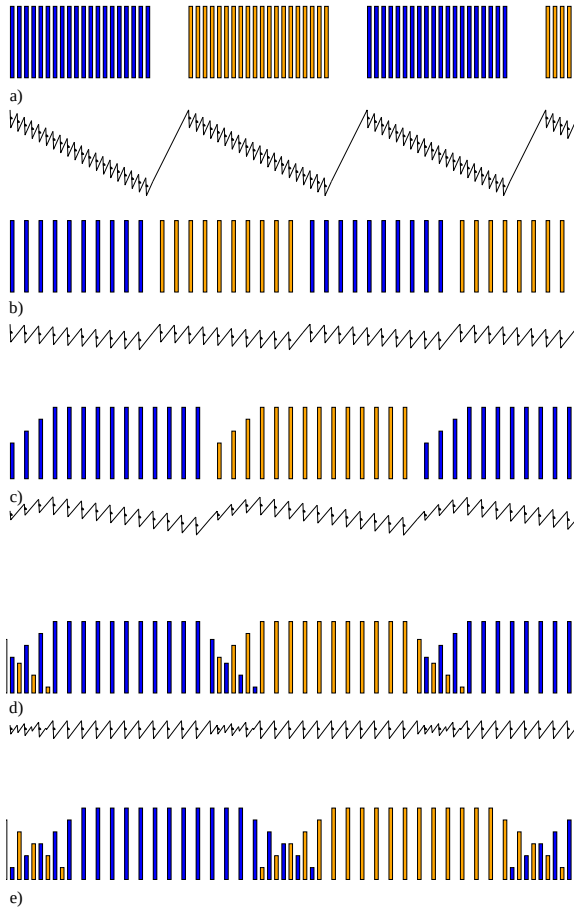

Figure 1: The charge distribution along the pulse—in case a) different trains are shown in different tones, in the other cases different half-trains are shown different tones. The number of bunches on the flat top is constant but different from the real value. The curves indicate the variation of the energy gain. Depending on the injector, a distribution in the range of d) to e) will be chosen.

the bunches of the first half are put into even buckets, and the bunches of the second half into odd ones, see Fig. 1b. In this case the beam-loading is not constant only where one switches from odd to even, or even to odd buckets. The first half of each train is sent into a delay line, using an RF-deflector at the end of the linac, running at half the linac frequency. The second half is deflected to the other side and passes with no delay. The delay line is adjusted to interleave the two halves of the train to form one, with

every bucket filled. This train has the length of an initial half train and is followed by a gap of the same length.

While this solves the problem in the case of constant charge per bucket, the beam-loading compensation in the main linac requires that each half-train starts with a charge ramp. The charge is thus increasing over the first few bunches. This would also create a significant variation in beam-loading (Fig. 1c). This is solved by adding a tail of bunches to the previous half-train which overlaps the ramp (Fig. 1d). This is feasible since different buckets are used for consecutive half-trains. The charge in the tail can be adjusted to make the beam-loading constant.

If the injector is only able to vary the charge per bunch slowly along the train, a longer ramp and a longer tail would be required, see Fig. 1e. In the following simulations, it is assumed that the charge rises linearly from zero to full intensity over the 20 bunches in the ramp and decreases, also linearly, in a tail of the same length.

The flat top of each train contains 47 bunches each with a charge of $q \approx 17.6\,\mathrm{nC}$ [2]. The total pulse ($92\,\mu\mathrm{s}$) is thus sufficient to feed 20 drive beam decelerator sectors.

3 COMPRESSION

The initial bunch length is assumed to be about $\sigma_z = 4\,\mathrm{mm}$ at an energy $E_i = 50\,\mathrm{MeV}$ with an energy spread of $0.75\,\%$ (L.Rinolfi [3]). While this spread is partly correlated with the longitudinal position, in the following it is assumed to be completely incoherent—to be pessimistic.

A simple calculation of the achievable compression was performed using a linear approximation. Since the exact longitudinal wakefield was not available, the values derived for an S-band structure [4] were used. The longitudinal wakefield amplitude $\hat{W}_L$ scales as $\hat{W}_L \propto f^2$ with the acceleration frequency f. The ratio of aperture a to wavelength λ is also different, here the scaling $\hat{W}_L \propto (\lambda/a)^2$ was used as an approximation.

In order to avoid large energy losses due to coherent synchrotron radiation in the combiner rings and in the bends into the decelerator, the bunch length in these sections has to be at least $\sigma_z = 2\,\mathrm{mm}$ (R. Corsini [3]). The final compression is therefore done afterwards. For the compression two different approaches are possible. One can either compress the bunch to a length of $\sigma_z = 2\,\mathrm{mm}$ inside the linac (preferably at low energy) and do the final compression after the bends. Or one can compress the bunch inside the linac in several stages as much as possible. Then it has to be uncompressed at the end of the linac to $\sigma_z = 2\,\mathrm{mm}$. Finally it has to be compressed again after the bends.

An example of the first approach uses an RF-phase for the beam of $\Phi_{RF} = -12^\circ$. The first compression is done at $E \approx 100\,\mathrm{MeV}$, achieving the required $\sigma_z = 2\,\mathrm{mm}$. The final compression step at the decelerator entrance yields $\sigma_z = 290\,\mu\mathrm{m}$ and an RMS energy spread of $\sigma_E = 18\,\mathrm{MeV}$ (case 1). Without wakefields (case 2) one would reach $\sigma_z = 340\,\mu\mathrm{m}$ and a final energy spread of $\sigma_E = 8.5\,\mathrm{MeV}$—this shows the relative independence of the result on the wakefield model.

Using the second approach, the bunch is compressed as much as possible at three positions along the linac, then uncompressed to $2\,\mathrm{mm}$, and recompressed after the bends (case 3). The bunch length achievable with this method is $\sigma_z \approx 170\,\mu\mathrm{m}$. This is significantly shorter than in for case 1 and the final energy spread of $\sigma_E = 13.4\,\mathrm{MeV}$ is also smaller. If the RF-phase is set to $\Phi_{RF} = 0^\circ$ after the first two compression steps (case 4) one can still achieve $\sigma_z \approx 200\,\mu\mathrm{m}$ with an energy spread of $\sigma_E \approx 11.4\,\mathrm{MeV}$. Figure 2 shows the phase space distribution after the final compression for this case.

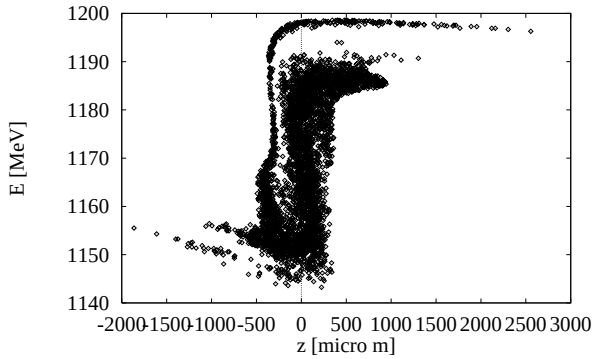

Figure 2: The phase space distribution of the particles after the last compression step in case 4. The particles represent different charges.

Table 1: Deviations from nominal values that result in a longitudinal shift of the bunches of about $10\,\mu\mathrm{m}$.

case		1	2	3	4
$\Delta G/G_0$	$[10^{-4}]$	0.45	0.4	0.5	0.4
$\Delta E_i/E_{i,0}$	$[10^{-4}]$	0.8	16	0.9	0.8
$\Delta\Phi_{\mathrm{RF}}$	$[0.1^\circ]$	0.12	0.1	0.12	0.12
$\Delta q/q_0$	$[10^{-2}]$	0.2	—	0.25	0.2

Energy variations of the bunches are transformed into longitudinal position errors by the bunch compression. These energy variations can be caused by variations of the initial beam energy E_i, the acceleration gradient G, the RF-phase and the bunch charge. Table 1 shows the size of these variations that lead to a longitudinal shift of $10\,\mu\mathrm{m}$. The differences in gradient and RF-phase are assumed to be constant along the accelerator, not random errors.

4 LATTICE

The lattice of the drive beam accelerator consists of simple FODO-cells with a constant quadrupole spacing of $3.9\,\mathrm{m}$. The phase advance per cell is about 116°. One $3.1\,\mathrm{m}$ long accelerating structure, consisting of 29 cells, and a beam position monitor (BPM) are placed between two quadrupoles. The iris radii of the cells of the structure vary from 42.2 to $54.4\,\mathrm{mm}$. The initial beam energy after the injector is $50\,\mathrm{MeV}$.

5 STABILITY

To evaluate the beam stability, simulations with PLACET [5] were performed for the first 2000 bunches assuming initial transverse emittances of $\epsilon_x = \epsilon_y = 100\,\mu\mathrm{m}$. Each of the 29 cells of a structure is simulated using its two most important transverse modes. Three cells were calculated with ABCI (L. Thorndahl [3]) at a frequency $f = 3\,\mathrm{GHz}$ and frequencies and loss factors of the modes were derived by interpolation. A short model structure using a single cell size has been built (L. Thorndahl [3]).

Due to the length of the pulse the structures have to be damped to avoid beam breakup. The measured upper bound of the damping Q of the transverse mode is $Q \leq 100$. The limit was due to the experimental setup, calculations for perfect loads predict $Q \approx 11$ (M. Luong [3]).

In the simulations each bunch is cut longitudinally into 21 slices. Using an undetuned structure with $Q = 100$ leads to an amplification of an initial beam jitter by a factor 15 for some of these slices. A reduction to $Q = 20$ reduces this to a factor of less than 2.

Detuning the structures by varying the iris radii from 42.2 to $54.4\,\mathrm{mm}$ reduces the amplification factor to less than 2 for a damping of $Q = 100$. Figure 3 shows the final positions of the slices after the linac. Within the region of constant charge, the bunch to bunch variations are relatively small, while in the transient parts where the trains overlap they are significantly larger. From train to train the variations are also small. Using the detuned structures, even a damping of $Q = 500$ does not increase the amplification factor significantly.

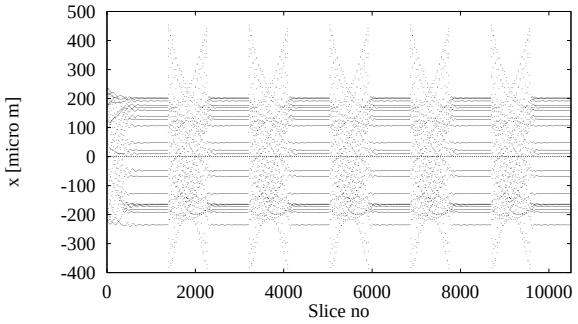

Figure 3: The final slice position for detuned structures with $Q = 100$. Each bunch is cut longitudinally into 21 slices, the first 500 bunches are plotted. The horizontal lines visible, are formed by equivalent slices of successive bunches. The slices of each bunch are filling the space between the minimum and maximum position.

An uncorrelated jitter of the quadrupoles of $\sigma_{quad} = 1\,\mu\mathrm{m}$ leads to a small movement of the beam of less than 0.06σ for any slice at the accelerator exit. The simple ATL-law is used to estimate the sensitivity to ground motion. In this model, the relative transverse offset Δy of two points, separated by a distance L, is given after a time T by $(\Delta y)^2 = ATL$. The value of the constant A is site dependent and can have a value of less than $A = 0.5 \cdot 10^{-6}\,(\mu\mathrm{m})^2/(\mathrm{sm})$[6]. For a test case, the maximum offset after $T = 10^5\,\mathrm{s}$ of any slice was 0.02σ and the average was 0.01σ without any feedback or steering. The linac is thus insensitive to ground motion.

The fast beam-ion instability [7] can also increase the beam emittance. A charged beam can ionise the rest gas in an accelerator. An electron beam will deflect the electrons that are set free in this process towards the outside. The positive ions however are accelerated towards the beam centre. In an unbunched beam they would oscillate. If in a bunched beam the ion oscillation frequency is smaller than the bunch frequency, the ions will be trapped. For the drive beam accelerator this condition is fulfilled. At the moment, simulations of this effect are not available for the drive beam, and analytic formulae [7] give no clear indication of importance of the problem.

6 ALIGNMENT AND STEERING

The initial position errors for quadrupoles are assumed to be $\sigma_{quad} = 500\,\mu\mathrm{m}$ and for beam position monitors and structures $\sigma_{BPM} = \sigma_{struct} = 100\,\mu\mathrm{m}$.

Already with a simple one-to-one steering the total emittance growth along the linac was found to be $3.5\,\%$ in a test case. The maximum position deviation of a slice from the beam centre at the linac exit was about 0.2σ.

7 CONCLUSION

The drive beam accelerator seems to be very stable if detuned and damped accelerating structures are used. Initial beam jitter is amplified by less than a factor 2 for any particle. The alignment tolerances are rather relaxed even when only simple steering is used for correction. The fast beam-ion instability remains to be investigated in detail.

HIGH CURRENT TRANSPORT AND ACCELERATION AT THE UPGRADED UNILAC

W. Barth, J. Glatz, J. Klabunde
GSI, Planckstraße 1, 64291 Darmstadt, Germany

Abstract

The UNILAC will be upgraded as a high current injector for SIS. This paper focuses on beam dynamics studies in the newly designed stripper section, the poststripper Alvarez accelerator and the transport line to SIS considering space charge effects along the UNILAC. Simulation results for the matching to the Alvarez linac, emittance growth effects in the poststripper linac and the beam transfer line to the SIS including the modified foilstripper and charge separation system will be discussed. The beam brilliance loss due to foil straggling and space charge forces will be calculated. Beam experiments at the present UNILAC under comparable space charge conditions are reported.

1 INTRODUCTION

Within the GSI high-intensity program, the present prestripper linac will be replaced by an RFQ and two IH-tanks [1] designed for the acceleration of high current, low charge state beams. The beam behavior influenced by space charge forces is simulated for different input phase space distributions through the complete system to the SIS. Emittance growth occurs in all sections of the UNILAC. A reduction of emittance growth could be expected by the newly designed gasstripper section at $1.4\,\mathrm{MeV/u}$. Beam dynamics calculations within the poststripper and the transfer line will be presented.

2 HIGH CURRENT BEAM MEASUREMENTS

At the present UNILAC, beam experiments with neon ions were carried out under comparable space charge conditions as expected for the upgraded UNILAC, particularly in the stripper region. The SIS could be operated at the space charge limit with Ne^{10+} beam. Measurements in the gasstripper section at $1.4\,\mathrm{MeV/u}$ are shown in Fig. 1. The Ne^{1+} beam accelerated by the Wideröe linac passes the gasstripper and is transported through the charge state analyzing system by four 30° bending magnets. The most abundant Ne^{7+} is selected for further acceleration, the stripping efficiency is about 40%. The emittance growth rates are shown at different current levels. For intensities up to $10\,\mathrm{emA}$ total current behind the $9\,\mathrm{mm}$ stripper aperture, the emittance growth is in good agreement with computer simulations, neighbouring charge states are taken into account. Simulations have indicated that the emittance growth can be reduced by increasing the diameter of the stripper tube from 9 to $16\,\mathrm{mm}$. Experimental and simulation results supported the new design of the stripper section described in the following paragraph.

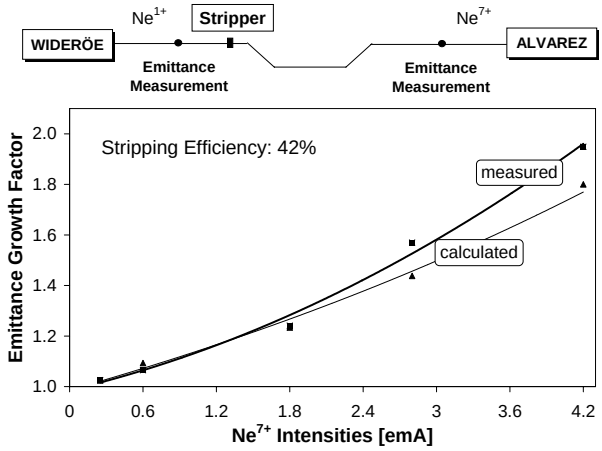

Figure 1: Measured and calculated emittance growth factors at different neon current levels.

3 THE NEW GASSTRIPPER SECTION

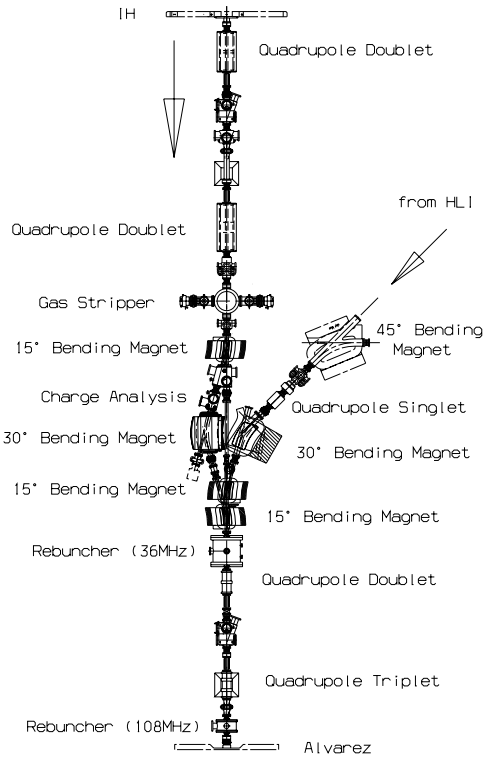

Figure 2: Layout of the new stripper section.

The design of the new transport line between the prestripper and the Alvarez linac is faced with different requirements: lowest emittance growth under considerable

space charge forces, charge state separation, achromatic transport after the bending magnets, transverse and longitudinal matching to the poststripper. The new design has to cope with the ion time-share operation on a $50\,\mathrm{Hz}$ pulse-to-pulse basis. The layout of the gasstripper section is shown in Fig. 2. The beam from the IH section is matched to the stripper tube by two magnetic doublets. After stripping the beam goes immediately into the first 15° bending magnet. The analyzing slit is directly before the second dipole (30°). The last dipole bends the beam back to the UNILAC axis. In the following transport line the longitudinal matching (with two rebunchers) and the transversal matching (with a quadrupole doublet and a triplet) to the poststripper accelerator is accomplished without any particle loss. The beam from the second injector (HLI) is delivered to the poststripper by a 180° bending section. All magnetic lenses, dipoles of the stripper section and the kicker magnet of the HLI transport line allow the pulsed operation.

4 CALCULATED EMITTANCE GROWTH FROM THE PRESTRIPPER TO THE SIS

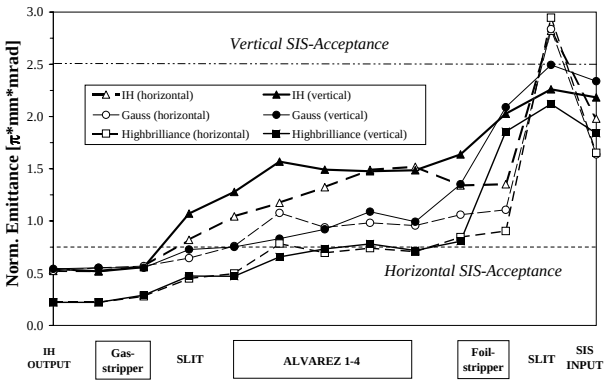

Figure 3: Variation of the horizontal and vertical 90% emittances from the UNILAC stripper section to the SIS input for different input beams. The transmission in all cases is approx. 95%.

For the simulations three input distributions are selected: the 'IH distribution' will be expected behind the new prestripper linac [2]. This particle distribution was calculated from an initial Gaussian distribution at the prestripper entrance with a current of $16.5\,\mathrm{emA}$ U^{4+}. In order to exclude effects of the distorted IH distribution, simulation begin with an ideal Gaussian distribution with the same 90% values of emittance at the IH exit. The limit of the system is evaluated by a high brilliant transversal Gaussian distribution as expected from the RFQ. In all three cases the beam was transformed through the stripper section, the poststripper accelerator and the transfer line with the same settings of the quadrupole gradients and rebuncher fields. In Fig. 3 and Fig. 4 the development of the horizontal and longitudinal 90% emittance. The calculated beam transmission in all cases is approx. 95%. In addition the space charge parameter SPC (relatively) is exposed in Fig. 5: $SPC \sim ParticleCurrent \cdot ChargeState^2 \cdot \beta^{-1} \cdot Bunchvolume^{-1}$.

In the following the beam behavior in the several UNILAC sections is discussed.

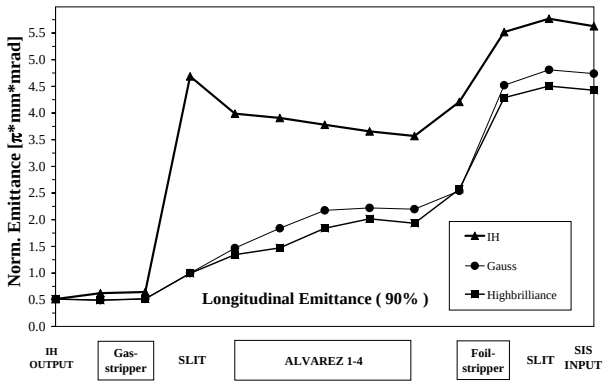

Figure 4: The longitudinal 90% emittances complementary to Fig. 3.

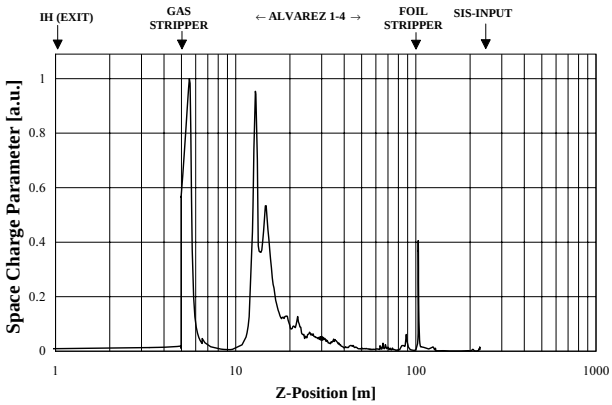

Figure 5: The Space Charge Parameter (SPC) along the stripper section, the Alvarez and the transfer line.

4.1 Gasstripper section

In the matching section to the gasstripper no significant emittance growth occurs, the jump of the charge state after stripping increases the SPC dramatically. Amplified by the reduction of the bunch volume, the emittance in all three planes accumulates until the slit of the charge state analysis, where the particle current abruptly decreases. To match the beam to the Alvarez a very small bunch length is indispensable. For the Gaussian distribution the transversal emittance growth factor at the Alvarez input is only 1.37, compared to 2.18 for the IH distribution, which occurs due to the longitudinal phase space aberrations in interaction

with the strong space charge forces after the stripping process. The emittance growth factor is optimized by iteration of the transversal beam divergence at the gasstripper. The transversal emittance of the high brilliant beam increases by a factor of 2.2, but the absolute emittance growth is comparable with the Gaussian case.

4.2 Poststripper Accelerator

Particularly in the first Alvarez section emittance growth is high, thereafter the effect is moderate because the acceleration gain becomes higher. The stripper section is optimized for low horizontal emittance growth at the expense of vertical beam quality. Because of that equipartitioning takes place for the IH distribution in the poststripper accelerator caused by strong space charge forces. If the same transverse distribution combined with a matched Gaussian one in the longitudinal phae space (IH modified) is used, the transversal emittance growth is reduced from 30% to 15%. To minimize emittance growth for beams with higher brilliance (Gauß, High Brilliance) the zero current phase advance in the periodic structure has to be increased from 45° to 54°. This can be achieved by 11% higher quadrupole field strengths.

4.3 Transfer Line to the SIS

In the transfer line the transverse matching to the foilstripper is not critical. With a narrow upright beam spot on the stripperfoil the emittance growth in the horizontal plane is minimized, while an increase of the vertical emittance is tolerated in view of the acceptance of the synchrotron (see Table 1: IH distribution with and without stripping) [3, 4]. Comparing the Gaussian and the high brilliant distribution with the IH one, an conspicuous increase of the vertical emittance caused by stripping effects has to be considered.

Table 1: Emittance growth (90 %) in the transfer line

		Foil (in)	Foil (out)	Charge Sep.	TK (out)
IH	horizontal	0.88	0.89	1.86	1.30
(with stripping)	vertical	1.10	1.36	1.52	1.47
IH	horizontal	0.91	0.91	1.16	1.31
(without stripping)	vertical	1.11	1.11	1.11	1.07
Gauß	horizontal	1.11	1.16	2.97	1.71
(with stripping)	vertical	1.36	2.11	2.51	2.36
High Brilliance	horizontal	1.20	1.28	4.18	2.34
(with stripping)	vertical	1.12	2.59	2.96	2.57

Fig. 6 displays the emittance growth factor due to particle scattering as a function of the distribution fraction at the same vertical beam size. The IH distribution has a very intense core (peaked distribution), the emittance growth is much lower for the outer area of the distribution. An inverted characteristic for the emittance growth as a function of intensity results from a transverse homogeneous KV distribution.

Increasing the charge state from $28+$ to $73+$ entails in a SPC boost which is only 40% of the effect in the gasstripper section.

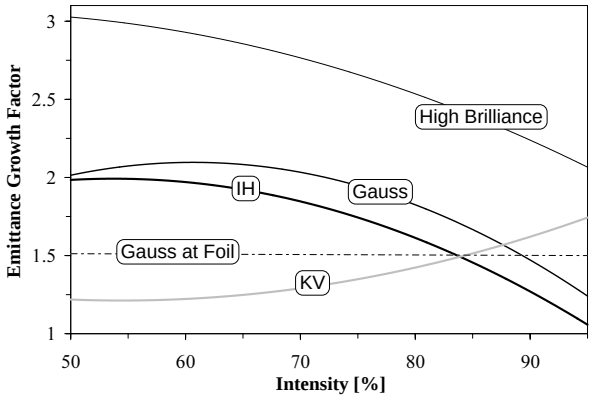

Figure 6: Emittance growth factor due to particle scattering at the foilstripper for several phase space distributions.

5 SUMMARY

The calculated deformation in the phase space distribution coming from the prestripper accelerator results in high emittance growth. The new stripper section may work very well for a Gaussian distribution. If a high brilliant beam is preserved the zero current phase advance in the poststripper has to be increased to minimize emittance growth. Beside the gasstripper section the first Alvarez tank is the most critical part due to space charge effects. The transport through the transfer line does not lead to considerable horizontal emittance growth. The vertical scattering effect in the foilstripper is much higher because of the upright beam spot and depends strongly on the phase space distribution. The final transverse emittance exceeds the acceptance of the SIS in all three cases. Nevertheless, the SIS can be filled up to the required 2×10^{10} particles per pulse U^{73+}.

ANALYSIS AND MODELING OF A STRIPLINE BEAM KICKER AND SEPTUM

B. R. Poole, G. J. Caporaso, Y. J. (Judy) Chen, L. –F. Wang
Lawrence Livermore National Laboratory, Livermore, California 94550 USA

Abstract

A fast stripline beam kicker and septum are used to dynamically switch a high current electron beam between two beamlines. The transport of the beam through these structures is determined by the quality of the applied electromagnetic fields as well as temporal effects due to the wakefields produced by the beam. In addition, nonlinear forces in the structure will lead to emittance growth. The effect of these issues is investigated analytically and by using particle transport codes. Due to the distributed nature of the beam-induced effects, multiple macro-particles (slices) are used in the particle transport code, where each slice consists of an ensemble of particles with an initial distribution in phase space. Changes in the multipole moments of an individual slice establish electromagnetic wakes in the structure and are allowed to interact with subsequent beam macro-particles to determine the variation of the steering, focusing, and emittance growth during the beam pulse.

1 INTRODUCTION

The stripline kicker is designed to spatially separate a high current electron beam for transport into two separate beamlines. However, to provide a significant angular kick to the beam, a magnetic dipole septum is required. This system is shown schematically in Figure 1.

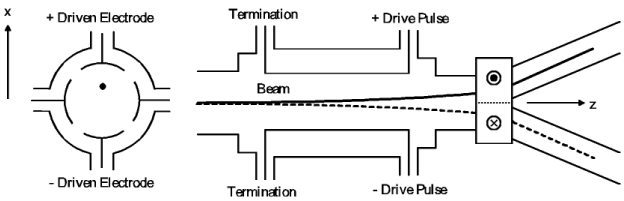

Figure 1 Kicker and septum configuration for dynamic beam steering in one plane

The operation of the system is as follows: A high voltage pulse is applied to the downstream ports of the kicker and the beam is spatially separated (kicked) by a combination of the transverse electric and magnetic dipole forces associated with the TEM waves propagating on the strip transmission lines. The beam is then directed into a septum magnet with opposite polarity dipole fields on either side of the plane separating the two downstream beam lines. All the upstream ports and the two downstream ports in the non-kick plane are terminated in a matched load impedance for the dipole transmission mode on the structure. It should be noted that steering in both planes can be accomplished by also driving the other pair of plates.

2 KICKER TEM FIELDS AND BEAM DEFLECTION

To steer the beam in *x*, opposite polarity high voltage pulses are applied to the downstream ports in the *y=0* plane. The potential within the kicker plates ($r<b$) is given by

$$V = \frac{4V_p}{\pi}\sum_{m=odd}\left(\frac{1}{m}\right)\sin\left(\frac{m\phi_0}{2}\right)\cos(m\phi)\left(\frac{r}{b}\right)^m \quad (1)$$

where b is the interior radius of the kicker plates, and ϕ_0 is the angle subtended by the kicker plates. The voltage applied to the plate is V_p giving a total steering voltage of $2V_p$. The solution is determined by solving for the potential in the region $r<b$, and using the boundary condition that the potential at $r=b$ is given by the appropriate applied plate voltages and that the potential in the gaps between the plates is zero. The TEM fields can be easily derived from this scalar potential. The *m=1* term in Equation (1) represents a transverse dipole force which provides the beam steering while the higher order terms will contribute to emittance growth in the beam. The beam deflection due to the combined electric and magnetic dipole forces is given by

$$\Delta x = \frac{\pi b V_p}{I_c Z_k \sin(\phi_0/2)} \quad (2)$$

where the critical current, I_c is defined by

$$I_c = \frac{\pi}{16}\frac{\gamma\beta^2 I_0}{\sin^2\left(\frac{\phi_0}{2}\right)}\frac{Z_0}{Z_k}\left(\frac{b}{L}\right)^2 \quad (3)$$

and I_0 = 17 kA, Z_0 = 377 Ω, L is the length of the kicker, b is the inner radius of the kicker plates, Z_k is the kicker impedance, and γ is the usual relativistic factor.

3 DIPOLE WAKE IMPEDANCE AND BEAM INDUCED STEERING

In our application, the beam current is sufficiently large as to induce substantial voltages and currents on the strip transmission lines. These voltages and currents are introduced on the transmission lines as the beam traverses the upstream and downstream gaps as well as from changes in the dipole return current as the beam is deflected. A detailed model has been previously described [1],[2]. The *m=1* transverse dipole wake impedance for this structure [3] is given by

$$Z_{\perp}(\omega)=\frac{8cZ_k}{\pi^2 b^2}\sin^2\left(\frac{\phi_0}{2}\right)\left(\frac{1}{\omega}\right)\left[\sin^2\left(\frac{\omega L}{c}\right)+j\sin\left(\frac{\omega L}{c}\right)\cos\left(\frac{\omega L}{c}\right)\right]. \tag{4}$$

The imaginary part of the dipole impedance, $Z_{\perp 0}=\mathrm{Im}[Z_{\perp}(\omega=0)]$ is a measure of the asymptotic beam deflection due to the beam-induced fields. It has been shown that the asymptotic beam deflection for an initially offset beam with current I_B injected into the kicker has the form [1]

$$x_{\infty}=x_0\cosh\left(\sqrt{\frac{2I_B}{I_c}}\right) \tag{5}$$

where x_0 is the injection offset of the beam. It is easily shown for sufficiently small beam currents that

$$x_{\infty}\approx x_0\left[1+\left(\frac{2\pi L}{\gamma\beta^2 I_0 Z_0}\right)I_B Z_{\perp 0}\right]. \tag{6}$$

To examine the relevant physics issues, a kicker has been designed and installed on the Experimental Test Accelerator (ETA-II). The ETA-II kicker has the following set of parameters: b=12.87 cm, ϕ_0=78°, Z_k=50 Ω, L=164 cm and I_c=3.9 kA. The outer enclosure has a radius of 19 cm. To verify the validity of the transmission line model the structure was modeled using a 3-D time domain electromagnetic code to determine the dipole impedance spectrum. Figure 2 shows a comparison of the dipole impedance as calculated from Equation (4) with numerical results from a 3-D time domain electromagnetic code for the ETA-II kicker. As can be seen there is a good agreement between the transmission line model and the 3-D code results. The differences can be attributed to end cavity effects associated with the feeds to the external ports and effects due to higher order modes in the structure.

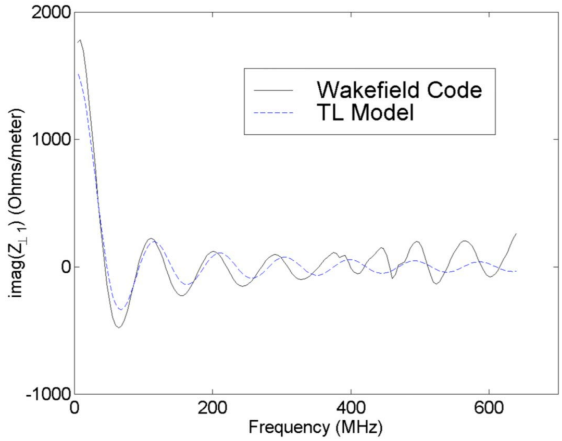

Figure 2 Dipole wake impedance

The effect of the wake impedance on the deflection of the beam can be quite dramatic. For example, for a 6 MeV, 2 kA beam initially offset by 2 cm going into the kicker, the tail of the emerging beam will be offset by 3.1 cm at the exit of the structure. These effects have been observed experimentally [4] and are consistent with theory.

4 NONLINEAR FORCES AND EMITTANCE GROWTH

From Equation (1) it is seen that for a dipole excitation of the kicker, all higher order odd multipoles will be excited in the structure. Although the higher order multipoles reduce in strength as $(r/b)^m$ it is possible under certain conditions that the beam will experience these fields, especially the *m=3* sextupole component. For example, with ETA-II parameters the space charge fields due to the beam may require that the beam entering the kicker have a large radius to enable the downstream beam to be at or near a waist when entering the dipole septum. This is important in order to minimize any emittance growth due to the nonlinear fields associated with the septum magnet. In order to estimate the effect of the higher order multipoles due to the kicker on the beam emittance, a simple particle transport code was developed. The code includes the external fields in the kicker region as defined by Equation (1) and is being expanded to include the beam-induced effects and space-charge effects self-consistently. Presently, the particles respond only to the external fields. However, we can estimate the emittance growth in the structure by using the external fields only. As an example, using the ETA-II kicker previously described, a 6 MeV beam is injected into the kicker with an unnormalized edge emittance of 13 cm-mrad and a convergence angle of .03 rad. The injected beam radius is 4 cm, which allows the beam to experience the higher order multipoles. Figure 3 shows a configuration space image of the emerging beam from the kicker showing a centroid location of 2.7 cm consistent

with Equation (2). The triangular image has been observed experimentally [4].

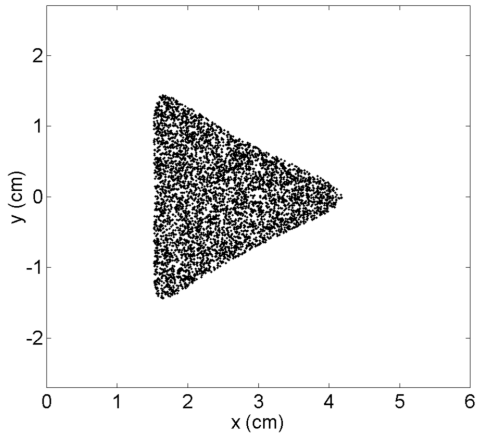

Figure 3 Configuration space image of beam emerging from kicker experiencing a large sextupole field

Despite the strong deformation of the beam image the emittance growth is predicted to be about 53% for this beam. However, transport calculations have also shown that it is possible to transport a smaller radius high current beam ~2 kA through the kicker giving an estimated emittance growth on the order of 2%.

5 MAGNETIC DIPOLE SEPTUM

The septum magnet provides an additional angular kick to the beam as it emerges from the kicker. The kick is in opposite directions on either side of *x=0*. The septum is shown schematically in Figure 4.

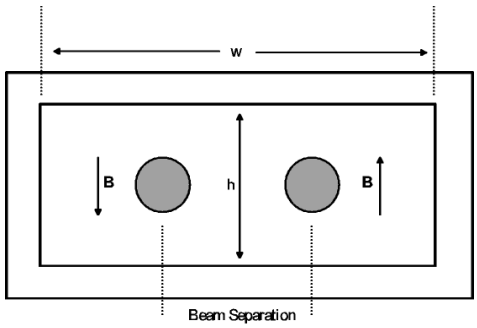

Figure 4 Magnetic dipole septum magnet

The dipole magnetic field required to produce a beam exit angle of ~15° is determined from

$$B\ell = \frac{mc}{e}\sqrt{\left(\frac{E_b}{mc^2}\right)^2 + 2\left(\frac{E_b}{mc^2}\right)} \times \left[\sin(\theta_i + \Delta\theta) - \sin(\theta_i)\right] \quad (7)$$

where ℓ is the axial length of the magnet, θ_i is the incident beam angle, $\theta_i + \Delta\theta$ is the desired exit beam angle, and E_b is the beam energy. A preliminary design for a dipole septum magnet to be used with the ETA-II kicker is being developed. The parameters for the design are an axial length of 20 cm, and a magnetic field of about 276 Gauss for a beam energy of 6.3 MeV. The dimensions of the aperture are about h=6 cm high and w=31 cm wide. Careful optimization of the design is required to minimize possible emittance growth in the transition region where the field changes sign. Currently, magnetic modules are being developed for particle transport codes to estimate the emittance growth through the septum magnet. With careful design including shims preliminary estimates show an emittance growth on the order of 4% through the septum magnet.

6 CONCLUSIONS

Self-consistent models are being developed for modeling the transport of high current space-charge dominated beams through fast beam kickers and dipole septum magnets. The effect of beam-induced forces due to the wakefields of the beam are included in the analysis. In addition, emittance growth due to nonlinear forces associated with higher order multipoles in both the kicker and septum have been estimated. Preliminary estimates of beam-induced steering are consistent with the experimental program [4]. The effect of space-charge, image forces, and fringe fields in the structures have yet to be included.

HIGHER-ORDER-MODES AND BEAM BREAKUP SIMULATIONS IN THE JEFFERSON LAB FEL RECIRCULATING LINAC*

L. Merminga, I.E. Campisi
Thomas Jefferson National Accelerator Facility, Newport News, Virginia 23606, USA

Abstract

Measurements were performed of the frequencies and external Q's of the first two Higher-Order Mode (HOM) dipole passbands in the eight superconducting cavities of the cryomodule used in the recirculating linac of the driver accelerator of JLab's IRFEL. Anomalous high-Q resonances were found, which could lead to beam instabilities at currents close to the operating current of the machine. These results led to more detailed simulations of its beam breakup (BBU) behavior. The analysis indicates that a few modes are responsible for the relatively low value of 27 mA of the threshold current. A simple modification of the superconducting cavities could lead to an increase of the threshold current by an order of magnitude.

1 INTRODUCTION

The Jefferson Lab Free Electron Laser is presently being commissioned at current levels of about 1 mA [1]. The driver accelerator is based on a recirculation design, which incorporates energy recovery as an important feature. The accelerating-decelerating linac consists of a slightly modified CEBAF 2 K cryomodule, containing eight 5-cell superconducting cavities operating in the TM_{010} π mode at 1497 MHz.

The Higher Order Modes (HOM) are extracted by two mutually orthogonal waveguides, with a frequency cutoff of 1900 MHz, terminated in loads thermally anchored at 50 K. Modes at frequencies below 1.9 GHz can only be extracted via the fundamental power couple (FPC). Four out of five dipole modes of the TE_{111} passband fall into this category, and their external Q's can be lowered only if some component of their fields is aligned with the FPC. In the case of strong polarization, orthogonal modes could exhibit large values of Q_{ext}.

Due to the energy recovery feature of this accelerator and the relatively low number of superconducting cavities involved in the process, even a few poorly damped modes can have a devastating effect on the beam, especially at the low energy end in either one of the passes through the cavities.

In this paper we describe the results of the measurements of frequencies and Q_{ext} values of the first two HOM dipole bands (TE_{111} and TM_{110}).

* Work supported by the US Department of Energy, contract DE-AC05-84ER40150

From these measurements, rough estimates of the upper and lower limits of the BBU threshold current were derived, which bracketed the operating current of 5 mA. This result forced us to more carefully re-evaluate the instability threshold by using the simulation code TDBBU [2] and the actual measured values, as described below.

2 MEASUREMENTS OF HOM'S

The TE_{111} and TM_{110} passbands' frequencies and Q's were systematically measured for all the superconducting cavities in the FEL linac [3]. Several modes exhibited high Q's (see table 1), with the highest Q's associated with the vertical polarization of the TE_{111} π/5 mode.

Figure 1 shows the correlation of Q's for all the modes observed. All modes except the TE_{111} π/5 (large circles) show a direct correlation, pointing to no preferred polarization alignment. The TE_{111} π/5 does not follow this correlation, indicating that the extraction efficiency is subject to strong polarization. Since this particular mode has most of the energy stored in the center cell, the strong polarization is possibly associated with overall mechanical bending of the cavity in the vertical plane, thus preventing that polarization to couple to the FPC.

Although the TE_{111} π/5 mode has been observed to have the highest Q_{ext}, it is actually the 4π/5 mode which contributes more to possible beam instabilities because of its substantially higher transverse impedance (Table 1).

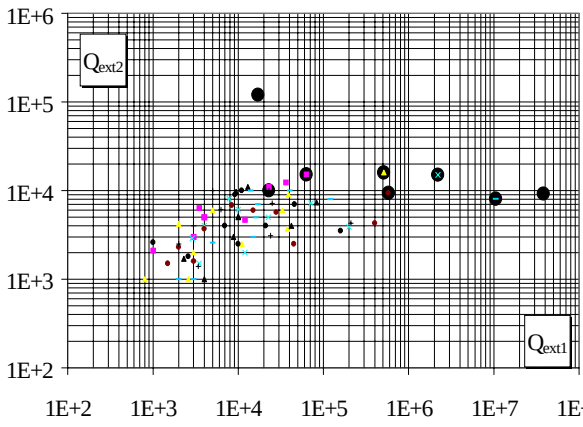

Figure 1 Distribution of external Q's for the first two dipole passbands in the eight FEL superconducting cavities. • represents the TE_{111} π/5 modes.

Table 1. Previously reported by Amato [4] (denoted by subscript A) and presently measured (subscript M) parameters for the most relevant modes for the FEL. The Q_M's in this Table are the highest measured in the whole cryomodule.

TE_{111}	$(Z"T^2/Q)_A$	$(Z"T^2/Q)Q_A$	Q_M	$(Z"T^2/Q)Q_M$
$\pi/5$ -x	2.0 E2	6.2 E6	1.2 E5	2.4 E7
$\pi/5$-y	2.0 E2	6.2 E6	3.8 E7	7.6 E9
$4\pi/5$-x	7.0 E4	1.1 E9	1.2 E4	8.6 E8
$4\pi/5$-y	7.0 E4	1.1 E9	4.0 E5	2.8 E10

Six out of eight cavities show that the vertically polarized TE_{111} $4\pi/5$ mode has a Q high enough to generate a shunt impedance of 1-3 10^{10}, two orders of magnitude larger than what originally measured by Amato [4]. The frequency of this mode falls right below the cutoff of the HOM extraction waveguides. A more effective extraction of this dangerous mode could be attained if a slight modification of future cavities could be made to allow propagation of this mode.

The simulations described below were performed both for the real system and for a modified system with realistically decreased Q_{ext} of the six cavities TE_{111} $4\pi/5$ modes.

3 SIMULATIONS

3.1 Method

Simulations of beam breakup were performed using the code TDBBU [2]. In it, every bunch is characterized by a phase space vector which gets updated according to the fundamental equations of dynamics described in Reference [5], as deflecting modes in each cavity impart kicks in the horizontal and vertical directions.

In the FEL simulations, a 10 MeV beam is injected into the linac, interacts with the HOM fields of each cavity, gets transported around the recirculation path and enters the linac again, 180° out of phase for energy recovery. As the decelerated beam traverses the RF cavities, it interacts with the HOM fields of the cavities again, and, as the beam energy becomes smaller, the transverse deflections imparted to the beam have a stronger effect. Therefore, we expect the threshold current to be lower in the case of recirculation with energy recovery than in the absence of energy recovery.

The beam is injected into the linac with energy equal to 10 MeV with a bunch repetition frequency of 37.4 MHz, the 40th sub-harmonic of the RF frequency. Each cavity is described by a 0.25m drift delivering an energy gain of 2 MV, followed by the "HOM-kick" section for the particular cavity and this is followed by another 0.25m drift delivering 2 MV energy gain, for a total of 8 MV/m acceleration gradient per cavity.

The "HOM kick" section includes all five TE_{111} and five TM_{110} horizontal and vertical modes. Each mode is characterized by its Q value, frequency, and transverse shunt impedance, as given in Ref. [4] scaled by the frequency of the mode.

The total path length of the recirculation is 501.5 RF wavelengths [5] and the transport matrix elements are calculated using DIMAD.

3.2 Results

The threshold current for a system containing the real cavity parameters and optics for the FEL was determined via several runs and found to be about 27 mA.

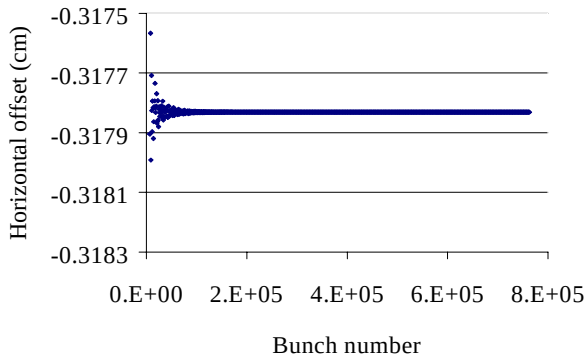

Figure 2 Horizontal bunch offset as a function of bunch number at 25 mA. The beam damps rapidly to a stable condition in the horizontal plane.

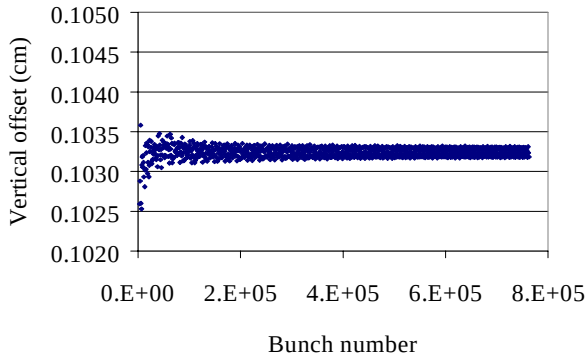

Figure 3 Vertical bunch offset at 25 mA. In the vertical plane the damping occurs more slowly than in the horizontal plane.

Figure 2 shows the convergence behavior at 25 mA for the horizontal plane and Figure 3 shows the convergence in the vertical plane at the same current. A clear divergence in the vertical place is observed at 28 mA (Figure 4).

In the horizontal plane, on the contrary, no instability is observed at these current values, since the relevant modes are polarized in such a way that those aligned with the horizontal axis are well damped by the fundamental power coupler.

Several other simulations with currents well above threshold were performed to determine the growth rate of the instability and to extract the functional dependence of growth rate on current. Figure 5 shows a typical run performed for currents well above threshold. In Figure 6 the growth rate is plotted as a function of current. From it, it is possible to get a relatively good agreement with the actual estimate of the threshold by direct simulation, by making only two simulation runs above threshold and extrapolating the threshold via the plot in Figure 6. The value thus obtained is approximately 35 mA, about 25% higher than what obtained by direct simulation.

The analysis of the mode impedance for the real cavities shows clearly that the TE_{111} $4\pi/5$ mode is in most cavities the one responsible for a major part of the current limitations. This mode often falls only a few MHz below the threshold for propagation in the HOM waveguide and it would be damped more effectively if the cutoff frequency of the HOM waveguide could be lowered by only one percent or so.

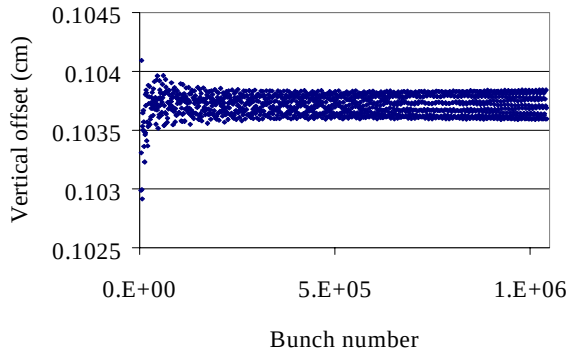

Figure 4 Vertical bunch offset at 28 mA. The beam becomes unstable at this threshold current.

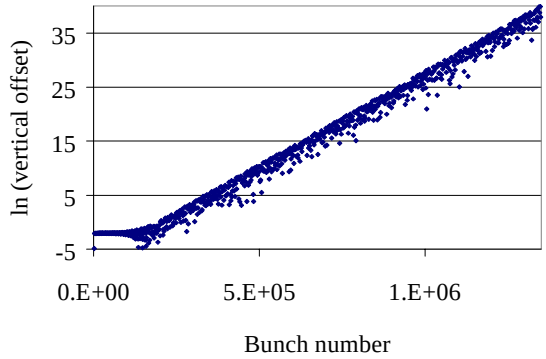

Figure 5 Logarithmic representation of the bunch offset for a current well above threshold, 200 mA in this case.

Such mechanical modification of the coupler might be possible with minimal effort [6]. Based on that assumption, we have recalculated the threshold current for the case in which the Q's of the TE_{111} $4\pi/5$ modes are lowered by a factor of 10 if above 10^5. This was done for cavities 1-6 in the cryomodule. The cavities with Q's already below 10^5 (7 and 8) were left untouched.

It is possible that the Q's of these modes is limited to about 5×10^5 because at these frequencies, slightly below the HOM waveguide cutoff, there is enough leakage of the evanescent mode in the waveguide to effect some damping. The $\pi/5$ mode, being at lower frequencies, exhibit considerably higher Q's, even two orders of magnitude larger.

The results of the simulations, performed in exactly the same manner as for the real measured Q's, indicate that the threshold current is now increased to 207 mA.

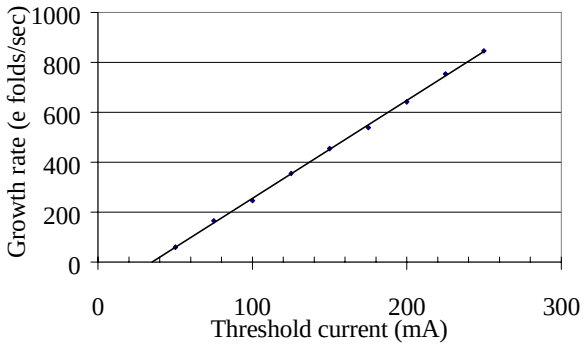

Figure 6 Growth rate of the bunch offset as a function of current. This plot can be used to estimate the threshold current as the abscissa intercept.

4 CONCLUSIONS

Detailed measurements of the Q's and frequencies of the first two dipole Higher Order Modes in the FEL linac indicated that the vertical polarization of some modes in several cavities are only marginally damped.

TDBBU simulations of the Beam Breakup threshold performed with the actual configuration yield a value of threshold current of 27 mA, only a factor of 5 higher than the design operating current.

Analysis of the mode shunt impedance indicates that with a slight modification of the cavities, a few dangerous modes could be more adequately damped. With such modification, the TDBBU estimate of the threshold current would be increased above 200 mA.

TESLA INJECTOR SIMULATIONS WITH MAFIA*

P. Schütt, T. Weiland
Darmstadt University of Technology, Fachbereich 18,
FG Theorie Elektromagnetischer Felder, Schloßgartenstraße 8, 64289 Darmstadt, Germany

Abstract

The TESLA Test Facility (TTF) is a test bed for the superconducting option of a linear e+/e- collider in the TeV regime. The injector delivers a 20 MeV beam with 1 nC charge per bunch of 1 mm length. It consists of an RF-gun, a superconducting 9-cell Capture Cavity and a chicane bunch compressor. The MAFIA modules TS2 and TS3, the particle in cell programs in 2D and 3D, as well as the module L, a tracking program, have been used to study the particle dynamics in the TTF, e.g. the emittance growth due to space charge effects in the bunch compressors. Dedicated interfaces for the three different simulation tools allow to study components separately and to hand over beam data from one accelerator section to another or one simulation tool to another, respectively.

1 INTRODUCTION

A typical linear accelerator consists of a diversity of components, which are usually developed with different design tools. When the beam dynamics in an accelerator is studied, the low energy part near the particle source usually requires the use of a simulation program that includes the calculation of space charge forces. On the other hand, the tracking of ultrarelativistic particles can be done much faster with a different class of simulation codes.

Problems may arise when parameters of the beam must be communicated between the different programs. Often, definitions e.g. for the units of the emittance differ. More over, beam models may be different: e.g. macroparticles in one code versus gaussian bunches in the next.

Within the electromagnetic CAD package MAFIA[1], three solvers are offered which allow the simulation of the full electrodynamics in the low energy part of the accelerator as well as the fast tracking in the high energy part. Interfaces are being developed to ease the handover of parameters from one code to the next.

In the low energy region, a handover of beam parameter from one accelerator element to the next is challenging even in the case where both are handled in the same code. This is due to the fields which accompagny the beam and must be interpolated from one calculation grid to the other without inducing numerical noise.

The status of this project is described in this paper.

2 SIMULATION TOOLS

2.1 MAFIA-TS2 and -TS3

TS2 and TS3 are the names of the Particle in Cell (PIC) modules in MAFIA. They have been used successfully for the computer aided design of klystrons and other RF sources[2]. The PIC programs solve Maxwell's equations in the time domain with a FDTD algorithm and in parallel, selfconsistently, integrate the equations of motion of the charged particles. These particles, in turn, are the source of the electromagnetic fields.

TS2 is the axisymmetric, two dimensional version, TS3 works with three dimensional cartesian coordinates. Both are fully relativistic and due to their basic physics algorithm a priori include all interaction of the charged particles and electromagnetic fields. Therefore, space charge, self magnetic fields, wake fields etc. are all included. Furthermore, both codes can use precalculated static and resonant fields, which are provided by other solvers in the MAFIA package.

2.2 MAFIA-L

L is a specialized module for the tracking of relativistic particles in an accelerator. It has been used to study single bunch and multibunch instabilities[3]. Featuring a modular description or the accelerator, including alignment errors, as well as optimization strategies, it is a tool for the overall design of a linear accelerator. The statistical description of the beam allows an uncorrelated energy spread and a phase jitter.

L calculates the longitudinal as well as the transversal dynamics of the beam. It includes realistic external fields. The transversal space charge forces may be calculated in a fast approximation, wake fields can be included by a quasi Green's function algorithm, where the Greens functions are provided by MAFIA-T2.

2.3 Interfaces

Several interfaces have been developed to facilitate the data exchange from one accelerator section to the next.

If both sections are calculated by L, the data exchange is trivial: beam data can just be reused.

In the case of the PIC codes, it is necessary to store not only beam data but also the field data for one period in a steady state. Furthermore, to avoid noise in the downstream component, the beam current must be artificially raised to

its nominal value over several RF periods. The algorithms for interfaces from TS2 to TS2 or TS3 have been published earlier[2].

Especially for the use in accelerator design, an interface from TS2 to L has been developed. This requires the translation between two different beam models: in TS2, the beam is described by a number of macro particles, characterized by their position and momentum at a fixed time. In L, the bunch at a fixed position in the accelerator is described by a number of time slices. These slices are characterized by their first and second order statistical moments of transversal position and momentums as well as their energy and their longitudinal position in time.

The interface has been built into TS2. During the calculation, all particles are registered when they cross the monitor plane, which is located at the beginning of the structure to be simulated in L. The slice parameters for L can then be calculated via statistics formulae. In order to keep as much information as possible, no further smoothing of the data is used.

It will rarely be necessary to hand data from L to TSx. But it can be useful to calculate single elements without the calculation of all upstream components in TSx. In order to facilitate the input of starting parameters, we plan to enable the input of Twiss parameters into TSx and to develop an interface from L to TSx.

3 NUMERICAL RESULTS

3.1 *Injector Layout*

Figure 1 shows schematically the layout of the TESLA FEL injector. A Laser RF gun delivers a beam with about 5 MeV. In a first superconducting TESLA structure, the capture cavity, it is accelerated to 15 - 20 MeV, then longitudinally compressed in a chicane and delivered to the first complete TESLA module.

The beam dynamics in the gun and possibly in the capture cavity must be simulated in TS2, because of the strong collective forces. Either at the end of the gun, or at the end of the capture cavity, L may take over.

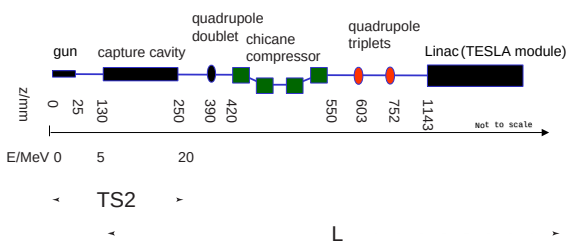

Figure 1: Schematic Layout of the Injector. The application regions of the MAFIA modules TS2 and L are indicated.

3.2 *The Gun*

Simulation results for the TESLA TTF gun have been published elsewhere [4]. For a correct treatment of the collective forces, a very fine resolution of the calculation grid is required: typically $\Delta z = 20\mu m$. The results have been compared to PARMELA calculations: when wake fields are artificially suppressed in MAFIA-TS2, both codes give the same results.

3.3 *The Capture Cavity*

The capture cavity has also been simulated with TS2 (see figure 2, next page). Since the spatial bunch dimensions are bigger here than in the gun, the resolution may be somewhat coarser: we used $\Delta z = 100\mu m$ and $\Delta r = 120\mu m$.

In order to reduce the numerical noise in the calculation, data were not taken from previous calculations, but initialized at the entrance of the cavity. The bunch length was $\sigma_z = 800\mu m$, the radius $\sigma_r = 600\mu m$. In the test case, we used an injection phase of $\Delta\varphi = -10°$. The start energy was 5.3 MeV with an uncorrelated energy spread of 13.3 keV. The maximum field amplitude in the cavity was 15 MeV/m.

3.4 *Handing Data over to L*

Close to the end of the capture cavity, an interface to L was placed in the TS2 simulation.

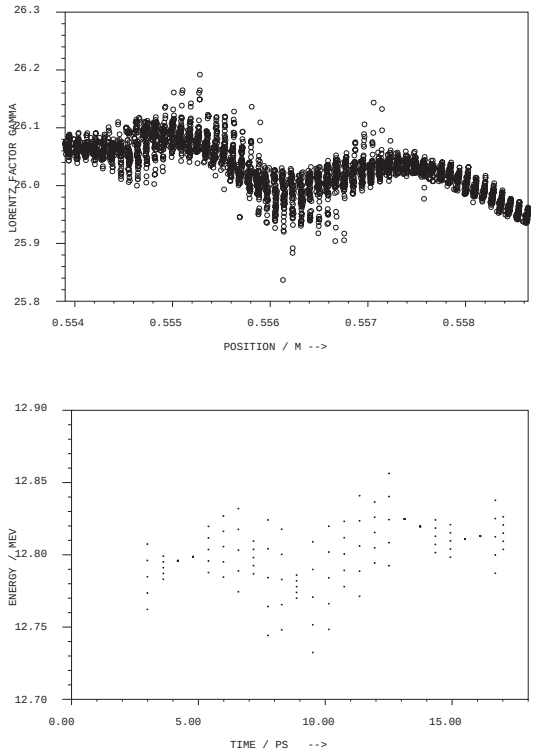

Figure 3: Energy distribution in the bunch at the end of the TS2 simulation (top) and at the start of L (bottom).

Figure 3 shows the energy distribution in the bunch as represented in TS2 and in L. In the TS2 graphic, the bunch moves from left to right, so the head of the bunch is on the right. In L, the energy is plotted as a function of time, therefore the head of the bunch is on the left. Slices in L

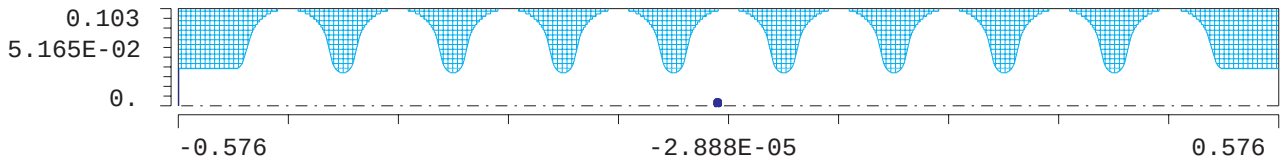

Figure 2: Capture Cavity as simulated in TS2. The structure is rotationally symmetric, the bottom line is the axis of rotation. The spot near the center shows the tiny dimensions of the electron bunch that moves along the axis from left to right.

carry different charges. The number of slices was chosen very high. Statistics is better for fewer slices at the cost of details in the distribution.

4 CONCLUSION

MAFIA provides tools to simulate the low energy part of a linear accelerator as well as a fast calculation of ultra relativistic particles with some approximations. Interfaces allow to use the result of one calculation as starting conditions for the next one.

5 ACKNOWLEDGEMENT

The authors wish to thank Stefan Setzer for his calculation of the capture cavity.

Abstract

We recently constructed, analytically and numerically, a new class of self-consistent 6-D phase space stationary distributions [1], which allowed us to study the halo development mechanism without being obscured by the effect of beam redistribution. In this paper we consider non-stationary distributions and study how the halo characteristics compare with those obtained using the stationary distribution. In contrast to bunches with a large aspect ratio we find that the effect of coupling between the r and z planes is especially important as the bunch shape becomes more spherical.

1 INTRODUCTION

A realistic treatment of halo formation must take into account 3-D beam bunches and 6-D phase space distributions. Barnard and Lund [2] performed numerical studies with a 3-D beam bunch using the particle-core model, drawing attention to the existence and importance of a longitudinal halo for a spheroidal bunch. However, all studies based on the particle-core model do not address the question of whether halo formation is influenced by the density redistribution which follows for a non-stationary beam, even if it is rms matched (See for example [3]). In fact, halo formation in 2-D due to the redistribution process in rms matched beams was shown, for example, by Okamoto [4] and Jameson [5]. We therefore continued our effort to study the halo development mechanism in 3-D beam bunches in the absence of the redistribution process [1]. Such an approach allowed us to study the fundamental mechanism of halo formation associated with the beam mismatch. To accomplish this we constructed a new class of stationary 6-D phase space distributions for a spheroidal beam bunch [1]. We then explored the formation of longitudinal and transverse halos in 3-D bunches in great detail [1].

Now that we have established the parameters which lead to halo formation in 3-D beam bunches for the 6-D self-consistent phase space distribution, we explore distributions which are not self-consistent, to determine the extent to which the relatively rapid redistribution in the 6-D phase space contributes to the formation of halos. This is the focus of the present paper.

2 NUMERICAL SIMULATIONS

In this paper we compare particle simulations performed for the 6-D stationary distribution given in [1] with the non-stationary 6-D Gaussian distribution, and the non-stationary 6-D uniform distribution. We also consider an axisymmetric beam bunch by putting $a = b$ with a, c being the minor and major semiaxes of our spheroidal bunch, respectively. Both the Gaussian and uniform distributions are constructed in the rms matched sense.

2.1 Stability of the Matched Distribution

Both numerical studies of the unstable modes and multi-particle simulations for the 2-D breathing KV beam with zero mismatch confirmed that the beam is unstable for tune depressions below $\eta = 0.4$ [6]. However, no halo was observed in the corresponding 2-D simulations. Similar studies for other 2-D rms matched distributions which are not stationary solutions of the Vlasov equation showed the existence of a halo for severe tune depression and zero mismatch [4]. The existence of a halo for such rms matched distributions was attributed to the unavoidable plasma oscillations generated by the initial density-redistribution process which is clearly shown in [4].

In our recent 3-D simulations [1] with the stationary distribution no such redistribution occurred. However, for the Gaussian distribution one can see the strong redistribution process which occurs very quickly in both the transverse and longitudinal planes. In contrast to the 2-D simulations [4] this redistribution process happens for both modest and severe space charge. In Fig. 1 we plot the maximum x and z among the million particles in our run for severe ($\eta_z = 0.27, \eta_x = 0.38$) and modest ($\eta_z = 0.65, \eta_x = 0.75$) tune depressions, respectively. Figure 2 shows the phase space $z - p_z$ diagram for $\eta_z = 0.27, \eta_x = 0.38$ without and with a low-density cut [1] which enables us to observe the halo structure clearly. Similarly, one can see the redistribution process for the uniform distribution. One again finds halo formation for both modest and severe space charge [7]. Thus, we have found that an rms matched 3-D beam can produce transverse and/or longitudinal halos (of relatively small extent) for a wide range of space charge intensity even when it is initially perfectly matched. Of course, from a practical point of view such halos are not important because the halo extent is very small for the mismatch factor $\mu = 1.0$. The important consequence is that the redis-

tribution process by itself (zero initial rms mismatch) does not lead to significant emittance growth.

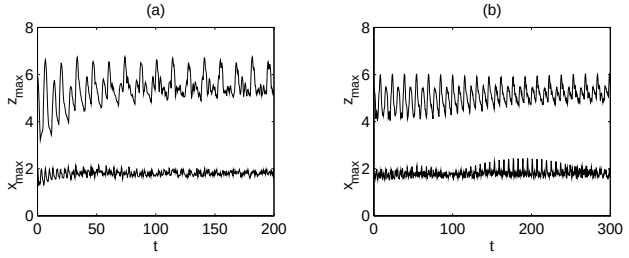

Figure 1: Maximum x and z as a function of time for initially matched beam $\mu_x = \mu_y = \mu_z = 1.0$ with 6-D Gaussian distribution ($c/a = 3$) a) $\eta_x = 0.38$, $\eta_z = 0.27$ b) $\eta_x = 0.75$, $\eta_z = 0.65$.

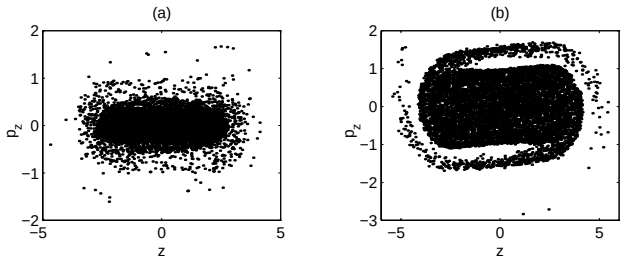

Figure 2: Longitudinal phase space diagram at $t = 50$ of initially matched beam $\mu_x = \mu_y = \mu_z = 1.0$ with 6-D Gaussian distribution ($c/a = 3$, $\eta_x = 0.38$, $\eta_z = 0.27$) a) without low-density cut (with 32,768 particles plotted) b) with low-density cut (with 20,000 particles plotted).

2.2 Initially Mismatched Beam

Numerical 3-D simulations with the initially mismatched non-stationary distributions described above confirm all the characteristics of halos observed for the stationary distribution [1]. The main difference is that for a non-stationary distribution the halo extent is larger (especially for the Gaussian) than the halo extent of the stationary distribution with the same initial mismatch parameters. As an example, in Fig. 3 we show the maximum x, z, emittance growth, $z - p_z$ diagram without the low-density cut and $r - p_r$ diagram (with angular momentum $|L_z| < 0.1$ to make the "peanut" diagram relatively clear) with initial $\mu_x = \mu_y = \mu_z = 1.5$ for the uniform distributions. The 6-D stationary distribution constructed in [1] gives a picture of halo development almost identical to the uniform non-stationary distribution except for a slight difference in the halo extent.

A systematic study for bunches of different shape (c/a) and mismatch factor μ (with simultaneous mismatch in all planes) was presented recently [1]. Below we present some examples of the mismatch in the transverse plane only. To compare our results with those available for a transverse

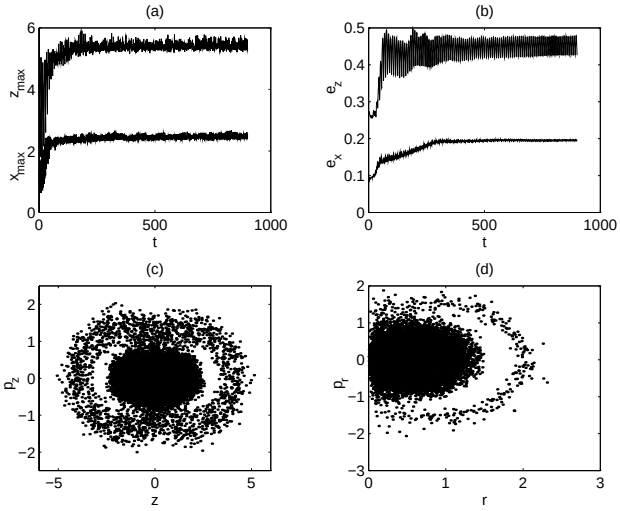

Figure 3: 6-D uniform distribution $\mu_x = \mu_y = \mu_z = 1.5$ ($c/a = 3$, $\eta_x = 0.53$, $\eta_z = 0.39$) a) maximum x and z b) emittance growth c) $z - p_z$ diagram at $t = 900$ (with 32,768 particles plotted) d) $r - p_r$ diagram at $t = 900$ for particles with the angular momentum $|L_z| < 0.1$ (with 25,000 particles plotted).

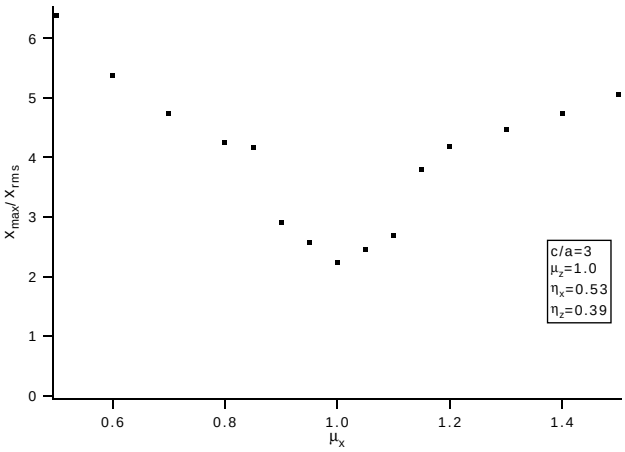

Figure 4: Extent of the transverse halo for the 6-D stationary distribution with zero longitudinal mismatch $\mu_z = 1.0$ ($c/a = 3$, $\eta_x = 0.53$, $\eta_z = 0.39$).

halo [8] we show in Fig. 4 the dependence of the transverse halo extent on the mismatch for fixed space charge, with tune depressions $\eta_z = 0.39$, $\eta_x = 0.53$. The main difference is the behavior near $\mu = 1.0$ which clearly shows the existence of threshold for halo formation in beams with stationary distributions. Similar behavior exists for the longitudinal halo [7] (the extent of the longitudinal halo is smaller than that of the transverse halo).

However, the existence of a threshold for halo formation observed in 2-D simulations and then confirmed by our 3-D particle simulations turns out to be a feature only observed for self-consistent stationary distributions. For example, Fig. 5 for the 6-D uniform non-stationary distribution has

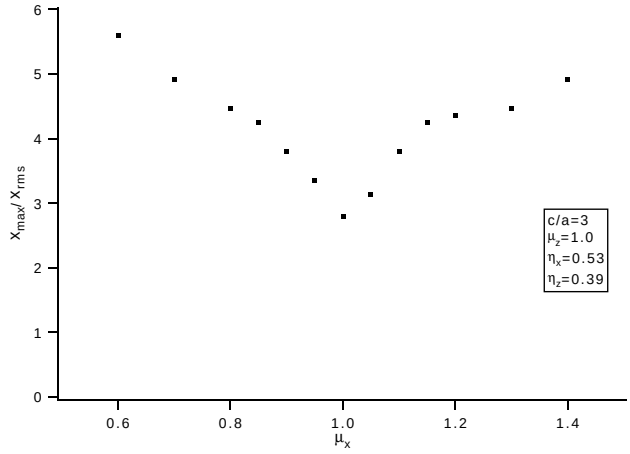

Figure 5: Extent of the transverse halo for the 6-D uniform distribution with zero longitudinal mismatch $\mu_z = 1.0$ ($c/a = 3$, $\eta_x = 0.53$, $\eta_z = 0.39$).

no obvious threshold behavior. In fact, we showed above that, in a non-stationary beam, a halo can form even for a zero initial mismatch. Therefore, in a "real" beam which goes through a redistribution and relaxation process one should not expect a threshold for halo formation due to a mismatch.

2.3 Coupling Effects

In performing 3-D simulations we encounter halo formation in a beam bunch, where we clearly see coupling between the longitudinal and transverse motion. It was already noted [1] that due to the coupling between r and z, a transverse or longitudinal halo is observed even for a very small mismatch (less than 10%) as long as there is a significant mismatch in the other plane. Further numerical investigation of this question showed that the effect of coupling becomes extremely important for nearly spherical bunches ($c/a \leq 2$) which is typical of the parameter range of interest for the APT design [9]. For example, for the short bunch with $c/a = 2$, with only a longitudinal initial mismatch ($\mu_z = 1.5$, $\mu_x = \mu_y = 1.0$), one finds particles at large amplitude in both the longitudinal and transverse directions, as can be seen in Fig. 6 for the 6-D stationary distribution. Of course, the intensity of particles in the transverse halo is much smaller than it is when there is in addition a transverse initial mismatch. (In our example in Fig. 6, we have 0.05 percent of the particles in the transverse halo with zero transverse mismatch compared with several percent in the longitudinal halo.) A similar effect due to coupling was seen for the non-stationary distributions.

3 SUMMARY

Recently we constructed, analytically and numerically, a new class of 6-D phase space stationary distributions for an azimuthally symmetric beam bunch which allowed us

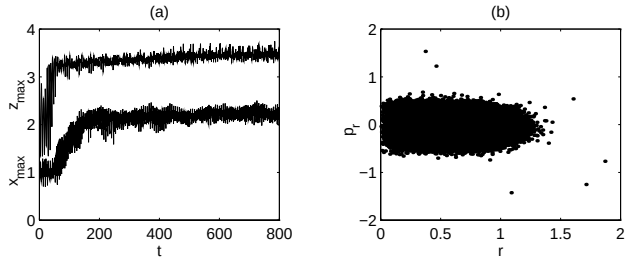

Figure 6: Coupling effect for the 6-D stationary distribution with zero transverse mismatch $\mu_x = \mu_y = 1.0$, $\mu_z = 1.5$ ($c/a = 2$, $\eta_x = 0.55$, $\eta_z = 0.45$) a) maximum x and z b) $r - p_r$ diagram at $t = 800$ for particles with the angular momentum $|L_z| < 0.1$ (with 25,000 particles plotted).

to study the halo development mechanism in 3-D beam bunches where no phase space redistribution occurs. After we established the parameters which lead to halo formation in 3-D beam bunches for the self-consistent 6-D phase space stationary distribution [1], in this paper we explored rms matched distributions which are *not* self-consistent, to determine the extent to which the relatively rapid redistribution of the 6-D phase space contributes to the formation of halos. We also found that the effect of coupling between the r and z planes is very important in the halo development mechanism and can lead to serious consequencies, especially for a very short beam bunch.

4 ACKNOWLEDGMENT

We thank Tom Wangler for helpful conversations. In addition RLG and AVF wish to thank Andy Jason and the LANSCE1 group for its hospitality during part of these studies.

W. M. Fawley
Lawrence Berkeley National Laboratory, Berkeley, California 94720 USA

Abstract

The accelerator for the second-axis of the Dual Axis Radiographic Hydrodynamic Test (DARHT) facility will accelerate a 4-kA, 3-MeV, 2-μs long electron current pulse to 20 MeV. The energy variation of the beam within the flat-top portion of the current pulse is ± 0.5%. The performance of the DARHT Phase II radiographic machine requires the transverse beam motion to be much less than the beam spot size which is about 1.5 mm diameter on the x-ray converter. In general, the leading causes of the transverse beam motion in an accelerator are the beam breakup instability (BBU) and the corkscrew motion. We have modeled the transverse beam motion in the DARHT Phase II accelerator with various magnetic tunes and accelerator cell configurations by using the BREAKUP code. The predicted sensitivity of corkscrew motion and BBU growth to different tuning algorithms will be presented.

1 INTRODUCTION

Transport simulations of the beam from the exit of the injector to the accelerator exit have been performed for the second axis of the Dual Axis Radiographic Hydrodynamic Test (DARHT) facility [1]. The motivation for performing these simulations was to establish engineering tolerances and design criteria to ensure that the DARHT-II facility meets performance goals. These goals are to produce four 60-ns long pulses, each with a time-integrated x-ray dose of 1000 R at one meter, with a 1 - 2 mm time-integrated x-ray spot. Transverse motion of the beam is a principle limitation in achieving the desired accelerator performance. Leading causes of the transverse beam motion typically are the beam breakup instability driven by injector noise and misalignments, and the corkscrew motion [2] caused by misalignments and chromatic aberration of optical elements. In this paper, we show that both corkscrew motion and misalignment driven beam breakup instability can be controlled effectively by using the corkscrew tuning V algorithm [3].We have also examined growth of beam breakup instabilities in these cells for various accelerator configurations.

*The work was performed under the auspices of the U.S. Department of Energy by LLNL under contract W-7405-ENG-48 , and by LBNL under contract AC03-76SF00098.

2 CONFIGURATION AND DESIGN PARAMETERS FOR DARHT II

The accelerator is arranged in eleven 8-cell blocks with pumping ports located between cell blocks. About one hundred solenoids are used to transport the beam. Three different cell configurations were used in the transport simulations. Two configurations are for a beam line aperture of 25.4 cm and differ only in the insulator/gap design of the cells. The final configuration has a larger, 35.6 cm, aperture for the first 8-cell block followed by ten 8-cell blocks with a 25.4 cm aperture.

To achieve the performance criteria of x-ray dose and spot size, the normalized Lapostolle emittance (95% of beam current) at the x-ray converter has to be no greater than 1500 π-mm-mr, and the transverse beam motion should be no greater than 10% of beam radius. The designed beam parameters are:
1) current of 4 kA in a 2 μs pulse with 200 ns rise time,
2) energy at the injector exit of 3 MeV ± 0.5% increasing to 20 MeV ± 0.5% at the accelerator exit, and
3) emittance (4 x Lapostolle emittance) at the injector exit of 500 π-mm-mr increasing to less than 1000 π-mm-mr at the accelerator exit.

3 BBU INSTABILITY AND TRANSVERSE IMPEDANCE

The beam breakup instability arises from the beam interacting with the accelerating cells' dipole TM modes. The transverse impedance is a measurement of the strength of the interaction. As the beam axis is offset from the cavity axis, these modes extract energy from the leading part of the beam and deflect the trailing part of the beam transversely. This instability typically sets the upper limit for a transportable beam current and the lower limit for the focusing field.

3 .1 Equations Governing BBU

The BBU instability is a convective instability. For the misalignment driven beam breakup instability, the maximum number of e-fold in the beam breakup instability growth is given by

$$\alpha = \frac{c}{l}\frac{I}{I_o} Z_\perp \int_0^L \frac{dz'}{\gamma k_c(z')} \ , \qquad (1)$$

and the peak growth will occur in the pulse after a time

$$\tau = 2\alpha Q/\omega_o \quad , \qquad (2)$$

where I is the beam current, I_o = 17 kA, $Z_\perp$ is the transverse cell impedance for the BBU mode frequency ω_o. The gap separation is l, and the accelerator length is L. For an electron beam pulse with a long rise time, the beam breakup instability driven by misalignment starts to grow at the head of the pulse and may not propagate into the flat-top portion of the pulse before the beam leaves the accelerator. Therefore, the beam breakup instability driven by misalignment is generally not a threat to a DARHT-II pulse with long rise time. In contrast, the beam breakup instability driven by injector noise would appear throughout the pulse length. BBU growing from injector noise a significant concern for the DARHT-II beam transverse motion.

3 .2 Transverse Impedance

Three DARHT-II accelerator cell configurations have been designed [4]. The configurations differ primarily in the geometry of the insulator and aperture size. However, only the impedance and frequency of the primary resonant modes are required for the purpose of the simulations. Table 1 lists the pertinent cell characteristics for BBU calculations. Note that $Z = c\, Z_\perp/\omega_o$. "Initial" and "current" refer to the insulator/gap designs under consideration.

Table 1: Impedances of different cell configurations

Design	Freq. (MHz)	Z/Q (Ω)	Q
Initial (25.4 cm ID)	262	34.9	2.0
	580	1.1	7.2
	672	3.9	6.9
Current (25.4 cm ID)	200	37.6	1.9
	535	7.3	3.8
Current (35.6 cm ID)	171	25.4	2.0
	443	4.3	4.2

4 CORKSCREW MECHANISM AND TUNING STRATEGY

Corkscrew motion is a differential oscillation of the beam centroid between the leading and trailing portions of a beam pulse driven by chromatic aberration of the focusing elements and misalignment of the machine. The DARHT-II accelerator's alignment requirement is to meet the alignment specification of the first axis of DARHT accelerator's: random 3-σ magnetic tilt to be 1.95 mrad and random 3-σ magnet offset to be 0.45 mm. There are about one hundred of solenoids with steering/correction coils along the DARHT-II accelerator.

The magnetic tune was chosen to focus the electron beam from an 8 cm radius at the exit of the injector to a 6 mm radius as rapidly as possible without adversely affecting the current distribution. The 6 mm radius is then maintained through the remember of the accelerator. The rapid increase in magnetic field slows the BBU growth as seen in equation (1).

The DARHT-I alignment specifications is expected to produce a corkscrew amplitude of several millimeters by the end of the accelerator without corrective measures. The "tuning-V" steering algorithm has demonstrated an order of magnitude reduction in corkscrew on the ETA-II accelerator. In the simulations described below, only one steering coil per 8-cell block was used to implement the steering algorithm.

5 SIMULATION RESULTS

The BREAKUP code was used to model the beam centroid's transverse motion in the DARHT-II accelerator. Both motion due to the BBU instability and corkscrew motion was included. Three different configurations were simulated. The gain factor, a figure of merit for BBU growth, is defined as BBU amplitude divided by the injector noise amplitude. The goal is to have a gain factor ≤ 20, or 3 e-folds based on an injector noise amplitude of 100 microns. The goal for the amplitude of the transverse motion, including corkscrew and BBU, is 0.6 mm.

Examples of the simulation results for misalignment errors are shown in Figures 1 and 2. The beam pulse was simulated for 350 ns including a 200 ns rise time. An energy variation of ±5% was imposed on the 150 ns of flat-top to model the effect of corkscrew on the longer 2-μs pulse. Two observations can be made from the results. First is that the BBU motion, the fast oscillation at the start of the pulse, extends only a short distance into the pulse and is insignificant compared to the corkscrew amplitude. Second, the V-tuning steering correction reduced the corkscrew amplitude by over an order of magnitude. The effects of injector noise and misalignment are shown in Fig. 3. The BBU motion extends throughout the pulse as expected while the corkscrew amplitude is relatively unchanged from the no noise case.

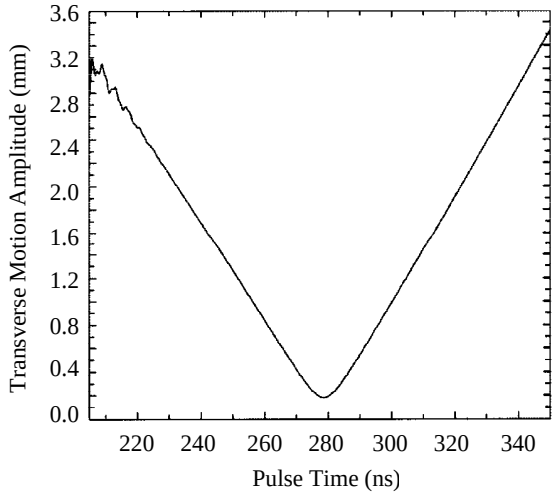

Figure 1. Simulated transverse beam centroid motion driven by misalignments with no steering correction.

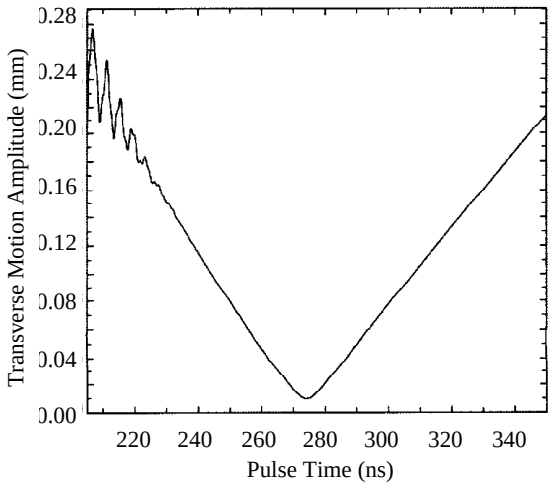

Figure 2. Simulated transverse beam centroid motion driven by misalignments with steering corrections. Note the change in vertical scaling from Fig. 1.

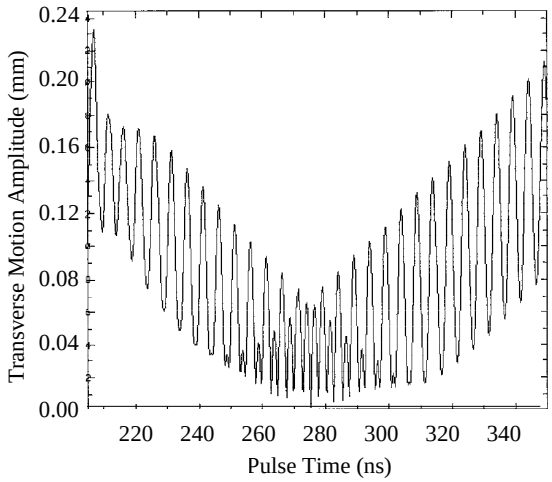

Figure 3. Simulated transverse beam centroid motion driven by misalignments and injector noise. V-tuning steering corrections used.

Results of the different configurations are summarized below. For all cases, the simulations included both misalignment and injector noise. The gain factor at the end of the first 8-cell block is listed in the results to emphasize the effect of the low focusing fields at the start of the accelerator. The first configuration modeled consisted of eleven 8-cell blocks with an aperture of 25.4 cm and used the "initial" cell impedance parameters. Results are shown in Table 2.

Table 2. BBU growth for "initial" accelerator cell design

Mode Frequency (MHz)	Gain Factor at exit of 1st block	Gain Factor at accelerator exit
262	2.9	132.7
672	2.1	115

Corkscrew amplitude at accelerator exit is 0.24 mm.

The second configuration modeled consisted of eleven 8-cell blocks with an aperture of 25.4 cm and used the "current" cell impedance parameters. Results are shown in Table 3.

Table 3. BBU growth for "current" accelerator cell design

Mode Frequency (MHz)	Gain Factor at exit of 1st block	Gain Factor at accelerator exit
200	3.1	34.3
535	3.1	34.3

Corkscrew amplitude at accelerator exit is 0.24 mm.

The third configuration modeled consisted of a 35.6 cm aperture 8-cell block followed by ten 8-cell blocks with apertures of 25.4. All cells used the "current" cell impedance parameters. Results are shown in Table 4.

Table 4. BBU with larger aperture first 8-cell block

Mode Frequency (MHz)	Gain Factor at exit of 1st block	Gain Factor at accelerator exit
170	1.9	12.2
200	1.5	10.7

Corkscrew amplitude at accelerator exit is 0.16 mm.

6 SUMMARY

Corkscrew motion can be kept well within design goals for the expected accelerator misalignments by applying the V-tuning algorithm. The BBU instability growth required the lower impedance characteristics associated with the larger aperture cells to stay below the desired gain factor. A possible factor not considered in the BBU growth is loss of the low energy head of the beam. This would lead to a faster rise time as the pulse travels down the accelerator. The gain factor will remain the same, so the issue is the magnitude of the shock excitation due to the short rise time and misalignments. If this excitation is no more than the injector noise, the BBU growth should remain within design goals.

EM-PIC SIMULATIONS OF e-BEAM INTERACTION WITH FIELD EMITTED IONS FROM BREMSSTRAHLUNG TARGETS*

P. W. Rambo and S. Brandon
Lawrence Livermore National Laboratory, Livermore CA 94550

Abstract

We investigate electron beam defocusing caused by field emitted ions from the bremsstrahlung target of a radiography machine using fully electromagnetic particle-in-cell simulations. This possibly deleterious effect is relevant to both current radiography machines (FXR) and machines being built (DARHT-2) or planned (AHF). A simple theory of the acceleration of ions desorbed from the heated target, and subsequent beam defocusing due to partial charge neutralization is in reasonable agreement with the more detailed simulations. For parameters corresponding to FXR (I_b=2.3 kA, ε_b=16 MeV), simulations assuming space-charge-limited emission of protons predict prompt beam defocusing. Time integrated spot-size measurement, however, is dominated by early-time small spot brightness, and so is not a sensitive diagnostic. Comparisons are made to available FXR data. We also investigate use of a recessed target geometry to mitigate field emitted ion acceleration; only modest improvements are predicted.

1 INTRODUCTION

Current radiography machines such as FXR, as well as future machines such as DARHT-2 and the proposed Advanced Hydrodynamic Facility (AHF), make use of an intense electron beam striking a high-Z target to generate high-energy bremsstrahlung radiation. It is necessary that the electron beam be focused to a small spot for good radiographic definition. In FXR and DARHT-2, and the proposed AHF machine, the beam is created in a linear induction accelerator (LIA), and is focused in a low applied-field drift region. Dale Welch [1] at MRC first identified a potential problem due to ion field emission for DARHT–2, arguing that target heating from the beam would quickly provide a source of ions which can be accelerated by the beam space-charge, and back stream toward the beam source. The excess charge neutralization then causes the beam to pinch, and subsequently defocus.We describe results from electromagnetic PIC simulations for FXR parameters, which predict prompt defocusing for space-charge-limited proton emission. Comparison to available experimental data suggests that the emission onset is substantially delayed in time or reduced from the space-charge-limit, if not absent entirely.

2 SPACE CHARGE LIMITED EMISSION AND BEAM DEFOCUSING

Welch has argued that once the target surface is heated beyond 400 °C, impurities are readily desorbed and ionized. These impurities, including both protons and carbon ions, are then free to be accelerated by the beam space charge potential. Nominally, FXR operates at a total current of I_b≈2.3 kA focused to a spot size of r_b≈0.1 cm; thus the current density is approximately J_b≈70 kA/cm^2 and particle flux J_b/e=5×10^{23} /cm^2·s. At the beam energy ε_b =16 MeV, ionization energy loss in Ta is $d\varepsilon/dx$≈20 MeV/cm at solid density, and the average energy increase per atom is approximately 0.2 eV/ns. Thus the target is very quickly heated, and any surface contaminants are expected to be available for ionization and subsequent acceleration.

A simple theory serves to estimate the properties of these emitted ions and their interaction with the electron beam; units are Gaussian, except where results in more convenient units are specifically indicated. Approximate the beam as a cylinder of radius r_b with uniform density n_b, both corresponding to the target focus. The beam is traveling at nearly the speed of light, c, with relativistic factor γ_b. The potential difference between the center of the beam and its edge, as well as the (radial) electric field are easily calculated; the axial field at the target will be approximately the same,

$$\Phi_b \approx \pi e n_b r_b^2 \approx I_b / c\,; \quad E_z \approx E_r = 2\Phi_b / r_b\,. \qquad (1)$$

For FXR parameters, this predicts an electric field at the target surface of order E_z≈1.4 MeV/cm. The current of emitted ions (mass $M_i=A_i m_p$ and charge $q_i=Z_i e$, with m_p the proton mass) may be estimated using the well known result for Child-Langmuir space-charge-limited current. Using the beam potential just estimated and a distance equal to the beam radius,

$$J_i \approx \frac{\left(2q_i / M_i\right)^{1/2} \Phi_b^{3/2}}{9\pi r_b^2}\,; \quad I_i \equiv \pi r_b^2 J_i\,, \qquad (2)$$

which predicts an emitted ion current I_i/I_b ≈0.2% for FXR. The ions are quickly accelerated to an energy of the order of the beam potential, and hence velocity $v_i=(2q_i\Phi_b/M_i)^{1/2}$. The ion density is then estimated from $n_i=J_i/v_i q_i$, showing the surprising result that the charge neutralization fraction f is a constant: f≈1/9. The contribution to the radial field from this ion charge is equal to the field generated by the beam decreased by the factor f, $E_+=fE_r$. In a time τ, the ions will move a length $L\approx\tau v_i$ and beam electrons will be radially accelerated as they traverse this distance to the target, t≈L/c. Equating the radial deflection to the beam radius gives an estimate for the time τ required to defocus the beam,

$$\delta r \approx \frac{1}{2}\frac{eE_+}{\gamma_b m_e}t^2 \approx \frac{1}{2}\frac{e}{\gamma_b m_e}\left(f\frac{2\Phi_b}{r_b}\right)\left(\frac{\tau v_i}{c}\right)^2 \equiv r_b\,, \qquad (3)$$

$$\tau \approx 5ns\frac{r_b(mm)}{I_b(kA)}\sqrt{\frac{\gamma_b A_i}{Z_i}}\,.$$

* This work was performed under the auspices of the U. S. Department of Energy by Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48

For FXR parameters, this theory predicts a time to defocus of $\tau \approx 10$ ns for proton emission, well within the pulse time of 60 ns. Of course this theory is quite simplified; we next turn to self consistent simulations.

3 EM-PIC SIMULATIONS

Direct particle-in-cell (PIC) simulation of intense beams has a long and successful history, both at LLNL and elsewhere. We have simulated ion emission and subsequent beam defocusing with both CONDOR, a well-tested design code developed over many years within A-division, and a new code, CODA, that allows non-rectangular zones. Both codes are fully relativistic, 2-1/2 dimensional (2-spatial dimensions in axisymmetric *Z-R* geometry, 3-velocity dimensions) electromagnetic (EM) PIC codes. The simulation geometry is a cylinder of radius 4 cm and length 25 cm with conducting boundaries. The beam is injected at the left hand boundary with an initial radius of 2.0 cm, and with uniform current density. The beam is injected with finite emittance so as to be focused at the target; no externally applied fields are present. The injected beam current is linearly ramped up in 10 ns, constant for 40 ns, then linearly ramped down again in 10 ns. The right hand end-plate forms the absorbing target, from which ions are emitted. No modeling of the target heating or surface physics is included; the space-charge-limited emission is simply turned on at a preselected time, over a specified radial region. Simulations presented here were all performed with CODA utilizing a converging mesh that allows much better resolution at the target surface, $\Delta r = 200$ μm and $\Delta z = 600$ μm.

The time history of the RMS beam radius at the target is shown in Fig. 1 from a typical simulation. The injected beam is characteristic of FXR, with $I_b = 2.3$ kA, $\varepsilon_b = 16$ MeV ($\gamma_b \approx 32$) and initially focused to a root-mean squared (RMS) radius $r_b = 0.06$ cm. Proton emission is turned on at t=15 ns, in the region $0 < r < 0.06$ cm. The initial pinch and subsequent defocus occur very quickly in

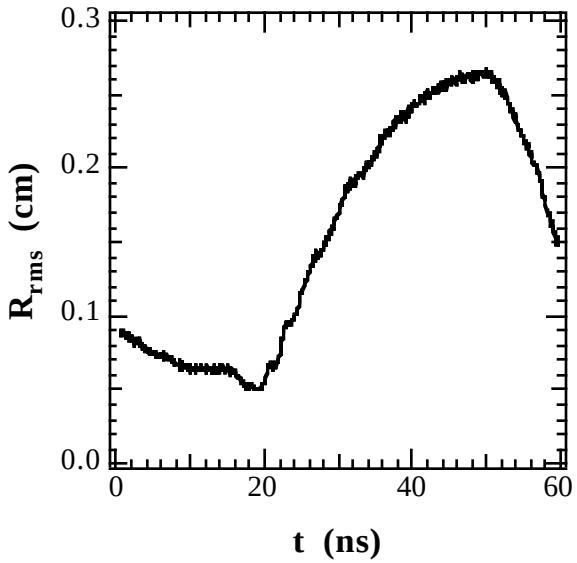

Fig. 1 Time dependent beam radius at target from a simulation of FXR with proton emission turned on at t=15ns.

agreement with our previous estimate. As the beam defocuses, emission decreases (from a peak of $I_i \approx 8$ A) because of the reduced electric field at the emission area. Many aspects of the simple theory previously developed are observed in these simulations, namely the magnitude of the axial electric field at the target surface, the time for pinching to occur, and the small ratio of emitted ion current to beam current (<1%). The scaling of the time to defocus, Eq. (3), with ion mass and beam current has also been confirmed by additional simulations. An important observation is that the total number of field emitted ions, N_i, is quite small: for this simulation $N_i = 5.7 \times 10^{11}$ at t=30 ns. This corresponds to a fraction of approximately 10^{-4} from a monolayer of equal area, suggesting that surface cleaning would be a very difficult proposition.

4 COMPARISON WITH FXR DATA

We now consider available data from FXR. Two principle measurements are used to assess spot quality at FXR; both are time-integrated radiographic measurements. The first uses an opaque "roll bar" to cast a shadow from the bremsstrahlung spot; the width of the edge of this shadow reflects the finite spot size. Careful unfolding of the data shows a central peak with FWHM spot size of 1.1mm, surrounded by a low density "halo" with relative brightness of a few percent of the central peak [2]. In the second measurement, forward bremsstrahlung dose is measured both with and without an 800 μm diameter collimator. The collimated dose is observed to be approximately 1/3 of the forward dose in the absence of the collimator; this is observed to be the case both for beam currents of 2.3 kA and 3.3 kA [3].

Although the experimentally observed small spot seems at odds with the defocusing seen in the simulations, e.g. Fig. 1, this is not necessarily so. Because the beam density at the target is inversely proportional to the square of the spot size, $n_b \propto I/r^2$, the bremsstrahlung emission from the defocused beam is very dim and a time integrated measurement can be dominated by the early-time small spot brightness. In Figure 2, we show the time integrated beam density at the target (normalized) as a function of radius from the simulation illustrated in Fig. 1. As can be seen, the contribution from the defocused beam is a low density halo. The level of the halo relative to the central peak is determined by the relative duration of the focused and unfocused periods of the time history. This is illustrated in Fig. 2, which also shows results from simulations with the ion emission turned on at 10 and 30 ns. The level of the halo is also affected by the defocused radius; allowing ion emission from a larger area increases the defocused beam spot, decreasing the relative beam density in the halo.

We next consider the collimated dose measurements. The angular spectrum of bremsstrahlung photons created by 16 MeV electrons striking a 1mm thick Ta target was calculated using a Monte Carlo code [4]; this angular spectrum is then used to determine the contribution to the forward dose from each simulation electron as it strikes the target. Figure 3 shows the time dependent forward

dose (normalized) for the simulation shown in Fig. 1. Because the electrons strike the target with larger angles

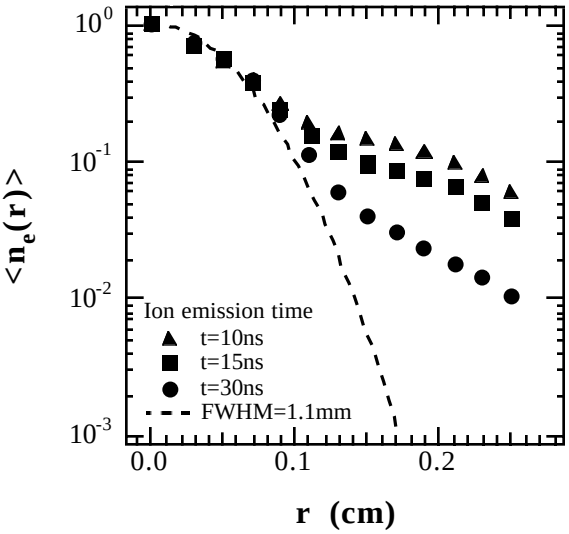

Fig. 2 Time averaged beam density at target from FXR simulations including proton emission; three different emission onset times are shown.

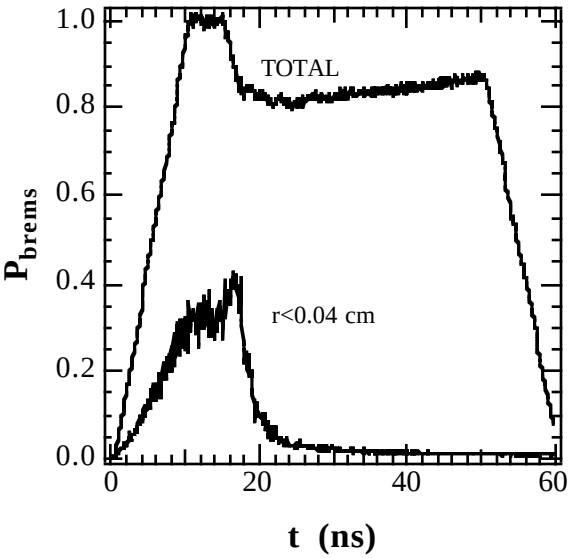

Fig. 3 Time dependent forward dose from FXR simulation including proton emission for t>15 ns.

after pinching, the total forward dose decreases approximately 20%. More importantly, however, the forward dose from electrons striking the target with r<400 μm is abruptly cut-off as the spot size increases. For this case the time integrated forward dose from electrons entering the target with r<400 μm is 0.14 of the total calculated forward dose. Again, this fraction varies with the onset time for ion emission; for onset times of 10 ns and 30 ns (see Fig. 2) the forward dose fractions are 0.10 and 0.23 respectively. With the beam current increased to I_b=3.3 kA, similar results are obtained except that the forward dose fraction is further decreased: for proton emission onset times of 15 ns and 30 ns the forward dose fractions are 0.11 and 0.20 respectively. The forward dose fraction for these simulations in the absence of ion emission is 0.30. Decreasing the focused beam radius to r_{RMS}= 0.05 cm (by decreasing the injection emittance) increases the unperturbed fractional transmission to 0.40; for this focus and I_b=3.3 kA, proton emission turned on at t=30 ns decreases the time integrated fractional forward dose to 0.26. Further decrease of the focused beam radius would be in disagreement with the spot size measurements.

Simulations were also performed with singly ionized carbon emission for comparison. Turning on C^+ emission at t=15ns for the I_b=3.3 kA case gives a forward dose fraction of 0.20 due to the slower defocusing, still significantly less than observed; delaying the C^+ emission until t=30 ns results in a forward dose fraction of 0.28.

5 DISCUSSION

We have seen from simulations with parameters relevant to FXR, that beam defocusing occurs quickly after the onset of proton emission. Time integrated spot size measurements are not a sensitive measure of defocusing, however, because the defocused beam only contributes a dim halo compared to the central peak from the small spot emission. But the level of the halo, observed to be a few percent relative to the central peak in FXR measurements, does rule out prompt proton emission, t<15 ns. The collimated dose is a more stringent test. Proton emission beginning at time earlier than t≈30 ns is inconsistent with the observation that one third of the forward dose is transmitted through an 800 μm collimator. Bounds on the emission of singly ionized carbon are only slightly less restrictive.

The simplest explanation is that ion emission is not occurring on FXR, or at currents reduced far below the space charge limit (approximately a factor of 30 decrease is necessary). This does not preclude a disastrous effect on machines with higher current densities, however, since there may still be a threshold for ion formation. Because of this, methods to minimize this effect are being pursued. In particular, we have simulated the effect of recessing the target so as to reduce the emitted ion current. Although the time for defocusing is increased, and the defocused beam spot size decreased, this still does not appear to be satisfactory. Used in conjunction with other means for isolating the emitted ions, however, might be acceptable. We look forward to experimental results from ETA-II (to be reported at this conference), including time resolved measurements that may give a more definitive answer concerning these effects.

Abstract

Transverse wakefield effects due to structure misalignments can be an important source of emittance degradation in a linear collider. Though important, it is difficult to measure local wakefield effects and identify the sources. Recently, we have developed a novel method for analyzing the beam dynamics in an accelerator based on BPM readings, that is independent of any machine models. This method relies on, instead, statistically analyzing an ensemble of readings from a large number of BPMs and for a large number of pulses. In addition, pulse-by-pulse information of beam (and machine) parameters are used. By taking advantage of the spatial correlation and temporal structure of all these signals, such analysis allows observation of beam dynamics at a level well below the single BPM resolution as well as studies of subtle beam dynamics effects. Using this method, which is quick and non-invasive, we are able to measure the transverse wakefield effects due to structure misalignments in the SLC linac.

1 INTRODUCTION

A beam, when passing by a misaligned accelerator structure, will excite transverse wakefields that kick different parts of the beam by different amounts and therefore blow up the beam emmittance. Such a wakefield effect can be a major source of luminosity degradation in a linear collider. However, it is very difficult to measure transverse wakefield effects due to the weakness of the signals and the difficulty of separating such effects from other sources of perturbations. Using the current dependency of the wakefield, one can separate the wakefield effects from other effects. One idea is to measure beam orbits at different currents and then calculate the difference. Unfortunately, such measurements hardly succeed. One reason is the limited resolution in orbit measurements. More importantly, when beam current is changed, many other beam parameters (as well as the orbit) will be changed also. To avoid problems coming with current change, bunch length change has been used but with limited success. To illustrate this problem, Table 1 shows the correlations of current (bunch length) change with other beam parameters that we are able to monitor in the linac of Stanford Linear Collider (SLC). It was computed with 5000 electron pulses collected under normal running conditions. Clearly such correlations have to be taken into account in order to measure the wakefield effects correctly.

Table 1: Correlation coefficients of beam current and bunch length with other beam parameters

	current ΔI	bunch length σ_z
horizontal position x	-0.17	-0.52
horizontal angle x'	-0.03	-0.15
vertical position y	-0.08	0.01
vertical angle y'	0.10	0.20
long. beam phase	-0.48	-0.20
beam energy	-0.37	-0.18
bunch length	0.05	1
beam current	1	-0.05

Recently, a novel approach to analyze beam dynamics has been developed which we call "Model Independent Analysis (MIA)". It is a statistical analysis of BPM data and does not rely on any particular machine model. There are two major parts in MIA. One is noise reduction and degree-of-freedom analysis via singular value decomposition of a BPM-reading matrix. The other is a physical base decomposition of the BPM-reading matrix based on the time structure of beam (and machine) parameters. The combination of these two methods allows one to go below the resolution limit set by individual BPMs and to observe the beam dynamics at a much finer level. Physical base decomposition is particularly useful for understanding various beam dynamics issues, because it takes all known signal correlations into accounts. In the next section we describe MIA. Then, in the following section we apply MIA to obtain information about the structure misalignments in the SLC linac and their transverse wakefield effects.

2 MODEL INDEPENDENT ANALYSIS [1]

The transverse beam position of a pulse depends on various physical variables such as the initial conditions of the pulse, the settings of magnets, and the RF conditions. We can Taylor expand the beam position b over all variables as

$$b = b(\bar{x}_1, \bar{x}'_1, \bar{\delta}, \bar{\sigma}_z, \cdots) + \sum_{v \in \{x_1, x'_1, \cdots\}} \left.\frac{\partial b}{\partial v}\right|_{v=\bar{v}} \Delta v + \frac{1}{2} \sum_{v_1, v_2 \in \{x_1, x'_1, \cdots\}} \left.\frac{\partial^2 b}{\partial v_2 \partial v_1}\right|_{\substack{v_1=\bar{v}_1 \\ v_2=\bar{v}_2}} \Delta v_1 \Delta v_2 + \cdots \quad (1)$$

where x_1, x'_1, δ, σ_z are respectively initial beam position, angle, relative energy, and bunch length, given as examples of possible physical variables; the over bar indicates the expansion points; $\Delta v = v - \bar{v}$ and so on. The zero order term may have complicated dependency on the variables

and is sensitive to the unknown BPM offset errors. To get rid of it, we subtract the average over a large ensemble of pulses and study the difference

$$b - \langle b\rangle = \sum_v \left.\frac{\partial b}{\partial v}\right|_{v=\bar v} (\Delta v - \langle \Delta v\rangle) + \frac{1}{2}\sum_{v_1,v_2} \left.\frac{\partial^2 b}{\partial v_2 \partial v_1}\right|_{\substack{v_1=\bar v_1\\ v_2=\bar v_2}} (\Delta v_1 \Delta v_2 - \langle \Delta v_1 \Delta v_2\rangle) \quad (2)$$

where $\langle\ \rangle$ indicates the average over an ensemble of pulses. Although we have found that some second derivatives (which characterize, e.g. the chromatic dependency of the betatron motion) may be significant at times, the third and higher order terms are generally negligible and will be dropped. We treat the first and second order terms on the same footing and rewrite Eq.(2) in a concise form:

$$b - \langle b\rangle = \sum_{\{q\}} q\, f_q \quad (3)$$

where the variable $q = \frac{\Delta v - \langle \Delta v\rangle}{\mathrm{std}(\Delta v)}$ or $\frac{\Delta v_1 \Delta v_2 - \langle \Delta v_1 \Delta v_2\rangle}{\mathrm{std}(\Delta v_1 \Delta v_2)}$ and f_q is the corresponding derivative $\left.\frac{\partial b}{\partial v}\right|_{\bar v} \cdot \mathrm{std}(\Delta v)$ or $\frac{1}{2}\left.\frac{\partial^2 b}{\partial v_2 \partial v_1}\right|_{\bar v_1,\bar v_2} \cdot \mathrm{std}(\Delta v_1 \Delta v_2)$. The physical variables are normalized by their standard deviations over the ensemble of pulses, so that all the q's are dimensionless and reflect the relative changes, while all the f's have the same dimension as the BPM readings.

For an ensemble of P pulses monitored with M BPMs, according to Eq.(3), the BPM-reading matrix B, consisting of $b - \langle b\rangle$, can be factorized as

$$B = QF^T + N \quad (4)$$

where $Q_{P\times d} = [\vec q_1, \cdots, \vec q_d]$, $F_{M\times d} = [\vec f_1, \cdots, \vec f_d]$, and $N_{P\times M}$ contains the noise associated with each BPM reading. The column vector $\vec q_i$ contains the P values of the i-th physical variable and $\vec f_i$ contains the M components of the corresponding physical pattern. The q's are referred to as temporal patterns or time structures of the pulses, while the f's as spatial patterns or physical vectors. Note that the BPM-reading matrix B is the central object of MIA analysis. Eq.(4) is called the physical base decomposition.

We assume all the physical vectors are linearly independent, i.e. F has full column rank given by d. They form a complete basis for the row space of the BPM-reading matrix (i.e. range of B^T). Unlike P and M which can be chosen at will, dimension d is determined by the dynamics. One of the MIA achievements is to determine d. Generally, d is a small number and, we choose P and M so that $d \ll M \ll P$ to obtain statistical benefits. Typical numbers that we use are $d \sim 10$, $M \sim 10^2$, and $P \sim 10^3$. For convenience, we normalize B, Q, and N by $\sqrt{P}$, so that the important (variance-)covariance matrices of BPM readings and temporal patterns (q's) can be formed simply as $C_B = B^TB$ and $C_Q = Q^TQ$.

According to Eq.(3), a beam orbit is a linear combination of a limited number of "basic" orbits given by the f_qs. In other words, the BPM reading pattern generated by each pulse is a superposition of certain basic patterns. This fact allows us to apply linear algebra concepts and matrix analysis techniques to the BPM data analysis. The statistical meaning of C_B and C_Q provides the connection between matrix analysis and statistical analysis.

Though SVD analysis of the BPM-reading matrix B (statistically, it is the principle components analysis of BPM readings) is a major aspect of MIA, it will not be described here due to space limitation. However this analysis is not crucial in the discussion of the wakefield effect measurements. What we will use is physical base decomposition of B using various kinds of pulse-by-pulse beam and machine parameters as tags –signals form a subset of the matrix Q. Mathematically, we know Q (or a subset of it) and B of Eq.(4), and need to solve for F. If we know all the physical variables with sufficient accuracy, the corresponding physical basis can be computed as

$$F^T = (Q^TQ)^{-1}Q^TB = C_Q^{-1}Q^TB \quad (5)$$

and the errors due to noise are generally proportional to $\frac{1}{\sqrt{P}}$. The first expression reflects the least-squares fitting aspect of the solution, while the second expression emphasizes the importance of taking care of correlations among the observed variables.

The accuracy of Eq.(5) does not rely on the number of BPMs used. It simply fits each BPM reading to various temporal patterns individually and ignores any correlations among BPM readings. In fact, the BPM noise can be reduced statistically by taking into account the correlations among BPM readings. Therefore, if we cut the noise first and then apply Eq.(5), the noise level can potentially be reduced by a factor of $\frac{1}{\sqrt{M}}$, and we have

$$F^T = C_Q^{-1}Q^TU\,\underline{S}V^T + O(\frac{1}{\sqrt{P\,M}}) \quad (6)$$

where USV^T is the SVD of B, and $\underline{S}$ indicates the zeroing of small singular values that are due to noise. This statistical error limit may be hard to achieve however due to problems such as machine instability and incomplete information in Q.

Usually we know only a subset of Q, say Q_s of $Q = [Q_s, Q_r]$. We can still calculate F_s according to Eq.(5) with Q_s, The error due to the missing part is

$$(F_s - F_s^{exact})^T = (Q_s^TQ_s)^{-1}Q_s^TQ_rF_r^T \quad (7)$$

Therefore, if the known subset Q_s are uncorrelated with (orthogonal to) the remaining unknown temporal patterns, i.e. $Q_s^TQ_r = 0$, then we would obtain the same results as if we had measured all Q. Otherwise, the unknown part of the physical basis (i.e. F_r) will be mixed into the measured parts. This is the major limitation of this method.

3 TRANSVERSE WAKEFIELD EFFECT MEASUREMENT

Because of the detrimental effects of transverse wakefield due to structure misalignments, various methods [2, 3] have been used for the detection and correction of such wakefield effects. In the following, we present some preliminary results where MIA is used to measure the transverse wakefield effects. At the SLC, in addition to the beam transverse position, we can monitor beam current, bunch length, incoming beam (longitudinal) phase, and relative beam energy on a pulse-by-pulse basis. Other signals such as klystron phases along the linac have not been used in the present analysis. As is shown in Table 1, there are significant correlations among these signals, especially for the wakefield sensitive variables. MIA takes all known correlations into account, and therefore should provide a better measurement of the wakefield effects. To investigate this, we generated a 5 corrector, 1.2mm, local bump in the linac of SLC and measured its wakefield effect via MIA. We used readings from the beginning to about the 1/3 point of the linac (LI02–LI13), and collected 3 sets of 5000 pulses under the conditions: before the bump was applied (a), after it was applied (b), and after the bump was removed (c). Each set of data took a few minutes to collect.

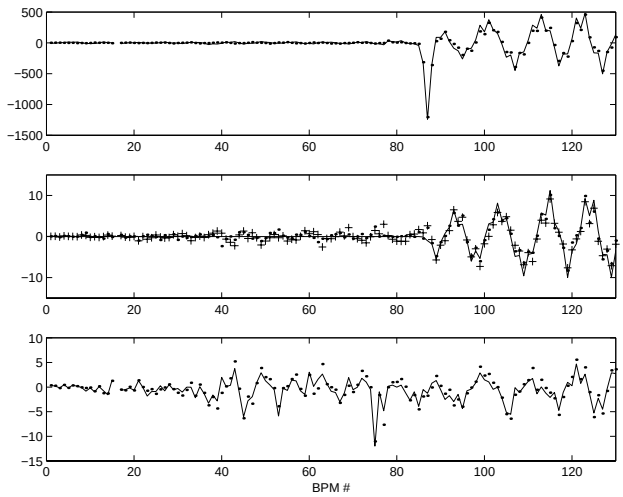

Figure 1: wakefield effect measurements in vertical plane

We applied MIA on all sets of data and then compared the vectors corresponding to the current jitter, and the results in y are shown in Figure 1 (all ordinate units are in μm). The top frame shows the differences of the averaged beam orbits. The solid line shows the difference between conditions b and a, while the dots are between conditions b and c. The corrector bump is clearly visible (it is not closed). The middle frame shows the difference of current vectors–the vectors correponding to current jitter. The dots are the differences between b and a, while the crosses are between b and c. The solid curve shows the calculated wakefield effect due to the bump. We see that the agreements are fairly good, especially when considering the fact that the BPM resolution is about 10 μm, which is as large as the signals. Furthermore, no external beam perturbation was used, and the signal is a rather weak 1.3% natural current jitter. As far as we know, such accurate transverse wakefield effect measurements in a linac are unprecedented. Note that the errors are on the order of a few microns, which is much larger than the statistical limit. Therefore, it is still possible to further improve both measurement and analysis. Frames 1 and 2 demonstrate that the current vectors obtained via Eq.(5) are correct. The bottom frame shows the current vectors of conditions a and c, which are the wakefield effects due to misalignments (and corrector offsets, etc.) in the normal running machine. An immediate application of such current vectors is the detection of structure misalignments and confirmation of wakefield calculations.

We performed a similar analysis in x also. We found that, one set of results agrees with the calculation while another has much larger deviations. The discrepancy in the horizontal cases may be due to some unknown jitter sources that are correlated with the current. We repeated these experiments several weeks later and obtained similar results in both the vertical and horizontal planes.

Our measurement results are still preliminary because limited machine time prevented us from thorough investigation. Nonetheless, they are very encouraging and promising. Since such measurements need not perturb the beam, they are basically non-invasive to normal machine operation and in principle can be done parasitically and quickly after the method matures. On the other hand, intentionally introduced larger current variation will improve the sensitivity to the misalignments. This method can potentially become a powerful tool for finding structure misalignments.

4 ACKNOWLEDGMENTS

We would like to thank M. Ross and N. Phinney as well as the SLC operation crew for their support. Special thanks is due to L. Hendrickson for her updating the SLC solo control program (SCP) to support our data acquisition. We would also like to acknowledge A. Chao, M. Lee, P. Raimondi, S. Smith, F. Zimmermann, and P. Tenenbaum for helpful discussions.

MULTIPLE COUPLING AND BEAM LOADING OF A RF CAVITY

H. Safa
Los Alamos National Laboratory, Los Alamos, 87545, NM, USA
& C.E.A. Saclay, 91191 Gif/Yvette Cedex, France

Abstract
Future high power accelerators are aiming at increasing the power transferred to the beam through radiofrequency (RF) cavities. Consequently, multiple main coupler drives may be required to withstand the high RF power needed per cavity. An analysis including multiple couplers and beam loading is described here, featuring the interaction between all couplers, the beam and the cavity. In this description, the beam is shown to act as if it were merely an additional drive for the cavity. Special focus is given to the case of superconducting cavities in a continuous (CW) operation mode. Some important conclusions derived from this analysis are briefly discussed as, for example, power coupler fault conditions or a way to handle the commissioning of an accelerator in a CW mode.

1 INTRODUCTION

The superconducting radiofrequency APT (Accelerator Production of Tritium) cavities will be driven simultaneously by two power couplers. Consequently, an analysis involving multiple couplers will be needed to understand the behavior of the interaction between the beam, the cavity and all the couplers, extending the beam loading introduction given in reference [**1**].

2 CAVITY, BEAM AND COUPLERS

Standard notations will be used to define the cavity parameters. If W is the stored energy, P_c the dissipated power and ω_0 the resonance pulsation ($\omega_0 = 2\pi F_0$), then the shunt impedance R and the quality factor Q_0 are defined by $P_c = |V_c|^2 / 2R$ and $Q_0 = \omega_0 \tau_0 = \omega_0 W / P_c$, $\tau_0 = Q_0/\omega_0$ is the filling time of the cavity. A superconducting cavity will have a very high R ($10^{12}\ \Omega$) compared to a normal copper cavity ($5.10^6\ \Omega$). This reduction of losses by more than 10^5 will increase the cavity filling time and the available beam power by the same amount. The cavity voltage V_c is arbitrarily defined through the effective length *l* of the cavity and the effective accelerating field E_{acc} :

$$V_c = E_{acc}\, l \qquad (1)$$

The cavity impedance is

$$Z_0 = \frac{R}{1 + jQ_0\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)} \cong \frac{R}{1 + jQ_0\frac{2\Delta\omega}{\omega_0}} \qquad (2)$$

If the injected time of a particle passing through the cavity is shifted by $\delta t = \phi/\omega$ as compared to the maximum energy gain, then the accelerating voltage will be

$$V_{acc} = V_c \cos\phi \qquad (3)$$

It can be shown that the induced voltage of a crossing particle with charge q on each mode of the cavity will simply reduce to $V_{ind} = -q\,(R/Q)\,\omega_0$ and the corresponding energy deposited $W = (R/Q)\omega_0 q^2/2$ will decay after the particle had passed with the time constant τ_0. Therefore, in a steady state regime, a current beam I_b will induce a total voltage $V_0 = -R\, I_b$. The induced voltage is always decelerating the particles. The beam can then be merely seen as a drive line having a fixed current source I_b with an equivalent voltage V_0 and will therefore be labeled drive 0 from now on. Let us now consider many RF lines (labeled 1,2,k) with characteristic impedances Z_{ck} coupled to the cavity through a coupling factor β_k. The external Q of each line k is defined as $Q_k = Q_0/\beta_k$ and the loaded quality factor Q_l results from $Q_l^{-1} = (\sum Q_k^{-1})$. Introducing the alpha coefficients $\alpha_k = Q_l/Q_k = \alpha_0\beta_k$, these will always be between 0 and 1[a], and obey the closure relation $\sum_k \alpha_k = 1$. The cavity detuning angle ψ is, by definition, $\tan\psi = -Q_l\,(2\Delta\omega/\omega_0)$. Each drive k will see the cavity impedance Z_0 in parallel with all the other drive impedances transformed to the cavity (R/β_m) through its own coupling coefficient β_k (Fig. 1). Consequently, drive k will see the overall impedance :

$$Z = \left(\frac{\beta_k Z_{ck}}{R}\right)\frac{1}{\frac{1}{Z_0} + \sum_{m\neq 0,k}\frac{\beta_m}{R}} = \frac{\alpha_k Z_{ck}}{(1-\alpha_k) - j\tan\psi} \qquad (4)$$

Therefore, the reflection coefficient ρ_k of drive k will be :

$$\rho_k = 2\alpha_k \cos\psi\, e^{j\psi} - 1 \qquad (5)$$

In order to get the different RF powers traveling on each line, we will use the incident and reflected voltages normalized to their relative coupling coefficient, that is $\left(V_{ik}/\sqrt{\beta_k}\right)$ and $\left(V_{rk}/\sqrt{\beta_k}\right)$. Each normalized drive should exhibit the same voltage $\frac{\left(V_{ik} + V_{rk}\right)}{\sqrt{\alpha_k}} = \text{constant}$. The cavity voltage is $V_c = V_{i\,0} + V_{r\,0}$, equal to the sum of all the induced voltages from each drive :

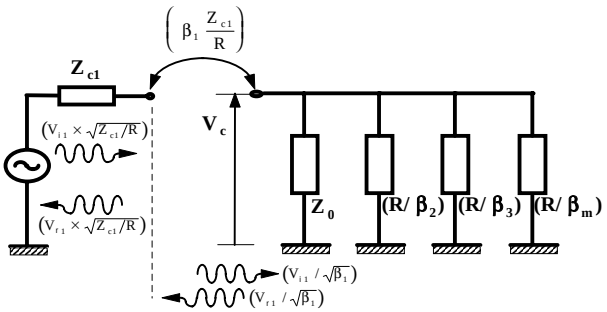

Figure 1. Impedance transform as seen from drive 1.

[a] This is an advantage over the use of the β (those can be infinite) as it significantly reduces computation errors.

$$\frac{V_c}{\sqrt{\alpha_0}} = \sum_m (1+\rho_m)\frac{V_{im}}{\sqrt{\alpha_m}} = \frac{(V_{ik}+V_{rk})}{\sqrt{\alpha_k}} \quad (6)$$

The above basic equations (6) will give all the return voltages including the cavity one. Once the incident powers (with their phases) and the coupling coefficients α_k are set, all the reflected powers in each line, the beam power and the cavity accelerating field may be deduced.

3 EXAMPLE OF TWO COUPLERS

Let us look more deeply at the case where two couplers are driving a single cavity. If the injected powers are P_1 and P_2 with phases θ_1 and θ_2, then, the corresponding normalized incident voltages are :

$$\begin{cases} V_{i1} = \sqrt{2RP_1}\, e^{j\theta_1} \\ V_{i2} = \sqrt{2RP_2}\, e^{j\theta_2} \end{cases} \quad (7)$$

And the reflected voltages derived from equations (6) :

$$\begin{cases} \frac{|V_c|e^{j\phi}}{\sqrt{\alpha_0}} = 2\alpha_0\cos\psi e^{j\psi}\frac{|V_{i0}|e^{j\theta_0}}{\sqrt{\alpha_0}} + 2\alpha_1\cos\psi e^{j\psi}\frac{|V_{i1}|e^{j\theta_1}}{\sqrt{\alpha_1}} + 2\alpha_2\cos\psi e^{j\psi}\frac{|V_{i2}|e^{j\theta_2}}{\sqrt{\alpha_2}} \\ \frac{V_{r1}}{\sqrt{\alpha_1}} = 2\alpha_0\cos\psi e^{j\psi}\frac{|V_{i0}|e^{j\theta_0}}{\sqrt{\alpha_0}} + \left(2\alpha_1\cos\psi e^{j\psi}-1\right)\frac{|V_{i1}|e^{j\theta_1}}{\sqrt{\alpha_1}} + 2\alpha_2\cos\psi e^{j\psi}\frac{|V_{i2}|e^{j\theta_2}}{\sqrt{\alpha_2}} \\ \frac{V_{r2}}{\sqrt{\alpha_2}} = 2\alpha_0\cos\psi e^{j\psi}\frac{|V_{i0}|e^{j\theta_0}}{\sqrt{\alpha_0}} + 2\alpha_1\cos\psi e^{j\psi}\frac{|V_{i1}|e^{j\theta_1}}{\sqrt{\alpha_1}} + \left(2\alpha_2\cos\psi e^{j\psi}-1\right)\frac{|V_{i2}|e^{j\theta_2}}{\sqrt{\alpha_2}} \end{cases} \quad (8)$$

The cavity voltage phase is, like in equation (3), noted ϕ, the reference phase taken opposite to the beam induced voltage, $V_{i0} = -R\, I_b$ with $\theta_0 = \pi$. The cavity power is $P_c = |V_c|^2/2R$, the beam power $P_b = \mathrm{Re}(V_c I_b^*) = |V_c| I_b \cos\phi$, and $\sum_k (P_{ik} - P_{rk}) = \sum_{k\neq 0}(P_{ik} - P_{rk}) - (P_c + P_b) = 0$ show that power is conserved. The reflected voltages are :

$$V_{rk} = \sqrt{\beta_k}\, V_c - V_{ik} \quad (9)$$

To minimize the generator power, all V_{rk} should be set to zero. That imposes to have for any line k :

$$\begin{cases} \theta_k = \phi \\ V_{ik} = \sqrt{\beta_k}\, V_c \end{cases} \quad (10)$$

And the external Q of each line have to be chosen so that

$$Q_k = \frac{P_c}{P_{ik}} Q_0 = \frac{|V_c|^2}{2(R/Q)P_{ik}} \quad (11)$$

A specific relation follows between the detuning angle ψ of the cavity and the beam phase ϕ :

$$\tan\psi = -(1-2\alpha_0)\tan\phi \quad (12)$$

In particular, if ($\alpha_0 = 1/2$), corresponding to the case of a matched single coupler ($Q_1 = Q_0$), then $\psi = 0$ for any phase ϕ. Whereas if ($\alpha_0 \ll 1$), general case for running a superconducting cavity with beam ($Q_0 \gg Q_1$), then $\psi \approx -\phi$. The cavity will have to be detuned by an angle equal to the opposite of the beam phase. For the APT cavities, where the beam phase is (- 30 degrees), this corresponds to a frequency shift of 947 Hz off resonance.

4 SENSITIVITIES

In order to match the beam, external couplings have to be adjusted using (11), powers and phases using (10), and detuning frequency using (12). Correlatively, the cavity voltage V_c and the phase beam ϕ will be the desired ones. Table I gives the sensitivity of each parameter.

Parameter	Nominal Values	Drive Phase	Drive Power	External Q	Beam Current
Variation	-	$\theta_i = \theta_{i\,nom} + - 10°$	$P_i = P_{i\,nom}(1+ -10\%)$	$Q_i = Q_{i\,nom}(1+ -10\%)$	$I_b = I_{b\,nom}(1+ -10\%)$
P_1 Reflected (W)	0	1500	119	472	2097
P_2 Reflected (W)	0	4872	393	0	2097
Beam Power (kW)	420	414	420 + - 20	420	416
Phase Angle Φ (°)	-30	-30 + - 7,7	-30 - + 1,15	-30 + - 0,02	-30 + - 5,1
Energy Gain (MeV)	4,20	4,14	4,20 + - 0,20	4,20	4,20 - + 0,42

Table I - Sensitivities of reflected powers, beam power, phase angle and energy gain on various parameters.

One can notice the importance of the drive phases. If the maximum allowable reflected power is for example 1‰ (200 W), they should be set equal to the phase angle ϕ to better than 2 degrees. Whereas the drive power, the external Q or the beam current may vary by as much as 6.3% for the same amount of reflection. Note the negligible effect of an external Q variation on ϕ. As a matter of fact, one can even get by without any adjustable coupling. Coupling can be pre-adjusted for each cavity, taking in account the variation of (R/Q) along the linac. Fixed coupling has the advantage of simplicity, reliability, and can avoid unwanted failures. On the other hand, adjustable coupling may reduce the total AC power consumption of the accelerator when operated at reduced current (at half current of 50 mA, a fixed coupling would require 12%[b] more RF power than an adjustable coupler).

5 FAULT SCENARIOS

5.1 Beam Failure

If the beam trips, then the couplers will have to withstand almost full reflection. The accelerating energy gain will exactly double in the cavity. The energy increase will rise with the time constant $\tau = \alpha_0\tau_0$ (46 μs for the 0.82 cavity). The amplitude control loop of the cavity should correct and bring back the voltage to its nominal value. This RF control feedback has generally a bandwidth exceeding 10 kHz and should easily compensate for the field variation. Therefore, the couplers will see the full 210 kW reflection only for about tens of microseconds, while hundred of microseconds after beam failure, the RF drive should be set back to 105 kW per coupler (again with full reflection). By that time, the RF drive can be shut down. Consequently, beam failure has no severe impact, provided RF control ensure that the cavity field would not exceed a given level.

5.2 Cavity Failure

The cavity may fail in many ways. It may experience a sudden change in its resonance frequency (due to mechanical stress or pressure), it may leak, it may exhibit field emission and finally it may quench. In the case of a quench, we are back to the above discussion during beam trip and that should be handled by a quench interlock. A

[b] This reduces to 9% for the whole accelerator taking in account the warm section, the cryoplant load and klystron efficiency.

shift in the resonance frequency would mainly impact the phase and should be corrected by the phase loop. If field emission occurs (inducing excessive Q losses and/or high X-ray levels), then the impact should be minimal. No effect will be seen on the couplers. The Q losses will induce higher cryogenic losses and the X-ray level can be monitored. In either case, the cavity field can be reduced accordingly to an acceptable level without having to react promptly by shutting down the RF or the beam (Here, one may allow a slow reaction time). Finally, in the case of a leak, a vacuum interlock should be set.

5.3 RF Power Failure

The RF system failure may concern power supply, klystron, circulator, divider or waveguide. In any case, the klystron is turned off. Cavity voltage will then be exactly opposite to the one without beam, the beam inducing exactly as much power as what it has been designed to receive. The required action is to detune the cavity far enough from resonance, reducing the beam induced voltage. A detuning frequency of 10 bandwidths (34 kHz) will reduce the beam power loss to less than 0.65% (1.37 kW).

5.4 Coupler Failure

The coupler might fail either because of a window problem (ceramic cracking, multipacting, breakdown, ...) or because of the coaxial part itself (breakdown, leaks, cooling, high dissipation, multipacting, ...). A coupler failure might lead to a serious failure (case of a leak, for example) where the beam and RF should be shut down and the cavity isolated.

6 ACCELERATOR COMMISSIONING

During commissioning, one might use either a pulsed beam and increase the duty cycle, or start at a very low CW current slowly increasing to reach its nominal value. Let us examine this latter case. In order to get the same accelerating energy and the same phase angle ϕ in the cavity, equations (8) give

$$\left|V_c\right|e^{-j\psi} = -2\alpha_0 \cos\psi R I_b e^{-j\phi} + 2\sqrt{\alpha_0\alpha_1}\cos\psi\left|V_{i1}\right| + 2\sqrt{\alpha_0\alpha_2}\cos\psi\left|V_{i2}\right| \quad (13)$$

If one recalls that the nominal value of cavity voltage for the nominal beam current I_{bnom} is

$$V_c = 2\alpha_0 \cos\phi\,(RI_{bnom}) \quad (14)$$

then, taking the imaginary part of (13) leads to the relation $\tan\psi = -(I_b/I_{bnom})\tan\phi$ which is equivalent to :

$$\left(\frac{\Delta F}{F}\right) = \frac{\tan\phi}{2Q_l}\left(\frac{I_b}{I_{bnom}}\right) \quad (15)$$

Therefore, the cavity frequency shift should be kept proportional to the current beam.

Taking the real part of (13) and using (14) with the nominal input voltages given by (10), one gets

$$2\left(\alpha_1\left|\frac{V_{i1}}{V_{i1nom}}\right| + \alpha_2\left|\frac{V_{i2}}{V_{i2nom}}\right|\right) = \left(1+\frac{I_b}{I_{bnom}}\right) \quad (16)$$

which, considering that the two ratios are identical, gives the input powers on each coupler

$$\left(\frac{P_{ik}}{P_{iknom}}\right) = \frac{1}{4(1-\alpha_0)^2}\left(1+\frac{I_b}{I_{bnom}}\right)^2 \quad (17)$$

In the case of the superconducting cavities, α_0 is very small and can be neglected. The input power required to achieve the same accelerating field at zero current beam is one fourth of the full power at nominal beam. Of course, almost all this power is then fully reflected. If the cavity frequency is changed according to (15) (linearly with beam current) and the input power according to (17) (quadratic with current), everything should remain stable while increasing the beam current. This should provide an easy way for commissioning the accelerator.

7 TRANSIENT ANALYSIS

In a transient mode, the use of the Laplace transform will make all the above relations, established for a steady state regime, straightforwardly extended. The Laplace transform of the cavity impedance is $Z_0 = R\dfrac{p}{p^2+\frac{p}{\tau_0}+\omega_0^2}$

which gives, once transformed through each drive k :

$$Z = \alpha_k Z_{ck}\frac{p/\tau}{p^2+(1-\alpha_k)\frac{p}{\tau}+\omega_0^2} \quad (18)$$

with the time constant $\tau = \alpha_0\tau_0$.

The reflection coefficient is like in equation (5)

$$(\rho_k+1) = \frac{2\alpha_k(p/\tau)}{p^2+\frac{p}{\tau}+\omega_0^2} \quad (19)$$

The basic equations (6) are still valid in the Laplace transform. In particular, using (6) and (19), one may write the cavity voltage as

$$V_c(p) = \frac{(p/\tau)}{\left(p^2+\frac{p}{\tau}+\omega_0^2\right)}\left(\sum_k 2\sqrt{\alpha_0\alpha_k}V_{ik}\right) \quad (20)$$

This function has two poles, solution of $\left(p^2+\frac{p}{\tau}+\omega_0^2\right)=0$, which are $p_\pm = -\frac{1}{2\tau} \pm j\omega_0\sqrt{\left(1-\frac{1}{4Q_l^2}\right)} \approx -\frac{1}{2\tau} \pm j\omega_0$. The cavity voltage as a function of time is then deduced by inverting the Laplace transform $V_c(t) = \int e^{pt}V_c(p)\,dp$:

$$V_c(t) = \left(Ap_+e^{p_+t} + Bp_-e^{p_-t}\right) + \left(\sum_k 2\sqrt{\alpha_0\alpha_k}V_{ik}\right)\cos\psi\, e^{j\psi}e^{j\omega t} \quad (21)$$

The first bracket is the transient one, with the time constant (2τ). The second term is the stationary solution. Finally, using the simplification $Q_l \gg 1$, the solution is :

$$V_c(t) = V_c(0)e^{-\frac{t}{2\tau}}e^{j\omega_0 t} + \left(\sum_k 2\sqrt{\alpha_0\alpha_k}V_{ik}\right)\cos\psi\, e^{j\psi}(e^{j\omega t} - e^{-\frac{t}{2\tau}}e^{j\omega_0 t}) \quad (22)$$

ANALYTICAL TREATMENT OF SINGLE BUNCH STABILITY IN A LINAC

G. Guignard, J. Hagel, CERN, Geneva, Switzerland

Abstract

Single bunch stability is analysed by solving the equation of motion of the particles travelling in a linac, for a Gaussian distribution of charge, a linear variation of the transverse wakefield along the bunch, a smooth focusing and negligible acceleration. The treatment is based on a non-standard perturbation expansion that has been specifically developed for this study and preserves at each order the intrinsic detuning likely to stabilise the resonant beam break-up. It provides a closed expression for the tune shift along the bunch resulting from BNS damping and autophasing, methods proposed in the past to control the emittance, and a first-order solution for the transverse off-sets within the bunch. The analytic result obtained makes it possible to study the behaviour of the solution and compute the emittance dilution in specific cases. The present theory is a useful complement to the numerical simulations done with the MUSTAFA code in the Compact Linear Collider scheme (CLIC). It also gives an interesting as well as comprehensive view of the physics involved in the single-bunch motion and the damping of the instability.

1 EQUATION OF MOTION

Since in most linear colliders a flat beam design (low vertical to horizontal beam size ratio) is used, emittance blow up due to transverse wakefields is most critical in the vertical plane. Disregarding acceleration, using a weak focusing model for the betatron motion and assuming a linearly varying wakefield within a single bunch the equation of motion reads as (refs [1, 2])

$$\frac{\partial^2 x(s,z)}{\partial s^2} + q^2[1+\Delta k(z)]x(s,z) = \frac{CW_0}{\gamma_0 l_B}\int_0^z \rho(z^*)(z-z^*)x(s,z^*)dz^* \qquad (1)$$

The two independent variables s and z describe the position of the bunch inside the linac, and the position inside the bunch, respectively. The quantity $q = 1/\bar{\beta}_y$ is the weak focusing tune, $\Delta k(z)$ a z-dependent additional focusing force (arising from a correlated energy spread and/or RF quadrupoles) and $\rho(z)$ the line charge density distribution. The constant C is defined by $C = 4\pi\epsilon_0 r_e N$ where N is the number of particles inside the bunch and r_e is the classical electron radius. W_0 is the value of the transverse wake at the tail of a truncated bunch in units of $V/(Asm^2)$. For $\rho(z)$ a truncated Gaussian distribution ($\pm 2\sigma_z$) has been used. In order to facilitate the analysis, the Gaussian has been replaced by its 4-th order Chebyshev approximation within $\pm 2\sigma_z$ which results into an error of not more than 4%. After normalisation the thus approximate expression for ρ becomes

$$\rho(z) = \frac{75}{46 l_B}\left[1 - \frac{41}{100}\left(\frac{4z}{l_B}-2\right)^2 + \frac{1}{20}\left(\frac{4z}{l_B}-2\right)^4\right] \qquad (2)$$

where $l_B = 4\sigma_z$.

We choose to deal with the effect of an initial offset α_0 as well as an initial slope along z. Although we do not consider here randomly misaligned quadrupoles and accelerating cavities, it has to be noted that these off-set and slope represent well the misalignment of a single component of the linac. The initial conditions are then

$$x(0,z) = \alpha_0 + \alpha_1 z \qquad (3)$$

$$\frac{dx}{ds}(0,z) = 0 \qquad (4)$$

2 SEPARATION OF VARIABLES AND AUTOPHASING

Equation (1) is a linear, partial, homogeneous integro-differential equation of second order. This type of equation can often be solved analytically by separating the two independent variables, i.e. s and z. Rewriting $x(s,z)$ as $x = X(s) + y(s,z)$ and performing some algebra leads to the following new equations for X and y

$$\frac{d^2X}{ds^2} + q^2 X = 0 \qquad (5)$$

$$\frac{\partial^2 y}{\partial s^2} + q^2[1+\Delta k(z)]y = X(s)\left[-q^2\Delta k(z) + \frac{CW_0}{\gamma_0 l_B}\int_0^z \rho(z^*)(z-z^*)dz^*\right] + \frac{CW_0}{\gamma_0 l_B}\int_0^z \rho(z^*)(z-z^*)y(s,z^*)dz^* \qquad (6)$$

The coherent motion (5) is given by the unperturbed betatron equation and its solution according to the initial conditions given above is

$$X(s) = \alpha_0 \cos qs = \alpha_0 \cos\frac{s}{\bar{\beta}_y} \qquad (7)$$

Considering the case of no z dependent focusing across the bunch ($\Delta k(z) = 0$), we face a resonant situation due to the fact that the frequency q of the unperturbed betatron motion appears on the right hand side and generates a secular solution in s. This is related to the well-known head to tail instability of a single bunch traveling through a structure with wakefields. In order to suppress the resonance excitation term, it is necessary to introduce a tune spread along

the bunch [3] cancelling the coefficient of $X(s)$ in Eq. (6).

$$\Delta k(z)_{AUTO} = \frac{CW_0}{\gamma_0 l_B q^2}\int_0^z \rho(z^*)(z-z^*)dz^* \quad (8)$$

In this paper we do not specify the mechanism creating the detuning (RF quadrupoles or correlated energy spread). However, in order to also study the bunch dynamics in the case of no correction or only partial correction through a z-dependent focusing, the actual detuning is defined as

$$\Delta k(z) = \lambda \Delta k(z)_{AUTO} = \lambda \frac{CW_0}{\gamma_0 l_B q^2}\int_0^z \rho(z^*)(z-z^*)dz^* \quad (9)$$

where $\lambda = 0$ means no correction while $\lambda = 1$ corresponds to the **autophasing condition** (8) (resonance suppressed). Inserting our definition (9) into Eq. (6) gives

$$\frac{\partial^2 y}{\partial s^2} + q^2\left[1 + \frac{\lambda CW_0}{\gamma_0 l_B q^2}\int_0^z \rho(z^*)(z-z^*)dz^*\right] y = (\lambda-1)\frac{CW_0}{\gamma_0 l_B} X(s)\int_0^z \rho(z^*)(z-z^*)dz^* + \frac{CW_0}{\gamma_0 l_B}\int_0^z \rho(z^*)(z-z^*)y(s,z^*)dz^* \quad (10)$$

3 PERTURBATIVE SOLUTION

Introducing the normalised bunch coordinate $\zeta = z/l_B$ and further separating y such as $y(s,\zeta) = \alpha_1 l_B \zeta \cos qs + v(s,\zeta)$ results in

$$\frac{\partial^2 v}{\partial s^2} + \bar{q}^2(\zeta) v = \frac{CW_0}{\gamma_0 l_B}\cos qs \times \left[[\alpha_0(1-\lambda) - \alpha_1 l_B \zeta \lambda]\int_0^\zeta l_B^2 \rho(l_B\zeta)(\zeta-\zeta^*)d\zeta^* + \alpha_1 \int_0^\zeta l_B^3 \zeta^* \rho(l_B\zeta)(\zeta-\zeta^*)d\zeta^*\right] + \frac{CW_0\epsilon}{\gamma_0 l_B}\int_0^\zeta l_B^2 \rho(l_B\zeta^*)(\zeta-\zeta^*)v(s,\zeta^*)d\zeta^* \quad (11)$$

where

$$\bar{q}^2(\zeta) = q^2\left[1 + \lambda E \frac{CW_0}{\gamma_0 l_B q^2}\int_0^\zeta l_B^2 \rho(l_B\zeta^*)(\zeta-\zeta^*)d\zeta^*\right] \quad (12)$$

In order to avoid secular terms and preserve the detuning of the oscillatory motion we use a specific **partial perturbation expansion** of the solution $v(s,\zeta)$. It consists of separating the perturbation of the (analytically) solvable part of the equation of motion (11), marked with E in (12), from the integral driving-term on the right hand side of (11) marked with ϵ. Both ϵ and E indicate that the associated terms contain products of the wakefield W_0 with the oscillation amplitude due to the wakefields $v(s,\zeta)$ and are perturbations w.r.t. the rest of the equation. The expansion is only done w.r.t. ϵ and not w.r.t. E describing the z-dependent tune shift. Then the perturbation series reads as $v = v^{(0)}(s,\zeta;E) + \epsilon v^{(1)}(s,\zeta,E) + \cdots$ and no resonant terms arise at any order. At the end of the computation, both ϵ and E are set to unity. A detailed description and justification of the partial expansion method introduced for this study is given in [2]. Setting $\epsilon = 0$ in eq. (11) leads to a linear, inhomogeneous differential equation of second order and its solution is

$$v^{(0)} = \left[\alpha_0\frac{\lambda-1}{\lambda} + \left(\frac{3\zeta}{7\lambda} - \zeta\right)\alpha_1 l_B\right][\cos qs - \cos(\bar{q}(\zeta)s)] \quad (13)$$

with

$$\bar{q}(\zeta) = q\left[1 + \frac{\lambda CW_0}{\gamma_0 q^2}\times \left(\frac{16}{23}\zeta^6 - \frac{48}{23}\zeta^5 + \frac{79}{46}\zeta^4 + \frac{1}{23}\zeta^3 + \frac{3}{23}\zeta^2\right)\right]^{\frac{1}{2}} \quad (14)$$

The equation for the first order perturbation contribution $v^{(1)}$ becomes

$$\frac{\partial^2 v^{(1)}}{\partial s^2} + \bar{q}^2(\zeta)v^{(1)} = \frac{CW_0 l_B}{\gamma_0}\int_0^\zeta \rho(l_B\zeta)(\zeta-\zeta^*)v^{(0)}(\zeta^*,s)d\zeta^* \quad (15)$$

The detailed solution of this equation is given in Ref. [2].

As a first example, Fig. 1 shows a typical solution (to order zero of the perturbation) of the form $y = \alpha_1\zeta l_B \cos qs + v^0(s,\zeta)$ at a distance of 520 m downstream of the linac. The increasing frequency of the incoherent bunch oscillations from the head ($\zeta = 0$) to the tail ($\zeta = 1$) of the bunch becomes clearly visible.

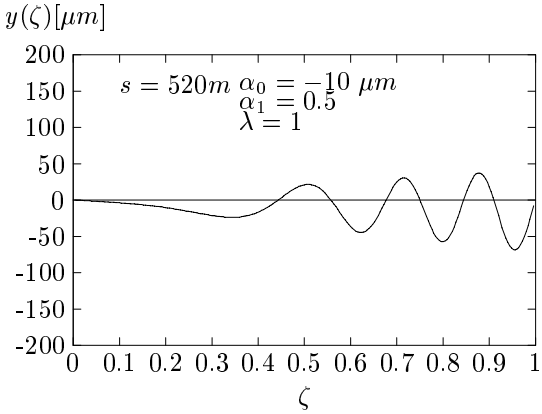

Figure 1: Autophasing solution in CLIC

Next we show in Fig. 2 the solution (including the first order term $v^{(1)}$ of the perturbation) for $\lambda = 0$, i.e. in the absence of detuning along the bunch. While the full line represents the analytical solution, the points indicate the results obtained with the tracking code MUSTAFA [4].

By comparison with the detuned example of Fig. 1, the amplitude of the oscillation increases significantly because of the resonant effect. However, some residual detuning remains visible due to the influence at large amplitudes of the last integral term in Eq. (11).

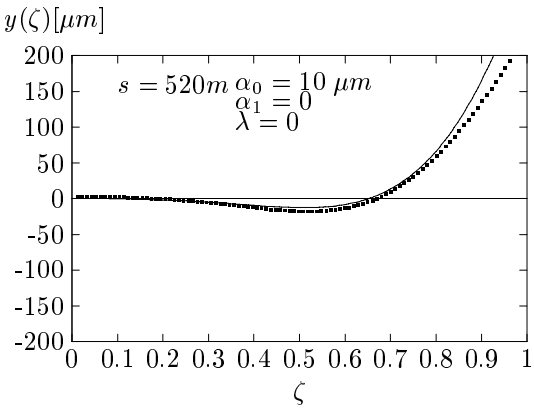

Figure 2: Resonant solution in CLIC at $s = 520$ m

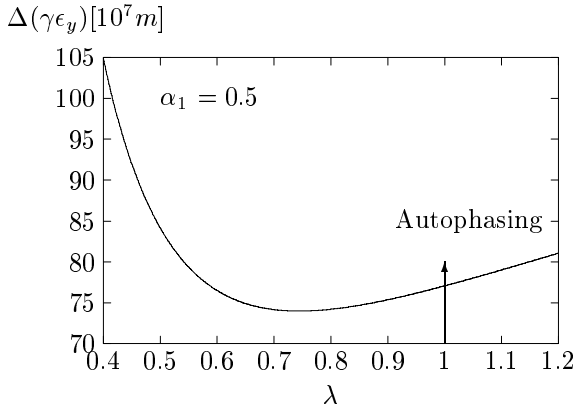

Figure 3: Asymptotic emittance growth as function of λ

4 EMITTANCE DILUTION

Since a low emittance beam is needed at the interaction point to provide high luminosity collisions, it is interesting to study the emittance dilution due to wakefields in the accelerating structures of the collider. If we consider the emittance increase due to transverse wakes in a single bunch, the total normalised emittance at the end of the main linac is given by

$$\gamma\epsilon_{tot} = \gamma\epsilon_{inj} + \Delta(\gamma\epsilon_y) \tag{16}$$

where

$$\Delta(\gamma\epsilon_y) = l_B\gamma_0 \int_0^1 \rho(\zeta) \left[qy^2(s,\zeta) + \frac{1}{q}\left(\frac{\partial y}{\partial s}(s,\zeta)\right)^2 \right] d\zeta \tag{17}$$

and $y = \alpha_1 l_B \zeta \cos qs + v(s,\zeta)$. Instead of v we use $v^{(0)}(s,\zeta)$ as given in Eq. (13) since it is believed to give the strongest contribution. Although y has then a relatively simple form, the integral in (17) becomes non elementary, leading to complicated expressions of trigonometric and Fresnel functions. However, it can be demonstrated that the emittance in the case of an initial offset tends to an asymptotic value as s goes to infinity. It is straightforward to compute this limit by only considering slowly oscillating terms in ζ as s increases and averaging the fast oscillating terms before performing the quadrature. As above, all the details are described in Ref. [2]. The result for the asymptotic emittance becomes

$$\lim_{s\to\infty}(\gamma_0\epsilon_y) = \gamma_0\epsilon_{inj} + \frac{a_{-2}}{\lambda^2} + \frac{a_{-1}}{\lambda} + a_0 + a_1\lambda + a_2\lambda^2 \tag{18}$$

where the parameters a_{-2} to a_2 are polynomial expressions of the transverse wakefield W_0 with coefficients that are rational functions of α_0 , α_1 , q and l_B. They are all listed in Ref. [2]. The form of the expression (18) makes it obvious that ϵ_y must have a certain minimum as a function of λ, since the first and second terms decrease with λ while the last two increase. Evidently $\lambda = 0$ leads to an infinite asymptotic emittance due to the resonance effect.

Fig. 3 gives an illustration of this effect for the case of $\alpha_0 = -10\ \mu m$, $\alpha_1 = 0.5$ and $0.4 < \lambda < 1.2$.

The same figure 3 clearly shows for $\alpha_1 = 0.5$ that **the autophasing condition is not leading in general to the minimum single bunch emittance**. Instead, the minimum is shifted to a lower value of λ where two effects are best balanced: namely an increase of the decoherence of the bunch with λ that leads to an emittance growth and a rise of the distance from the resonance with λ that induces an emittance reduction. The actual (flat) minimum of the emittance in this example appears at a value of λ near 75% of the one corresponding to the autophasing condition.

5 CONCLUSIONS

The equation of the transverse single-bunch motion has been analytically solved for initial off-set and slope along the bunch, similar to those generated by the misalignment of a single linac element. Weak focusing is used and the acceleration within a linac sector is not included. The transverse wakefield along the bunch is taken as linear and the charge density approximated by Chebyshev polynomials. The transverse displacement $x(s)$ is split into a coherent term $X(s)$ and a part $y(s,z)$ that depends on the position z in the bunch. A particular partial perturbation treatment worked out by the authors is then applied in order to keep the detuning property through all orders and prevent the creation of artificial resonances. In this way, zero and first order solutions for x as well as the asymptotic emittance dilution for $s \to \infty$ have been derived as functions of the fraction λ of the wakefield that is damped. They all agree with the results of the code MUSTAFA and confirm the existence of a given λ where the single-bunch emittance blow-up is minimum. This minimum is proven not to correspond generally with autophasing.

APPLICATION OF THE MODE MATCHING TECHNIQUE TO THE ANALYSIS OF WAVEGUIDE ARRAYS

A. Jöstingmeier, M. Dohlus and N. Holtkamp, DESY, D-22607 Hamburg, Germany

Abstract

In this contribution the mode matching technique is applied to compute the absorption characteristics of a two-dimensional array of rectangular waveguides. This analysis is motivated by a proposal of a broadband absorber for TESLA. Outside the waveguide array the so-called Rayleigh expansion is used which represents the electromagnetic field in terms of space harmonics whereas the complete modal spectrum of eigenmodes is taken into account inside the waveguides. In the case of normal incidence the validity of the presented method is confirmed by MAFIA computations. The absorption characteristics for various angles of incidence are calculated for a broad frequency range. The accuracy of the results is checked by a study of convergence. It is shown that the Rayleigh expansion has to be modified if the waveguide array is excited by an ultra-relativistic beam instead of an incoming plane wave. Numerical results for the beam parameters are presented for an array of parallel-plate waveguides and compared with those obtained by other methods.

1 INTRODUCTION

A HOM (higher order modes) absorber for TESLA has been proposed in [1] which consists of an array of rectangular waveguides surrounding the beampipe (Fig. 1). This absorber is used to extract the HOM in the THz region from the superconducting accelerating structure and to attenuate the extracted fields by the ohmic wall losses of the rectangular waveguides.

For the sake of simplicity we consider instead of the circular waveguide array a two-dimensional infinite planar grating (Fig. 2). The absorption characteristics of this model are expected to be very close to those of the original absorber because the free-space wavelength is much shorter than the curvature of the structure in the relevant frequency range.

Such a grating can be analyzed by the application of the mode matching technique. Above the grating the electromagnetic field is expanded in terms of an infinite series of spatial harmonics, which is known as the Rayleigh expansion; and inside the waveguides the field is represented by the complete spectrum of TE and TM waveguide modes. Matching the waveguide aperture tangential electromagnetic field, yields an infinite algebraic system of equations the unknown of which are the field expansion coefficients [2].

The ratio describing how much of the power of the incoming wave is coupled into the waveguides is denoted as the grating efficiency. It is used to estimate the power absorption properties of the structure. This quantity is calculated for a grating with typical absorber dimensions over a broad frequency range and for various angles of incidence.

If we use a grating as HOM absorber we have to keep in mind that such a structure itself also contributes to the beam impedance. The second part of this paper is therefore dedicated to the computation of the beam parameters of infinite periodic structures.

The mode matching technique is employed to calculate the electromagnetic field which is excited by an ultra-relativistic bunch of particles in the presence of an infinite array of parallel-plate waveguides (Fig. 3). Subsequently the beam parameters are calculated by making use of the results of the field analysis. In [3] it has been demonstrated that the results of this planar model can also be used for a circular configuration if certain scaling laws are taken into account.

The Rayleigh expansion for the field representation above the grating is known to be complete which means that it can be used to represent any kind of pseudo-periodic field. Nevertheless it has to be modified for an ultra-relativistic beam since the phase advance of the exciting

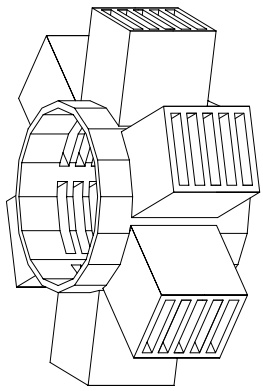

Figure 1: Sketch of the waveguide array absorber.

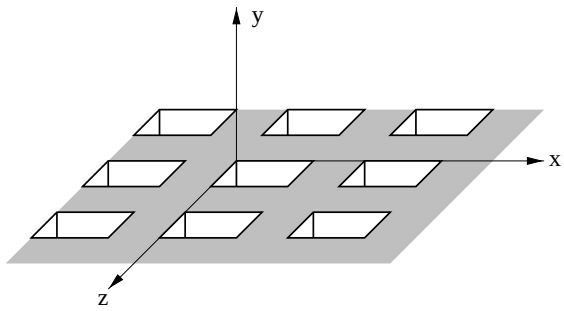

Figure 2: Two-dimensional planar grating.

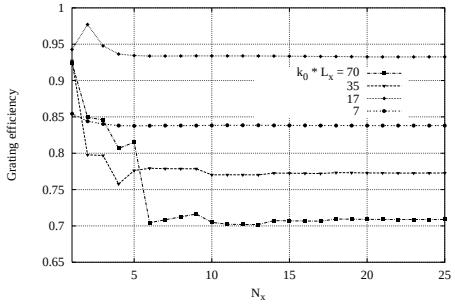

Figure 4: Grating efficiency as a function of the number of field expansion terms for various frequencies.

current is in this case equal to the vacuum wavenumber. Consequently the zeroth order spatial harmonic satisfies the Laplace equation instead of the usual wave equation. Thus we have to use a constant and a linearly increasing function in the x-direction as expansion terms for the y-component of the magnetic field instead of the zeroth order spatial harmonic of the standard Rayleigh expansion.

2 ABSORPTION CHARACTERISTICS OF A RECTANGULAR WAVEGUIDE ARRAY

The mode matching technique leads to an infinite system of equations for the unknown field expansion coefficients which has to be truncated if the method is implemented on a computer. Therefore it is essential to study the convergence of the results with respect to the number of field expansion functions.

Fig. 4 shows the grating efficiency as a function of the maximum order of the spatial harmonics in the x-direction for a grating with typical dimensions of the proposed absorber. The normalized wavenumbers $k_0 L_x = 70$, 35, 17 and 7 correspond to frequencies of approximately 2000, 1000, 500 and 200 GHz, respectively. For a frequency of 200 GHz accurate results are already obtained for $N_x = 5$ whereas $N_x = 20$ is required for a frequency of 2000 GHz. Thus $N_x = 20$ is used for all further calculations which means that approximately a (1500×1500) linear system of equations has to be solved. Assuming this parameter, a typical frequency scan with 1000 points requires about 2 d of cpu-time on a modern workstation.

If the electric field vector of the incoming wave goes along the x- or the z-direction the grating analysis reduces

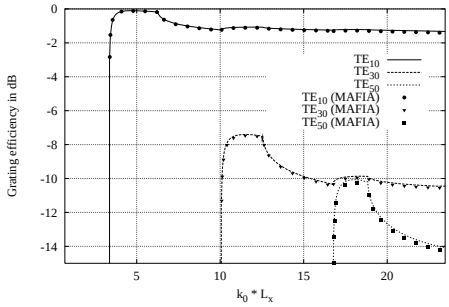

Figure 5: Comparison between the MAFIA computer code and the presented mode matching technique.

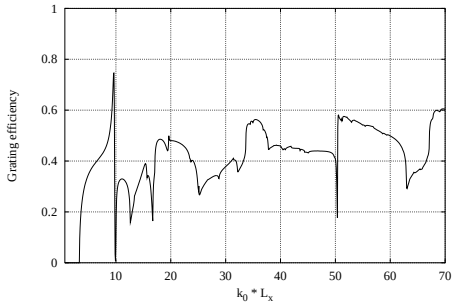

Figure 6: Absorption characteristics for a nearly grazing incident field.

to a waveguide discontinuity problem which can also be solved using the MAFIA computer code [4]. Fig. 5 shows the excitation of the TE_{10}, the TE_{30} and the TE_{50} rectangular waveguide modes as a result of both methods. It is found that in the investigated frequency range from 100 GHz to about 700 GHz the results agree very well.

In the case of normal incidence the grating efficiency is greater than 0.6 (except for frequencies which are very close to the cutoff frequency of the fundamental mode of the rectangular waveguide) which means that more than 60% of the power of the incoming wave is extracted by the grating. Nevertheless the grating efficiency decreases for obliquely incident fields. But even if the angle between the direction of propagation of the incoming wave and the grating interface is only $15°$ the average grating efficiency is still about 40% (Fig. 6).

3 BEAM PARAMETERS OF AN INFINITE PERIODIC STRUCTURE

Fig. 7 shows the real part of the beam impedance for a planar grating as a function of frequency. The maximum normalized wavenumber which is $k_0 L = 200$ corresponds to a frequency of about 10 THz for a period length of the grating of 1 mm. The beam impedance is calculated at 32768 frequency points and 200 spatial harmonics are taken into account.

The beam impedance is a smooth function of $k_0 L$ in the frequency range from dc to $k_0 L = \pi$. On the other hand it starts to oscillate rapidly at for higher frequencies where the first higher order spatial harmonic turns from evanescent to propagating with respect to the x-direction. This leads to resonances between the magnetic wall and

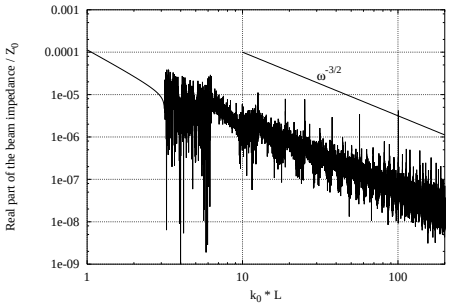

Figure 7: Real part of the beam impedance for a planar grating as a function of frequency. Parameters: $L = 4/15\,\text{mm}$, $L_0 = 0.5L$ and $d = 35\,\text{mm}$.

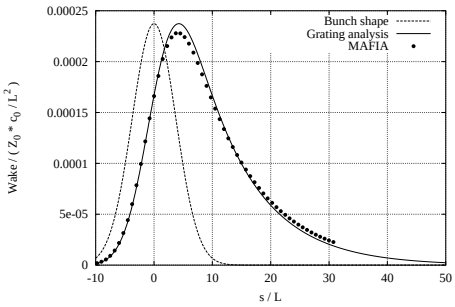

Figure 8: Comparison of the wakefields between the presented mode matching analysis and the MAFIA computer code. Parameters: $L = 4/15\,\text{mm}$, $L_0 = 0.5L$, $a = 5\,\text{mm}$ and $\sigma = 1\,\text{mm}$.

the grating interface with a high spectral density because $d = 35\,\text{mm} \gg L = 4/15$ mm.

In Fig. 7 a logarithmic scale is used for both axis. Thus a curve which is proportional to $\omega^{-3/2}$ corresponds to a straight line with a slope of $-3/2$ which is also given in this Fig. From the two curves it can be concluded that the averaged beam impedance also drops as $\omega^{-3/2}$ which has already been shown in [5].

In Fig. 8 the wakefields corresponding to the presented mode matching analysis and the MAFIA computer code [4] are compared. For the MAFIA calculations a corrugated circular beampipe with a length of 200 periods is assumed. The wakefield corresponding to the mode matching technique is obtained by scaling the result from the equivalent planar model. The agreement of the two wakefields is quite good which confirms the validity of the presented method.

The dependence of the wakefield on the bunch length is illustrated in Fig. 9. The results which are presented in this Fig. are valid for a circular configuration with a radius a. The curves converge to an asymptotic wakefield corresponding to an infinitely small bunch length. For the given parameters the wakefield gets very close to the asymptotic curve ($\sigma/L = 0.1$) for a bunch length in the order of one grating period. Such an asymptotic wakefield has also been used in [6] where it is approximated by a special fit.

4 CONCLUSIONS

The mode matching technique has been applied for the analysis of a two-dimensional array of rectangular waveguides which serves as a model for a HOM absorber. A

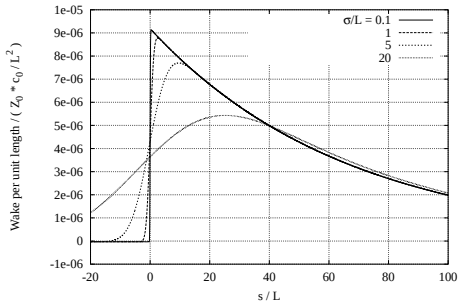

Figure 9: Dependence of the wakefield on the bunch length. Parameters: $L_0 = 0.5L$, $a = 262.5L$.

detailed study of convergence has been carried out in order to demonstrate the accuracy of the presented method. Furthermore the validity of the results has been checked by comparing the excitation of the rectangular waveguide modes with corresponding numbers from MAFIA computations for the special case of normal incidence. The analysis of a grating with typical absorber dimensions has shown that the average grating efficiency is quite high. Although this quantity decreases as we approach the case of grazing incidence the overall absorption properties of such a grating seem to be acceptable. In the second part of this contribution the mode matching technique has been applied to compute the electromagnetic field excited by a bunch of ultra-relativisitic particles traversing a planar grating. It has been shown that the standard Rayleigh expansion which is usually used to represent the field above the grating has to be modified in this case. The beam parameters have been calculated for various structures; and the validity of the presented method has been checked.

SIMULATION STUDY OF THE BUNCHING SECTION OF X-BAND KLYSTRONS

S.Matsumoto, S.Michizono, H.Tsutsui, Y.H. Chin and S.Fukuda
High Energy Accelerator Research Organization (KEK), Tsukuba, Ibaraki, 305-0801 Japan

Abstract

A precise simulation of a klystron is useful not only to understand its operation but for the design work. For this purpose, MAGIC code, which is a 2.5 dimensional PIC code for self-consistent simulation of plasma physics problems, is used to simulate the entire klystron performance including the production of the beam at the gun, the modulated beam motion and the beam-cavity interaction at the output cavity as well as the gain cavities. In this article, the simulation of the buncher section of KEK XB72K, a relativistic X-band klystron, is described.

1 INTRODUCTION

An X-band klystron is a possible RF power source in future linear colliders. The design performance of such a klystron is high. In R&D of such a klystron, a precise simulation of the performance is preferred. For this purpose, we recently adopted MAGIC code at KEK. MAGIC is a 2.5 dimensional fully electromagnetic and relativistic Particle-in-Cell (PIC) code for self-consistent simulation of plasma physics problems[1]. The primary inputs of MAGIC simulation are the electromagnetic boundary condition on the perimeter (simulation boundary) and the initial condition of beam.

In a klystron simulation, the geometry of the klystron determines the physical boundary (conductor perimeter), while in the gun region, for example, an external DC field should be given properly along a line between the cathode and the anode. This kind of lines is also a part of the perimeter. As for the initial condition of beam, MAGIC can simulate the thermal emission from the cathode surface. The focusing solenoidal field is included as an external field in the simulation. We calculate this field by POISSON code[2].

In our simulation study, the whole klystron structure breaks into three simulation sections. This separation is technically unavoidable since the whole length (from the gun to the output cavity) of our klystron is too long for a single simulation. In a MAGIC simulation, 1024 is the maximum number of the grids (cells) in z direction (the direction of beam axis). If the grid size in z is 0.2 mm (this is the case of our simulation), about 20 cm is the maximum length.

The stream of beam particles and electromagnetic fields from the upstream simulation section can be transferred to the downstream by MAGIC IMPORT/EXPORT command. Once EXPORT command is invoked, MAGIC records the fields and particles on the "export line" for a specified duration of time. The data is launched by IMPORT command on the "import line" in the downstream simulation section which should be matched to the export line. This technique works if there is no backward wave and particles and a klystron is the case. The separation into these simulation sections is done at the middle of the long drift tubes.

The first section is the gun section where the DC beam from the gun is simulated[3]. The beam energy is specified here by the cathode voltage. The next region is the buncher section which includes the input cavity, the gain cavities and the penultimate cavity. The RF voltage supplied at the input gap modulates the beam. The last section simulates the output cavity. The actual output cavity has two ports to conduct the power. The ports are represented by an equivalent axisymmetric load in the simulation[4]. The output power is estimated as the consumed power in this load.

In the present paper, the simulation of the buncher section of XB72K, an X-band klystron developed at KEK [5], is described. This section is divided into 2 subsections, since the whole section is still long for a single simulation. The first half covers the input and gain cavities while the last half includes the penultimate cavity.

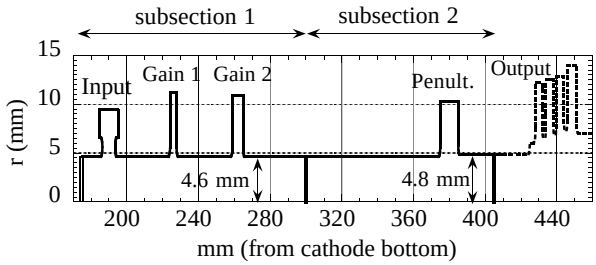

Figure 1: The structure of the buncher section of XB72K. The import line from the gun section is located at 170 mm and the export line is at 410 mm. There is another line at 300 mm, which divides the section into two. These lines are indicated by the double lines in the figure. The TW output structure of XB72K#9 is also shown in the figure.

2 SIMULATION METHOD

2.1 Input cavity

MAGIC can simulate straightforwardly the gain cavities or the penultimate cavity. However, the simulation of the input cavity is not straightforward since it has a port (not axisymmetric) through which the power comes in (or out). In our simulation, the input cavity is removed and its electrical effect is represented by an external field on the gap line, a new boundary which is defined as the (shortest) straight line between the nose cones of the cavity. The external field, $E_z(z,t)$, is calculated primarily as the electric field of the trapped mode of the input cavity with the operation frequency. It is

$$E_z(z,t) = \frac{V_g}{d}\,\bar{e}(z)\sin\omega t,$$

where V_g is the gap voltage, d is the gap length (7 mm in our case) and $\bar{e}(z)$ is a function shown in Fig. 2. In the simulation (with beam), $E_z(z,t)$ is applied on the gap line as an external field. Fig. 3 shows the electric field generated by $E_z(z,t)$. The gap voltage V_g is related to the input power P as

$$V_g^2 = \rho P.$$

We adopt ρ such that $V_g = 2.0\,\mathrm{kV}$ when $100\,\mathrm{W}$ input power. The dependence of ρ on the beam energy or beam current is small thus we neglect it.

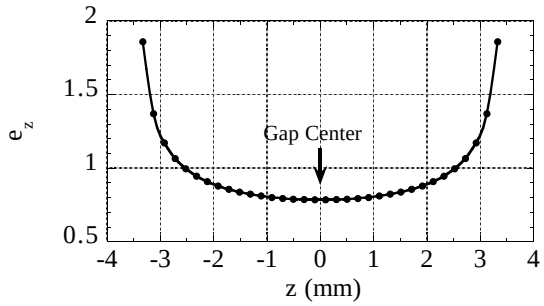

Figure 2: The function $\bar{e}(z)$ of XB72K input cavity.

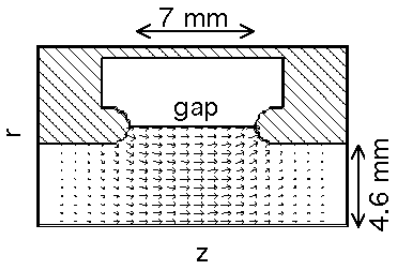

Figure 3: A snapshot of the electric field. The external field is given on the gap. The arrows indicate the direction and strength of the electric field at this moment.

2.2 Gain and Penultimate cavities

The resonant frequency of the gain and penultimate cavities is shifted from the operation frequency (11.424 GHz) as tabulated below. The resonant frequency can be measured by EIGENMODE command. All the cavities were tuned within at most 0.5 MHz by a tiny change of the cavity radius.

Table 1: Frequency Shift of cavities

Cavity	*df* (MHz)	Cavity	*df* (MHz)
1 (input)	0	3 (Gain)	+26
2 (Gain)	+12	4 (Penult.)	+376

2.3 Other issues

We use uniform spatial grids. The grid size in z is 0.2 mm overall while that in r is $4.6\,\mathrm{mm}/15 \sim 0.3$ mm in the drift tube and a little small grid is used in the cavity space. We set the time step manually to be $1/360$ cycle (for the entire simulation sections). This step is smaller than the default step set by MAGIC automatically from the given grid size.

The external field on the boundary should be started from zero value and slowly raised to its desired value. Otherwise we often see the numerical oscillation occurs. The similar treatment should be done when we import particles. SCALE is a MAGIC command for this trick.

We are interested in the beam and fields in their stationary state. Realization of such a state requires a finite duration of time in the simulation. For example, in Fig. 4, the evolution of the gap voltage at the 2nd gain cavity is shown. The voltage becomes constant after about 20 nsec, which is 230 RF cycles. Although the relaxation time should depend on the current carried by the beam or the beam energy as well as the frequency shift of the cavity, the duration of 300 cycles is enough for the first subsection while 200 cycles is enough for the second subsection.

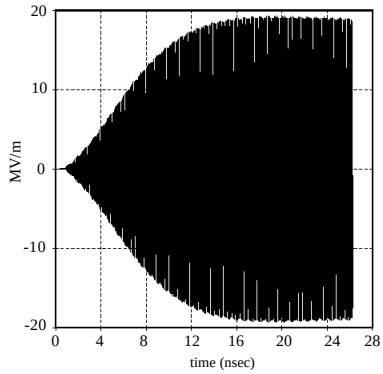

Figure 4: The averaged electric field strength (in unit of MV/m) on the gap line of the 2nd gain cavity. It saturates after about 20 nsec. Beam energy is 525 kV and input power is 300 W.

3 SIMULATION RESULTS

3.1 Modulation and its enhancement

Let us see how the bunching process is seen in the MAGIC simulation. As an example, we show the case of XB72K#9 with the beam energy being 525 kV and input power being 300 W. Fig. 5 is a snapshot of the beam energy in the first subsection as a function of z. We clearly see the enhancement of the energy modulation occurred at the gain cavities. The modulation in energy (velocity) is turned to be the density modulation downstream and this is actually seen in the next subsection. See Fig. 6. The cavity in the figure is the penultimate cavity which enhances the bunching process. The bunching process can be more clearly seen in the current growth along the z direction, which is calculable from

MAGIC output. See in Fig. 7. The enhancement of bunching by the cavity can be seen as a kink of the growth curves.

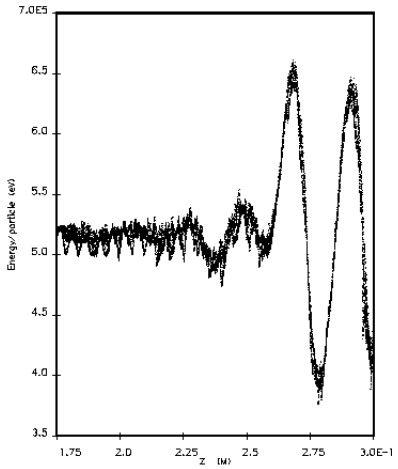

Figure 5: The snapshot of the beam energy along the longitudinal direction z.

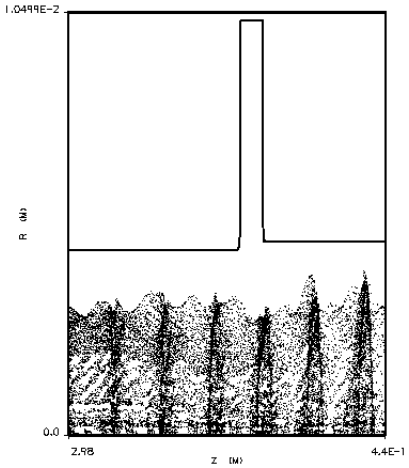

Figure 6: The snapshot of the particle distribution in subsection 2.

The output power can be estimated in the next simulation section by using the exported data from the buncher section. The simulation of the #9 TW output structure predicts 80.5 MW in this particular case. Since DC current is 458 A (the perveance is 1.2×10^{-6}), therefore MAGIC simulation for XB72K #9 predicts the efficiency of 33% at 525 kV. A discussion on the MAGIC predictions and experimental results is found in Ref. [6]. The MAGIC predictions agree well to the observations so far [7].

3.2 Required CPU time

Required CPU time is 10.5 hours for first subsection (duration 300 cycles) and 7.5 hours for the second subsection (200 cycles) in pentiumII-300 MHz PC. The number of the

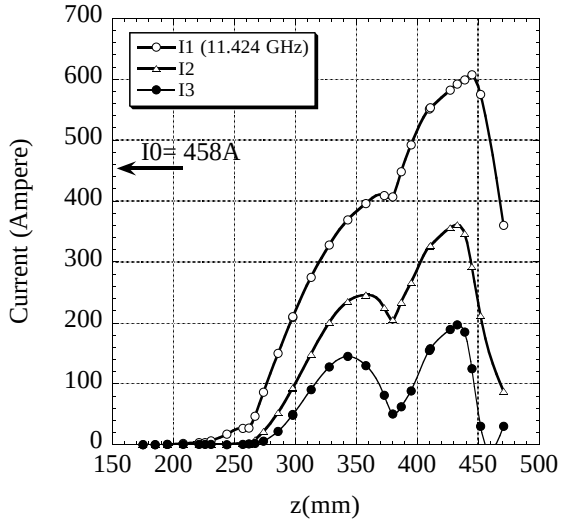

Figure 7: The RF current growth in XB72K #9. Beam voltage is 525 kV, 300 W input. The fundamental ($I1$) as well as the second ($I2$) and third ($I3$) harmonics are shown. The ratio of $I1$ to $I0$ (DC component) reaches about 1.3 in the output cavity but decays rapidly.

macro-particles emerge from the import line of the first subsection is about 3800 per a single cycles (360 time steps). This number is not changed throughout the whole simulation sections (unless the particles hit the wall). CPU time depends largely on the number of the macro particles appeared in the simulation region. The grid size, the time step and the number of macro particles that we used so far are rather conservative.

4 SUMMARY

The basic techniques for simulating a klystron by 2.5D MAGIC code are established. Although the code primarily solves the problem, we still need a trick like the port approximation for the input cavity, as shown above. Eligibility of the trick is checked by the experiment or by the other code. So far the MAGIC model is a good simulator of a klystron.

HIGH ENERGY BEAM TRANSPORT BEAMLINE FOR LEDA*

W. P. Lysenko, J. D. Gilpatrick
Los Alamos National Laboratory, Los Alamos, NM 87544 USA
M. E. Schulze
General Atomics, Los Alamos, NM 87545

Abstract

Here we describe the High Energy Beam Transport (HEBT) for the Low Energy Demonstration Accelerator (LEDA), which is part of the Accelerator Production of Tritium (APT) project. We used the TRACE 3-D linear design code[1] for the first-order design and performed r-z and 3-D particle-in-cell (PIC) simulations to study the beam distribution and halo. TRACE 3-D predicts rms beam properties well. The PIC simulations are important for determining the presence of beam halo, which is present for some tunes. We propose halo experiments to help validate our simulation codes for modeling nonlinear space charge.

1 REQUIREMENTS

The HEBT, which matches the 6.7 MeV 100 mA CW beam from the RFQ into the water-cooled nickel beamstop must meet the following requirements:

- **Match beam to beamstop**. The rms size of the beam at a point 45 inches past the entrance of the beamstop must be 44 mm in both transverse directions.
- **Provide space for equipment.** Diagnostics and other equipment take up a certain amount of length.
- **Have rms beam sizes $<$ 1/5 of aperture radius.** Inside the HEBT, we require the rms beam sizes to be less than than one-fifth of the bore radius.
- **Be insensitive to beam or quadrupole errors.** The rms beam sizes and phase-space centroids must be within the safe operating range of the beamstop.
- **Minimize beam halo generation.** Under normal operation, we do not want any beam to be scraped off in the beamline. To meet his requirement, we must ensure that no beam halo is introduced.

2 BEAM PHYSICS

We can increase the focusing strength of the lattice by decreasing the distance between quadrupoles. With sufficient external focusing, the relative strength of the space-charge force is decreased to harmless levels. The 100 mA beam current forces us to use four quadrupoles. If there were less space charge, only two or three quadrupoles would have been sufficient to match the RFQ beam to the beamstop.

* Work supported by the US DOE, Defense Programs.

When the beam reaches the last quadrupole, the bunch length is 4.5 times its original value and space charge is no longer important. In the drift to the beamstop the beam is in the zero-emittance regime ($\epsilon_x << x_{max} x'_{max}$). We can approximate the beam by a point source located near the final quadrupole. Emittance growth does not significantly affect the beam size. The linear TRACE 3-D code is a good predictor of beam size even though it cannot model emittance growth produced by space-charge nonlinearities.

The beam from the RFQ has a fairly uniform core and no long tails in the x and y distributions. The HEBT should preserves these qualities and not introduce any beam halo. To compute these effects, we need particle simulations, which can take into account details in the phase-space distribution and nonlinear space-charge forces.

3 DESIGN PROCEDURE

We used TRACE 3-D to design the beamline. We fixed the quadrupole positions, providing space for beamline instrumentation and diagnostics. The input beam used rms values from RFQ simulations. We specified the beam at the match point, 45 inches past the start of the beamstop, and let the TRACE 3-D optimizer determine the magnet gradients. Our results depended on the specified values of α_x and α_y at the match point. (These determine the cross-over points, which must be near the final quadrupole.) We searched for tunes having rms beam sizes everywhere less than one-fifth the bore radius.

When we ran particle simulations (see below), we found some tunes developed halos. That is, the distributions in x or y developed long, Gaussian-like tails. This happened in two situations. First, we got halos whenever the quadrupoles were too far apart. We also got halos whenever the beam size in x or y was very small at some point in the upstream part of the HEBT. Because of this effect, we accepted only tunes with fairly constant beam sizes.

4 TRACE 3-D DESIGN

Figure 1 shows the TRACE 3-D output for our standard tune. The graph shows the initial and final phase-space ellipses at the top and the transverse profiles at the bottom. The beam is traced from the RFQ end wall to the 45-inch match point, i.e., 45 inches past the start of the nickel beamstop. The scale for the x and y profiles (4.5 mm total) is appropriate for the beam in the region of the quadrupoles. The

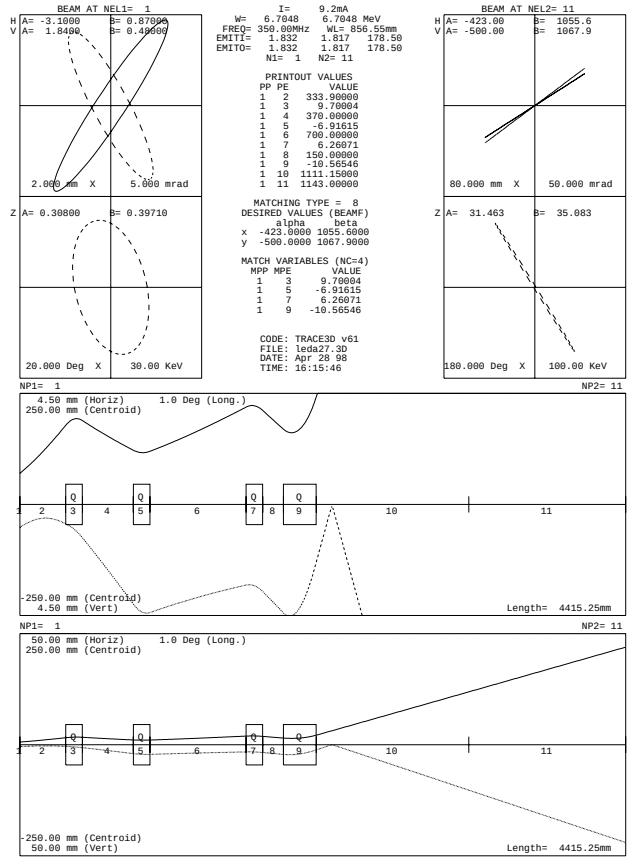

Figure 1: TRACE 3-D output for the standard tune. The beam is traced from the RFQ end wall to the 45-inch match point. The transverse profile plot is repeated at the bottom with a larger scale to show the beam in the beamstop.

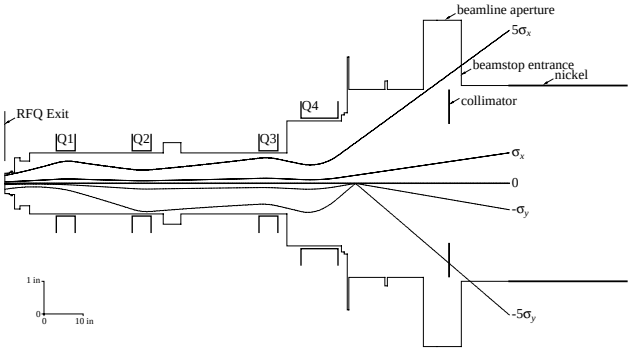

Figure 2: The 1-σ (rms) and 5-σ beam profiles compared to the minimum aperture in the HEBT beamline.

lower part of Fig. 1 shows the profile with a scale of 50 mm total to show the expansion of the beam in the beamstop. In our TRACE 3-D simulations, we use rms emittances and thus the plots show the rms beam sizes. The current we use (9.19 mA) is the actual current (103 mA) divided by $5/\sqrt{5}$. Figure 2 shows the rms and 5$\times$rms profiles together with the minimum beam apertures in the HEBT.

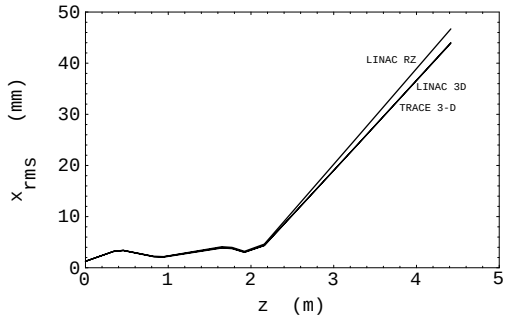

Figure 3: Rms value of x as a function of z for the r-z and 3-D PIC simulation using the LINAC code and the TRACE 3-D code. The two 3-D codes produced similar results.

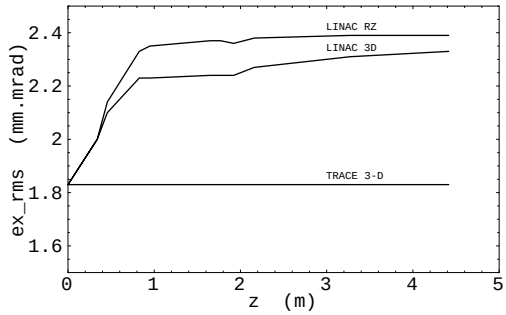

Figure 4: Rms value of x emittance as function of z.

5 SENSITIVITY STUDY

We studied the sensitivity of the beam at the beamstop to errors in the quadrupoles (strengths and offsets) and to various errors in the input beam. We found no errors that could not be handled by our diagnostics and control system. The beam spot at the beamdump depends on the beam current. While lower-current beams have a smaller spot size, the current density (current per unit area) is smaller than for the normal, full-current beam. There is no need to retune for different currents.

6 PIC SIMULATIONS

We verified our TRACE 3-D designs with particle-in-cell (PIC) simulations. We ran r-z and fully 3-D PIC simulations. Figure 3 shows $x_{\rm rms}$ as a function of z for our standard tune as predicted by TRACE 3-D and the r-z and 3-D versions of the PIC code LINAC[2]. The two 3-D codes agree very well but the r-z code produces slightly different results. As Fig. 4 shows, there is about a 30% emittance growth. This did not affect the TRACE 3-D result for the beam size because the emittance is so small. The conclusion is that 3-D effects are important but nonlinearities are not in predicting rms beam size. Our TRACE 3-D designs produce the correct rms beam at the match point.

PIC simulations are essential in determining if our tunes generate halos. Figure 5 shows the TRACE 3-D output for

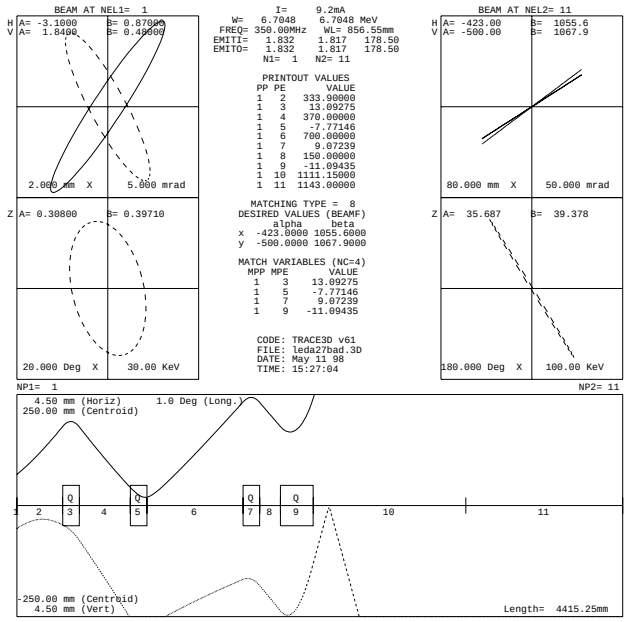

Figure 5: TRACE 3-D output for a bad tune, which has a halo in the x-direction. Halo-generating tunes have a small waist in the upstream part of the beamline.

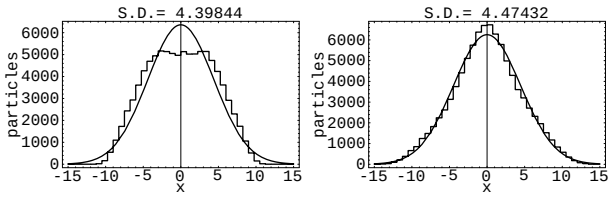

Figure 6: Beam profiles in the x-direction at the match point for the standard tune (left) and the bad tune (right).

another tune that produces the same beam at the 45-inch match point. Only the quadrupole settings are different. The input and final beams and all lengths are the same as before. We see that the beam has a small waist in x early in the HEBT. We find this characteristic is always associated with the existence of a halo. Figure 6 shows the x distribution in a 3-D PIC simulation at the 45-inch match point for both the standard and bad tunes. Also shown are Gaussians having the same rms values as the actual distributions. The halo is generated in the first part of the second quadrupole, just before the waist. Figure 7 shows the phase-space scatter plots in the x direction at the beginning and the center of Q2. We see that the distribution becomes very nonelliptical because of the nonlinear space-charge forces.

7 HALO EXPERIMENTS

Table 1 shows properties of the x profile at the wire scanner for both the standard tune and the bad tune. Also shown are a uniform (rectangular) and Gaussian distribution having the same sigma ($<x^2>^{1/2}$) value. A good way to characterize whether or not we have a halo is to determine the

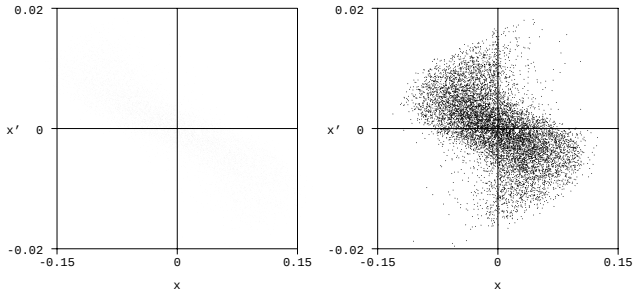

Figure 7: The x-x' phase-space scatter plots for bad tune at start of Q2 (left) and center of Q2 (right).

Table 1: Properties of x distributions at wire-scanner.

Beam	$<x^2>^{1/2}$ (mm)	$x_{\max}$ (mm)	$<x^4>/<x^2>^2$
Uniform	16	28	1.8
Gaussian	16	∞	3.0
Standard	16	41	2.2
Bad	16	56	2.9

kurtosis of the x or y distribution. The kurtosis is simply the fourth moment of the distribution, normalized by the square of the second moment to obtain a dimensionless quantity. The fourth moment depends on the whole beam distribution. It should be easy to measure even if the wire scanner does not have a large dynamic range (the amount of beam for the bad tune that is past the maximum $|x|$ value of the standard tune is only 0.35%).

8 CONCLUSION

Our HEBT design meets all readily quantifiable requirements. Our 3-D PIC simulations verify that the TRACE 3-D design code can accurately predict rms beam properties. Nonlinear space-charge effects are important, however. We have found that having adequate focusing (no less than four quadrupoles) and a good tune are essential to avoid halo formation, which could result in undesirable particle losses before the beamstop.

The codes clearly indicate when halo formation occurs. We therefore propose that we do some halo experiments at LEDA. We can obtain the required information from the wire-scanner data. If we verify the simulations' predictions about the differences between the good and bad tunes, we will have greatly increased confidence in the ability of our codes to correctly model nonlinear space-charge effects.

BEAM DYNAMICS SIMULATION OF THE SPALLATION NEUTRON SOURCE LINEAR ACCELERATOR*

H. Takeda, J. H. Billen, T. S. Bhatia
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

The accelerating structure for Spallation Neutron Source (SNS) consists of a radio-frequency-quadrupole-linac (RFQ), a drift-tube-linac (DTL), a coupled-cavity-drift-tube-linac (CCDTL) [1], and a coupled-cavity-linac (CCL). The linac is operated at room temperature. We discuss the detailed design of linac which accelerates an H^- pulsed beam coming out from RFQ at 2.5 MeV to 1000 MeV. We show a detailed transition from 402.5 MHz DTL with a 4 βλ structure to a CCDTL operated at 805 MHz with a 12 βλ structure. After a discussion of overall feature of the linac, we present an end-to-end particle simulation using the new version of the PARMILA code [2] for a beam starting from the RFQ entrance through the rest of the linac. At 1000 MeV, the beam is transported to a storage ring. The storage ring requires a large (±500-keV) energy spread. This is accomplished by operating the rf-phase in the last section of the linac so the particles are at the unstable fixed point of the separatrix. We present zero-current phase advance, beam size, and beam emittance along the entire linac.

1 LINAC STRUCTURES

We consider the DTL, CCDTL and two types of CCL part of linac structure. At the linac structure change between structures, we apply discontinuous accelerating electric fields between structures to maintain a continuous real-estate phase advance per unit length. The design phase was made continuous at the structure junctions to avoid the abrupt longitudinal separatrix change. The DTL with focusing lattice FOFODO structure accelerates the 2.5-MeV H^- beam from the RFQ to 20 MeV. Between the RFQ and the DTL, we have a symmetric beam chopper section which consists of a number of quadrupoles and three buncher cavities.

The CCDTL then takes the beam from the DTL and accelerates it to 94 MeV. To match the beam from the DTL to the CCDTL, we use the first two cavities (4 cells) of the CCDTL operating at –90° and adjust the first four quadrupole magnet strengths. Each cavity in the CCDTL contains a drift tube. A focusing (or defocusing) quadrupole magnet follows every two CCDTL cavities. In the DTL the transverse lattice is of type FOFODODO with a 4 βλ period at 402.5 MHz. Starting in the CCDTL the transverse lattice changes to FODO with a 12 βλ period at 805 MHz. The term FODO (pronounced "foe-doe") refers to singlet quadrupole magnets arranged in an alternating gradient focusing system. The letter O was originally a numeral zero, and indicates a drift space between a focusing magnet F and a defocusing magnet D.

Above about 95 MeV the efficiency of a conventional CCL exceeds that of the CCDTL. The 805-MHz CCL continues the 12 βλ periodic transverse lattice of the CCDTL. The first part of CCL consists of 8-cavity segments separated by singlet quadrupole magnets and accelerates the beam to 165 MeV. Above 165 MeV, the CCL consists of 10-cavity segments and completes the acceleration to 1000 MeV. The 8-cavity segments are used at lower energy to provide more space for the quadrupole magnets and diagnostic elements. This entire CCL maintains the FODO lattice structure with a transverse period of 12 βλ [3]. Table 1 shows the linac characteristics. Figure 1 shows the cavity field along the linac. The field is discontinuous, but the "real-estate" longitudinal focusing force which is proportional to E_0T averaged over a transverse focusing period is continuous, where E_0 is the average axial electric field and T is the transit-time factor. Figure 2 shows the design phase along the linac. Figure 3 shows the zero-current phase advance per transverse focusing period through the CCDTL and CCL.

Table 1. Linac characteristics

Linac Type	Energy (MeV)	Length (m)
DTL	2.50 to 20.275	8.712
CCDTL	20.275 to 94.428	68.78
CCL1	94.428 to 164.65	46.24
CCL2	164.65 to 1000.	369.94

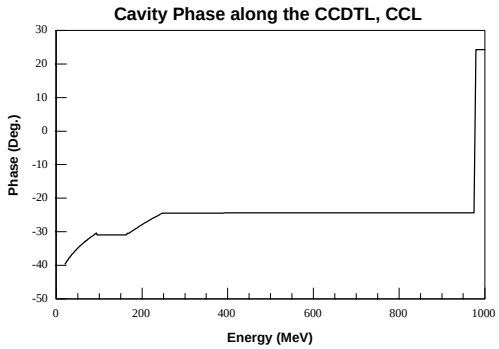

Figure 2. The design phase starting in the CCDTL. The phase change near the end of the CCL from –24 to +24 degrees increases the energy spread as required for ring injection.

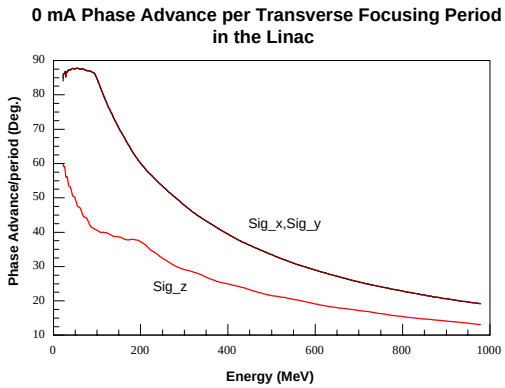

Figure 3. Zero-current phase advance per 12 βλ in the CCDTL and CCL.

2 DTL TO CCDTL TRANSITION

To achieve a smooth beam match between the DTL and the CCDTL, we require that the transverse and longitudinal real-estate phase advances are continuous across the matching section. The longitudinal matching section consists of the first two CCDTL cavities with a total of 4 accelerating gaps operating at –90°. The transverse matching section consists of four quadrupole magnets after the first segment of the CCDTL. The zero-current transverse phase advance at the end of the DTL is 57.35° with a transverse period 4 βλ at 402.5 MHz. The equivalent phase advance at the entry to the CCDTL, which operates at 805 MHz is 86.025° (= 57.35*12/(4*2)). The longitudinal phase advance is 40° over the transverse period 4 βλ. This translates to 60° at the CCDTL entry. Table 2 shows the matching section linac parameters. Figure 4 shows the transverse and longitudinal beam profiles at the matching section performed with the TRACE 3-D code [4].

Table. 2. Matching section parameters at the CCDTL.

Beam Element	Parameters
Drift	13.27 cm
Q between DTL and CCDTL	–2.692 T
Drift	7.0 cm
Q1	+2.161T
Q2	–2.278T
Q3	+2.261T
Q4	–2.199T
First 2 Cavities	1.9529 MV/m, –90°

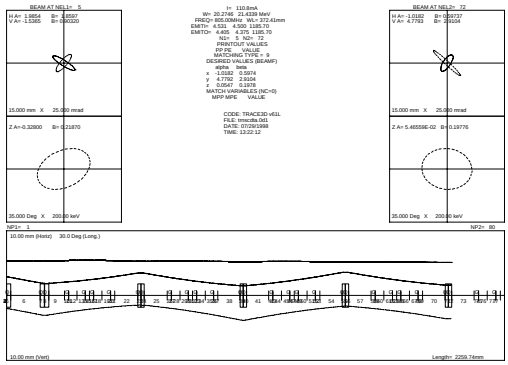

Figure 4. Beam profiles in the first few lattice periods of the CCDTL. This part of the structure is used to match the beam from the DTL.

3 PARMILA SIMULATION FROM DTL TO CCL

Starting at the entry to the DTL with the RFQ exit beam distribution we performed a PARMILA 10,000-particle simulation. The normalized rms emittance was 0.01845 π cm-mr in the transverse phase plane, and 0.1056 π deg-MeV in the longitudinal plane. The beam microbunch current was 55.4 mA. Figure 5 shows the rms beam radius, the maximum radius, and the linac aperture along the linac. It shows that we have sufficient beam clearance along the linac. Figure 6 shows the normalized rms emittances through the linac. The artificial discontinuity in longitudinal emittance at 20 MeV is caused by the doubling of the rf frequency.

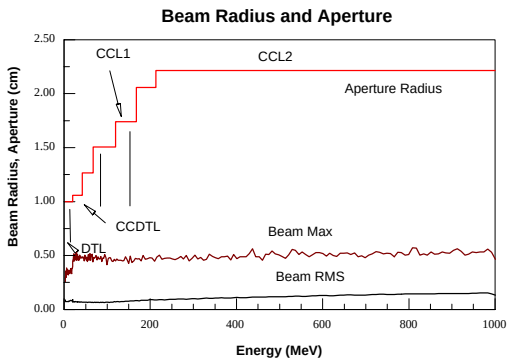

Figure 5. Linac aperture and beam size along the linac.

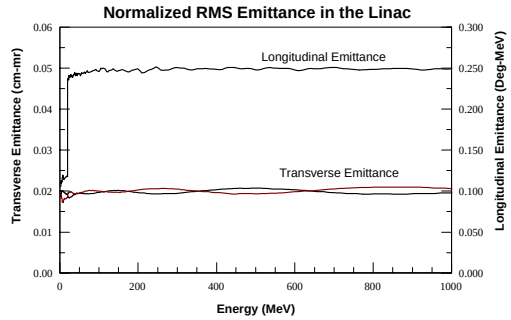

Figure 6. The normalized rms emittances are constant along the linac.

The beam profiles x, y, phase ϕ and energy W through the entire linac from DTL to CCL are plotted in Figure 7. By shifting the rf phase to operate at +24 degrees for the last five 10-cavity segments of the structure, the energy width increases from ±163 keV to ±667 keV.

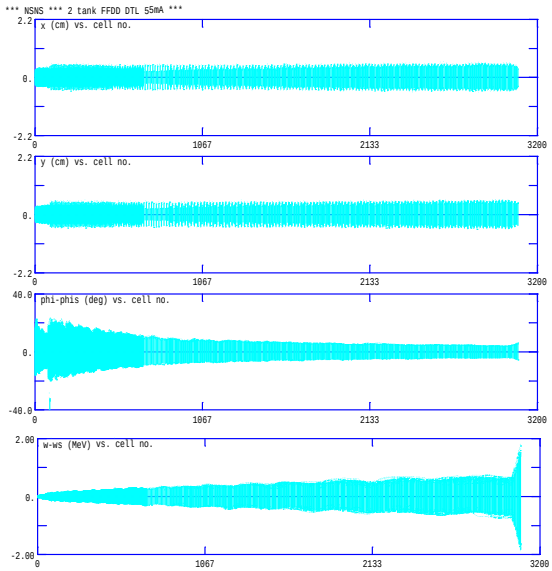

Figure 7. The beam profiles x, y, phase ϕ, and energy W along the linac from DTL. Shifting the rf phase to +24° expands the beam energy width.

4 END-TO-END PARMILA SIMULATION FROM RFQ TO CCL

A 30-mA beam with normalized transverse rms emittance 0.2 π mm-mrad was generated with 4-d waterbag distribution for the RFQ input. The RFQ accelerates the beam to 2.5 MeV. Then a medium-energy beam transport section (MEBT), which houses the chopper and consists of 18 quadrupole magnets and 3 buncher cavities, guides the beam to the DTL. At the entry to the MEBT, the normalized rms beam emittances are 0.206 π mm-mrad transversely and 0.1π MeV-deg longitudinally. Figure 8 shows the x and y beam profiles at the interface between the MEBT and the DTL.

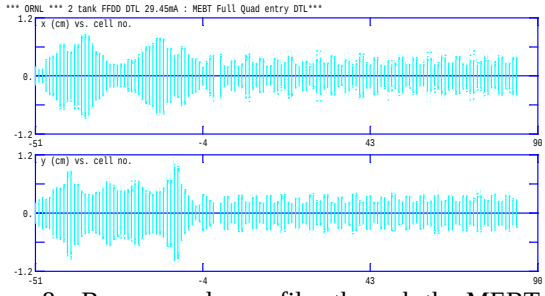

Figure 8. Beam x and y profiles through the MEBT and DTL for a 29.4-mA beam.

Figure 9 shows the x, y, phase, and energy profile of the end-to-end simulation showing from the MEBT through the CCL. The beam starts at the RFQ.

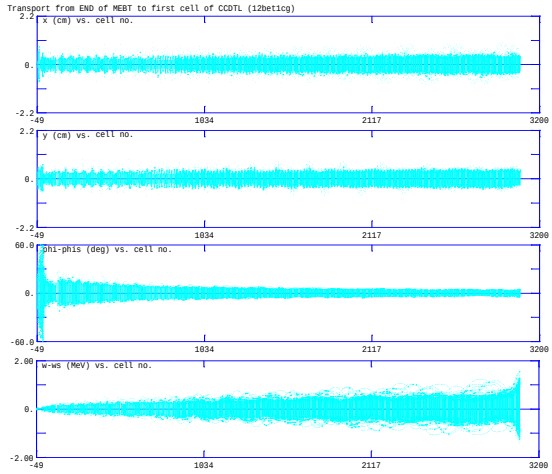

Figure 9. End-to-end simulation for a 29.4-mA beam. The profiles are the same as in Figure 7. The plot shows the profiles starting at the MEBT, but the simulation started at the RFQ entrance.

5 SUMMARY

The PARMILA simulation from the DTL to the end of CCL shows that the beam could be accelerated to 1000 MeV without loss by the sequence of linacs DTL, CCDTL, and CCL.

New criteria arise when high-current CW linacs are considered. The main requirements for such linacs are beam acceleration with very low beam losses and reduced intervane voltage. In such cases the traditional algorithms can lead to undesired versions of the RFQ.

New concepts for parameter choices based on optimization methods and scientific visualization of space charge-dominated beam are incorporated in the new multilevel codes RFQ.3L [1]**.**

This new RFQ code package gives users the possibility to proceed successfully from input data up to accelerating-focusing channel design and space-charge-dominated (SCD) beam simulation. There are two main features: a maximum of scientific visualization for each calculation step and the possibility to cut off undesired linac versions long before the time-consuming calculations start. The package contains codes with three levels of mathematical model complexity.

The first-level codes make only a preliminary choice of the main parameter arrays on the basis of a simplified physical model. These codes are richly supplied with visual information, which helps to quickly find the best linac version.

The second-level codes are used for channel data calculations with the real shape of the RFQ vanes. Information from the first level codes is used as input data.

The third-level codes are based on information from the first and second level codes and on complex PIC-models that are needed for a correct beam simulation in the chosen channel version.

In the case of the IPHI high-current CW RFQ, radiation purity (minimum of lost particles) and reduced intervane voltage are considered as the main optimization criteria**.**

RFQ.3L codes have been used to find the region of RFQ parameter space most likely to satisfy the design requirements. The process is fast because the beam simulation is used only for the final RFQ version. RFQ.3L gives an user intellectual advises and helps him to come to the best RFQ version by the shortest way.

The first level stage the channel, data must be chosen in a way that beam transmission can be as large as possible. The periods of vane modulation are calculated at the second stage taking into account the "ideal" vane shape (2 terms potential) and nonlinear space charge forces. The functions $U(n)$, $m(n)$, $\varphi_s(n)$ and $R(n)$ obtained at the first stage are used as input data. The third level codes LIDOS.PIC are used for beam simulation. Beam is represented as a set of macro-particles and Poisson equation is solved at every step with boundaries in the form of "ideal" vane shape. The amount of macro-particles is 50 000. A saved cartoon is used for the presentation of the beam transport. Phase portraits all along the RFQ are showed on cartoon's pictures, as well as plots of several beam parameters (transmission factor, rms emittance, mean longitudinal and transverse kinetic energies…). Information on lost particles, their input distribution, total lost power and maximal lost power per unit length are also obtained. Distribution of lost particles as functions of length along the RFQ, number of RFQ periods and particle energy are presented.

When the RFQ structure is chosen (first level) and primarily checked (third level), the 3D calculation of the real external electrical fields (i.e. fields from the electrodes, without the beam Coulomb field) is performed for the real form of the electrodes. On this stage the second-level codes are used. These codes calculate the distribution of the field potential for each cell in an electrostatic approach. The calculations are the solution of the Laplace equation with the relaxation method. As the field is supposed to be quadruple-symmetrical, the potential distribution is calculated only for one quarter of the whole region. As the parameters of neighbor cells (modulation, mean radius, length) are very close to each other and the fields differences in them occur to be less than the calculations accuracy, then base cells are used for the definition of the fields in the whole channel. The field in a cell is calculated as a function of two parameters: m - the electrodes modulation- and the ratio $s = R_0/L$, where L is the cell length. Cells are chosen based on those parameters and the fields $E(m_n,s_n)$, $E(m_n,s_{n+1})$, $E(m_{n+1},s_{n+1})$ are then calculated. Thereafter, the field in cells with intermediate values of m and s is calculated with a linear interpolation between the three base fields. Total number of base points is 39. The new length of the cells are calculated taking into account the efficiency of acceleration in real fields using the dependencies of $\varphi_s(n)$ and $m(n)$ defined previously.

On the last stage, the calculations of the particles dynamics is performed taking into account Coulomb forces and real shapes of the electrodes. The code

LIDOS.PIC is used for this task where the calculated real fields are used instead of the ideal fields. On this stage study of different tolerance influence (channel axis displacement, different sorts of voltage deviations) on beam dynamics are also performed.

The above code tools were used for RFQ designing in favor of IPHI Project (CEA, France) [2]. The following parameters were preset as well as some restrictions and requirements:

Accelerating Particles	protons
Input Energy	0.095 MeV
Output Energy	5 MeV
Beam Current	100 mA
Total Beam Emittance	0.15π cm·mrad
Operating Frequency	352 MHz
Peak Surface Field	< 29.5-30 MV/m
Kilpatrick Factor	< 1.6
Length	about 8 m
Beam Transmission	> 90%
Power of Lost Particles	< 1–1.5 KW

Minimum of Lost Particles with energy more than 3 MeV

A strategy was elaborated for creating a RFQ version who satisfies the conditions set above. A lot of versions were examined to create the needed channel. Following is the essence of this strategy: If the calculations show that particles capture in the accelerating regime is sufficiently high (~ 95%) then one can conclude that the regularities for the equilibrium phase φ_s variation and for the acceleration rate *UT* are defined finally. To prevent transverse particles losses in the last part of the channel (particles with high energy), it is necessary to increase the focusing strength when they achieve the first minimum of phase oscillations (first focus) and to increase the aperture of the following channel part. Besides, it is necessary to satisfy the upper limit of the field $E_r=U/R_0$. The aperture increase must be accompanied with the proportional voltage increase. The increasing of the focusing strength diminishes the size of the beam halo in the region of first focus. Simultaneously, the aperture decrease at this location leads in halo losses in a channel region where particle energy slightly differs from the input value. According to calculations and investigations there is a range where the raise of the transverse beam size due to the decreasing focusing strength is compensated by the aperture increasing. Thus we can avoid losses of high-energy particles in the last channel part. To keep the product $U \cdot T$ constant, we must also change the vane modulation.

The best RFQ version with constant U and R_0 was first calculated (U = 91.6 kV, R_0 = 4 mm). This version gave good transverse and longitudinal captures but leads in losses of high energy particles. In order to minimize power of lost particles the plots $U(n)$ and $R_0(n)$ were chosen and correction of $m(n)$ was made. In optimal case the mean bore was decreased from 4 to 3.6 mm and then increased up to 5 mm. Intervane voltage must be increased up to 25% from input to output. Vane modulation at the RFQ output does not exceeded 1.5. It means that bore radius is increasing not only at the cost of $R_0(n)$ increasing, but also at the cost of $m(n)$ decreasing. The chosen parameters are showed on Figs. 1-2 as functions of the period number. In Tables 1 and 2 RFQ parameters are given.

Table 1. Main RFQ Parameters

Operating Frequency	352 MHz
Length (w/o output part)	7.906 m
Electrical Length	9.28 (λ=0.85 m)
Number of Periods	267 (534 cells)
Bore Radius, mm	4 → 3.43 → 3.95
Vane Modulation	1→ 1.53
ρ/R_0	0.85
Vane Voltage, kV	91.6→ 82.4→ 114.4
Kilpatrick Factor	1.62 – 1.64

Table 2: Parameters of RFQ Parts

	W, MeV	φ_s, deg	Cell Nos	L, m
Matching Section and Shaper	0.104	-83	180	1.098
Gentle Buncher	0.72	-40	190	1.7
Acceleration	5	-35	164	5.108
Total	5		534	7.906

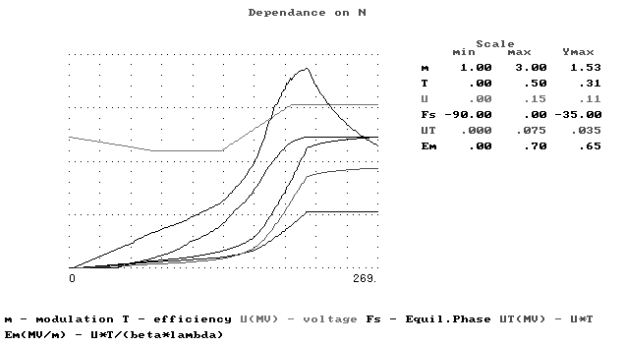

Fig.1.

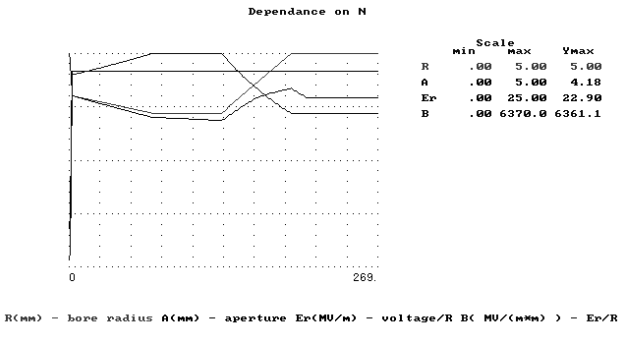

Fig.2.

The arrays of the calculated fields in the input section and in regular channel are got united. The united array is used for beam dynamics calculations We have not understood that sentence.

The results for different RFQ versions are presented below in Tables 3-5. We indicate the beam normalized emittance, *E*, the overall beam transmission, *Trans*., the accelerated particle, *Acc*., as well as the integrated power of lost particles, *P*. All results are presented for a beam current of 100 mA. The initial particles distribution is a uniform filling in the 4-dimensional ellipsoids in phase space X,X',Y,Y' with uniform distribution along the longitudinal coordinate *Z* and without longitudinal velocities spread. Version 0 is with constants *U* and R_0. Versions 1a and 1b correspond to RFQ structure with ideal RF fields (no multipoles, with images effect), 1c – with real RF fields. The next versions are presented for real RF fields and beam emittance of 0.15π cm·mrad.

Table 3

Version	• *(π·cm·mrad)*	*Trans* (%)	*Acc* (%)	*P* (kW)
0	0.1π	97.7	97.0	1.55
1a	0.1π	98.1	96.8	0.59
1b	0.15π	97.6	96.2	0.80
1c	0.15π	95.9	92.8	0.92

As it is seen from the Table 3 new version 1b with ideal fields leads practically to the same results as version 0, even for greater emittance (0.15π versus 0.1π). The comparison of versions 1b and 1c shows that in real field the overall current transmission suffer a diminution of 1.7% and a capture diminution of 3.5%. For the investigation of the influence of real fields, non-linearity in matching section on overall current transmission there was performed the calculation of the particles dynamics for the intermediate version when the real regular part was combined with ideal matching section. The difference occurs to be practically zero. One may conclude that the non-linearity of the regular channel field diminishes both the overall current transmission (95.9 versus 97.6) and the number of accelerated particles (96.8 versus 98.6). Note that the definition of the input beam parameters matching with real nonlinear channel represents itself a separate problem. When the mean square emittance $\langle xx' \rangle$ calculated in z points only slightly oscillates through z, then we have a good beam matched.

Among all calculated effects, a great interest was expressed to study the influence of a channel axis displacements on output beam parameters as well as influence of a tilt of intervane voltage. In Table 4 resume this analysis.

Version 2a – the channel axis is uniformly shifted of 0.1 mm in x and y.

Version 2b – the channel is divided in 4 sections, the ends of sections are shifted of ± 0.1 mm in *x* and *y*, and the axis represents broken line without tears.

Version 2c – the channel is divided in 4 sections, the beginning of each section is shifted on –0.1 mm in *x* and *y*, the end of each section is shifted on +0.1 mm, the channel axis has tears at sections ends.

Table 4

Version	*axis*	*Trans* (%)	*Acc* (%)	*P*
1c	ideal	95.9	92.8	0.92
2a	straight	95.5	92.6	1.05
2b	broken	95.5	92.5	1.06
2•	disrupt	93.6	90.6	2.18

As it is seen from the table, the most dangerous are the independent shifts of sections ends (no continuity of the channel).

The influence of RF fields tilts in RFQ sections on beam motion was a goal of the next series of beam simulation. There are results for the following versions:

3a - RF fields are decreased at the beginning of each of four sections by 5%, and increased at the ends by 5%; 3b – reversed for 3a, +5% then –5%; 3c - RFQ linac was considered as unique section. At the beginning of the linac, RF fields are increased by 5%, at the ends - decrease by 5%; 3d - RFQ linac was considered as unique section. At the beginning of linac RF fields are decreased by 5%, at the ends - increased by 5%. All RF variations are linear.

Table 5

Version	*Section Nos*	*RF Field*	*Trans (%)*	*Acc (%)*	*P*
1c	1	Nominal	95.9	92.8	0.92
3a	4	Increasing	93.2	90.5	2.58
3b	4	Decreasing	95.3	92.0	1.54
3c	1	Increasing	94.9	91.3	1.32
3d	1	Decreasing	96.4	93.9	0.73

As is easy to see, the RF field tilts from smaller values at the beginning of sections to larger ones at its ends decrease beam transmission in a greater extent that the opposite case. Nevertheless, the last case (version 3b) leads to a beam halo growth on longitudinal phase plane.

The third level code formally called LIDOS.PIC also implement error studies (vane voltage, misalignment and tears…). It can be used to help the designer to set the manufacturing precision and to get the expected transmission for multi errors.

MULTI-FIDUCIAL TECHNIQUES FOR TRACKING LARGE PHASE SPACE DISTRIBUTIONS IN NON-LINEAR FIELDS

S.M. Lidia*
E.O. Lawrence Berkeley National Laboratory, Berkeley, CA 94720 USA

Abstract

One of the challenges in tracking intense beams through linacs is to account for the differences in non-linear forces experienced by portions of the beam separated by large regions of phase space. In many situations, the high-order maps generated by a single fiducial trajectory fail to capture or describe the dynamics of distant particles within the beam. I describe here a technique which overcomes this difficulty by piecing together lower-order maps induced by multiple fiducial orbits. This atlas of maps can more accurately track the evolution of a beam spread over a large phase space region. I discuss applications of this technique to simulating beam dynamics in two-beam accelerators.

1 INTRODUCTION

Particle dynamics in relativistic klystrons pose several thorny problems for simulations. Possibly the most important element of the dynamics in a relativistic klystron two-beam accelerator (RK-TBA) [1] occurs in the longitudinal phase space. The beam is modulated at high frequencies (11 - 40 GHz), and each bunch carries a charge of 10's-100's of nC. Space charge effects will produce debunching forces (a capacitive impedance) which is counteracted by (inductively) detuning the rf output structures. A bunch will undergo numerous synchrotron oscillations during transport through the full-scale device. Also, the bunches are not short compared to the rf wavelength; they typically subtend 60°-120° of rf phase. Hence, they sample very non-linear fields in the rf output structures.

From this description we can identify the main problems present in a device simulation. The beams are sufficiently intense that space charge forces present more than a small perturbation. The beamline elements are necessarily spaced close together, and this requires treatment of overlapping, non-linear fringe fields. Transverse focusing is strong so that a complete betatron oscillation occurs between rf output cavities (~1 m). Transverse emittance, while low, is still sufficiently large that particles at the beam edge sample significant non-linearities present in the beamline elements. The instantaneous energy spread is large (~10%) to handle the low-frequency BBU, and to produce the bunching by rf rotation. The particle simulation, of necessity, must track many, many particles to provide adequate sampling of both the beam phase space and the fields experienced.

One of the main disadvantages of tracking by mapping can be seen immediately. The resultant map is fundamentally a power series expansion about the initial and final coordinates of the fiducial orbit. When the extent of the beam distribution in phase space is no longer 'small' in some sense, then the map generated about the given fiducial orbit loses accuracy when applied to the outlying particles. There are various solutions that may be applied to this problem. The pre-calculated fiducial may not faithfully represent the orbit of the beam centroid, but another fiducial may be found which does. The order of non-linearity carried by the calculation may be too low to adequately describe the given external field structure. Increasing the order of the calculation may be sufficient. However, these 'fixes' make for a good solution only when the beam occupies a small enough region of phase space such that a single fiducial orbit and the map it induces captures the essential dynamics.

In many applications of intense, modulated beams, however, this is not the case. These beams are most often present in single pass, linear beamlines, with constantly changing parameters. The beams may also have a relatively long pulse length with respect to any time-dependent rf fields they encounter. To sufficiently capture that interaction via a single map would require a degree of non-linearity far too high, and involve the computation of too many map coefficients, that the intrinsic efficiency of the method would be quickly lost. This problem is only compounded when self-field effects are included.

2 CONSTRUCTION OF A MULTI-FIDUCIAL MAP

The construction and evaluation of the multi-fiducial map upon the particle coordinates is straightforward. Algorithmically, it may be described by a sequence of simple steps. In any calculation, the beamline under consideration is initially divided into a set of mapping intervals. Beam particles are propagated by mapping successively through each interval. We define a 'center' fiducial as a single orbit that continuously threads through all the mapping intervals. This single fiducial is important to maintain as it provides a single reference frame, and hence a reference 'clock' and 'meter stick', for

* The author may be contacted via email at SMLidia@lbl.gov.

the problem. Each mapping interval is defined by referring to the coordinates of this center fiducial.

For each interval, the beam phase space is partitioned and a set of nominal values of coordinates are selected, one set for each region. These nominal coordinate sets provide the initial values for 'sub-fiducials' and their associated maps to be constructed. The particles in each region are then propagated according to these local maps. The number and method of partitioning is highly dependent upon the physics to be modeled. Partitioning should represent a balance between the order of non-linearity carried by the calculation, the degree of non-linearity present in the external fields and sampled by the beam, and the non-homogeneity of the beam density profile when self-fields are a concern. For example, in a magnetostatic transport region, only a single fiducial and map may need to be calculated. Whereas, in a region with time-dependent rf fields where the wavelength and period of the external fields is comparable to the bunch length and transit time of the beam, then perhaps 10 or more fiducials may be required. When self-field effects are included, the number of partitions may depend upon the non-uniformity of the beam density profile.

3 LONGITUDINAL BEAM DYNAMICS IN AN RF CAVITY

As an example to illustrate the method, I consider the problem of tracking a bunched beam through an rf cavity. Here, I follow only a single bunch, where the modulation carried by the beam is comparable to the rf period of the cavity, as in the case of an RK-TBA. Also, I will only consider the longitudinal phase space. The center fiducial is placed at the center of the beam distribution, with the sub-fiducials at locations that span the interval in arrival time (t) of the bunch at a given beamline position (z). The initial bunch distribution and fiducial positions is shown in Figure 1.

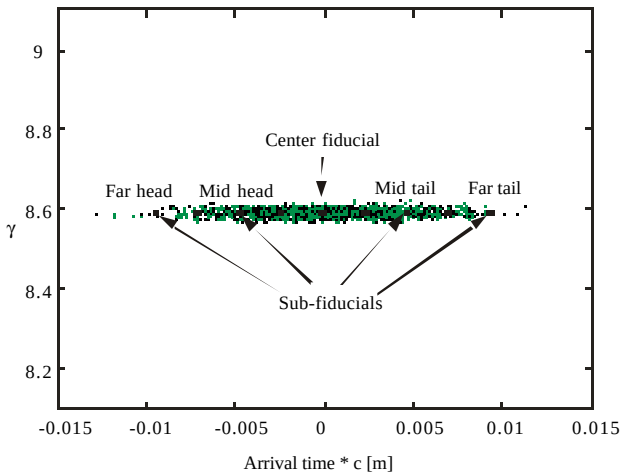

Figure 1. Initial fiducial coordinates and beam distribution in longitudinal phase space.

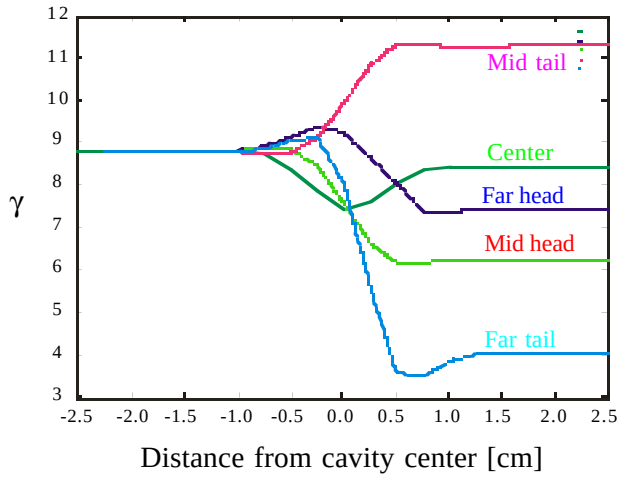

Figure 2. Fiducial trajectories in an rf cavity

3.1 Fiducial Particle Trajectories

The fiducial trajectories are calculated using the exact single-particle equations of motion. During transit through the rf cavity field, different fiducials will experience different forces due to arrival time differences. The final coordinates of the various fiducials will generally differ in a non-linear way. The fiducial trajectories in this case are shown in Figure 2.

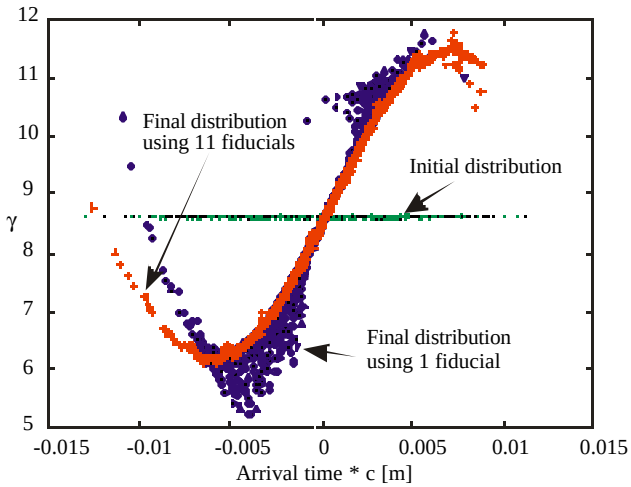

Figure 3. Final longitudinal beam distribution under a 3rd order map with multiple fiducials

3.2 Comparison of Single Vs. Multiple Fiducial Calculation

The maps induced by the fiducial orbits can, in principle, be calculated to arbitrary order. The accuracy of the mapping for outlying particles is determined by this order parameter. In Figure 3 is shown the results of the mapping through the rf cavity for two cases. The first case uses a 4th order Hamiltonian, with a single fiducial (identical to the center fiducial in Figures 1 and 2). The second case uses a 3rd Hamiltonian, but with 11 fiducials. In the first case, the combined effect of sampling only low-order field variations and tracking outlying particles

leads to inaccuracies. The final distribution suffers additional local energy spread growth, and does not exhibit the appropriate curvature, as seen in the head of the bunch. The second case avoids these problems by sampling the fields at the location of the outlying particles. The effects of errors in the field evaluation and in large coordinate deviations between particles and their associated fiducials are kept small.

4 INCLUSION OF SELF-FIELD EFFECTS

4.1 Split Operator Algorithm

Two separate mappings are applied to the particle phase space coordinates using split-operator techniques [2]. These techniques are based on splitting the Hamiltonian into pieces that can be solved exactly (or through some desired order of accuracy), and then combining the separate maps to produce an approximate map for the full Hamiltonian. Split operator symplectic integration algorithms, including the well known 'leap-frog' algorithm of plasma physics simulations [3], are widely used in the treatment of Hamiltonian systems.

The total Hamiltonian is represented in the form

$$H_{tot} = H_{kin} + H_{ext} + H_{self} , \qquad (1)$$

where H_{kin} is the kinetic portion describing single-particle motion in the absence of all fields, H_{ext} is the contribution from external fields, and H_{self} is the contribution from self-fields. The maps from the first two contributions are calculated together, while the map resulting from self-forces is calculated separately. A combined map is then produced to advance particles over an interval τ. Accurate through second order in this step, the combined map is expressed as

$$M_{tot}(\tau) = M_{kin+ext}(\tau/2)\, M_{self}(\tau)\, M_{kin+ext}(\tau/2). \qquad (2)$$

The self-fields are determined by numerical solution of Poisson's equation on a 3-D Cartesian grid in the beam's rest frame. Standard techniques are used to solve for the fields at the grid nodes. For accurate representation of the 3-D fields from a bunched beam, we may use grid sizes up to 64x64x512 nodes, as well as 10^4-10^5 macroparticles.

4.2 Changing Representations

Since we are solving the Maxwell equations at a given instant in time, the particle distribution be represented at a given moment. However, for the single particle maps, we represent the particles at a given beamline location (z), with a spread in arrival time (t). To faithfully calculate the self-forces, then, we must change the distribution from a 'constant-z' to a 'constant-t' representation.

The multi-fiducial approach again provides some utility. A visual aid to the process of changing representations is provided by the 'world-line' diagram of the fiducials, Figure 4. The fiducial trajectories (z vs. t) are shown as world-lines. The constant-z beam distribution is shown as black line segments. The first step is to calculate the motion of the sub-fiducials about the center fiducial, and the associated non-linear maps. This brings all the fiducials to the same time, but at different beamline positions (green lines and arrows). The particles attached to a given sub-fiducial are still spread in time (red line segments). The last step is to apply a linear transformation to all the particles associated with a given fiducial, to bring them to the nominal time (blue line segments). The beam distribution now exhibits a spread in beamline position consistent with observation at a given moment in time.

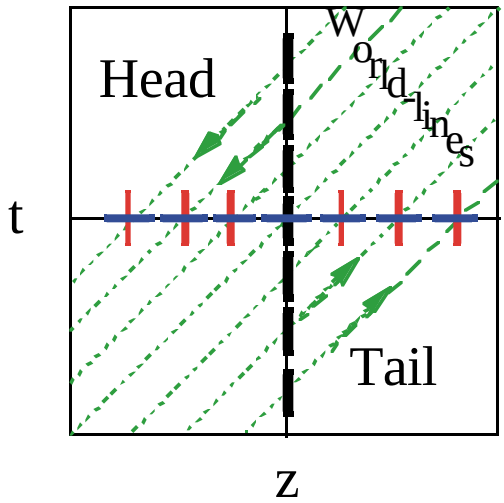

Figure 4. Changing beam distribution representation from constant-z to constant-t.

5 CONCLUSIONS

I have presented a new method for improving the accuracy of tracking algorithms, by using low-order integrators and multiple fiducials. Extensions to self-field calculations have also been made.

PRODUCTION OF NEGATIVE HYDROGEN AND DEUTERIUM IONS IN MICROWAVE-DRIVEN ION SOURCES*

David Spence, Keith R. Lykke **
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

We report progress we have made in the production of negative hydrogen and deuterium atomic ions in magnetically-confined microwave-driven (2.45 GHz) ion sources. The influence of source surface material, microwave power, source gas pressure and magnetic field configuration on the resulting ion current is discussed. Results strongly suggest that, at least in our source, vibrationally excited molecular hydrogen, the precursor to atomic negative ion production, is produced via a surface mechanism suggested by Hall et al. [1] rather than via a gas phase reaction as is generally believed to be the case in most ion sources.

1 INTRODUCTION

In order to accumulate (store) or accelerate large currents of protons (H^+) in circular machines, it is necessary, from phase-space considerations, that the ions be injected into the circular storage/acceleration ring in the form of negative ions, H^-, with the H^- being stripped of its electrons to form H^+ at the point of injection. Linac accelerator performance can also be significantly improved through simultaneous acceleration of positive and negative ion beams. Suitable positive ion sources are available now, but negative ion source development has lagged somewhat.

All advanced high current H^- sources currently available, including surface sources and RF driven (2MHz) volume sources require the addition of cesium in order to achieve high H^- current. This is undesirable for several reasons, not the least being the technical problems associated with introduction of cesium into the source in a controllable manner over a long period of time. Moreover, all high current RF H^- and D^- sources developed to date consume tens of kilowatts of power and can only produce beams of a few mA per square centimeter of extraction aperture when operating cw (i.e., 100% duty factor).

Our novel approach to high current cw H^- and D^- formation involves modification of an extremely simple low power consumption (100's of watts vs. 10,000's for other type) microwave-driven source.

*Work supported by US DOE via Laboratory Directed Research and Development Funds.

Previous attempts elsewhere [3] at negative ion extraction from this type of source have been singularly unsuccessful. Our approach involves application of pioneering studies by Hall et al. [1] which demonstrated the effectiveness of freshly evaporated tantalum surfaces in producing copious quantities of vibrationally excited molecular hydrogen (a required precursor to H^- formation). The observations of Hall et al. appear to never have been deliberately, or successfully, applied to the production of high-current cw H^- or D^- beams.

2 APPARATUS AND SOURCE DIAGNOSTICS

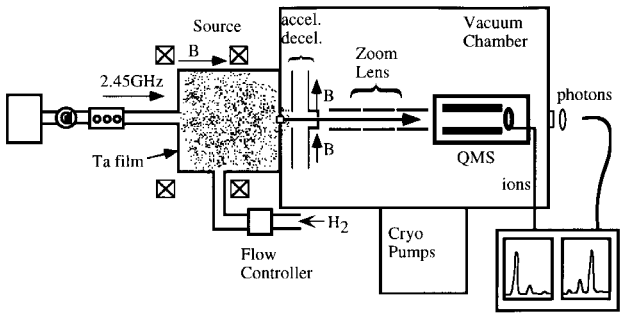

Figure 1: Schematic of apparatus.

The major components of our apparatus shown in Fig. 1 include a magnetically-confined microwave-driven (ECR) source purchased from Atomic Energy of Canada, Ltd. which is powered by a 2.45 GHz microwave generator (2 kW). The microwave generator is coupled to the source via a circulator and a four-stub autotuner. The ion source is attached to a large high-vacuum oil-free diagnostic chamber with a base pressure of $1x10^{-8}$ Torr.

Ion beams extracted at few hundred volts from the 5 mm source aperture by an accel-decel arrangement are primarily collected on the decel electrode that is in the configuration of a faraday cup. A 0.5 mm aperture in the decel electrode allows a small portion of the beam to be transported to a quadrupole mass spectrometer (QMS) via an electrostatic zoom lens for quantitative beam composition measurement. Light from the ion source is monitored by an optical monochromator by a clear line-of-sight through the QMS (sapphire window). The monochromator continuously monitors the atomic hydrogen Balmer α radiation (656 nm) to give a measure

of the atom concentration in the source under varying conditions.

3 H^-, D^- PRODUCTION MECHANISMS AND RESULTS

The mechanism for production of H^- is via the dissociative attachment of slow (<2 eV) electrons to vibrationally excited molecular hydrogen [H_2(v)], i.e.,

$$e_{slow} + H_2(v) \rightarrow H^- + H \quad (1)$$

The initial production of H_2(v), the precurser of H^-, is generally accepted to be by excitation of ground state hydrogen H_2 in the gas phase by fast electrons, i.e.,

$$H_2 + e_{fast} \rightarrow H_2(v) + e_{fast} \quad (2)$$

It is the initial production of H_2(v) that is the limiting step in the production of H^-.

Our novel cw H^- source takes advantage of observations (in experiments not directly related to ion sources) that copious quantities of H_2(v) are produced by recombinative desorption of two hydrogen atoms on a tantulum surface (M) (the Eley-Rideal reaction mechanism) i.e.,

$$H(g) + H(ads)M \rightarrow H_2(v)(free) \quad (3)$$

where H(g) is an atom in the gas phase and H (ads) is an atom adsorbed on a tantalum surface.

In order to produce H_2(v) via equation (3) we have sputtered a thin layer of Ta on the inner surface of our ion source. Our earlier experiments [3] used a bulk Ta liner to the source, which, though effective in producing H^- ions led to strong effects. Namely, Ta like other transition metals strongly absorbs hydrogen, which would periodically escape the metal in large pressure bursts. Use of a thin Ta film avoids this unwanted effect. Also, in order to prevent destruction of H^- by fast electrons in the source the solenoids are centered over the microwave window rather than over the center of the source. This results in the magnetic field diverging at the extraction aperture and diverting hot electrons. Failure to do this initially resulted in no H^- ions being extracted.

Electrons necessarily extracted along with the negative ions were removed from the beam prior to mass analysis by a weak (~30 Gauss) transverse magnetic field in the region of the accel-decel electrodes. About 100 mA of extracted electrons were collected on these electrodes.

Simple arguments show that if production of H_2(v) occurs via equation (2) (as previously generally believed), then production of H^- (D^-) is proportional to $[e]^2$, where [e] is the electron density in the plasma, whereas if it is via equation (3) then H^- (D^-) production is proportional to $[e]^3$. If one assumes that [e] is proportional to microwave power (as we can demonstrate for H^+ production), then the H^- current will be proportional to $(power)^3$. This is indeed what we observed, shown in Fig. 2 below, thus confirming a novel mechanism for production of H^- and D^-.

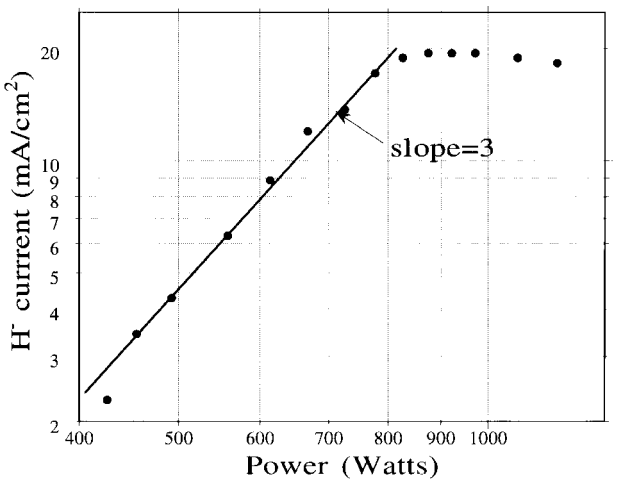

Figure 2: Log-log plot of H^- (D-) current extracted from microwave driven (ECR) source vs. microwave power to source. Plot indicates current is proportional to cube of power and strongly supports the surface production of H_2(v) hypothesis.

Based on the ratio of total H^+ extracted to H^+ sampled by the mass spectrometer in other experiments, we estimate that a total H^- current of 4-5 mA being extracted from the 5 mm diameter source aperture.

A comparison of the performance of our H^-, D^- ECR source compared with the arc-driven CWDD source at ANL, the previous D^- cw current record holder, is shown in the table below.

	Current	Beam Aperture	Current Density	Power Consumption
Present cw source H^-, D^-	4-5 mA	5 mm	20 mA/cm^2	700 W
CWDD source D^-	22 mA	23 mm	4 mA/cm^2	50,000 W

Because of H_2/D_2 isotope effects, the production rate for D- is generally much lower than H^-, often by a factor greater than ten. This results from H_2(v) production via equation (2) leading to low vibrationally excited levels from which the isotope effect is pronounced, whereas H_2(v) via equation (3) is expected to lead to populations of high vibrationally excited levels from which the isotope effect can disappear. This is what we observe in our experiments. Figure (2) shows H^- and D^- mass spectra obtained under identical experimental conditions where the cw ion currents are represented by the areas of the peaks and are essentially the same for H^- and D^- and indicating little or no isotope effect.

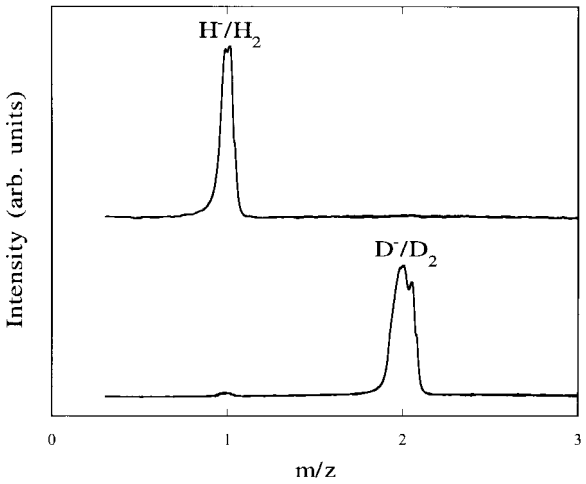

Figure 3: Mass spectra of H^-/H_2 and D^-/D_2 extracted from modified microwave driven (ECR) ion source. Spectra obtained under identical source conditions (power, density, etc.) shows no isotope effect for H^- D^- production. A first for any type of source.

BEAM SIMULATIONS FOR THE H-INJECTOR UPGRADE AT LANSCE

Ralph R. Stevens, Jr., William Ingalls, Oscar Sander, Ben Prichard,
and Joseph Sherman
Los Alamos National Laboratory, Los Alamos, New Mexico 87545

Abstract

An upgrade program is being carried out at Los Alamos to increase the peak beam current from the present H^- injector to provide 200 μA average current for the proton storage ring at LANSCE. In order to meet this objective, the injector must provide at least 30% more current than presently available. More optimal operation, however, requires a factor of two higher peak current in order to reduce circulating losses in the ring. At these higher currents, a lower beam emittance is needed to limit beam losses in the linac. Beam simulations have been carried out to model the operation, of the present injector and to determine what changes will be required to operate with these higher beam currents. A collaboration with the Lawrence Berkeley National Laboratory (LBNL) is now in progress to modify our present converter ion source to produce 40-mA peak of H^- beam current with reduced beam emittance. Beam simulations show that a new 80-kV accelerating column will be needed to accelerate and transport these higher current beams with acceptable beam size and divergence. Experimental results for the initial phase of this program are presented together with a comparison to these beam simulations.

1 INTRODUCTION

The upgraded H^- injector must produce high-duty factor, low-emittance H^- beams with good reliability and availability in order to meet the operational requirements at the Los Alamos Neutron Science Center (LANSCE). The present surface converter ion source provides the reliability and availability needed [1]. Previous work at LBNL with a similar barium converter source [2,3] has demonstrated that a factor of two increase in converter efficiency can be obtained for this type of ion source by filtering the primary plasma. Experiments carried out with a cesiated molybdenum converter [4] have demonstrated that the required 40 mA of beam current can be produced.

The design of a new accelerating column was carried out by first benchmarking the ray-tracing code PBGUNS against the operation of the present accelerating column. Then this code was used to determine what changes were needed to design a column capable of accelerating higher beam currents with the required exit beam parameters.

2 LANL ION SOURCE

The configuration of the present LANL converter ion source together with the 80-kV accelerating column is shown in Fig. 1.

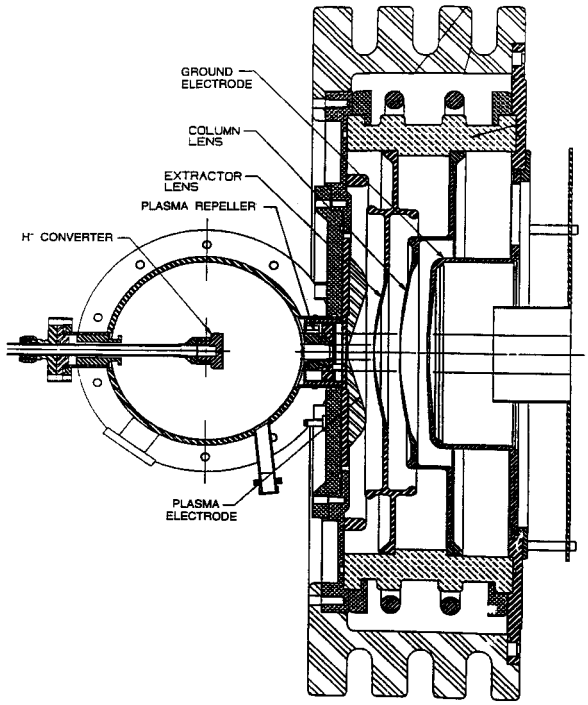

Figure 1: Layout of the LANL converter ion source with the present accelerating column.

The H^- ions are sputtered from the surface of a cesiated molybdenum converter electrode and are subsequently accelerated to several hundred electron volts by the cathode sheath formed at the converter surface by the applied bias voltage. These ions are self-focused by the spherical surface of the converter and form a converging beam that exits the source at the plasma electrode. The ion beam is collimated both by the 1.0-cm diam. plasma electrode aperture and by the plasma repeller assembly within the source itself. The emittance of the beam extracted from the ion source is determined by the geometrical admittance. For low converter voltages, the beam fills the phase space available and the beam emittance is equal to the ion source admittance. The extraction electrode is located 2.5 cm from the plasma electrode and has a 2.2-cm diam. aperture. The extraction voltage required for our present 16-mA production beam is only 12 kV. This is

a consequence of the high energy (250 eV) of the converter beam and of the relatively low plasma density at the plasma electrode. The difference between the extraction voltage and the total column voltage is applied across two high-voltage gaps in the column with the intermediate voltage being variable. For the present operation, this voltage difference is split equally between these two high-voltage gaps.

3 BEAM SIMULATIONS

The ray-tracing code PBGUNS Version 3.20 [5] has been used to model the production of the H- beam in the ion source and the subsequent acceleration in the 80-kV accelerating column. This code computes beam trajectories starting at the converter surface and propagates the beam through the ion source plasma and then subsequently accelerates the beam through the 80-kV accelerating column into the low-energy beam transport (LEBT) line. Emittance plots can be produced at four positions along the beam line, and the evolution of the beam phase space can be followed through the system as the ion source and accelerating column parameters are varied.

4 TEST STAND PROGRAM

To carry out the development of a new ion source, the LANSCE ion source test stand (ISTS) was rebuilt to have the same configuration as the injector in the accelerator. Thus, it now provides a means for testing ion source improvements and modifications in an off-line environment [6]. A spare converter ion source was mounted on the ISTS, and beam tests were carried out which demonstrated that the operation of the ion source on the test stand was the same as that on the injector.

Although the PBGUNS code had been benchmarked against experiments for positive ion sources, there has not yet been a similar validation for the negative ion sputter sources that we are using [7]. We decided, therefore, to carry out an experimental program to compare the simulation predictions to the emittance data taken with our present ion source. A series of emittance scans were taken at the first emittance station (EM-1) in which the ion source parameters were held constant and the extraction voltage was varied from 8 kV to 15 kV. A typical emittance scan for the 12-kV case is shown in Fig 2.

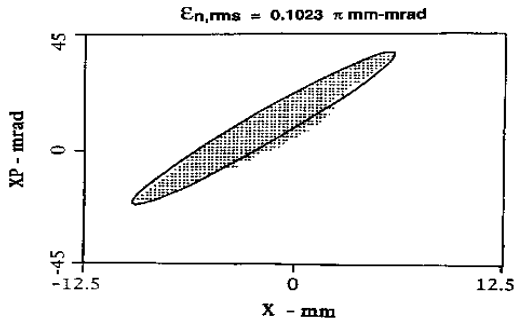

Figure 2: Horizontal emittance scan of a 16-mA H^- beam at the column exit with 12-kV extraction voltage.

Simulations were then run for all the extraction voltages with the ion source parameters fixed at the production values. The calculated phase-space distribution for the 12-kV extraction voltage case is shown in Fig. 3.

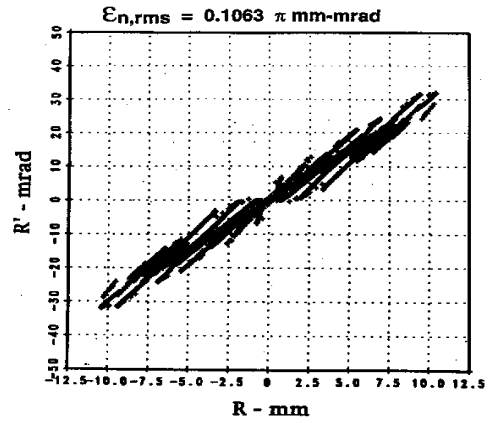

Figure 3: Calculated emittance distribution of a16-mA H^- beam at the column exit for 12-kV extraction voltage.

The experimental data observed at EM-1 and the corresponding PBGUNS simulations are compared in Table I.

Both the ray-tracing code and the emittance analysis code

Table 1: Comparison of Emittance Data and PBGUNS Simulations

kV Extraction Voltage	π mm-mrad Normalized rms Emittance		Mismatch Factor	cm Beam Size		mrad Beam Divergence	
	EM-1	PBGUNS		EM-1	PBGUNS	EM-1	PBGUNS
8.0	0.0984	0.1096	1.53	0.880	0.879	29.19	18.41
9.0	0.1096	0.1065	1.53	0.893	0.924	31.34	21.88
10.0	0.1003	0.1071	1.30	0.853	0.948	30.68	24.85
11.0	0.1032	0.1040	1.23	0.848	0.941	31.86	25.79
12.0	0.1023	0.1063	1.20	0.803	0.939	31.08	27.44
13.0	0.1018	0.1044	1.26	0.763	0.913	30.78	27.21
14.0	0.0100	0.1036	1.27	0.714	0.891	29.97	27.44
15.0	0.0972	0.1028	1.32	0.672	0.856	29.86	27.57

carry out a second moments analysis to determine the rms emittance of the beam. We see that for the rms emittance the experimental data and beam simulations agree to within a few percent. We note that for the converter source being modeled, the beam size and divergence values given by PBGUNS on the emittance plots are closely approximated by the 2rms values calculated by this code, i.e., by the beam parameters of a 4rms beam. We have, therefore, chosen to compare the beam parameters for the experimental beams with the 4rms beam parameters calculated by PBGUNS. We see that the beam sizes for the observed EM-1 beams are typically 10% smaller than the calculated 2rms beam size and that the observed beam divergences at EM-1 are approximately 15% larger than the 2rms divergence values. Thus, while the beam code calculates the phase space area correctly, there are still systematic differences between the measured and simulated beam size and divergence which probably arise from errors in the location of beam transport elements or errors in the assumed space-charge neutralization model. Work is in progress to resolve these discrepancies.

5 HIGH-VOLTAGE COLUMN SIMULATIONS

Having established that the LANSCE H^- injector beam can be modeled with the PBGUNS code, we carried out simulations for the higher beam currents. We first determined the performance of the present injector systems as we increased the extracted beam current. We increased the extraction voltage to keep the beam perveance constant in the extraction gap as the extracted current was increased. Thus, as the beam current was increased from 16 mA to 40 mA, the extraction voltage was varied from 12 kV to 22 kV. The variation of beam emittance and beam sizes at several locations in the beam line are shown in Fig. 4.

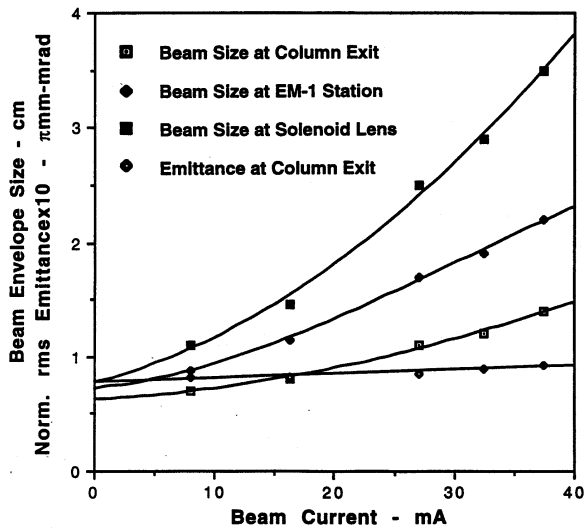

Figure 4: Beam emittance at the column exit and beam sizes in the LEBT as a function of extracted current.

We see that the emittance of the beam at the column exit remains essentially constant over this range of currents for the perveance matching employed in the extractor gap. The beam size in the beam line increases continuously with increasing current and exceeds the aberration limit in the solenoid lens (half the bore aperture) for 27 mA and fills the bore aperture for currents approaching 40 mA. Thus, the present injector can be used for beam currents up to 27 mA without emittance degradation, but a new accelerating column with stronger focusing will be required for beam currents at the 40 mA level.

Several accelerating column designs have been studied using this simulation code. The beam profiles for a high gradient tetrode column with a decel ion trap and for the present accelerating column are presented in Fig. 5. The beam envelope sizes in the LEBT for the tetrode design with 40 mA are essentially the same as those with the present column for 16-mA beams.

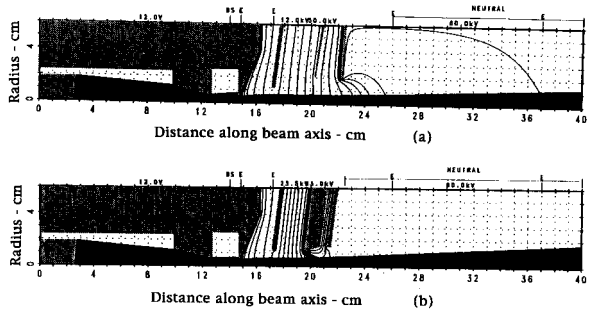

Figure 5: Trajectories and equipotentials for the 16-mA production beam with the present accelerating column (a) and for a 40-mA beam with a high gradient tetrode column (b).

Abstract

Design and testing of the prototype ion source for the Los Alamos Neutron Science Center (LANSCE) Facility is described.

1 INTRODUCTION

The next generation spallation neutron sources, such as the upgrade of the Los Alamos Neutron Science Center (LANSCE) Facility will require high intensity negative hydrogen (H^-) beams. Lawrence Berkeley National Laboratory has been contracted by Los Alamos National Laboratory to develop an H^- ion generator that can meet the upgrade LANSCE neutron source requirement. Specifically, the output current of the new H^- ion source has to increase from 16 to 40 mA. In addition, source emittance, reliability, and availability will need to be improved. All of which must be achieved while operating under the facility's prescribed 12% duty factor (1 ms pulse at 120 Hz).

In order to meet the LANSCE source requirement, the Ion Beam Technology (IBT) Program at LBNL chose the surface-conversion multicusp ion source as the base candidate. The present LANSCE H^- source is also a surface-conversion source [1]. However, the H^- output current doesn't improve much beyond 20 mA with higher discharge power. Previous experimental study at LBNL demonstrated that if the surface converter source is operated with a magnetic filter, the H^- output current generated by a barium converter can increase without saturation with increased discharge power [2]. Based on this study, a prototype ion source has been developed to utilize the multicusp magnet arrangement as a filter. Cesium is used to enhance the H^- yield.

2 ION SOURCE CONFIGURATION

LBNL has been developing multicusp surface conversion ion sources for many years [3,4]. The typical multicusp H^- surface conversion source is primarily composed of a plasma chamber and a negatively-biased converter electrode as illustrated in Figure 1.

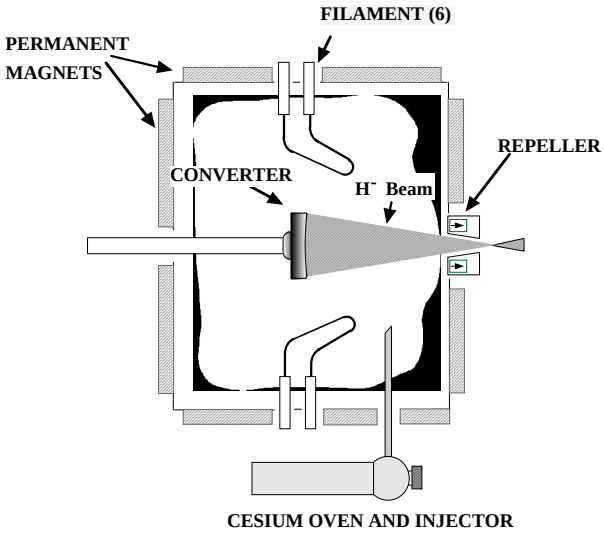

Figure 1: Schematic of the surface conversion ion source.

The positive ions present in the hydrogen plasma (H^+, H_2^+, H_3^+) are accelerated towards the converter surface. H^- ions can then be formed either by a backscattering process or by a sputtering process when the ions impinge on the converter surface. The converter is coated with a low work-function metal such as cesium to enhance negative ion conversion.

The current LANSCE ion source has a cylindrical body and the negative ions are extracted radially. The two filament cathodes are located on the cylinder end flanges. The LBNL prototype, Figure 2, is also of cylindrical design, however the negative ions are extracted along the source axis. This allows six filaments to be placed within the magnetic field generated by the cusp magnets on the wall (Figure 3).

The magnets provide a filter field which reduces the number of energetic electrons in the main plasma volume. This reduces the negative ion stripping due to energetic electrons. A converter of twice the area of the current converter is also used. The radius of curvature is increased to maintain the same projection angle. The axial position of the converter was optimized for maximum H^- output.

[i] Permanent address: Kernfysisch Versneller Instituut, The Netherlands.

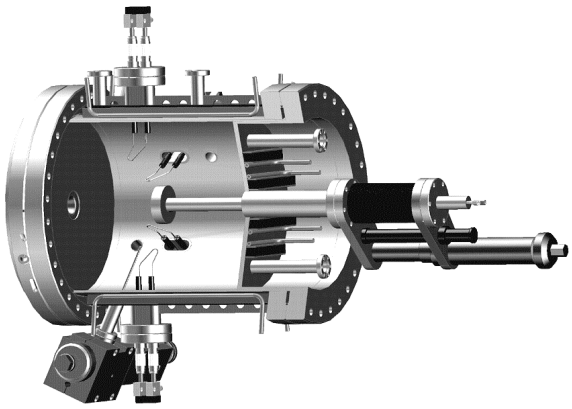

Figure 2: A 3-D rendering of the prototype ion source.

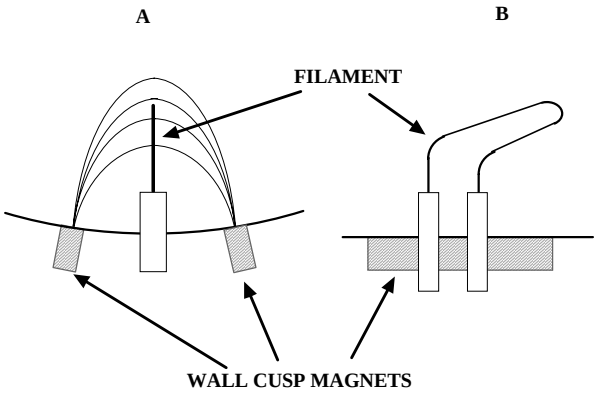

Figure 3: Location of the filament within the wall cusp magnet field. A. View along longitudinal axis. B. Viewed side on.

The prototype source utilizes a repeller electrode similar to the one in the current LANSCE ion source [1] This electrode is typically biased a few volts positive with respect to the anode to repel electrons. It also incorporates a dipole cusp arrangement in the extraction region which deflects the energetic electrons produced by secondary emission from the converter surface.

Figure 2 shows a 3-D rendering of the prototype ion source. The vacuum manipulator is used to optimize the converter position. In order to reduce cesium consumption, the ion source is designed for the walls to run at approximately 100° C, so as to avoid condensation of cesium in cool areas.

3 EXPERIMENTAL RESULTS

The prototype ion source has been operated at the design specifications. Figure 4 is a plot of H^- output as a function of arc power. The arc voltage was 80 volts, the source pressure was 1.2 mTorr and the converter voltage was 330 volts. It can be seen that the highest H^- current measured exceeded the required 40 mA. The duty factor was 12 %, 1 msec pulses at 120 Hz. Figures 5 and 6 show the H^- beam pulses at 12 % duty factor. These results were obtained without the normal LANSCE accelerator system.

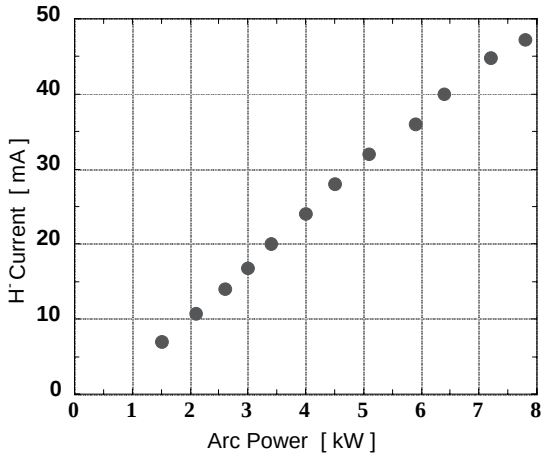

Figure 4: Plot of H^- current as a function of arc power

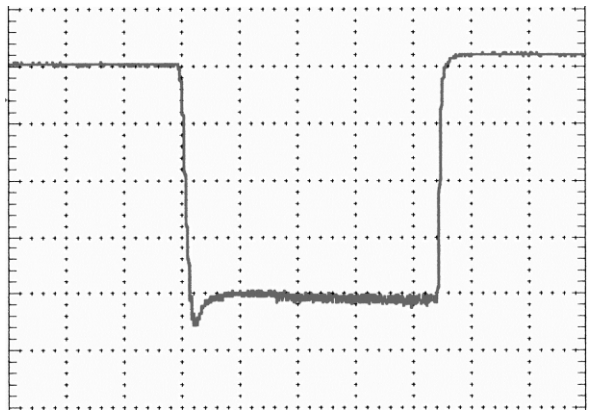

Figure 5: An oscilloscope display of the 40 mA H- pulse. The vertical scale is 10 mA/div. The time scale is 250 µsec/div.

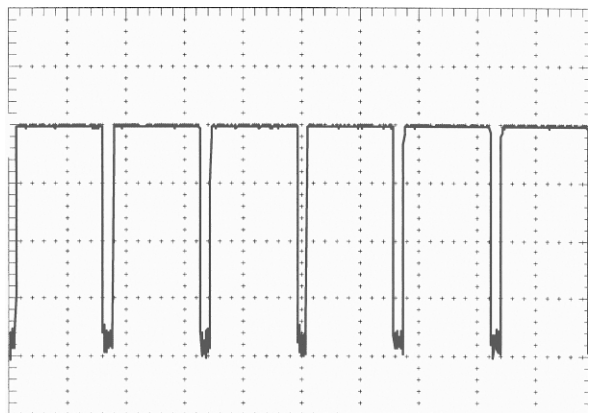

Figure 6: An oscilloscope display of the H- pulse at 12% duty factor. The vertical scale is 10 mA/div. The time scale is 5 msec/div.

4 CONCLUSIONS AND FUTURE PLANS

It has been demonstrated that the prototype ion source for the LANSCE upgrade can produce the required 40 mA of H^- at a 12 % duty factor. When operating with diligence the day to day operations show well reproducible results. The most significant problem with this source is getting a compromise between wall temperature and cesium injection. A low wall temperature requires constant cesium injection. If the wall is too hot, the cesium vapor pressure gets too high and the plasma is dominated by cesium ions and the H^- output tapers off requiring higher arc power to attain the 40 mA output. However, the present source is not constructed to allow for simple control of wall temperature; this issue will be addressed in the next design.

An earlier version of the proposed source design fabricated from existing components was tested at LBNL and is now being tested on the LANSCE Test Stand. The results obtained at both laboratories are similar. LANSCE is planning to make emittance measurements with the prototype source to compare with the present LANSCE operation source.

At this time a new production source is under design that will include features indicated by testing of the prototype ion source. One of the main concerns is the ability to adjust the wall temperature. The design is near completion and fabrication is expected to take about two months. Testing is expected to begin in early November.

Abstract

A joint program is underway between the SRRC (Synchrotron Radiation Research Center, Taiwan) and ANL (Argonne National Laboratory, USA) for developing a high current L-band photocathode rf guns. We have constructed an L-Band (1.3 Ghz), single cell rf photocathode gun and conducted low power tests at SRRC. High power rf conditioning of the cavity has been completed at ANL. In this paper we report on the construction and high power test results. So far we have been able to achieve > 120 MV/m axial electric field with minimal dark current. This gun will be used to replace the AWA (Argonne Wakefield Accelerator)[1] high current gun.

1 INTRODUCTION

The generation of high gradients (> 100 MV/m) in wakefield structures requires a short pulse, high intensity electron drive beam. The goal of the AWA is to demonstrate high gradients and sustained acceleration of charged particle beams using wakefield methods. The main technological challenge of the AWA program is the development of a photoinjector capable of fulfilling these requirements. The laser photocathode source was designed to deliver 100 nC bunches at 2 MeV to the drive linac. The photocathode gun is a single cell standing wave cavity with designed peak field of 90 MV/m on the cathode[2]. However, due to surface contamination and damage during the initial rf conditioning of the original gun, the peak electric field on axis is only limited to 55 ~ 65 MV/m rather than the designed field 92 MV/m due to the severe dark current beam loading[3].

A collaboration between SRRC and ANL has been established to construct a new L-band single cell photocathode rf gun and associated test stand. The goals of this collaborative research effort are to characterize the beam produced by this gun, and to study high field breakdown phenomena, dark current, and quantum efficiencies of various photocathode materials.

2 FABRICATION AND COLD TESTING

The gun cavity structure is shown in Figure 1. The cooling channel is built inside the cavity body instead of just attaching it to the outer surface. The cavity is also equipped with a tuner and a field strength monitor.

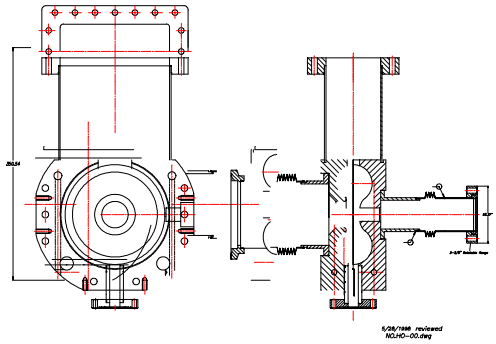

Figure 1: Assembly drawing of the gun cavity

The cavity was CNC machined several times to reach the correct resonant frequency and critical coupling. The cavity surface (mounted on a rotating stand) was then polished using 3M Imperial Lapping Films (60, 40, 30, 15, 12, 9, 5, 3, and 1 micron) and then Buehler Micropolish II Alumina Suspensions (1, 0.3 and 0.05 micron).

The cavity components were brazed together in a vacuum furnace in several stages to allow the joining of various components. After brazing and applying Vac Seal to eminent possible small leaks around the joints between the WR-650 waveguide and the cavity, it was vacuum tested using a Helium leak detector (Balzers HLT 160) and found to be Helium leak tight to better than 10^{-10} standard c.c./sec. However, it was found that the resonant frequency had been shifted down by 2.5 MHz and the

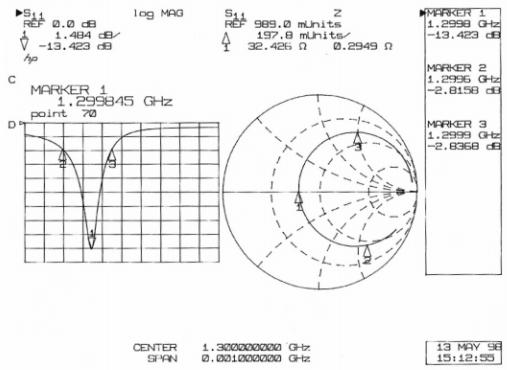

Figure 2: Reflection coefficient of gun cavity measured using HP8510C network analyzer.

coupling coefficient shifted from 1 (critical coupling) to around 1.5 (over coupled). The frequency shift is corrected back to 1.3 GHz using the tuner. Figure 2 is the measured plot in atmosphere and room temperature from the HP 8510C network analyzer after the cavity was installed and tuned at ANL. The measured unloaded quality factor is around 13000, while the URMEL prediction for the unloaded quality factor is around 15000.

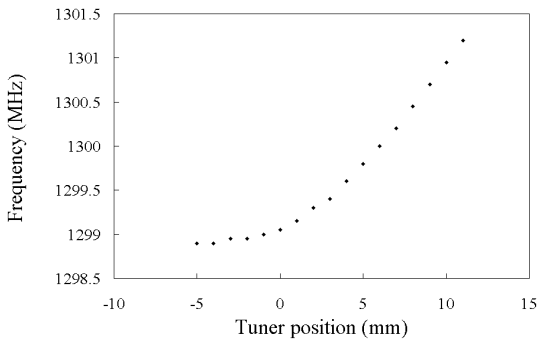

Figure 3: Measured resonant frequency dependence of tuner position.

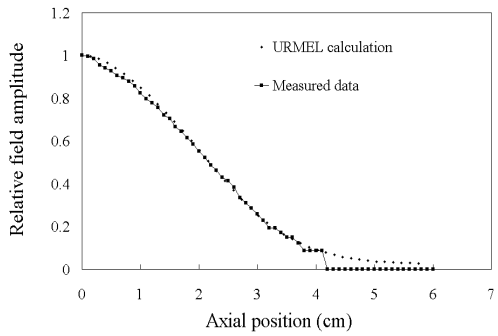

Figure 4: Longitudinal E-field profile on axis.

Figure 3 shows the measured frequency response to the tuner position (the tuning sensitivity is appear to be 1.8 MHz/cm in the linear region of the curve). Since the frequency is very sensitive to the cathode slug position, we use the tuner to fine tune the frequency. The cathode is held flush with the cavity inner surface to avoid arcing due to the discontinuity.

A ceramic bead of 2 mm diameter was used to perform the bead pull measurement. Figure 4 shows the longitudinal E-field profile along the central axis of the cavity from the bead pull measurement results and the URMEL prediction.

Bucking and focussing solenoids were also designed, constructed and measured at SRRC. The measured magnetic field profile is in close agreement with the POISSON calculation.

3 EXPERIMENTAL SETUP

The layout of the L-band rf gun test stand is shown in Figure 5. The whole system was first assembled and vacuum tested at SRRC and then shipped and installed at ANL in May, 1998. Two Molecular Drag pumps (16 CFM) and two oil free magnetic suspension Turbo Molecular Pumps (400 l/s) were used for roughing and baking. Two sputtering ion pumps (60 l/s) and one Non-Evaporable Getter (NEG) pump (500 l/s) were used to reach a base pressure of around 1.6 nTorr and maintain the pressure at around 13 nTorr during conditioning of the cavity.

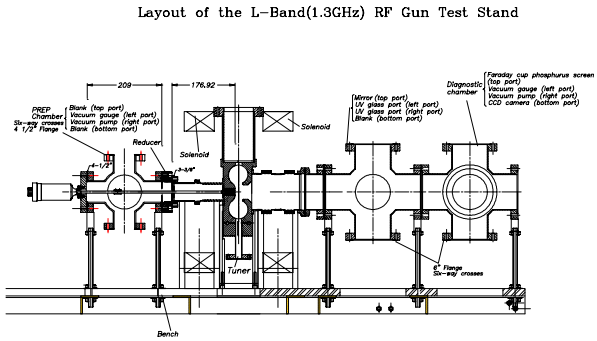

Figure 5: Layout of the L-band rf gun test stand.

4 HIGH POWER TEST RESULTS

RF conditioning of the gun proceeded smoothly. During the conditioning, the vacuum was kept under 50 nTorr and the occurrences of breakdown were kept to minimum. The forward, reflected rf power and dark current were also monitored continuously. Figure 6 shows the forward power to the gun with peak power of 2 MW. Figure 7 gives the reflected rf power and it shows almost no detuning of the gun due to the dark current.

In fact, because this gun was over coupled after brazing, the loading from the dark current will move it toward critical coupling to some extent. Since the field monitor was not instrumented yet for this test, one can only estimate the surface field using the rf reflection coefficient and the dark current. For 2 MW forward power with no reflection, we have estimated the surface field at the cathode center to be 100 MV/m[2]. This is somewhat larger than the designed value of 92 MV/m at 1.5 MW. At 100 MV/m, dark current is about 13 nC per rf pulse, in comparison with the original AWA gun which is 40 -60 nC at ~ 60 MV/m.

Further rf conditioning has been done to further reduce the dark current and increase the axial electric field to 120 MV/m. With a few additional days of conditioning, we have increased the rf forward power to 3 MW, still with no dark current induced rf reflection, with the equivalent photocathode field of 117 MV/m. The peak electrical field on the nose cone is 152 MV/m. Measured dark current is 25 nC /pulse. This is a 40% above the designed field and should be able to provide improved performance over the original AWA gun. Figure 8 shows the dark current transported out of the gun versus the forward rf power (surface field). It clearly shows the exponential dependence of the surface field. Below 70 MV/m, no significant dark current was observed. However, it goes up quickly as the surface field increases.

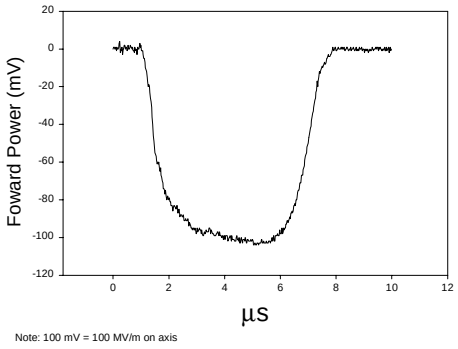

Figure 6: Measured forward rf power to the gun. This is a scope trace that measures envelope of rf pulse with calibrated diode detector. The peak voltage corresponds to 2 MW peak rf power.

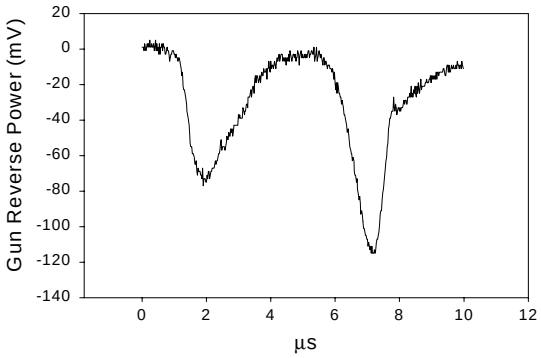

Figure 7: Reflected rf power from the gun. It shows that after the gun was filled, no reflection was observed.

5 SUMMARY

The first L-band rf gun cavity resulting from the joint collaboration between SRRC and ANL has been constructed, installed and conditioned. The high power test results are very encouraging. Input rf power was applied to rf cavity and increased from 100 kW level to 2 MW level within two days. Further conditioning increased the accelerating gradient in excess of 120 MV/m at the photocathode. The dark current measurement results show little effect of beam loading at this power level. We will replace the current AWA drive gun with this new gun, which should enable us to obtain shorter electron beams, and thus improve the gradients obtained in wakefield acceleration experiments.

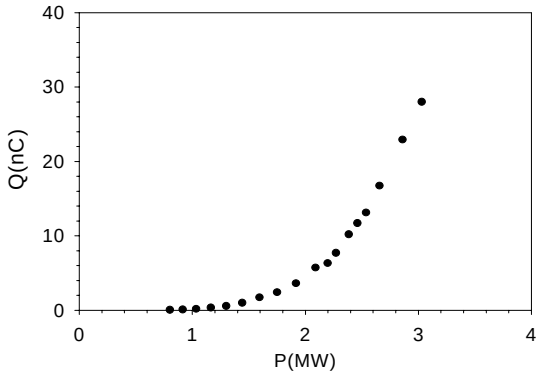

Figure 8: Measured dark current at the down stream against the surface field (forward rf power). It shows the exponential dependence and the maximum dark current observed was 30 nC at 120 MV/m (3 MW).

6 ACKNOWLEDGMENTS

We would like to thank Mr. T.T. Wu from ITRI for operating the vacuum brazing furnace. We would also like to thank Mr. M.H. Huang and Mr. C.H. Chang of SRRC for helping the construction of the solenoid, and Mr. F.Y. Lin and Dr. C.S. Hwang of SRRC for helping the measurement of the solenoid field profile. We would also like to thank the kind help from Mr. V. Svirtun, Mr. R. Nielson, and Dr. J. Noonan of ANL-APS, and Mr. R. Taylor of ANL-HEP during installation of the gun. EXTRACTION AND LOW ENERGY TRANSPORT OF NEGATIVE IONS*

A. Lakatos, J. Pozimski, A. Jakob, H. Klein,
Institut für Angewandte Physik, Universität Frankfurt, 60054 Frankfurt, Germany

Abstract

High perveance negative ion beams with low emittance are essential for several next generation particle accelerators (i. g. spallation sources like ESS [1] and SNS [2]). The extraction and transport of these beams have intrinsic difficulties different from positive ion beams. Limitation of beam current and emittance growth have to be avoided. To fulfill the requirements of those projects a detailed knowledge of the physics of beam formation the interaction of the H^- with the residual gas and transport is substantial. A compact cesium free H^- volume source delivering a low energy high perveance beam (6.5 keV, 2.3 mA, perveance K= 0.0034) has been built to study the fundamental physics of beam transport and will be integrated into the existing LEBT section in the near future. First measurements of the interaction between the ion beam and the residual gas will be presented together with the experimental set up and preliminary results.

1 INTRODUCTION

The production and transport of high current negative ion beams is a key issue for future high current accelerators. For ESS, as an example, an H^- beam with 70 mA at 55 keV (K=0.0035) and ε_n = 0.1 πmmmrad is required using non Liouvillian stacking schemes for the accumulation rings. An ion source has been developed in Frankfurt, which is now able to deliver an H^- current even higher than necessary [3]. To reduce particle losses at high beam energy (above the coulomb barrier) and to maximise the available current the beam has to be treated carefully between the plasmaelectrode and the first RFQ. External and internal fields can induce emittance growth, space charge forces and interactions of the beam with the residual gas can limit the transportable current.

Different extraction and ion beam transporting schemes are under discussion [4,5], each have various positive and negative aspects. To improve the H^- to e^- ratio magnetic filterfields (i. g. dipoles) are used. In our case these filterfields are in conjunction with dipole fields for electron dumping. The quality of beam extraction simulations suffers from these additional magnetic fields in the low energy part of the extractor. The destruction of the rotational symmetry together with the space charge forces causes emittance growth and particle losses within the extraction system. High residual gas pressure near the extractor together with the high cross section for stripping will influence the transmission as well as space charge compensation.

LEBT of high perveance ion beams suffers from high space charge forces. Generally two systems are used:

electrostatic or magnetic lenses. The use of electrostatic lens systems has to deal with the full space charge and therefore has limited current transport capabilities. They suffer from high space charge forces causing in conjunction with field aberrations serious emittance growth. Magnetic lens systems can use space charge compensation to reduce the necessary focusing force and the radius of the beam in the lenses. Hence the emittance growth due to lens aberrations and self fields is reduced. In Frankfurt an experiment is under construction to investigate the influence of various parameters on beam formation and transport under space charge compensated and decompensated conditions. On behalf a H^- source has already been built. After the essential operation conditions for the source are studied the source will be incorporated into the existing **L**ow **E**nergy **B**eam **T**ransport (LEBT) line.

The details of the beamline layout are shown in Fig. 1.

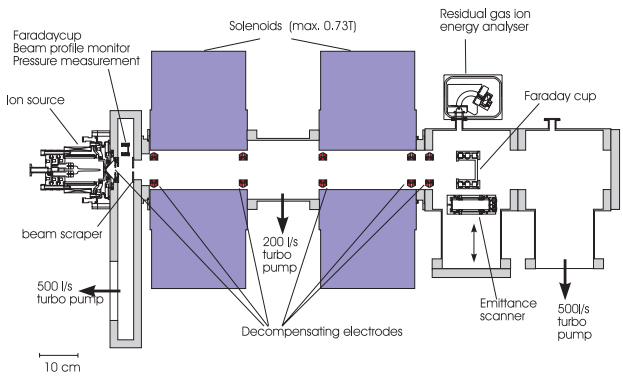

Figure 1: Schematic drawing of the experimental set up of the Frankfurt LEBT line.

An existing double solenoid (max. field 0.73 T) LEBT capable with the ESS scenario will be used for our investigations of high-current beam transport of negative ions. Therefore different beam diagnostic elements have been installed. Emittance measurement device and residual gas ion energy spectrometer and Faradaycups are available along the beampath. The degree of

* Work supported by BMBF under contract No. 06 OF 841

compensation can be regulated by decompensating ring electrodes as well as by varying the residual gas pressure in the LEBT. The measured beam properties, e. g. transverse emittance, degree of space charge compensation support the design of the future LEBT for negative ions.

2 ION SOURCE

An schematic drawing of the ion source for our experiment is shown in Fig. 2.

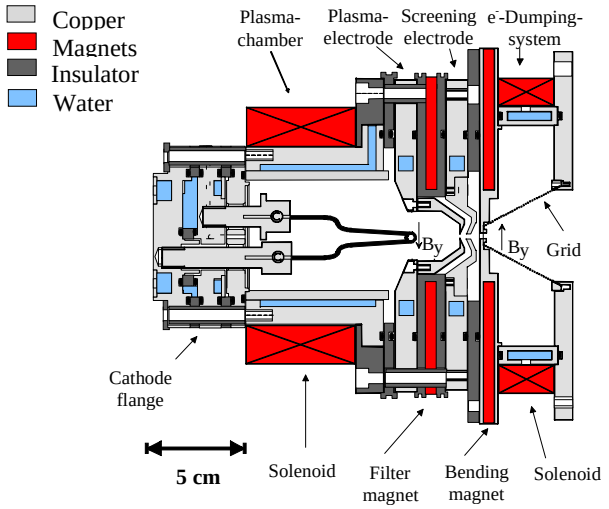

Figure 2: schematic drawing of the ion source.

The ion source [6], is of the volume type using a gas discharge driven by a hot cathode to atomize the H_2 molecules. The electrons are radially enclosed by a solenoidal field. A magnetic dipole filter field (electrical exited) near the extraction area is used to separate slow and fast electrons and therefore enhance the H^- production [7]. To inhibit influence on the diagnostic devices the source will be operated cesium free. This will limit the plasma density and therefore the ion current. The design value for the current density delivered by the plasma was chosen to be 20 mA/cm^2 a commonly reached value for cesium free H^- sources [8]. The H^- to e ratio has to be above 0.02 due to current restrictions by the high voltage power supply.

For the ion beam formation a single aperture accel - decel system is used. Various numerical simulations of the beam extraction using the IGUN [9] code have been performed for different extraction geometries. The goal was to build a compact triode extraction system insensitive to plasma density variations delivering a high perveance ion beam with minimised emittance.

The simulations have been performed for different ion current densities (0-50 mA/cm^2), different extraction voltages (4,5 and 6 kV) and aspect ratios between 0.2 and 1.2. The simulations showed that the boundary conditions are fulfilled for an aspect ratio of S = 0.375 and an extraction of 3 mm diameter. For the matched case a beam emittance of $\varepsilon_{n,RMS}$ = 0.001 πmmmrad (4kV) is calculated. For a current density of app. 25 mA/cm^2 delivered by the plasma generator a 4 keV H^- beam with 1.77 mA beam current is delivered. This will correspond to a beam perveance of K=0.0045 which is app. 30 % higher than proposed for the ESS project [6].

3 EXPERIMENTAL SET UP

To study the fundamental behavior of the ion source for different parameters of the plasma generator a test bench was installed. The details of the test bench layout are shown in Fig. 3.

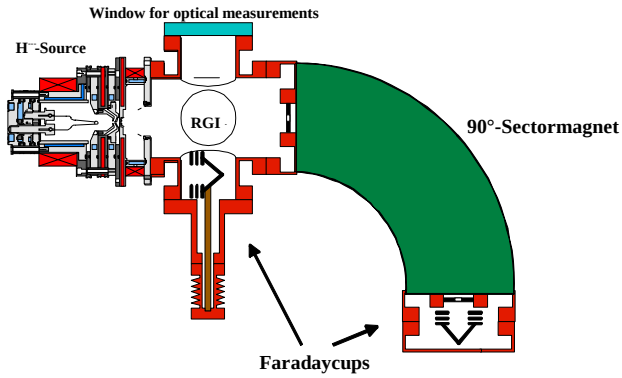

Figure 3: : Schematic drawing of the experimental set up of the test bench for the H^--source.

Multiple beam diagnostic elements like a magnetic spectrometer, a residual gas ion (RGI) energy spectrometer and Faradaycups have been installed. A window gives the opportunity to analyse the radial density profile of the extracted beam by using the incident light emitted by collisions of the beam ions with the residual gas atoms. Additionally the residual gas pressure can be varied in the test bench.

4 MEASUREMENTS

After the design parameters of our H^--source have been reached, the mass spectra of the emerging particle beams have been investigated by the use of the 90° sectormagnet, to prove that H^- has been measured in the Faraday cup.

Fig. 4 shows two spectra measured using a H^--beam of appr. 2 mA at a beam energy of 6.5 kV. The gas pressure inside the ion source has been 0.133 hPa and $5*10^{-6}$ hPa in the diagnostics chamber (mostly H_2 due to the gasflow from the source). The lower curve (for the negative charged particles) show peaks according to the extracted electrons and H^--ions (due to the electron dumping the spectrum does not indicate the extracted H^-/e^- ratio).

By changing the polarity of the magnetic dipole field we observed also positive ions. The mass of the ions have been calculated under assumption of an ion energy of 6.5kV as well.

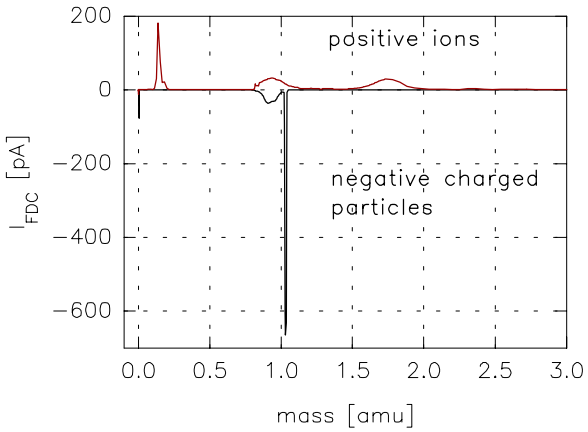

Figure 4: mass spectra of an extracted beam.

The ion energy of the positive ions which possibly are produced by interaction of H^- and electrons with residual gas atoms in the extraction area (at highest gas pressure) cannot be determined without additional investigations due to the fact that neither the ion mass (possible candidates are H^+, H_2^+, H_3^+, N^+, N_2^+, H_20^+) nor the energy is known. To exclude most of the possibilities two additional experiments already have been performed.

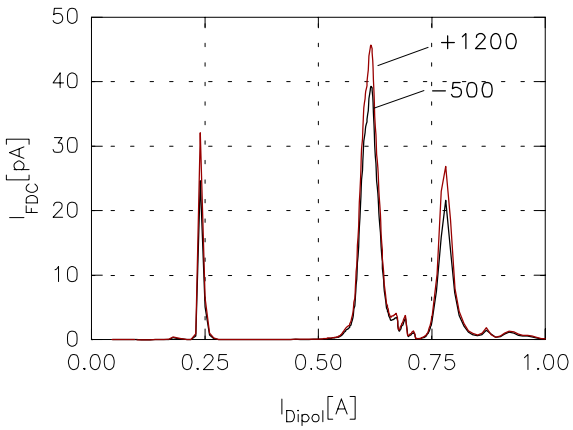

Figure 5: mass spectrum with decelerate potential of 1.2 kV and reference spectrum.

Fig. 5 shows the results of an experiment were the polarity of the secondary electron suppression electrode in front of the Faradaycup of the sector magnet has been changed from negative to positive (compared to ground potential). The electrode was biased up to +1200V (limited by constructional reasons). It is supposed that all positive ions with a kinetic energy below 1200 eV will be suppressed and therefore not detected. As shown in Fig. 4 the detected current is higher (due to the secondary electrons) than for the reference spectra and therefore it is likely that most of the positive ions have energies above 1200 eV. This indicates that their origin is not from inelastic collisions of H^- and e^- with heavy atoms (like N_2,H_20). Fig. 6 shows spectra measured at different extraction voltages (4.5-6.5 kV). We expected a change of the energy of the positive ions.

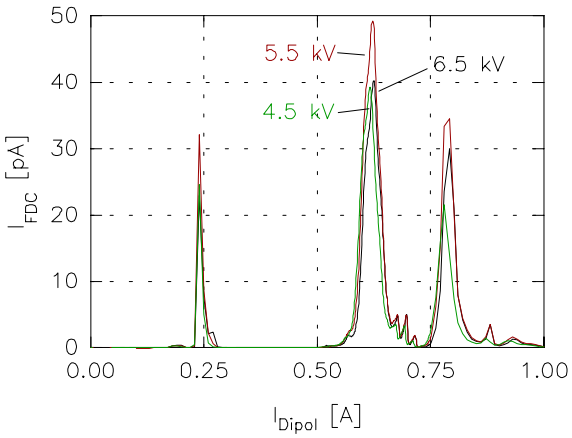

Figure 6: spectra gained for different extraction voltages.

if their energy is determined by the momentum exchange at interaction, but only minor changes of the measured positive spectra can be observed**.** Therefore an additional process determining the energy of the positive ions have to be assumed. Further work to understand these results in more detail are planed.

5 OUTLOOK

After the source tests on the separate test bench the source will be incorporated into the existing LEBT. The experiments will start with a DC beam to study the influence of the external parameters (filter fields, solenoids, residual gas pressure, voltage on decompensation electrodes, source noise) on emittance and transmission. For a next step the set up is already prepared for pulsed mode operation.

STABLE AMPERE LEVEL EMISSION OF ENERGETIC ELECTRONS BY ELECTRICALLY EXCITED FERROELECTRIC CERAMICS

I. Boscolo, A. Scurati
University of Milano and INFN, Dipartimento di Fisica via Celoria 16, 20133 Milano, Italy

Abstract

Stable emission of energetic electrons from ferroelectric ceramic of PLZT type, i.e. lead zirconate titanate lanthanum doped, in form of thin disks have been obtained with a proper design of the front electrode. The current is about 1 A square centimeter and the energy is a couple of keV. High density, more than 50 A square centimeter, is obtained in the plasma assisted configuration. The electron expulsion from the surface is due to the spontaneous polarization switching induced by a high voltage pulse applied to proper metallic electrodes deposited as thin film on the two surfaces of the disk. In passing from the usual front electrode having the structure of an interconnected grating, to an electrode being a pattern of disconnected patches contained within a ring, the electron emission passes from erratic with samples and decaying with the number of shots to stable in both cases. This change in the behavior is explained by the fact that the sandwich of the continuous electrode and the grating constrains the domain switching and the relevant charge carriers motion within the part of material covered by metal, whilst a quasi-free surface allows the domain switching all over the whole area with the consequent flux of electrons in and out of the sample surface. In the plasma assisted emission, the front electrode must be the normal grating because the plasma in this electrode configuration is homogeneous.

1 INTRODUCTION

Electrons emitted from a ferroelectric cathode [1] come from ground to the crystal surface and then they are acted upon by the spontaneous polarization. This vector can be set in either direction with respect to the front (emitting) surface, depending on the sign of the voltage pulse applied at the rear electrode. With positive excitation (negative voltage), surface domains switch with the positive side pointing towards the front surface and then relax back. Therefore, in the first stage they attract screening electrons, then they push them out. With negative excitation, the negative side of the spontaneous polarization sweeps out the electrons loosely bound at the surface defects.

The process of excitation and relaxation must be of non-equilibrium type in order to have strong emission, so that the surface electron diffusion in the evolution towards an equilibrium state occurs through the material-vacuum interface [2]. Hence, the ceramics suitable for electron emission are the so-called ferroelectric relaxors [3] and antiferroelectric material with fast transition under the action of an electric field. The material used in the emission experiments was lead lanthanum zirconate titanate, called PLZT, with components proportion 4/95/5 and 8/65/35, where the numbers refer respectively to lanthanum, zirconium and titanium atom percentage. PLZT 4/95/5 material is in antiferroelectric (AFE) phase at the working room temperature, and it makes the transition to FE phase under the action of an electric field higher than 15 kV/cm, while PLZT 8/65/35 is in FE phase [4]. The emission observed [4, 5] with ceramic disks having the usual grating interconnected by a metallic ring, see fig.1, as front electrode had stable behavior neither with the number of shots in a single sample, nor in the level of emission (many times the emission was zero) for samples equal in composition, preparation and electroding. Instead, the emission obtained with an ensamble of

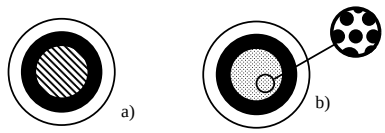

Figure 1: Sketch of the two electroding types of the front surface: the stripes are 200 μm with an interdistance of the same width.

metal islands surrounded by a metal ring was quite stable.

The application of an electric field higher than 10 kV/cm through the samples, induces not only the spontaneous polarization switching within the crystal, but also the plasma formation on the cathode surface [4]. Both processes generate electrons, but the former process generates a group of electrons that are energetic, whilst the latter generates only non-energetic electrons.

We call the emission due to the switching of the spontaneous polarization, ferroelectric emission (FE).

2 DISCUSSION OF THE RESULTS WITH THE GRATING AS ELECTRODE

The set-up is described in ref [5]. A virgin emitting sample typically starts to emit FE electrons, then the emission slows down and finally stops after about one hundred shots. This cycle repeats after the rejuvenation of the sample. PLZT 4/95/5 samples show always switching peaks, because of the antiferro-ferroelectric transition, while non-emitting PLZT 8/65/35 samples show no sign of switching current after a certain number of shots. We have ob-

served that the ferroelectric emission is recovered, at least partially, after the reversion of the electrical pulse and after a long rest of the sample, one-two days.

The fact that switching and emission currents go to die in pair, lead to think that there is a mechanism which progressively blocks the domain switching of the uncovered stripes and/or confines the electric field under the metal stripes. This blocking mechanism could be due whether to a domain screening process, or to the formation of macrodomains so the spontaneous polarization does not relaxes back, as it occurs in normal ferroelectrics. The fact that many times there is no emission even if a well pronunced switching current is present (as is the case with PLZT 4/95/5) leads to say that either the switching occurs only inside the zones covered by metal, that is it does not propagate laterally, or the surface becomes passivated for screening and surface mutation due impurities, gas desorption, electron reduction, etc., or finally, the switching mechanism is not enough fast to prevent an evolution of the crystal configuration after the excitation through a complete internal migration of the charge carriers after multishots operation. The possibility of the confinement of the electric field under the metal area is supported by the growth of oxygen-deficient dendrite tips under the metal [6] which cause the increasing of the local field and the decreasing of the switching time.

3 RESULTS WITH A PATTERN OF METALLIC ISLANDS AS ELECTRODE

Different pattern of metallic islands have been tested: a) a pattern obtained by deposition of a uniform 100 Ågold film (this deposition auto-arranges itself in separate patches), b) a very thin silver paste film, which auto-arranges as a patchwork; c) a uniform filling of the surface holes (we remember that the material is porous) by a carbon paste and d) an Au evaporation with a mask of 50 μm diameter islands with an interdistance of 50 μm. A sketch of the pattern is shown in fig. 1.

The samples without the metal islands (with the external metal ring only) did not work.

We have observed that the samples emit always with the new type of electrode, but the nearer the interdistance between the islands the more stable the emission resulted. The results obtained by holes filling are reported.

No accelerating voltage has been set through the diode gap by purpose, because we wanted to catch at the anode Faraday cup only the energetic ferroelectric electrons. An accelerating voltage would have mixed the relatively few FE electrons within the huge amount of electrons extracted from the plasma sheet.

a) Negative pulse at the rear electrode

The signals of the emitted current reported in figs. 2,3 show a good stability. With PLZT 4/95/5 there are two current peaks, while there is only one for PLZT 8/65/35 and in this second case the signal amplitude is 2-3 times higher and longer than the first. These characteristics were

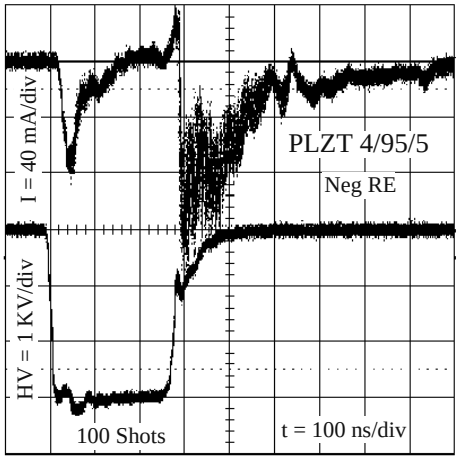

Figure 2: The superposition of 100 current signals, upper trace, and voltage signals, lower trace, is reported. The voltage pulse is applied to the rear electrode (RE), and the sample was a PLZT 4/95/5, as written in the frame, of 0.7 mm thickness.

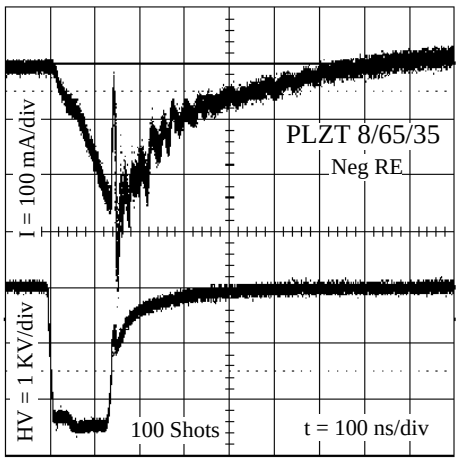

Figure 3: Ibidem as previous figure, but here the sample was a PLZT 8/65/35 of 1 mm thickness.

observed also with the grating, but here the second pulse in 4/95/5 material is substantially stable in time. For all the comparisons the reader is referred to the signals published in references [4, 5, 7]. The almost linear increasing of the 8/65/35 signal is explained by the continuous spontaneous polarization switching all along the excitation pulse. We notice that the very narrow pulses superimposed on the signals resemble the well known Barkausen pulses.

The first pulse is due to the building up of the spontaneous polarization oriented towards the rear electrode [5], while the second peak is due to the relaxation of the spontaneous polarization. The relaxation process of the spontaneous polarization is longer than its building up because in this latter case it is driven by the fast voltage pulse, and in the former case the ferroelectric state is metastable.

b) Positive pulse at the rear electrode

The signals of the emission are shown in fig.4 and 5.

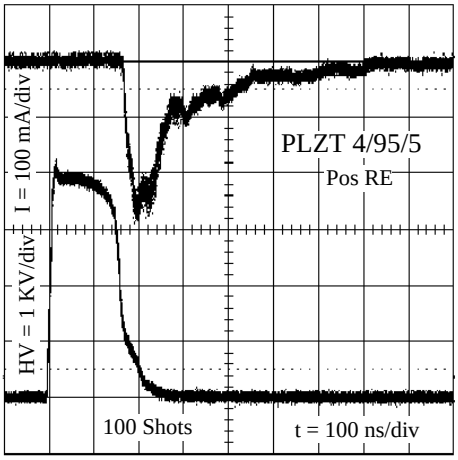

Figure 4: As in fig. 2 but with positive pulse to the rear electrode of a PLZT 4/95/5 sample.

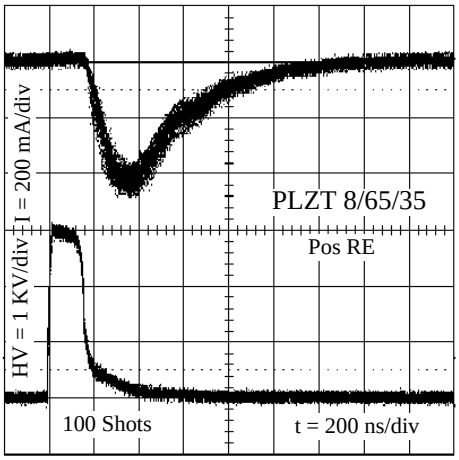

Figure 5: As fig.4 but for PLZT 8/65/35.

In this case the emission occurs at the relaxation of the spontaneous polarization P_s.

For the samples electroded with 100 Åfilm, the emission stopped after a certain number of shots because of the sweeping out of the metal islands.

4 DISCUSSION

The observations on samples with the grating lead to claim that a fast aging process is present for the application of a sequence of unipolar pulses. The neat separation of the cathode material in two parts, one under the metal stripes and the other one outside should induce a process of switching limitation within the covered zones and passivation of the uncovered surface.

The plasma which forms on the surface, owing to the high voltage of the excitation pulse, pushes further towards the surface passivation.

The screening and passivation processes do not occur for samples having disconnected metal patches as electrode. The disconnected electrode avoids the possible segregation of the electric field and so of the polarization switching under the covered zones. Our phenomenological view of operation is that the front of the voltage pulse propagates as a wave to the front surface, so inducing the co-propagation of polarization switching. As a consequence the surface switches into a substantial conduction state: in fact, the dP/dt current signal results in this configuration as high as with a completely electroded surface, further, in ref. [8] it was measured a high mobility of the charge carriers within the stressed region.

When the voltage excitation pulse is over, the surface goes to equilibrium by diffusion of the charge carriers through the surface towards the external ring or through the bulk. The paths of the electrons through the surface are not fixed because the surface state of a ferroelectric ceramic is dynamical and the surface is like a patchwork of peaces, whose properties [9] range from metallic to insulating.

We notice that in the grating case the plasma starts along all the rims of the stripes and covers the 200 μm in few hundreds of nanoseconds, in the other case that time is much longer because the plasma starts from the rim of the outside metal ring (it is connected to the pulser) and has to cover some millimeters of surface space.

It must be recognized that we are not able to give a clear phenomenological model explaining both the substantial unreliable operation with the first electroding and the reliable operation with this second electroding.

5 CONCLUSIONS

A stable copious emission of energetic ferroelectric electrons from a ferroelectric ceramic disk, under the application of a fast high voltage pulse, has been obtained when the electrode of the emitting surface was made as a uniform pattern of un-connected metal patches contained within a metallic ring.

TIME-RESOLVED IMAGING FOR THE APS LINAC BEAMS*

A. H. Lumpkin, W. J. Berg, B. X. Yang, M. White
Advanced Photon Source
Accelerator Systems Division
Argonne National Laboratory
Argonne, IL 60439 USA

Abstract

The particle-beam imaging diagnostics for the Advanced Photon Source (APS) injector linac have been enhanced by the installation of optical transition radiation (OTR) screens and the use of Ce-doped YAG crystals as beam profile monitors. Both converters have improved spatial resolution and time responses compared to the standard Chromox (Al_2O_3:Cr) screens used elsewhere in the linac. These enhancements allow us to address the smaller beam sizes (< 100 μm) and the critical micropulse bunch length of higher brightness gun sources. For the linac macropulse of 30-ns duration composed of 86 micropulses at S-band frequency intervals, only the OTR mechanism is prompt enough to separate individual micropulses and to allow streak camera measurements of the micropulse averaged bunch length. Tests have been performed at 400 to 625 MeV using the gated DC thermionic gun source. Beam sizes less than σ_x=30 μm have been observed with a micropulse bunch length of σ_t= 2-3 ps using OTR. First results on the lower-emittance rf thermionic gun are briefly discussed.

1 INTRODUCTION

The imaging of particle beams on linacs via intercepting screens and video cameras is a well-established practice. However, the time-resolving of individual micropulses in an rf linac macropulse and the measuring of micropulse bunch length requires a radiation conversion mechanism that is prompt compared to the time scale of interest [1]. In the case of the Advanced Photon Source (APS) injector linac, the addition of a lower emittance gun and the critical need for high peak currents in the developing self-amplified spontaneous emission (SASE) free-electron laser (FEL) application have motivated our enhancement of these diagnostics [2]. Optical transition radiation (OTR) screens and Ce-doped YAG crystals have been installed in selected places in the beamline. Both converters have improved spatial resolution and time responses compared to the standard Chromox (Al_2O_3:Cr) screens used elsewhere in the linac. Of the three converters only the OTR screens provide the response required to separate the S-band micropulses and to allow streak camera measurements of the micropulse averaged bunch length and longitudinal profile. At low currents the YAG:Ce provides good spatial resolution like OTR, but we report an apparent "size-blurring" effect for the YAG:Ce converter as current is increased that may limit its usefulness. Many tests have been performed at 400 to 625 MeV using the gated DC thermionic gun source to commission the diagnostics, and the first results with the rf thermionic gun were obtained in the summer of 1998.

*Work supported by U.S. Department of Energy, Office of Basic Energy Sciences, under Contract No. W-31-109-ENG-38.

2 EXPERIMENTAL BACKGROUND

The APS facility's injector system uses a 250-MeV S-band electron linac and an in-line 450-MeV S-band positron linac. The primary electron gun is a conventional gated DC thermionic gun. For one alternate configuration an rf thermionic gun, designed to generate low-emittance beams (< 5 π mm mrad) and configured with an α magnet, injects beam just after the first linac accelerating section [3,4]. Then both in-line linacs can be phased to produce 100- to 650-MeV electron beams when the positron converter target is retracted.

The rf gun's predicted, normalized emittance at higher peak current is lower than that expected of the DC gun, and correspondingly smaller beam spot sizes (< 100 μm) should result. In an early test we used a Ti OTR foil to cover half of a standard intercepting screen based on Chromox of 0.25 mm thickness (rotated 45° to the beam). The 45° angle also directed the OTR light out the same 90° port as the Chromox radiation. Previous experiences on the Los Alamos linac-driven FEL with a low-emittance photoelectric injector (PEI) showed the OTR screens could be used for profiling small beams [5]. This assembly allowed us to steer the e-beam from one converter to the other to compare observed beam spot sizes for spatial resolution tests and assess response time. Because the Chromox decay was so slow, we used a Spiricon video digitizer that could digitize and save images to disk at a 15-Hz rate. This proved more than adequate to track the Chromox decay time.

In addition, we subsequently installed a Ce-doped YAG single crystal of 0.5 mm thickness (obtained from Startec) normal to the beam direction with a polished metal mirror at 45° to the beam just behind it. A separate actuator was used to insert the OTR screen (Molybdenum mirror from Melles Griot) so that its surface was at 45° to the beam.

The light was transported out of the linac tunnel to an optics table via two 150-mm-diameter achromat lenses. The Chromox, OTR, or YAG:Ce light could be viewed by a Vicon charge-coupled device (CCD) camera; a charge-injection device (CID) camera; a Stanford Computer Optics Quik-05 gated, intensified camera; and/or a Hamamatsu C5680 dual-sweep streak camera. The synchroscan unit was phase-locked to 119.0 MHz, the 24th subharmonic of the 2856-MHz linac frequency. A low jitter countdown circuit has been built using Motorola ECLIN PS logic to generate the 24th subharmonic with sub-ps jitter [6].

3 EXPERIMENTAL RESULTS

3.1 Radiation Converter Comparison

As mentioned in the previous section, comparisons were made for Chromox versus OTR and YAG:Ce crystals versus OTR in the past year. In the first series, the beam was initially steered into the high efficiency Chromox. The electron beam optics were then adjusted to give the "best focus" on the OTR screen. The size was recorded, and then the beam was steered back to the Chromox. For beam sizes in the 150-μm regime as measured by OTR, we observed a larger size in the Chromox. We then estimated the Chromox-limiting resolution by subtracting the OTR image size from the total observed Chromox image size in quadrature. This resulted in a limiting value of σ_{res} ~ 200 μm as reported previously [7].

The response time of the Chromox was determined by triggering a single macropulse from the DC gun at 1 Hz and recording the succession of video images on the Spiricon hard disk. The digital images were then analyzed and intensities plotted as a function of elapsed time from the trigger. The 30-ns-long macropulse was like a delta-function in time compared to the Chromox decay time. In Fig. 1 this decay of image intensity is shown, and the 1/e value was determined as 300 ms. Using the OTR screen, only one frame had an image since OTR is indeed prompt versus video rates. The Chromox decay time is even long compared to macropulse separations of 30 ms at the 30-Hz rate.

In the YAG:Ce and OTR comparison, the tests were performed in a similar manner. Over the course of brief tests at 100-mA average beam current (about 3 nC in a macropulse), we repeatedly observed a larger beam size with YAG:Ce than with OTR. In the June 12, 1998 experiments we first established our beam size comparisons at low currents of 30 and 60 mA. We used an elongated vertical focus (aspect ratio H/V of 1/10) because this seemed to result in the smallest sizes we could make: 70 μm (FWHM) or 30 μm (σ). This value is close to the calculated resolution of the transport line. The neutral density filter difference of 2.0 was used at this reference point, and the camera position in Z was adjusted to compensate for

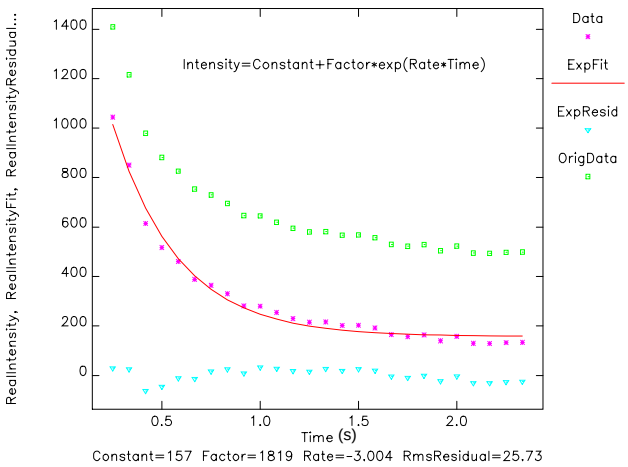

Figure 1: "X" Data with background subtracted are fitted to an exponential. The 1/e time is about 300 ms.

the YAG surface and OTR mirror surface location difference. These low-current data basically normalize and validate the screen comparison in terms of calibration factors, source strength compensation, camera saturation, and bremsstrahlung effects in the YAG:Ce. As shown in Fig. 2, at 100 mA and higher the YAG:Ce images are observed to be increasingly larger with current than the OTR images. There is a slight increase in the OTR image with current. The threshold for this "size-blurring" effect for this particular crystal/mirror and these conditions is 1.1 to 1.6 pC/μm^2 using the FWHM size. If the one-sigma beam sizes are estimated using a Gaussian shape assumption, the threshold is $(2.35)^2$ times smaller or 0.2 to 0.3 pC/μm^2.

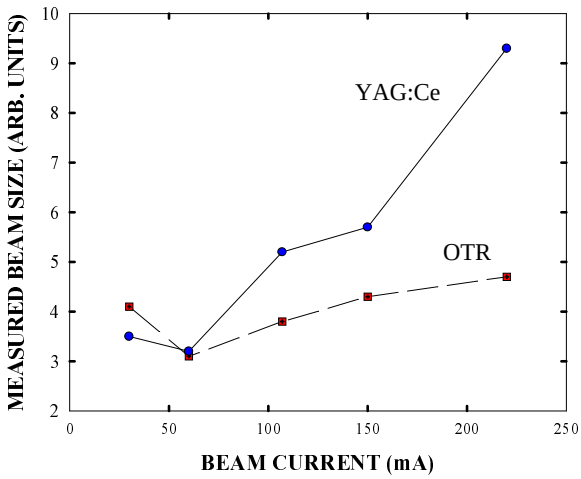

Figure 2: Comparison of observed beam image sizes using OTR (dashed line) and the YAG:Ce converter screens. Noticeable YAG:Ce (solid line) image size growth is observed beginning at ≤ 100mA and with spot size of about 40×400 μm^2 ($\sigma_x \times \sigma_y$).

Simplistically speaking, there may be a saturation-like phenomenon in the peak-intensity regime that results in the half-maximum intensity points growing relative to the peak. How the very large number of Ce-related impurity levels could be exhausted is unclear. Alternatively, mechanisms involving radiation trapping or photoionization may be involved [8]. The very small beam spots from a PEI that involve several hundred pC could easily approach this threshold observed in these 625-MeV tests. These charges and beam energies are higher than used in the single micropulse experiments previously [9]. Further tests and a search for alternative explanations are planned.

The reported response time for this YAG:Ce is 80 ns (FWHM) [9] so it averages the micropulses in a 30-ns macropulse. A measure of this was shown by comparing the micropulse bunch length seen with OTR to the YAG:Ce result. The OTR result was 4 ps (FWHM) while the YAG:Ce decay filled the 150-ps field of view and completely obscured the micropulse structure and a fortiori, the bunch length. The OTR result is very similar to that obtained previously by an rf phasing technique [10].

Table 1 summarizes these comparisons of the radiation converter spatial resolution, temporal response, and conversion efficiency. The limiting resolution number for APS-installed screens of Chromox and YAG:Ce are given and the OTR number estimated. The OTR response time is only an estimate, but this surface phenomena should be in the regime of the skin depth for visible light in a metal [11].

Table 1: Comparison of the Chromox, YAG:Ce, and OTR Converter Screens for Particle Beam Imaging at 600 MeV at APS

Screen	Spatial Resolution σ (μm)	Temporal Response	Intensity Arb. Units
Chromox (0.25 mm)	200	300 ms	1
YAG (0.5 mm)	<30 low current <100 200 mA	80 ns	1
OTR	<10	~ 10 fs	$\sim 2 \times 10^{-3}$

3.2 RF-Gun Accelerated Beam

On August 12, 1998 our first images of the rf-gun beam at 400 MeV were obtained at this station at the end of the linac. Both OTR and YAG:Ce images were obtained with the YAG:Ce size again being larger than the OTR size for ~160-mA average current and an approximate 130×130 μm^2 spot size. A preliminary synchroscan streak image gave a σ_t = 3 to 6 ps result even though no optimization of the rf gun had yet been done.

4 SUMMARY

In summary, the time scales for time-resolved imaging on the APS linac have been significantly enhanced. The targeted beam spot sizes of 100 μm (σ) can be addressed by YAG:Ce at low current (areal charge density) and OTR at higher currents. Micropulse bunch lengths at the ps-regime can also be addressed now. Optimization of the accelerated rf gun beam will be facilitated by these enhanced techniques.

Abstract

Beam position measurements are being designed and fabricated for the Low Energy Demonstration Accelerator (LEDA), a 20-MeV, 100-mA-cw proton-accelerator, presently under construction at Los Alamos [1]. Similar position measurements will provide position information for a steering scheme within the Accelerator Production of Tritium (APT) linac magnetic lattice. The steering scheme, which centers the beam in the magnetic lattice, uses two position measurements and two translatable quadrupole magnets every 5.5-FODO-lattice periods. What makes these beam position measurements unique is how they will attain, maintain and verify the required accuracy. The position measurement systems consist of micro-stripline beam position monitors (BPMs) and RF coaxial cables, log-ratio processors, on-line error correction sub-systems, and a control system interface including associated algorithms and computer software. This paper discusses the mapping of the BPM probe response, the algorithm used to calculate low beam-velocity response, and the expected log-ratio processor performance.

1 INTRODUCTION

1.1 Beam Position Measurement Purpose

During the commissioning and operation of the LEDA radio frequency quadrupole (RFQ), beam position measurements serve two purposes. They provide sufficient beam position information for centering the 6.7-MeV beam both in the high energy beam transport (HEBT) magnetic lattice and on the high power beamstop, and they verify that the quadrupole magnetic field settings are properly set.

For APT, position measurements provide sufficient information for centering the beam in the magnetic lattice throughout the linac and HEBT. By placing BPM pairs within quadrupole magnet bores separated by ~90 degrees of phase advance, both beam position and trajectory angle are acquired. For example, early in the coupled cavity drift tube linac (CCDTL), where the phase advance per FODO lattice period is 78 degrees, two BPMs are installed in two focusing quadrupole magnets separated by a defocusing quadrupole magnet.

1.2 APT Steering Schemes

The CCDTL BPM placement scheme repeats every 5.5-lattice periods, allowing operators to correct for various static random errors. This scheme was simulated using budgeted beam-position-measurement errors similar to those shown in Table 1 and multiple quadrupole magnet misalignments, field amplitude errors, and other errors. For a 25-mm radius BPM, the total budgeted position-measurement precision and accuracy is 0.06- and 0.21-mm, respectively. Typical accuracy errors include BPM alignment errors and precision errors include RF cable isolation and BPM vibration.

Table 1: Beam-position measurement-error budget table using a 25-mm radius BPM.

Measurement Components	Precision (mm)	Accuracy (mm)
BPM	0.01	0.12
RF Cable Plant	0.0003	0.02
On-line Calibrator	0.03	0.16
Log-Ratio Processor	0.04	0.04
TOTAL	0.05	0.21

APT beam steering is accomplished by translating a quadrupole magnets pair for each BPM pair with the last steerer residing in the same focusing quadrupole magnet as the first BPM [2]. The additional half FODO lattice in the steerer/BPM-pair placement period allows a single axis of the beam's central trajectory to be corrected every 11-lattice periods.

2 MEASUREMENT SYSTEM

2.1 System Description and BPM Design

The position measurement system consists of four components; the BPM and its associated set of RF cables, an electronics processor, on-line error correction circuitry,

* Work supported by the US Department of Energy

and an Experimental & Physics Industrial Control System (EPICS) interface [3,4,5].

The BPMs are a four-electrode micro-stripline design with electrode characteristic impedances of 50-Ω. Each BPM has a physical feature that provides alignment verification with respect to the facility alignment references and ultimately with respect to the linac magnetic lattice. These alignment features also serve as a method to mate the BPM to its mapping fixture so that it's mapped electrical characteristics are directly related to the measured beam position. For the pictured LEDA HEBT BPM shown in Fig. 1, four optical-alignment-monument mounts are welded on the downstream vacuum flange. Those APT BPMs that are mounted within quadrupole magnets have additional constraints. For these BPMs, construction processes and materials are used to minimize the BPM's permeability and to ensure that the quadrupole magnetic fields are undistorted.

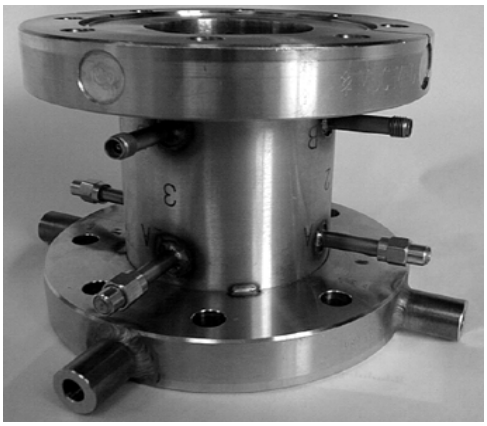

Figure 1: This LEDA 5-cm-aperture micro-stripline BPM has a 45 degree subtended angle and a 5-cm-length electrode.

2.2 Log-Ratio Electronics Processor

The electronics processor uses a log-ratio technique for analyzing the beam's position by demodulating and converting each BPM-electrode 350-MHz-signal current into a logarithmic signal voltage [6]. Each logarithmic lower-bandwidth analog voltage is digitized. The opposite-electrode converted signals are then subtracted from each other to produce a stream of digital words that represent the detected log-ratio beam position.

Previously, demodulating logarithmic amplifiers were only available with limited input bandwidths. These limited bandwidth amplifiers forced the addition of a RF down converter to translate the BPM-electrode's fundamental RF signal to a frequency within these earlier amplifier's operational range. However, low-cost very-broad-bandwidth logarithmic amplifiers are now available and allow the exclusion of down converter circuitry in log-ratio processor designs. For example, the Analog Devices, Inc. AD8307 logarithmic amplifier has a 500-MHz bandwidth over a 92-dB dynamic range and can operate at frequencies near 900-MHz with a reduced dynamic range.

As with previous versions, the logarithmic function is created by a series of amplifier stages that successively detect the RF signals and approximate the logarithm function in a piecewise linear fashion. Due to the detection technique, this type of logarithmic amplifier systematically deviates from the ideal logarithmic function. Fig. 2 shows how these deviations will effect the operation of the log-ratio processor. These data were acquired from a single AD8307 amplifier detecting a 350-MHz RF signal. The output signal mean and rms noise were acquired for each 1-dBm step of input signal power. The mean data were fitted to a logarithmic function and the residuals were plotted to show function-deviation information versus input beam current, where input beam current is derived from input signal power. Note that the logarithmic function deviation is approximately ±0.7-mm for a 50-mm aperture BPM over four decades of beam current. This deviation represents a worst case condition. In previous log-ratio processors, these amplifiers exhibited very similar logarithmic-function systematic errors. When used in pairs, the log-ratio detection method has a lower sysetmatic error behavior [5].

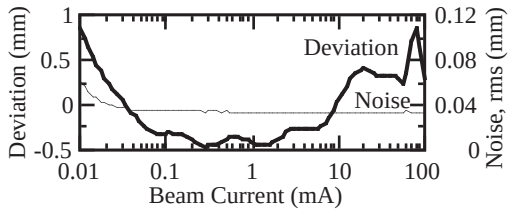

Figure 2: The above data show expected 350-MHz log-ratio position-detector performance using an AD8307 integrated circuit.

Fig. 2 also displays the rms noise characteristics of the AD8307 amplifiers. Because these logarithmic amplifiers contain many stages of detection and amplification, their noise figures are typically much larger than other beam position processing techniques. However, the AD8307 noise characteristics are sufficiently low to easily meet the APT and LEDA position measurement precision requirements. Note that these amplifiers are expected to provide beam position measurement precision of 0.04 mm within a 50-mm aperture BPM.

2.3 Error Correction and EPICS Interface

A unique feature of this particular measurement system is how the system's accuracy is maintained. During normal BPM operation, an RF relay connects a properly matched terminator to the downstream port of each BPM electrode. Additionally, this relay may also be switched to inject a 350-MHz signal from a stable and well-characterized 4-way RF splitter into each BPM electrode for measurement-system error correction. This error correction method will allow accelerator operators and commissioners, from within the accelerator control room, to verify and correct most measurement system errors. Early implementations of the log-ratio processor have

shown that systematic errors may be corrected to within a factor of X2 of the precision error using signal injection techniques [4,5].

Another unique feature is the method used to interface the log-ratio circuitry to EPICS. The current design calls for both the log-ratio processor and on-line correction module to be implemented as register-based VXI modules, and located in the same VXI crate. This module organization allows direct control and rapid automatic operation of both modules from the same control computer, typically referred to as an input/output controller (IOC). Both modules will implement full digital control and data acquisition via the VXI bus.

3 BPM CHARACTERIZATION

3.1 Mapping Characterization Process and Data

A mapping fixture was developed for LEDA and APT to accurately characterize the BPM beam-position response [7]. As a thin wire with an injected 350-MHz signal is accurately moved across a BPM aperture, the RF fields from the injected signal induce RF currents on the BPM electrodes. RF signal data from individual electrodes are acquired and the power ratios between opposing electrodes are calculated for each wire location. The resultant data maps are then fitted in a least squares sense to a 3rd-order 2-dimensional equation [8].

Fig. 3 shows a typical map of the 50-mm aperture BPM planned for use in the LEDA HEBT with its fitted 3rd-order surface fit. Typical mapped offsets and sensitivity terms are 0.07 mm and 1.36 mm/dB, respectively. The typical sensitivity terms are within a few percent of the theoretical values of 1.39 dB/mm based on a analytic circular-BPM model [6,9].

3.2 Low Beam-Velocity Correction

Because the relative beam velocities are low for the LEDA and APT CCDTL and coupled cavity linac (CCL) beams, the bunched beam fields deform such that the BPM offset, sensitivity, and 3rd-order terms will be slightly different from those acquired by the mapping fixture. A technique has been developed to correct these terms for low velocity beams and has been verified with beam experiments [9]. The technique consists of the following steps:

1. With β=1, adjust the electrode subtended angle and radius in the analytic model so that a new model-based map agrees with mapping fixture data.
2. Decrease β in the analytic model to agree with the expected beam velocity.
3. Produce new analytically-derived map.
4. Perform forward and inverse least-squares fits.
5. Change manufactured offsets in the initial mapped data by using the new low-β BPM sensitivity.

This procedure has been performed on 50-mm aperture LEDA BPMs and has shown sensitivities will increase to 1.76 dB/mm.

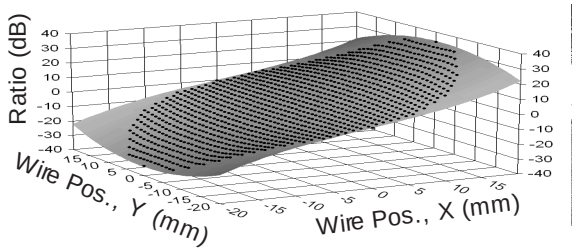

Figure 3: Position-sensitivity map of a BPM showing an opposing-electrode signal ratio for each wire location.

4 SUMMARY

This paper has discussed current LEDA and APT beam position measurement developments. These developments include the APT and LEDA beam steering scheme, changes to the log-ratio processor, the BPM characterization processes, and corrections to the BPM sensitivity due to low beam-energy effects.

LASER DIAGNOSTIC FOR HIGH CURRENT H⁻ BEAMS*

Robert E. Shafer
Los Alamos National Laboratory, Los Alamos, NM 87545

1 INTRODUCTION

Laser systems have been in use at the Los Alamos LAMPF 800-MeV proton linac and on various low energy H^- beamlines since about 1980 to do research or diagnostics on the accelerated H^- beam. The basis for these systems is that the threshold for photodetaching an electron is about 0.75 eV, and the photodetachment cross section rises to about 4 x 10^{-17} cm^2 for photons of about 1.5 eV (800 nm).

A Q-switched laser, when triggered, fully discharges in a few ns. Thus a small Q-switched laser with, say 50 mJ pulse energy and 10 ns pulse length, has the instantaneous power of 5 MW. Furthermore, a 50 mJ pulse at 1064 nm wavelength contains over 2 x 10^{17} photons. Because of the large photodetachment cross section, a significant fraction of the beam can be neutralized during the laser pulse. The Q-switched laser beam can either be focused to select a thin slice of the transverse beam profile, or defocused to nearly uniformly illuminate the entire beam.

Because neither the laser photon nor the recoiling photodetached electron transfer significant momentum to the H^0 atom, the neutralized beam maintains nearly the original phase-space parameters of the H^- beam from which it was extracted.. Furthermore, because the neutralized beam will not be deflected by either electric or magnetic fields, the H^- beam parameters can be deduced from measurements on the drifting neutral beam, even after it is separated from the H^- beam by magnetic fields. Measurements on the neutral beam are neither disruptive to the primary beam, nor destructive to the beam diagnostic.

2 THEORY

2.1 Photodetachment Cross Section

A plot of the photodetachment (stripping) cross section vs. photon energy, in the rest frame of the H^- atom, is shown in Fig. 1 [1-3].

The threshold is at about 0.75 eV and the peak cross section, 4 x 10^{-17} cm^2, is at about 1.5 eV. Because the binding energy of the remaining 1s electron in the neutral hydrogen atom is 13.6 eV, it will not be stripped by the laser.

*Work supported by the U.S. Dept. of Energy.

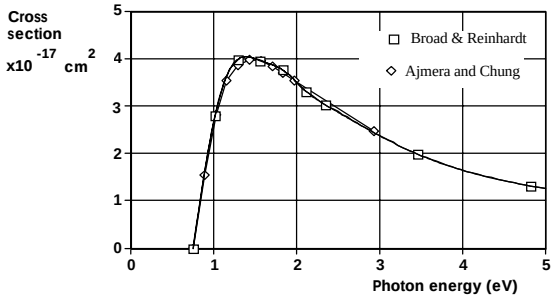

Figure 1. Photodetachment cross section of H^- vs. photon energy in the H^- rest frame.

2.2 Lorentz Transformation

Because H^- beams can be accelerated to energies of 1 GeV or more, there is a very sizable relativistic shift of the laser photon energy to higher energies in the H^- rest frame, often referred to as a "Lorentz boost". The photon energy E_{CM} in the H rest frame is related to the laser photon energy E_L by the equation

$$E_{CM} = \gamma E_L (1 - \beta \cos\theta_L)$$

where β and γ are the Lorentz parameters of the H^- beam, and θ_L is the laboratory angle of the laser beam relative to the H^- beam.

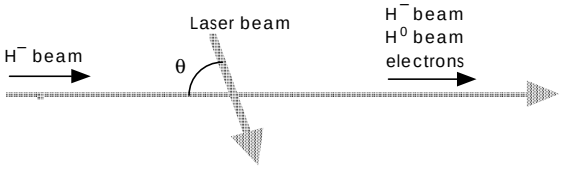

Figure 2. Geometry for laser photodetachment

2.3 Photodetachment Yield

For a Gaussian-profile laser beam with N_L photons intercepting a Gaussian-profile H^- beam of current I_b at an angle θ_L, the yield Y_1 (number of neutral hydrogen atoms produced per laser-H^- beam crossing) is given approximately by

$$Y_1 = \frac{I_b N_L}{e\beta c}\frac{1-\beta\cos\theta_L}{\sin\theta_L}\frac{\sigma_N(E_{cm})}{2\pi\sigma\ \sigma_L}\int_{-\infty}^{\infty}\exp\left(\frac{-x^2}{2\sigma_b^2}\right)\exp\left(\frac{-x^2}{2\sigma_L^2}\right)dx$$

$$= \frac{I_b N_L}{\sqrt{2\pi}\, e\beta c}\frac{1-\beta\cos\theta_L^b}{\sin\theta_L}\frac{\sigma_N(E_{cm})}{\left(\sigma_b^2+\sigma_L^2\right)^{1/2}}$$

where σ_b and σ_L are the transverse rms sizes of the H^- and laser beams normal to the plane of incidence, and $\sigma_N(E_{cm})$ is the photodetachment cross section at photon energy E_{cm} in the H^- rest frame.

The yield of photodetached H atoms for a 50 mJ 1064 nm Nd:YAG laser pulse on a 50 mA, 1-GeV H^- beam, using θ_L = 85º, E_{cm} = 2.22 eV (Lorentz-boosted photon energy in rest frame of H^-), βc = 0.875 x 3 x 10^{10} cm/s (beam velocity) N_L = 2.68 x 10^{17} (photons per laser pulse), $\sigma_b = \sigma_L$ = 0.2 cm (rms width of laser and H^- beams), σ_N (E) = 3 x 10^{-17} cm^2 (photodetachment cross section at energy E_{cm}), is Y_1 = 1.25 x 10^8 H^0 atoms per laser pulse (single crossing). For a 10 ns laser pulse, this is an instantaneous H^0 'current" of 2 mA (4% of H^- current).

This technique can also be used for low-energy (< 10 MeV) H^- beams, because the detachment cross section (Fig. 1) is 3.5 x 10^{-17} cm^2 at 1.17 eV (1064 nm). Because the yield is inversely proportional to β, the H^0 yield is larger for low energy beams. In the above example, if the beam energy is lowered to 2.5 MeV, the yield increases to 1.6 x 10^9 atoms (51% of H^- current).

2.4 Yield Enhancement

A variety of mirror configurations for reflecting the laser beam through the H^- beam many times are possible. The simplest configuration is two parallel front-surface mirrors. Another configuration is an internally-reflecting cylindrical mirror with its axis aligned along the beam. To take advantage of the temporal resolution of a very short Q-switched laser pulse, which is useful in maximizing signal to noise, the effective photon lifetime in the mirror should not exceed a few ns. An effective lifetime of 10 ns corresponds to a photon path length of about 300 cm, equivalent to about 30 reflections inside a 10-cm diameter mirror assembly. Thus the optimum mirror assembly needs to reflect the laser beam through the H^- beam only about 30 times, an easily achievable number even with modest mirror reflectivities.

2.5 Backgrounds

There are two sources of background uniquely associated with H^- beams. They are magnetic stripping and residual gas stripping. If not controlled, these stripping mechanisms can contaminate the signal obtained by laser stripping. For high current, high energy H^- beams, these loss mechanisms can also contribute to a significant amount of activation. A beam loss of a watt per meter at 1 GeV can lead to activation levels in the range of 10's of mrad/hr.

A relativistic H^- beam can be stripped by the Lorentz-transformed magnetic field of a typical beamline magnet. The theory of electric and magnetic field stripping of H^- beams is discussed by Sherk [4] and by Jason [5]. As an example, the stripping loss rate of a 1-GeV H^- beam in magnetic fields of 0.3 T, 0.35 T, and 0.4 T is 0.12, 7.4, and 164 ppm per meter respectively.

A relativistic H^- beam can also be stripped by inelastic collisions with residual gas atoms. The cross sections for this process have been evaluated by Gillespie [6]. As an example, the cross sections for stripping a 1-GeV H^- beam in hydrogen and nitrogen gas are about 1.2 and 8.9 x 10^{-19} cm^2/atom, and scale approximately as $1/\beta^2$. For a 1 x 10^{-7} torr (273 K) vacuum, these cross sections represent stripping losses of about 0.08 and 0.6 ppm per meter respectively.

3 EXPERIMENTAL APPLICATIONS

3.1 Commercially Available Q-Switched Lasers.

Inexpensive shoe-box sized Q-switched Nd:YAG lasers can produce 10-ns long, 50 mJ, 1064-nm pulses (or harmonics) at 60 Hz. These units are totally enclosed, and can be installed directly on a beamline. The 1064-nm line is nearly ideal for general diagnostics on H^- beams, because of its proximity to the peak in the photodetachment cross section. The 10-ns pulse width is adequate for many applications where good temporal response is required, and this can be improved if necessary by using external polarizers and pockels cells.

Solid state laser diodes, with outputs of several watts, may be useful as a device for extracting very small average currents from a H^- beam, but they are probably not suitable as a beam diagnostic. This is because the solid state laser cannot achieve the very high peak power available in a Q-switched laser, required to discriminate against the backgrounds.

3.2 Experimental Layouts and Measurements

A generic layout for a laser diagnostic is shown in Figure 3. In Fig. 3, the Q-switched laser beam intercepts the H^- beam at an angle θ_L. A mirror assembly produces multiple passes of the laser beam. A dipole magnet separates the neutral beam from the H^- beam. If a dipole magnet, such as in a bend, is not possible, then a weak dipole field will deflect the detached electrons, which can be detected. After the neutral beam emerges from the dipole magnet, it may be foil-stripped to produce a proton beam. A variety of beam diagnostics for characterizing the resultant proton beam are possible. Because the proton beam is low power, the diagnostic may totally intercept the protons.

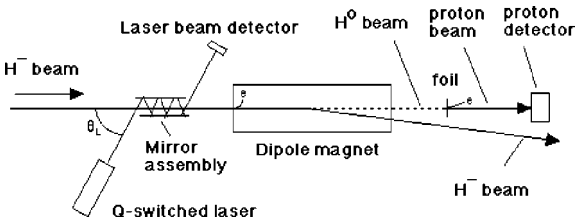

Figure 3. A generic arrangement for laser beam diagnostics.

A laser beam for transverse beam diagnostics can either be a thin "laser wire", neutralizing only a thin slice of the incident H^- beam, or intercept the entire beam [7-9]. The width of the laser wire can be of the order of 0.2 to 0.4 mm. If used in a high dispersion region, it may be

possible to measure the H^- energy spread. For measuring the proton yield, possible proton diagnostics include phototube-scintillator assemblies, Faraday cups, secondary-emission monitors, etc. Because the photodetachment yield is higher at low energies, lasers may be a good substitute for intercepting wire scanners, which are particularly hard to use in low energy, high dE/dx H^- beams.

A very specific application in the proposed Spallation Neutron Source project is to measure the beam current in a 1.18 MHz, 280-ns-wide, beam chopper gap, which must be less than about 1 x 10^{-5} of the 28 mA H^- beam (about 0.3 μA). The laser system with mirrors can extract a neutral current of about 0.10 μA from this gap for 10 ns, equivalent to about 6200 particles. This can be measured using either charge or scintillator pulse detection techniques to determine the cleanliness of the gap. The very high dynamic range and charge sensitivity required for the beam-in-gap measurement is also useful for exploring the halo region of the primary beam. This is a difficult measurement to make with normal beam profile diagnostics.

When measurement of the photodetached H^0 atom or proton is difficult, measurement of the photodetached electron is possible. The electron has about $1/1840^{th}$ of the proton rigidity, and is easily deflected into detectors by weak magnetic fields. This technique has been used in photodetachment experiments. The photodetached electron is easily deflected by space charge forces in high current H^- beams, however, so the electron signal cannot be analyzed for obtaining accurate H^- beam emittance information.

Resonances in the photodetachment total cross section near the n=2 threshold (10.953 eV) have been used to measure H^- beam momentum and momentum spread [10]. In this experiment, a 50 mJ Q-switched Nd:YAG laser operating at 266 and 355 nm was used. Both the Feshbach resonance (10.926 eV, width 30 μeV) and the shape resonance (10.975 eV, width 25 meV) can be used for this measurement, although the widths and strengths of these resonances are not ideal.

4 CONCLUSION

Laser photodetachment can be used on high current, high energy H^- beams to carry out a wide variety of beam diagnostic measurements parasitically during normal operation, without having to operate the facility at either reduced current or duty cycle. Suitable Q-switched laser systems are small, inexpensive, and can be mounted on or near the beamline. Most of the proposed laser-based diagnostics techniques have already been demonstrated.

Abstract

The beam operation of the damping ring of the KEK accelerator test facility (ATF) has been started since January 1997 for the development of the technologies to achieve a low emittance beam, which is required in future linear colliders. The ATF consists of a injector linac, the damping ring and a beam extraction line for a beam diagnosis. An operation of the extraction line has been started since November 1997. However, the beam position at the extraction line was not stable for the reason why extraction kickers did not work stable and the longitudinal beam oscillation is still remained in the damping ring at extraction timing and so on. Therefore, we established the method to correct measured beam size and evaluated the horizontal emittance. In this paper, we report the performance of jitter subtraction method for the horizontal beam size. The amount of the evaluated horizontal emittance was 1.37 ± 0.03nm.

1 INTRODUCTION

It was reported that a small beam emittance was measured by synchrotron radiation at several synchrotron radiation storage rings. In ESRF, extremely small horizontal and vertical emittances, 3.5nm and 0.04nm, were evaluated with X-ray pinhole camera[1]. It is difficult to measure the horizontal emittance with small systematic error by utilizing the synchrotron radiation in the ATF damping ring, because a fraction of horizontal beam size due to horizontal dispersion and energy spread was comparable or greater than that from horizontal emittance. However, ATF has a beam extraction line, which contains a beam diagnosis section of the extracted beam. Operation of the ATF extraction line has been started since November 1997.

2 ATF EXTRACTION LINE

In the ATF extraction line, there is a beam diagnostic section, which is designed to be horizontal dispersion free and the quadrupole magnets are designed to form FODO cells.

There are an integrating current transformer (ICT) and 14 single path strip-line type beam position monitors (BPMs) at the extraction line. And four wire scanners are located to measure a beam size and to evaluate a beam emittance[2]. Wires of each wire scanner are mounted to wire mounts. And the wire mounts are rotated by $45°$ to horizontal plane as shown in Figure 1. The wire positions are read out by measuring the wire mount positions with digital position gauges. And scattered γ-rays by wire scanners are detected by an air Čerenkov detector with photomultiplier (PMT). All of these beam monitors at the ATF extraction line are read out in the single beam passage simultaneously. Thereby, we can examine a correlation between all monitors in the ATF extraction line.

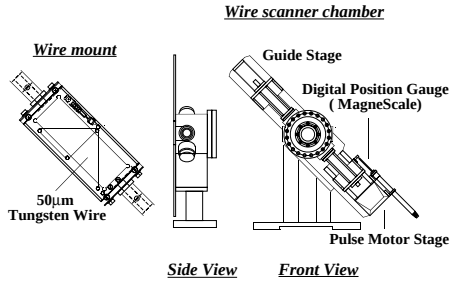

Figure 1: Schematic figure of wire scanner used in ATF.

3 DISPERSION CORRECTION

The magnet setting, especially steering magnets, is often changed for various beam studies, because ATF damping ring is a test accelerator. It changes dispersion in the damping ring and as consequence in the extraction line. Residual horizontal dispersion at the beam diagnostic section produces an additional beam size and a longitudinal beam oscillation make additional horizontal position jitter as proportional to the dispersion. Thereby, we must make dispersion correction every time at the beginning of beam diagnosis on the extraction line. The dispersion function at the extraction line is evaluated by measuring orbit difference with different rf frequency in the damping ring (rf ramp method). At a beam injection timing, the damping ring rf must be synchronized with a linac rf. However, the damping ring rf frequency can be changed between a beam injection and the next beam injection in order to measure the dispersion function.

Dispersion correction was carried out as following procedures. At first, beam positions were measured by BPMs for five rf frequency offsets, +2kHz, +1kHz, 0kHz, -1kHz and -2kHz. Slopes $\Delta x_{\mathrm{ramp}}/\Delta f_{\mathrm{RF}}$ were evaluated with linear fitting using MINUIT[3] software package and horizontal dispersions were evaluated as

$$\frac{\eta_x}{\alpha_{\mathrm{M}}} = -f_{\mathrm{RF}} \frac{\Delta x_{\mathrm{ramp}}}{\Delta f_{\mathrm{RF}}} \tag{1}$$

for each BPM locations in the extraction line. Horizontal dispersions at locations of wire scanners were evaluated using a fitting with two parameters of η_x, η_x' at the entrance of extraction line on restricted condition of design momentum compaction factor α_{M}. Linear optics model for the extraction line was used for the fitting. Finally, a calculation of magnet settings to suppress horizontal dispersion at beam

diagnostic section were carried out based on the dispersion measurement. Consequently, strength of some quadrupole magnets were changed to suppress horizontal dispersion.

4 JITTER SUBTRACTION

Horizontal beam position of the extracted beam was not stable for the reason why one of extraction kickers[4] discharged, which was located at the extraction line. An amount of horizontal beam position fluctuation was 50-200μm at the beam diagnostic section and the beam fluctuation affected to horizontal beam size measurement, because a typical horizontal beam size of 30-100μm at the beam diagnostic section was comparable to the beam fluctuation. We applied a position jitter subtraction to a beam size measurement.

Horizontal beam offset at arbitrary position x_3 is calculated from offsets at other two locations x_1, x_2 as follows

$$x_3 = \frac{R_{12}(s_3,s_1)}{R_{12}(s_2,s_1)}x_2 - \frac{R_{12}(s_3,s_2)}{R_{12}(s_2,s_1)}x_1 \qquad (2)$$

at the dispersion free section. Where $R_{12}(s_j,s_i)$ is a transfer matrix component from s_i to s_j. As more than two horizontal positions are possible to be measured by BPMs, we can estimate a horizontal beam offset at arbitrary position. An expected position resolutions for the position estimation depends upon a BPM readout resolution as follows

$$\begin{aligned}\sigma_{x_3} &= \sqrt{\left(\frac{R_{12}(s_3,s_1)}{R_{12}(s_2,s_1)}\right)^2 + \left(\frac{R_{12}(s_3,s_2)}{R_{12}(s_2,s_1)}\right)^2}\,\sigma_{x,\mathrm{BPM}} \\ &= f(s_1,s_2,s_3)\,\sigma_{x,\mathrm{BPM}} \end{aligned} \qquad (3)$$

with $\sigma_{x,\mathrm{BPM}}$ the BPM readout resolution. As any set of BPM readout positions can be applied to x_1, x_2 in Eq. (2), the set of BPMs should be chosen to make the resolution factor $f(s_1,s_2,s_3)$ minimize for each noticeable locations s_3.

We applied the position estimation method to beam size measurement using wire scanners. The set of BPMs used for position estimation and corresponding resolution factor $f(s_1,s_2,s_3)$ are listed in Table 1. As mentioned above, horizontal beam positions at the wire scanners were fluctuated pulse by pulse. However, we can expect a beam position with respect to wires by using the position estimation of Eq. (2). And the beam position with respect to a wire can be expressed as

$$x_{\mathrm{WS}} = \frac{x_{\mathrm{DG}}}{\sqrt{2}} - \left(\frac{R_{12}(s_{\mathrm{WS}},s_1)}{R_{12}(s_2,s_1)}x_2 - \frac{R_{12}(s_{\mathrm{WS}},s_2)}{R_{12}(s_2,s_1)}x_1\right) \qquad (4)$$

with s_{WS} the wire scanner location, x_{WS} the beam position with respect to the wire and x_{DG} the digital position gauge readout on the wire scanner, which was divided by $\sqrt{2}$ to convert the horizontal position by its 45° tilt. A typical readout of PMT signals for wire scanner MW1X is shown in Figure 2(a) as a function of wire positions. It was found that PMT signals were scattered over wide range. On the other hand, Figure 2(b) shows PMT signals as a function of the x_{WS} in Eq. (4) and horizontal position jitter was well corrected.

Wire Scanner Name	BPM1	BPM2	$f(s_1,s_2,s_3)$
MW1X	ML11X	ML10X	0.758
MW2X	ML12X	ML10X	0.432
MW3X	ML12X	ML9X	0.868
MW4X	ML10X	ML11X	0.370

Table 1: The list of resolution factor for each monitors located at beam diagnostic section. BPM1, BPM2 are the set of BPMs for the minimum resolution factor.

5 EMITTANCE EVALUATION

Two different methods are used for horizontal emittance evaluation. One is a waist scan method, and the other is a four wire method. The waist scan method is the method to evaluate a beam emittance by measuring a beam size with single wire scanner while changing strength of a quadrupole magnet located upstream of the wire scanner. The beam size square changes as quadratic as shown in Figure 3. We evaluated a horizontal emittance by the waist scan method with MW1X, MW2X and MW3X. Waist scan method with MW4X was not carried out, because a horizontal beam size at MW4X was insensitive to a strength change of quadrupole magnets located upstream of the monitor. The results are listed in Table 2.

The four wire method is the method to evaluate a beam emittance by measuring beam sizes with four wire scanners. In this method, Twiss parameters α_x, β_x and horizontal emittance are evaluated from a fitting for the beam sizes at the four wire scanner locations, knowing the optics information between them. The result of the fitting are shown in Figure 3(d). The ellipse shows the evaluated beam distribution in phase space (x,x') at the entrance of the extraction line. And four lines show the measured beam size boundaries converted to the same phase space. Result is also listed in Table 2. All evaluated horizontal emittances with both of waist scan and four wire methods agreed within 2σ and the averaged horizontal emittance was obtained as

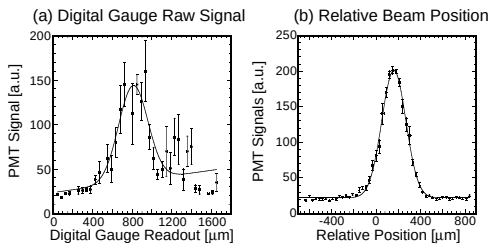

Figure 2: Result of a position jitter subtraction to magniscale readout position of wire scanner. (a) PMT signals as a function of wire readout position, (b) PMT signals as a function of evaluated relative beam position to wire.

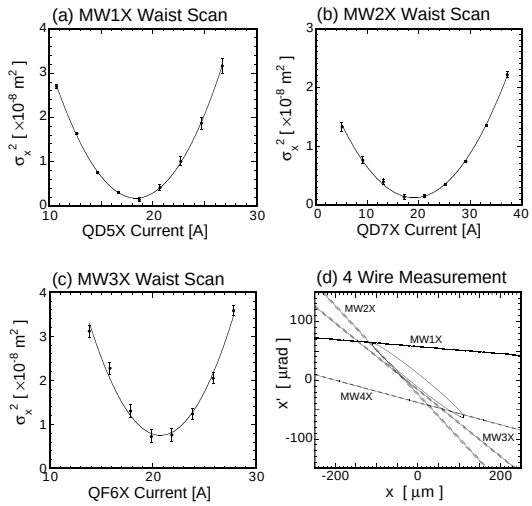

Figure 3: Beam size measurement result. (a),(b),(c) are results of waist scan method for each monitors, and (d) shows a result of four wire method.

1.37 ± 0.03nm.

The fitted Twiss parameters were compared for a verification of consistency of the horizontal emittance evaluations. Factor $B_{\rm mag}$ is defined as

$$B_{\rm mag} = \frac{1}{2}\left[\frac{\beta_2}{\beta_1} + \frac{\beta_1}{\beta_2} + \beta_1\beta_2\left(\frac{\alpha_1}{\beta_1} - \frac{\alpha_2}{\beta_2}\right)^2\right] \quad (5)$$

for two different set of Twiss parameters α, β. The evaluated $B_{\rm mag}$'s are also shown in Table 2. In the calculation of $B_{\rm mag}$, each measurement was used as one set of Twiss parameter and an averaged Twiss parameter of the other three measurement weighted by their errors was used as the other. It was found that all $B_{\rm mag}$ were close to unity. Thereby, evaluated horizontal emittance had the consistency each other.

6 CONSIDERATION

The evaluated horizontal emittance was a little bit larger than design natural emittance of 1.12nm. A momentum spread was evaluated by measuring a beam size with screen monitor at about 1.7m of huge horizontal dispersion region of the extraction line and the evaluated momentum spread was increased with increasing a bunch current as shown in

Method	Emittance [nm]	$B_{\rm mag}$
MW1X Waist Scan	1.47 ± 0.06	1.05 ± 0.09
MW2X Waist Scan	1.27 ± 0.06	1.00 ± 0.03
MW3X Waist Scan	1.38 ± 0.05	1.07 ± 0.11
Four Wire	1.29 ± 0.11	1.07 ± 0.34
Average	1.37 ± 0.03	α_x:3.83 β_x:6.77

Table 2: The results of horizontal emittance. "Average" is an averaged data weighted by their errors.

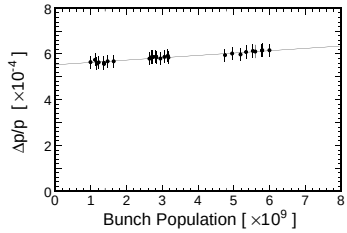

Figure 4: Result of momentum spread measurement. There was clearly intensity dependence.

Figure 4. A horizontal emittance is expected to increase with the momentum spread as

$$\epsilon_x = \frac{J_\epsilon}{J_x}\left\langle \frac{1}{\beta_x}\left[\eta_x^2 + (\beta_x\eta_x' + \alpha_x\eta_x)^2\right]\right\rangle_{\rm arc}\left(\frac{\sigma_p}{p}\right)^2, \quad (6)$$

where J_x and J_ϵ are the damping partition number for horizontal and longitudinal direction and the angular bracket means average over the arc section. As momentum spread was enhanced by about 8-12% at the bunch population of 3-5$\times 10^9$ in Figure 4, the horizontal emittance should be 1.31-1.41nm for the beam intensity. This horizontal emittance agreed with the evaluated horizontal emittance of 1.37 ± 0.03nm.

7 SUMMARY

The horizontal emittance was evaluated by the horizontal beam size measurement at the ATF extraction line with position jitter subtraction method. The horizontal emittance was 1.37 ± 0.03nm and this was a little bit larger than the design natural emittance. However, this difference can be explained by intensity dependence of the emittance. Measured horizontal emittance well agreed with the designed one.

8 ACKNOWLEDGEMENT

We would like to express our thanks to Professors H. Sugawara, Y. Kimura, M. Kihara and K. Takata for their encouragement of this work. And we wish to thank to Drs. S. Kamada, T. Naito, K. Oide, S. Takeda and N. Toge of KEK and M. Takano of Toho Univ. and D. McCormick, M. Minty, M. Ross, M. Woodly and F. Zimmermann of SLAC for various useful discussions. We also thank to the ATF operation group for their support to the beam experiment.

REQUIREMENTS FOR THE RF CONTROL OF THE VECTOR SUM FOR SUPERCONDUCTING PROTON LINACS

M. Hüning, S.N. Simrock, DESY, Notkestr. 85, D-22603 Hamburg, Germany
T. Schilcher, PSI, CH-5232 Villigen, Switzerland

Abstract

Superconducting accelerator technology has demonstrated its superior performance in large scale machines such as CEBA at TJNAF and is increasingly used for new accelerator designs. Until now this technology has found its main application in electron accelerators. However nowadays proton accelerator designs for the European Spallation Source (ESS) and the Accelerator Driven Transmutation Technology (ADTT) also study the feasibility of superconducting linacs. In contrast to the highly relativistic electron beams the proton beam exhibits an increased susceptibility to voltage fluctuations in the acceleration system induced by microphonics and dynamic Lorentz force detuning. Although low beam loss is an important criterion for linac design, studies of the longitudinal dynamics appear to be a good indicator for beam stability in presence of fluctuations of the accelerating field. Control of the vector sum of multiple cavities driven by one klystron is desirable for cost reasons but does not allow for control of individual cavity fields. In this paper we study the performance of such a system.

1 INTRODUCTION

The technology of proton accelerators has progressed considerably in the past three decades [1]. Several high intensity proton accelerators with high peak or average beam currents of the order of 100 mA are presently under study for applications such as: spallation neutron sources, kaon factory, nuclear transmutation technology, energy amplifier, and muon collider drivers. The implementation of superconducting acceleration systems [2,3] appears to be attractive since it could lead to substantial cost savings in machine operation especially if multiple cavities are driven by one common high power klystron.

An important design criterion for a high intensity proton linac is beam loss control since the beam loss should not exceed 1 nA/m to allow for hands-on maintenance after a long operation period. Particle loss is caused by a small number of particles outside the dense beam core, called the beam halo. The origin and formation and dynamics of the halo have been studied intensively and significant progress has been made in recent years. In superconducting linacs where multiple cavities are driven by a single klystron beam loss may be enhanced by microphonics which are a result of mechanical vibration modulating the resonance frequency of the high Q cavities. In this paper we develop a simple model to determine the impact of fluctuations of the accelerating field on beam energy. For simplicity only the longitudinal dynamics of the bunch centroid are analyzed. Bunches with excessive energy deviations are considered as potential candidates for beam loss. An important result of this model is an upper limit for the microphonics noise levels permitted for accelerator operation.

2 BEAM DYNAMICS MODEL

The energy gain of the bunch centroid when passing a single cavity can be described as

$$\Delta V = V_o \cdot T \cdot \cos(\phi_S),$$

where V_o is the cavity voltage, T is the transit time factor, and ϕ_S the phase angle between beam current and accelerating field. The transit time factor is a function of the bunch velocity $\beta = v/c$ and the phase angle depends also on β according to $\Delta\phi = (2\pi f L)/(c\beta)$, where f is the operating frequency of the rf cavities, and L the drift space between the center of two adjacent cavities. Thereby the dynamics inside the cavities have been approximated by a cavity with length zero and the surrounding drift space.

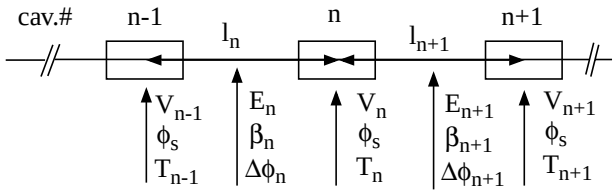

Figure 1: Definition of parameters used for the beam dynamics model.

Changes in transit time factor due to finite cavity length are however considered. For a given linac configuration one can calculate the deviations of beam energy, bunch velocity, and phase of the accelerating field with respect to a reference particle.

$$E_{n+1} = E_n + V_n \cdot \cos(\Delta\phi_n + \phi_s) \cdot T_n(\beta_n)$$

$$\beta_{n+1} = \sqrt{1 - \frac{m_p^2 c^4}{(E_{n+1})^2}}$$

$$\Delta\phi_{n+1} = \Delta\phi_n + \frac{2\pi f l_n}{c} \cdot \left(\frac{1}{\beta_n} - \frac{1}{\beta_{ref}}\right)$$

In the model the transit time factor of a m-cell cavity is derived from the transit time factor $T_1(\beta)$ of a single cell cavity as:

$$T(\beta) = T_1(\beta) 2 \cdot \frac{\cos\left(\frac{m-1}{2}(x-\alpha)\right) - \cos\left(\frac{m+1}{2}(x-\alpha)\right)}{m \cdot (1-\cos(x-\alpha))}$$

with

$$T_1 = \frac{\sin(x/2)}{(x/2)} \text{ for } E(z) = \text{const.}, \; x = \frac{2\pi L_n}{\beta\lambda}, \; \alpha = \frac{k}{m}\pi$$

k=1...m depending on selected passband mode. Here k/m=1 i.e. $\alpha = \pi$ for a standing wave structure. L_n is the length of the cavity.

3 LINAC PARAMETERS

To determine the impact of fluctuations of the accelerating field on the longitudinal dynamics of the bunch centroid the parameters of two recently proposed linac designs have been selected (see Table 1).

4 SIMULATION RESULTS

Based on the beam dynamics model and the sample linac parameters the quantities of interest have been determined for several cases:

1. stochastic cavity amplitude and phase errors along the linac with uniform distribution. The simulation has been performed with various sets of errors for injector and linac.
2. stochastic cavity amplitude and phase errors along linac but the vector-sum of an ensemble of 2 or 4 cavities perfectly regulated.

Table 1: Sample Linac Parameters

	LINAC 1	LINAC 2
Frequency [MHz]	700	700
Linac Energy [MeV]	1700	1300
Number of cavities	102 & 308	166
Number of cells / cavity	5 & 5	5
Injection energy [MeV]	211 & 470	70
Beta of cavity	0.64 & 0.82	0.37 .. 0.91
Cav. centroid spacing [m]	2.0 & 2.1	0.5 .. 1.36
Synchronouse phase [deg]	-35 & -30	-20
Energy gain/cav. [MV]	2.5 & 4.0	3.9 .. 9.8
Cavity gradient [MV/m]	5.2 & 5.9	10

The deviation of the final linac energy from the reference energy can be used to determine the potential for beam loss. The simulations show that small field fluctuations result in a moderate increase in energy spread while larger errors - depending on the distribution along the linac - may result in basically zero energy gain in the linac due to phase slippage. Particles which do not experience a net energy gain in the linac are likely to be lost due to the lack of rf focusing. Some of the results of the simulations for the different case studies are shown in Table 2. The probability of beam loss is equivalent to linac energy gain less than 90%.

Table 2: Linac Energy Spread (Bunch-to-Bunch) and Particle Loss

[1]All errors assume a uniform distribution; [2]total number of runs is 100000 [3]no rf feedack applied; [4]vector-sum of 2 repectively 4 cavities is perfectly regulated; [5] number of runs only 12000;

The number of random error sets for most simulations has been 100000 which means there is still a chance of the order of 10^{-5} that a bunch might get lost. The table shows that for a reasonable phase and amplitude injection error of 1 deg. and 1% respectively the linac can tolerate phase and amplitude perturbation levels of severals degrees and percent. A summary of the results is shown in Figure 2.

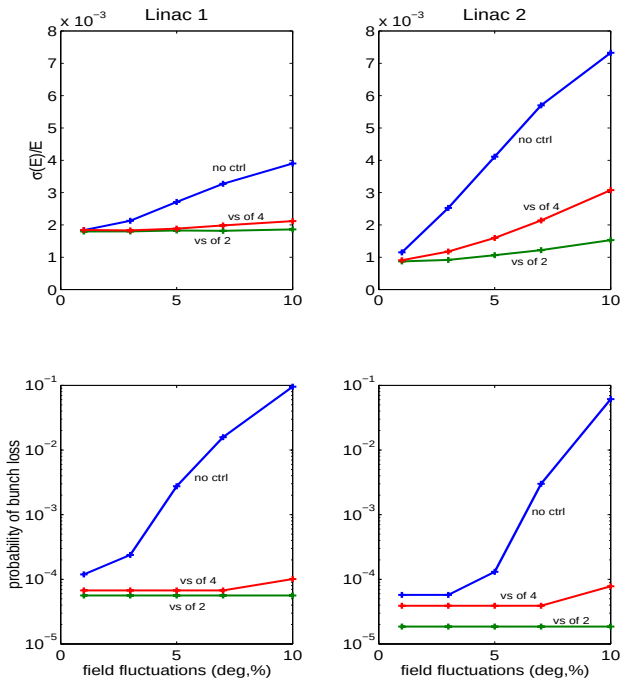

Figure 2: Energy spread and bunch loss as function of amplitude and phase errors in the linacs.

5 CONSIDERATIONS FOR THE CONTROL OF THE VECTOR SUM

The rf control for the vector sum of multiple cavities can be improved significantly if the energy gain and the beam arrival time or beam phase at the entrance of the following ensemble of multiple cavities can be controlled. This can be accomplished by control of the vector sum amplitude and phase which provide linear independent control of the beam energy gain and beam phase in the vicinity of the synchronous phase.

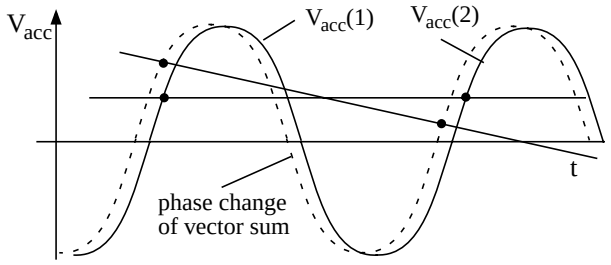

Figure 3: Principle of beam energy and beam phase control

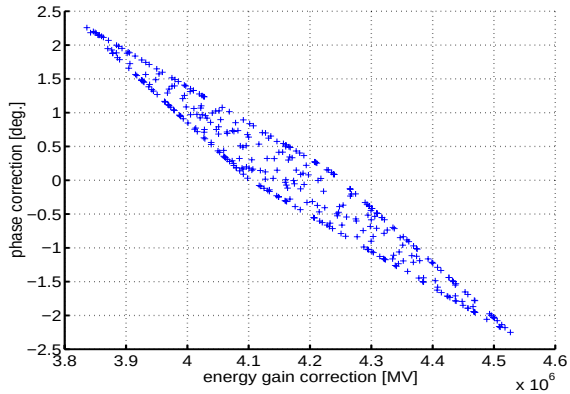

Figure 4: Energy gain and beam phase correction range at the low energy end of Linac 1. The vector sum of 2 cavities is controlled and varied by ±3 deg. in phase and ±10% in amplitude.

The principle of beam energy and beam phase control is shown in Figure 3. A change in cavity phase or amplitude will result in the arrival time at the following cavity. With proper choice of vector sum amplitude and phase the energy and beam phase at the following cavity can be controlled within the boundaries shown in Figure 4. The control range is larger at the low energy end of the linac.

6 CONCLUSION

The control of microphonics and Lorentz force detuning in superconducting cavities for proton accelerators has been a major concern. This is especially true if only vector sum of several cavities which are driven by one common klystron is controlled. The simple model presented for the analysis of the accelerating mode driven longitudinal dynamics of the bunch centroid has shown that surprisingly large levels of microphonics are acceptable even in the case of vector sum control of 4 cavities.

TIME DELAY COMPENSATION FOR THE DIGITAL RF CONTROL AT THE TESLA TEST FACILITY

H. Imsieke, A. Kholodnyi, S.N. Simrock, DESY
Notkestr. 85, D-22603 Hamburg, Germany

Abstract

Time delays or dead times between inputs and outputs are an inherent characteristic of digital feedback systems. The time delay limits the maximum allowable gain required for system stability. Modern control theory provides a scheme called Smith predictor which has the potential to improve control performance significantly. The method is based on model internal control which works well if the dynamics of the plant are slow compared to the time delay. In this paper we analyze the performance improvement that can be achieved in the TTF rf control system where the time delay is dominated by computational delay. In this system the time delay of 4 microseconds and sampling period of 1 microsecond are short compared to the cavity time constant of 700 microseconds. Attention is paid to both theoretical and practical aspects.

1 INTRODUCTION

The cavities in the TESLA Test Facility are operated in pulsed mode at gradients of up to 25 MV/m with each klystron driving multiple cavities. Significant Lorentz force detuning and control of the vector-sum are the main issues for the low level rf controls. A digital feedback system has been developed [1] to provide flexibility in the control algorithms, precise calibration of the vector-sum, and extensive diagnostics and exception handling. The main features are a sampling rate of 1 MHz for the individual cavity signals, digital in-phase and quadrature detection, calculation of the vector-sum which includes gradient calibration and the correction of phase offsets, and feedback algorithm.

The presently implemented version of the feedback employs a proportional controller and has demonstrated excellent performance [2] especially in combination with the adaptive feed forward [3]. Due to the large time delay of 4 microseconds in the feedback loop the loop becomes unstable at gains exceeding 40 dB. The need for a high gain to maximize error suppression results in a small range of usable gains. Therefore a compensation of the loop delay appears to be attractive since it could improve the robustness and possibly increase the performance of the feedback loops.

2 TIME DELAY

The time delay in the feedback loop is given by:

- 500 ns conversion time of the 14 bit, 2 MHz ADC
- 200 ns writing to the comm-port of the TMS320C40
- 1000 ns multiplication with rotation matrix for individual field calibration and calculation of the vector-sum
- 200 ns writing to next comm-port of C40
- 1000 ns for the feedback algorithm (subtract setpoint, multiply with gain table, and add feedforward)
- 200 ns to write to the DAC
- 200 ns delay in the klystron
- 800 ns cable delay

The sum of the delays is about 4 µs. The implementation of the Smith-Predictor and Kalman filter might add up to 2 µs to the total delay. Time delay increases the phase shift between input and output signals and thus limits the maximum allowable gain. The system becomes unstable if the loop gain exceeds unity gain while the phase exhibits 180 deg. The phase shift due to delay is proportional to the frequency and is 180 deg. at 125 kHz for a delay of 4 µs. The phase margin of the rf system with a loop gain of 40 dB, and the cavity pole (first order) at 200 Hz is approximately 60 degrees at the unity gain frequency of 20 kHz.

3 SMITH PREDICTOR STRUCTURE

In 1957 O.J. Smith presented a control scheme to predict the reaction of a plant P to the output of a controller C thereby providing the potential of improving the control loops with delay (Figure 1).

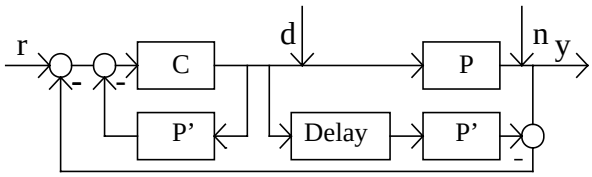

Figure 1: Smith Predictor structure

The total delay time in the feedback loop can be ascribed to the plant. P' is the model of the plant without delay time, r is the setpoint, y the output, d disturbances in and before the cavity and n measurement noise. With exact model matching and no disturbances or noise, the controller would only get signals from the model and the delay would be removed from the control loop as shown in Figure 2. The outer feedback loop in Figure 1 accounts for uncertainties of the model and disturbances.

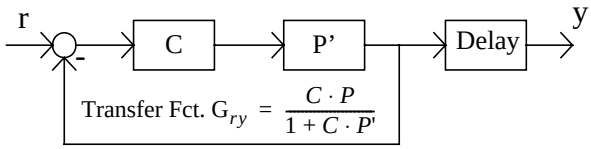

Figure 2: Desired Feedback with SP.

4 IMPLEMENTATION

The response of a single cavity to the beam current and the generator current can be described by two coupled first order differential equations for the envelope of the cavity voltage:

$$\begin{bmatrix} \dot{V}_{Re} \\ \dot{V}_{Im} \end{bmatrix} = \begin{bmatrix} -\omega_{1/2} & -\Delta\omega(t) \\ \Delta\omega(t) & -\omega_{1/2} \end{bmatrix} \begin{bmatrix} V_{Re} \\ V_{Im} \end{bmatrix} + \begin{bmatrix} R \cdot \omega_{1/2} & 0 \\ 0 & R \cdot \omega_{1/2} \end{bmatrix} \begin{bmatrix} I_{Re} \\ I_{Im} \end{bmatrix}$$

where V is the complex cavity voltage, I the complex current (generator + beam), $\omega_{1/2}$ (=π*operating frequency of 1.3 GHz/loaded quality factor ~$3*10^6$) the half width of resonance, $\Delta\omega$ the cavity detuning, and R the cavity shunt impedance.

A macropulse consists of cavity filling (500 μs), flat top with beam injection (800 μs), and field decay. The goal of the control system is to maintain a constant accelerating voltage during the flat top. The cavity is predetuned to minimize the power required to control the dynamic detuning which is a result of the Lorentz force. The cavity detuning should be zero in the middle of flat top. The cavity model used in the predictor should reflect the dynamics of the time varying Lorentz force detuning but has been omitted for simplicity. The field error resulting from such a simplification is comparable to the error caused by 1% quality factor or shunt impedance difference between model and plant (worst case: around 0.01%). The error caused by detuning is slowly changing and repetitive and can therefore be compensated by adaptive feedforward.

With a peak detuning of one bandwidth (realistic for 25 MV/m gradient) a step input on the real part of generator current would cause an error in the imaginary part of 7×10^{-4} after 1us. This crosstalk corresponds to a loop phase error of 0.04 deg. and can therefore be neglected.

The cavity is thus represented by a decoupled discrete State Space model with complex input and output vectors. The model parameters are calculated from the cavity bandwidth, which itself is calculated from the voltage decay time constant, and the cavity shunt impedance

$$V_{t+1} = (1 - (\omega_{1/2} \cdot T)) \cdot V_t + R \cdot \omega_{1/2} \cdot T \cdot I_t$$

where V and I stand for either real or imaginary component at time t. T is the sampling time of 1μs.

The model for multiple cavities can be obtained by superposition and can be approximated by that of a single cavity if the spread of the loaded quality factor is not too high. The spread should not exceed 25% to keep the model error below 3%. An improved model could consist of two cavities with different bandwidths. The model parameters are determined off-line.

The delay time can be adjusted in 1 μs steps by storing the control signal in memory and even in finer steps of 0.02 μs by selecting the time at which the 50 MHz DSP writes the data to the DAC. The delay is measured with a test program and then the program with correct DAC output time is written into the DSP. With model delay errors up to 0.1 μs, there's a decrease in maximum allowable gain off about 1% for every 0.01 μs mismatch.

5 PERFORMANCE

The performance of the rf system can be measured in terms of achieved field stability or disturbance rejection, the quality of setpoint tracking (important for fast varying setpoints as needed for FEL operation), and feedback loop stability which should be tolerant (or robust) with respect to parameter variations.

5.1 Stability

The maximum gain for stable operation is limited to 1400 (exactly two times the optimum gain, because overcorrection by more than 100% means instability) due to the 1 μs delay in the internal feedback loop.

While the bode plot without model uncertainties is easily interpreted due to the separation of the delay time, its meaning for the SP with parameter uncertainties is not easily understood. However since a numerical model analysis and the pole-zero map (obtained with a rational approximation of the closed loop SP transfer function) give similar results near the ideal case, stability margins were obtained with these methods. They show that realistic model mismatch of a few percent reduces the critical gain to ~1200.

If the klystron is operated close to saturation, its nonlinearity limits the maximum gain, so that it could be necessary to replace the actuator signal with the measured incident wave to the cavity. This scheme would also include time varying phase errors in the klystron and the vectormodulator. The measured klystron output would provide the correct control signal, thereby increasing stability and reducing sensitivity to klystron power fluctuations.

5.2 Setpoint Tracking

Figure 3 shows the response of the SP to a change of the setpoint. Operation with optimum gain will cause the cavity field to reach the desired setpoint in 1 μs time assuming availability of sufficient power from the klystron. If a beam current induces a voltage ΔV in steady state, the cavity field will change ΔV/700 in 1 μs. The optimal gain for reference tracking is therefore around 700 which is well below critical gain.

5.3 Disturbance Rejection

The ability to suppress disturbances is not improved significantly by the smith predictor, as shown in Figure 4. The slow response to a beam induced perturabtion is due to the presence of the cavity poles in the transfer function from the disturbance to the output,

$$G_{dy} = P \cdot (1 - G_{ry}).$$

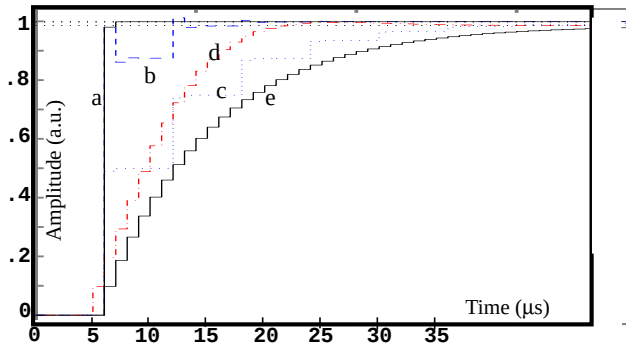

Figure 3: Step response of the transfer Function G_{ry} for a) optimal SP b) SP with 20% lower cavity quality factor c) SP with 50% gain decrease due to klystron nonlinearity d) normal feedback with gain of 70 e) SP with gain of 70.

The first term in the bracket is independent of the feedback gain. This means that the time constant of the error correction is not a function of the gain. It is however possible to modify the model and the controller so that the pole cancels with a zero of the transfer function [4] or to add the difference between cavity and model to the input of the model in order to adapt it to the disturbed cavity (a scheme called observer). Pole cancellation reduces the maximum allowable gain, is sensitive to parameter uncertainties, and slower than the latter method.

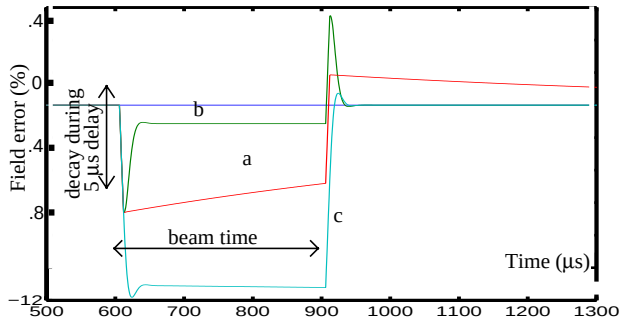

Figure 4: Reaction of the cavity field to a beam induced transient, a) optimal SP b) SP with Observer c) normal feedback.

Even with faster disturbance correction, the beam still causes a drop in the cavity field of 1/700 ~ 0.14 % per µs delay time in the feedback loop after injection. This can only be prevented by the use of feedforward. For the klystron noise, a faster disturbance rejection would have no influence. Errors caused by detuning would be reduced approximately by 50% on flat top with a gain of 700, but much better with an additional observer. The observer is useful against stochastical detuning by microphonics which cannot be suppressed by feedforward.

A controller with an integrator does not perform significantly better, and decreases stability margins due to phase advance.

6 FEEDFORWARD SCHEMES

Because the digital control system can measure the beam current in real time it can compensate it with a delay of about 1-2 µs. This scheme can reduce the beam induced transients considerably.

Another approach is the calculation of a feed forward table which is added to the control signal sent to the plant. This accounts for the absence of the beam in the model and microphonics influences. The feed forward table is repeatedly calculated from the difference between model and plant, with the error decreasing each step. In this way it also adapts itself to slowly changing system parameters. In contrast to this adaptive feed forward, a feed forward table needed to trace the setpoint optimally in the ideal case is calculated with model parameters and proportional gain and is added to both model and plant. This has to be updated only when these parameters are changed. Without Smith Predictor, there would be only one (adaptive) feed forward for all repetitive errors.

7 CONCLUSION

The main advantage of the Smith Predictor is faster setpoint tracking. With the existing feed forward, this workload is removed from the feedback with the exception of stochastic errors. These errors act almost exclusively in or before the plant, so the SP offers only little improvement. A major drawback is the amplification of measurement noise with higher gains, which has to be suppressed significantly. For this purpose a Kalman filter, which estimates the state of the plant in presence of klystron and measurement noise, is currently under development. The measurement is also disturbed by an offset in the rf mixer output which varies over the macropulse. This has to be cancelled out too to allow better performance than present feedback.

The klystron nonlinearity restricts the SP performance. The power margin could be too little for the desired high gains, and with equal gain, a standard feedback controller would outperform the SP. To assure stability the nonlinearity has to be known for the model calculations.

RF CONTROL STUDIES FOR MODERATE BEAMLINE COUPLING BETWEEN SRF CAVITIES*

Lawrence R. Doolittle and D. X. Wang
Thomas Jefferson National Accelerator Facility, Newport News, Virginia 23606 USA

Abstract

When an SRF accelerator is designed, there is motivation to move the cavities close together on the beamline. Assuming the beamline apertures are not shrunk as well, this compaction (which will increase the overall accelerating gradient and/or lower the dynamic cryogenic heat load) increases the inter-cavity coupling. Within certain limits, the control system can compensate for this coupling by retuning each of the cavities. This paper describes constraints on the RF system, tuners, couplers, and control systems that are required to provide stable operation of cavities in the presence of inter-cavity coupling that exceeds the loaded bandwidth of an individual cavity.

1 INTRODUCTION

Many cost optimizations have discussed the tradeoff between accelerator capital and operating costs, acceleration gradient, cryogenic capacity, and RF Power. One contributing term in those equations is η, the ratio of the active accelerating cavity length to the overall accelerator length, sometimes called the "filling factor" or "packing fraction." While the effect of packing fraction on a new machine is debatable (since the relative cost of cavity meters and other meters can be hard to identify), when upgrading an existing machine with fixed total length, η has a clear effect, particularly on the cryogenic load. A cavity cell and the manufacturing technology will set the familiar cavity parameters ω, Q_0, and the shunt impedance per unit length (r/Q). For a given acceleration voltage V and active accelerator cavity length ηL, the cryogenic power dissipation is

$$\mathrm{Power} = \frac{V^2}{\eta L Q_0 (r/Q)}.$$

Thus, η is the only parameter under the designers' control that can change the relationship between voltage gain and dynamic cryogenic load.

Historic values of η are in the 0.3 to 0.6 range. The existing CEBAF accelerator linac has $\eta = 0.42$, and the baseline design of our Energy Upgrade studies calls for raising η to 0.58, by increasing the number of cells per cavity from 5 to 7[1].

Between cavities is a beam pipe of length b, whose radius a is normally set by beam impedance or beam aperture needs. The coupling $d\omega$ between two cavities is given by $\Delta\omega \cdot \exp(-kb)$, where $k^2 = k_0^2 - (2.405/a)^2$, and the proportionality constant $\Delta\omega$ represents the coupling between the resonant fields in the end cell and the evanescent TM_{01} fields in the beam pipe.

Increasing η will normally involve decreasing b, at which point the coupling $d\omega$ has the potential to rise enormously. Accelerators to date have kept $d\omega$ much smaller than the cavity bandwidth, to avoid potential problems that could arise from stronger coupling. The rest of this paper will discuss those problems in detail, and how they could be worked around.

2 DEFINING EQUATIONS

In the most general form, ignoring wall losses in the cavity ($\beta \gg 1$), in the rotated coordinate (phasor) sense where the instantaneous gradient $E(t)$ in a cavity is given by $\mathrm{Re}\{Ee^{j\omega_0 t}\}$,

$$\frac{dE}{dt} = -(\omega_f - j\omega_d)\cdot E - jd\omega_- \cdot E_- - jd\omega_+ \cdot E_+$$

$$+2\omega_f \sqrt{R_c}\cdot K - \omega_f R_c \cdot I_b$$

For cavities at the end of a string, this formula involves phantom cavities, which should be treated as if they had zero gradient.

Table 1: notation

ω_f	bandwidth, $\omega_0/2Q_L$
ω_d	frequency offset from ω_0
E_-	gradient of upstream cavity
E_+	gradient of downstream cavity
$d\omega_-$	coupling to upstream cavity
$d\omega_+$	coupling to downstream cavity
K	specific drive amplitude
R_c	coupling impedance per length, $Q_L(r/Q)$
I_b	beam current

Typical self-consistent units of K and R_c are $\sqrt{\mathrm{Watts/m}}$ and Ω/m. The quantities E, K, and I_b are complex numbers; the rest of the parameters are real. The definitions of E, K, R_c, and I make physical and numerical sense on a macroscopic scale. Over a length l, a beam of current I gains El energy using KK^*l power, when the matching condition $E = IR_c$ holds.

The per-cavity ω_0 component of the beam current depends on the string beam current I_{bs} according to $I_b =$

* Work supported by the U.S. DOE Contract # DE-AC05-84ER40150

$I_{bs}e^{j\phi}$, where ϕ is the phase-of-flight along the beamline to cavity of interest.

If we restrict ourselves to the steady-state where $dE/dt = 0$, and additionally set $E_- = v_- E e^{-j\theta_-}$, $E_+ = v_+ E e^{j\theta_+}$, and $I_b = i_b E e^{j\phi}$,

$$\frac{K}{E} = \frac{1}{2}\sqrt{R_c} i_b e^{j\phi} + \frac{1}{2\sqrt{R_c}\omega_f}\left(jd\omega_- v_- e^{-j\theta_-} + \right.$$

$$\left. \omega_f - j\omega_d + jd\omega_+ v_+ e^{j\theta_+}\right)$$

When the right hand side is separated into its real and imaginary components, the quantity ω_d (controlled by the tuners) only appears in the imaginary part. Moving the tuners to minimize the power therefore results in the zeroing of that imaginary part, which happens when

$$\frac{\omega_d}{\omega_f} = i_b R_c \sin\phi + v_- \frac{d\omega_-}{\omega_f}\cos\theta_- + v_+ \frac{d\omega_+}{\omega_f}\cos\theta_+$$

Indeed, the tuner operation is equally sensitive to tuning with no inter-cavity coupling, when all cavity voltages are held fixed. The remaining real part gives the power at optimum cavity tune,

$$\text{Power} = \frac{1}{4}R_c E^2 \left(i_b \cos\phi + \right.$$

$$\left. \frac{1}{\omega_f R_c}(v_- d\omega_- \sin\theta_- + \omega_f - v_+ d\omega_+ \sin\theta_+)\right)^2$$

If $\sin\theta_- \neq 0$ and $\sin\theta_+ \neq 0$, only small amounts of coupling can be tolerated without requiring excessive Klystron power. The bad cases are one end of the string (which end depends on the sign of $\sin\theta$), and any case where $v_- d\omega_- \sin\theta_-$ does not exactly cancel $v_+ d\omega_+ \sin\theta_+$. Ordinarily one wants the ability to adjust each cavity gradient independently based on its performance capabilities. This independence can be recovered by setting $\sin\theta_+ = \sin\theta_- = 0$, at which point the coupling terms all but disappear from the Power equation.

3 DISCUSSION

The coupling between the cavities can provide an opportunity to measure the relative phases of the cavities. Without this measurement, the cavities' phase relative to the beam must be individually measured. Of course, with strong coupling, the relative phases must be set properly or the limited klystron power will not allow operation at full gradient. Figure 1 shows this phenomenon—curves show the input drive required as a function of phase for 10 Hz and 1 kHz coupling, under no-beam conditions. The flat reference line shows the power needed for 400 μA beam current. Other parameter values assumed for this example are $\omega_f = 235\text{s}^{-1}$, $R_c = 1.34 \times 10^{10}\Omega/\text{m}$, $E = 12\text{MV/m}$, $l = 0.7\text{m}$, and $v_- = v_+ = 1$.

One would certainly hope to operate a cavity string by attaching single-cavity control systems to each individual

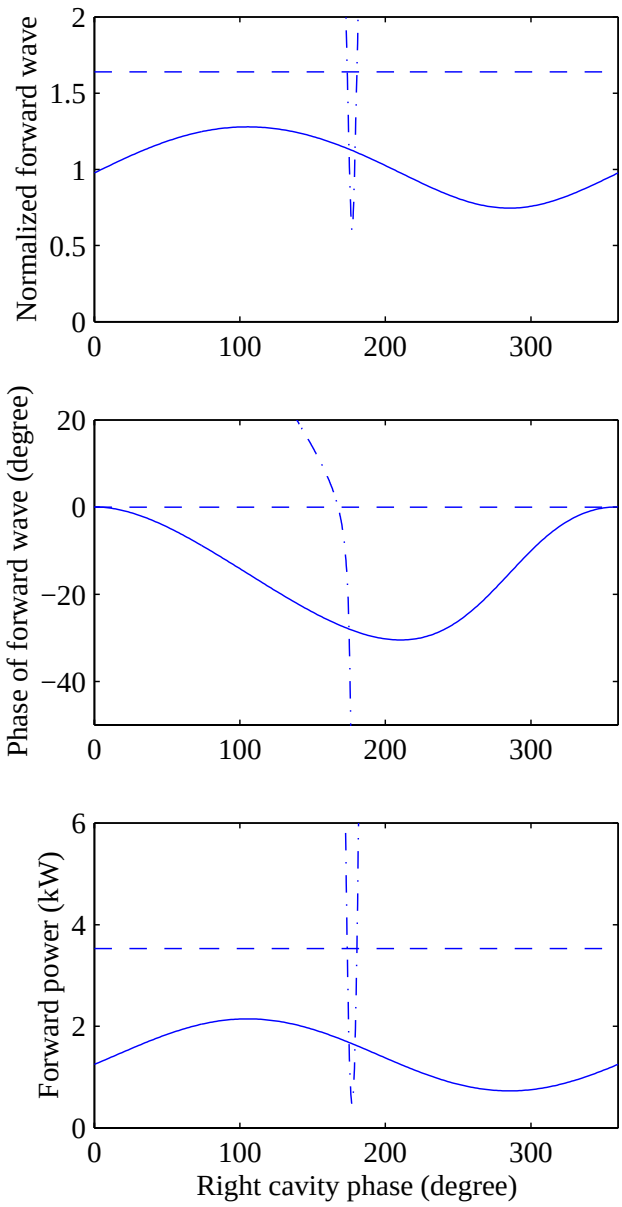

Figure 1: Drive required *vs.* neighboring cavity phase for 10 Hz coupling (solid) and 1 kHz coupling (dash-dot). A reference line (dashed) is given for the power required with beam.

cavity, so that $2\omega_f\sqrt{R_c}K = A(s)\cdot(E_s - E)$, where $A(s)$ is the (diagonal matrix) gain and E_s represents the setpoints. The undesirable alternative is some hopelessly complex centralized control that understands the $n \times n$ inverse of the coupling matrix. The equation of motion of the simpler system is

$$M \cdot E = A(s)E_s$$

where if we make the simplifying assumption that all cavities and coupling terms are identical, $M_{i,i} = s + \omega_f + j\omega_d + A(s) = p$ and $M_{i,i+1} = M_{i+1,i} = jd\omega$. The stability criteria are based on the zeros of $\det(M)$; to first order

in $d\omega$,

$$\det(M) = p^{n-2}(p_i^2 + (n-1)d\omega^2),$$

where n is the number of cavities in the string. One can clearly see that there are $n-2$ unperturbed stability criteria based on zeros of $s + \omega_f + j\omega_d + A(s)$. There are also two more cases involving global string modes, based on zeros of $s + \omega_f + j\omega_d + A(s) \pm j\sqrt{n-1}d\omega$.

Strong inter-cavity coupling makes a string more difficult to turn on. One sensible approach is to turn them all on slowly and proportionally, so that v_- and v_+ are constant. The tuners can center the system for minimum RF power under low gradient conditions, when there is plenty of available RF power. The only phenomenon the tuners have to compensate for during the ramp to full gradient is the ponderomotive frequency shift with gradient.

If a cavity trips, it's probably best to immediately turn RF off to the whole string and let it coast to a stop. Even if the adjacent cavities' RF systems could maintain their fields (a job made easier since the beam is probably turned off by the first cavity trip), some of their power would flow to the tripped cavity, which is not desirable.

Longitudinal alignment sensitivity can be significant. Historical assembly patterns at CEBAF, where that axis of alignment was not relevant, showed fluctuations of 6 mm. Between thermal contraction, manufacturing and assembly errors, and coarse tuning, 2-4 mm is a reasonable target for our 0.5 to 0.7 m long, λ=20 cm, cavities. Still, that implies uncontrolled phase differences between cavities of ϕ=0.1 radians. This error can be accommodated in two ways: If $\sin\theta = 0$, power does not flow between cavities. RF characteristics without beam are ideal, but individual cavities are miscrested with respect to the beam. The total crest for the module can still be zeroed, but the overall voltage gain has slipped some. If $\sin\phi = 0$, individual cavities are crested properly, but large amounts of RF power move from cavity to cavity. For a given (measured) set of cavity gradient and Klystron power capabilities, inter-cavity and external coupling bandwidths, and longitudinal cavity positions, numerical optimization can construct a set of phases that optimizes the total voltage delivered to the beam.

As discussed above, the sensitivity of a coupled cavity string to tuner motion is unchanged from the uncoupled case. That is, the curvature of the Power *vs.* tuner position relationship is not affected by the coupling. On the other hand, the position of that curve's minimum becomes sensitive to the voltage ratio between adjacent cavities (v_- and v_+). This sensitivity is one more reason to demand a tuner subsystem capable of short response times and no backlash. If a coarse tuner/fine tuner pair is used, the required range of the fine tuner is the sum of all effects that must be corrected. To the traditional list of pressure and ponderomotive compensation, inter-cavity coupling adds another term: the estimated maximum value of $v_- d\omega_- \cos\theta_- + v_+ d\omega_+ \cos\theta_+$. A reasonable choice for the maximum voltage ratio is in the 2 to 3 range, when cavities are more mismatched than that one would probably turn off the weak cavity.

When a cavity is turned off, it must also be detuned. Normally this is done to keep the cavity fields low in the presence of exitation from the beam. In a coupled-cavity system, excitation will also come from neighboring cavities. The neighbors of a detuned cavity must have their tuning corrected to reflect the changed pattern of voltage setpoints.

4 CONCLUSIONS

With the right phase relationship between cavities, coupling equal to or greater than the bandwidth of the cavity appears technically feasible. Tuning individual cavities can cancel all the reactive elements of the system. For any particular gradient pattern, proper tuning will result in drive requirements unchanged from the no-coupling case. The dynamic stability of the string is perturbed, and some reduction in feedback performance should be expected. The control system needs to be agile enough to measure the coupling and implement turn-on scenarios that involve coordination between the cavities.

THE RF SYSTEM FOR THE CEBAF POLARIZED PHOTOINJECTOR*

Mark Crofford, Curt Hovater, George Lahti, Chip Piller and Matt Poelker
Thomas Jefferson National Accelerator Facility
12000 Jefferson Ave., Newport News, VA 23606

Abstract

Jefferson Lab's CEBAF electron accelerator has recently begun delivering spin-polarized electrons for nuclear experiments. Spin-polarized electrons are emitted from a GaAs photocathode that is illuminated with pulsed laser light from a diode laser synchronized to the 3rd subharmonic (499 MHz) of the accelerating cavity frequency (1497 MHz). Up to three experimental halls (A, B and C) are served by the photoinjector each with their own beam requirements. To accomplish this, three independent diode lasers are synchronized and combined to illuminate the GaAs photocathode emitting a 1497 MHz pulse train of electrons. In addition an RF bunching cavity approximately 2 m down stream from the photocathode is used to compensate for space charge effects at the higher beam currents. The RF system that controls these elements is a modified VME based system. Custom RF VME modules control phase and amplitude for each laser diode and the bunching cavity. Power requirements were satisfied with commercial RF amplifiers, 5 W for the diode lasers and 10 W for the bunching cavity. Simple software algorithms using the EPICS control system correct phase and amplitude drifts. The RF system is compact, simple and allows for easy hardware or software modifications.

1 INTRODUCTION

The 5.5 GeV CEBAF accelerator at Thomas Jefferson National Accelerator Facility (Jefferson Lab) is arranged in a five pass racetrack configuration, with two superconducting radio-frequency (SRF) linacs joined by independent magnetic 180° transport arcs. The continuous electron beam is composed of three interlaced variable intensity beams that can be independently directed from any of the five passes to any of the three experimental halls. This allows three simultaneous experiments at the same or different energies and currents. Electrons are emitted through a polarized photocathode [1]. All of the experimental halls (A, B and C) are fully operational.

Recently a new laser system for the polarized source has begun operation that allows each of the experimental halls to independently choose current and operational duty factor [2]. Three diode lasers are biased with an RF frequency of 499 MHz. The light from the lasers is then optically combined to form a 1497 MHz pulse train. The light then illuminates a GaAs photocathode, producing polarized electrons. Precise phase control between the lasers is essential for proper acceleration. The 499 MHz laser pulses must be 120° apart to construct the 1497 MHz signal. Amplitude control is also important since each laser's pulse length is determined both by the dc bias and the RF bias. The laser's pulse length determines the electron bunchlength leaving the photocathode. The RF system also includes a bunching cavity to help reduce space charge effects over the wide current range (100's pA to 180 μA) demanded by the users.

Previously a CEBAF RF control module had controlled the laser for the photocathode (single laser) [3]. This system is based around a CAMAC interface and is designed to control a superconducting accelerating cavity. While this control system has been excellent for superconducting accelerating cavities, it has only been marginal for controlling RF systems like laser diodes and normal conducting cavities. Therefore it was decided to design a system that better met the needs of the laser diodes and was compatible with the EPICS/VME interface.

2 LASER RF SYSTEM

The laser RF controls are a VME based system using the EPICS control system [4]. Drifts associated with these RF systems are mostly thermal; thus we chose a rather slow (10 Hz) feedback system. A dedicated EPICS IOC (Motorola MV 167) is used to control the phase and amplitude of the three laser diodes and the bunching cavity. The update rate of the EPICS control system met our need. Should faster update rates be necessary, speeds up to 1 kHz are possible by putting the software into VxWorks directly on the IOC. Choosing the VME bus allowed us to use economical and readily available VME cards. In addition the EPICS collaboration already had the drivers available for the ADC/DAC (VMIVME 4514A) and I/O (VMIVME 2532A) cards and only slight modifications were necessary. The VME crate is a custom crate with a modified P2 backplane to handle the control signals. RF signals are hard wired to the back of the crate. Blindmate™ connectors allow for easy VME module removal.

* Work supported by the Department of Energy, contract DE-AC05-84ER40150.

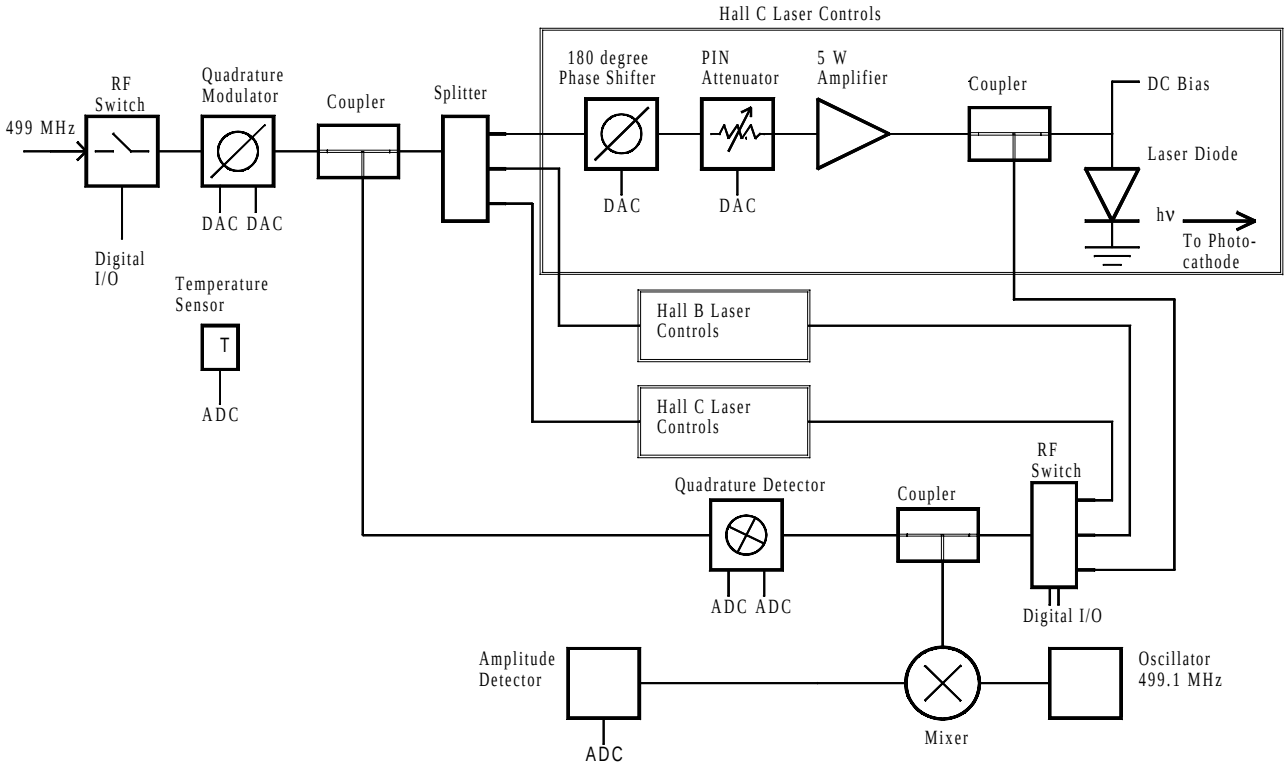

Figure 1 Block diagram of the laser diode RF system.

Figure 1 shows a block diagram of the RF system. The specifications for phase and amplitude control are 1^o and 1% respectively. Considering the relaxed control specifications it was decided to do the entire signal processing at the operating frequency of 499 MHz. This also allowed the system to use one of the pre-existing 499 MHz chopping cavities as a reference; the cavity is located less than 3 m away. The controls are divided into three VME modules: Reference Drive, Phase Shifter Module, and Detector Module. The reference module consists of a 360^o (I/Q) phase shifter for global phase adjustments and a 3-way splitter to supply the RF to the individual laser diodes. In addition it provides a coupled signal to the detector module. The phase shifter module consists of three 180^o varactor capacitor phase shifters (Synergy Microwave) used to align the phase between the three laser diodes. The phase between the lasers is coarsely (+/- 5^o) set using hard-line. The varactor phase shifters were chosen over I/Q phase shifters for cost reasons and since it was not necessary to have 360^o of phase shift capability. The phase shifters are controlled by 12 bit DACs. 5 W solid state amplifiers (Microwave Power Equipment) are used to RF bias the laser diodes. Inside each amplifier a voltage controlled PIN attenuator is used to control the RF bias on the laser diode. Approximately 1 W of RF power is needed for the laser diode RF bias. The detector module detects drifts due to cable or components (most notably the amplifiers). An RF signal is coupled back from each laser diode to the detector module. To economize on RF parts the three RF signals are muxed through an RF switch into a 360^o phase detector (quadrature detector) and amplitude detector. The EPICS control software continuously switches among the three RF signals. The error signals are then fed through the VME back plane to the ADC. The amplitude detector is an Analog Devices RMS to DC converter operating at an IF of 100 kHz. This was chosen over a typical Shottky diode because it is less susceptible to temperature drifts.

Key to the design process was minimization of thermal drifts. All RF electronics is next to the laser diodes in the tunnel (previously the RF electronics had been located up in the klystron gallery, 10 m above the tunnel). Temperature sensors on the VME cards are continuously monitored for any abnormalities. All the RF components on the VME cards and components were thoroughly characterized in an environmental chamber. It was intended to use the temperature sensors to provide a mechanism to remove thermal drifts using the component characterizations. This was deemed unnecessary after measurements in the CEBAF tunnel showed that temperatures vary less than 2^o C over long periods of time (weeks).

The feedback for the system presently only includes the cables to the laser diodes. Drifts across the laser diodes and optics are assumed to be minimal (< 0.5^o). If tighter tolerances are needed in the future, a laser diode detector can be incorporated in the optical path and the signal fed back into the controls.

3 BUNCHER RF SYSTEM

The buncher cavity is a pillbox design with reentrant nosecones that is operated in the TM_{010} mode at 1497 MHz. The cavity is constructed from stainless steel with copper plating on the RF surfaces, a process with which we have had good success at Jefferson Lab [5]. Three equally spaced ports located around the circumference of the pillbox cylinder are used to interact with the magnetic field of the TM_{010} mode. Manual adjustment of the resonant frequency is achieved via a micrometer controlled plunger mechanism, which is attached to the first port. RF power is delivered to the cavity via a critically coupled inductive coaxial loop probe located at the second port. A small undercoupled loop probe mounted on the third port samples the field for feedback and control. The cavity loaded Q is approximately 2500 and the R/Q is 125.

The cavity is designed to operated between 1 kV/m and 35 kV/m. Since power requirements are small, less than 5 Watts, heating from conductive losses is not a concern and so no internal cooling is necessary. Temperature stabilization is realized through the use of an external water jacket and insulating blanket. The RF phase and amplitude regulation requirement for the cavity control system is 1^{o} and 1%. As with the laser diodes the feedback takes place through EPICS. Phase control is provided by an I/Q phase shifter (IF Engineering) operating at 1497 MHz and, similarly, phase detection is performed using an I/Q phase detector. Amplitude control is accomplished using a pin attenuator (Anaren) and diode detector in a similar fashion as with the diode laser controls. The reference frequency (1497 MHz) is provided from a pre-existing bunching cavity located further downstream. A single VME card controls the buncher cavity and it is housed along side the other cards for the diode laser controls.

4 SOFTWARE

The software is a low-level application built on the EPICS control system. The interface to the VME hardware is via specifically written EPICS device support that communicates with the commercially available boards. This is mostly a straightforward EPICS database application, using standard records. It uses 12 Capfast database schematics with about 270 records, 26 ".c" subroutine files, and 2 ".st" sequencers. Most of the database records scan at 1 Hz, with the feedback loops running at 10 Hz.

The feedback loops are implemented in software, using the standard feedback control model (i.e. compare the measured hardware value to the user requested value, and vary the hardware set point to drive this comparison toward zero). Each of the three seed lasers and the buncher has independent feedback loops, a phase loop and gradient loop for each. Temperature regulation can be handled by these loops using a 1 Hz scan rate. However, for the buncher beam loading effect, a 10 Hz rate was needed. If a higher rate is desired, then part of the EPICS database will need to be converted into ".c" code to be run as a VxWorks task.

The software incorporates alarms and addresses trouble shooting. The feedback loop parameters can be altered for diagnostics (e.g. variable scan rates, free running or manual trigger modes, and hardware simulation). The user's interface to the alarms and troubleshooting begins with a basic set of good-bad indicators. The top indicator is for the combined status of both subsystems (three laser and buncher). If it shows good, then there is no need to look further. The rest of the basic indicators show more specific status. If an indicator shows bad (warning or fault), then the user can bring up various screens that show the specific problems (e.g. analog value out of range, loss of communication). The built-in troubleshooting screens provide condensed information of what needs to be done and by whom and in what order, and gives reference to the full troubleshooting guide document.

5 SUMMARY

The system has been operational since March of 1998 and has had no major problems. During commissioning of the system, a bug in the phase feedback algorithm caused the systems to run off crest, but this was quickly discovered and fixed. The decision to go with the VME platform over existing CEBAF RF controls has made the system much easier to upgrade and maintain, especially considering the compatibility with the EPICS control system.

WAVEGUIDE HARMONIC DAMPER FOR KLYSTRON AMPLIFIER*

Yoon Kang, Ali Nassiri
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

A waveguide harmonic damper was designed for removing the harmonic frequency power from the klystron amplifiers of the APS linac. Straight coaxial probe antennas are used in a rectangular waveguide to form a damper. A linear array of the probe antennas is used on a narrow wall of the rectangular waveguide for damping klystron harmonics while decoupling the fundamental frequency in dominent TE_{01} mode. The klystron harmonics can exist in the waveguide as waveguide higher-order modes above cutoff. Computer simulations are made to investigate the waveguide harmonic damping characteristics of the damper.

1 INTRODUCTION

In the APS linac klystron amplifiers, the connectors for the high-voltage connection to the ion pump were burned by the klystron harmonics power. The metallic tube connected to the ion pump passes the higher frequency harmonics power, and the metal screen used to decouple the harmonics was not very effective. Even though more effective rf shielding may be possible, it was not desirable for quality vacuum pumping. The tube to the pump has a cutoff frequency higher than the fundamental klystron frequency, but the harmonic spectrum power, shown in Figure 1, is not attenuated sufficiently. In the APS, five klystrons are used. Each klystron normally delivers 5-microsecond 35-MW peak power pulses to the accelerating structures. The average power of harmonic spectrum in the waveguide is estimated as several tens of watts. In order to eliminate the heating due to the harmonic power, a damping circuit is needed in the waveguide. The harmonic frequency power in the output cavity of the klystron amplifier may couple to the waveguide in the form of waveguide higher-order modes as well as the dominant mode. The klystron harmonic frequency power caused some problem in the APS storage ring, so the harmonics were damped by multiple probe antennas mounted on the narrow wall of the waveguide. A damper design of similar function is needed in the 2.856-GHz linac system. For this reason, the waveguide harmonic damper designs were studied using computer simulation.

2 HARMONIC DAMPER

In the waveguide transmission line, during normal operations, the fundamental frequency propagates as a travelling wave to the load cavity structure that works as a matched load. However, since the accelerating cavity structure is a narrowband load, the harmonic frequency spectrum may form standing wave resonances in the waveguide between the klystron output cavity and the cavity structure.

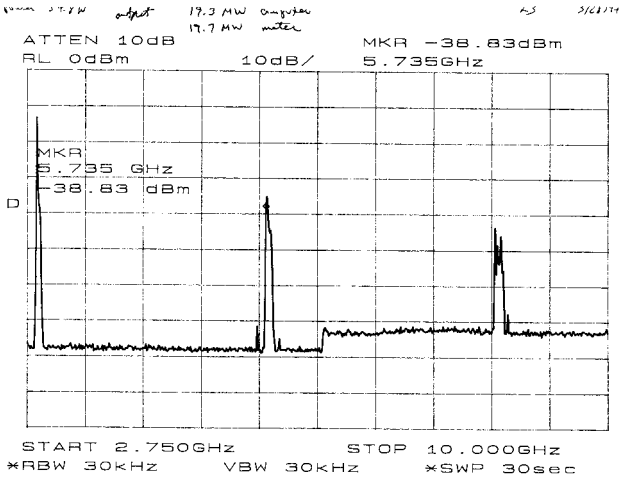

Figure 1. Harmonic spectrum of 2.856-GHz klystron amplifier output.

Figure 2 shows the waveguide harmonic damper design employing coaxial probe antennas. A linear array of five probe antennas is used on a narrow wall of the rectangular waveguide for damping klystron harmonics while decoupling the dominent TE_{01} mode. The rf power for the accelerating structure from the klystron is transmitted in the dominant TE_{01} mode. The harmonic frequencies from the klystron amplifier not only exist in the TE_{01} mode but also in higher-order waveguide modes. Higher order TE_{mn} and TM_{mn} modes couple to the antennas if m=odd and do not couple to the antennas if m=even. The index n must be nonzero for both TE and TM modes.

For the fundamental frequency, the antennas may reflect some power without delivering power to the matched load of the coaxial probes. The input matching of the damper section is important for power transmission of the fundamental frequency. Ideally, the probe antennas do not disturb the TE_{01} mode at the fundamental frequency. However, actual antennas can cause some

mismatch for the frequency. Therefore, it is important to find the optimum antenna spacing for minimum reflection at the input.

The waveguide with uniformly spaced antennas is considered a periodic loaded transmission-line structure with a matched load at the output. From [1] it can be shown that minimum reflection occurs if the spacing between antennas is a quarter wavelength. In Figure 2 the antennas are spaced by a quarter wavelength so that the combined reflection from all antennas is minimized at the input. However, since mutual coupling between the antennas and the higher-order mode excitation exist due to finite antenna dimensions, it may be necessary to check the optimum spacing of the antennas for minimum reflection at the input.

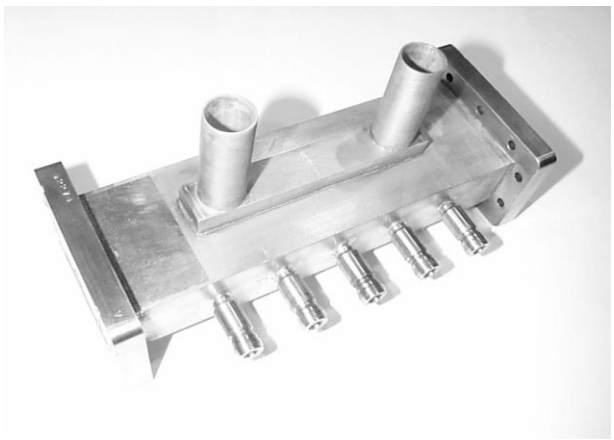

Figure 2. Waveguide harmonic damper with coaxial probe antennas.

3 SIMULATION

The damper structure has been simulated using the High Frequency Structure Simulator (HFSS) code [2]. In the simulations, eight modes were used to predict the input matching and harmonic damping with the structure. The simulations showed that the antennas convert the fundamental TE_{01} mode to some higher-order modes, and these modes do not couple to the antenna terminations if a mode is below cutoff. Since a uniform rectangular waveguide works as a high-pass filter for each mode, the harmonic frequencies, nf_o (n=2,3,4,5,…), can couple to antennas as higher-order waveguide modes.

The distance between the antennas is no longer a quarter wavelength at the higher harmonic frequencies that exist as higher-order waveguide modes. Note that the higher-order modes have pass-bands only above the cutoff frequencies of corresponding higher-order modes. Figure 3 shows the structure used in the simulation.

Figures 4 and 5 show the calculated generalized scattering parameters, $S_{1\_n,1\_n}$ and $S_{2\_n,1\_n}$, respectively, for the first four modes. Figure 6 shows the propagation loss of the four modes in the waveguide damper. Only four modes are shown in the plots for convenience. The fundamental frequency propagates in the dominant TE_{01} mode and the S_{11} is lower at the frequencies around 3GHz. These results of simulations show the properties of reflection, mode excitation and conversion, and damping characteristics of the waveguide modes due to the probe antennas. Probe antennas used in the calculation were 1.2” long and 0.121” in diameter.

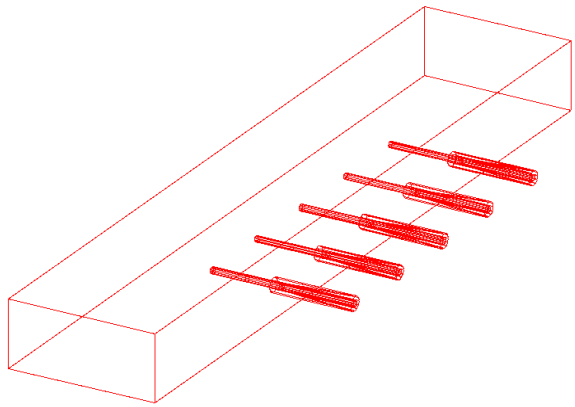

Figure 3. Damper structure with coaxial probe antennas.

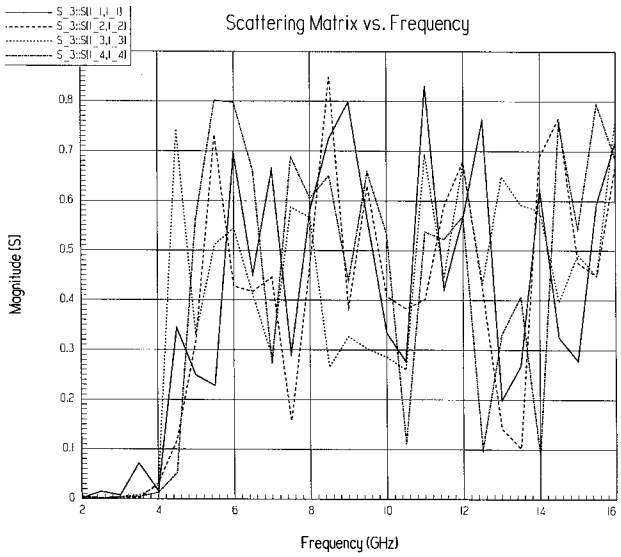

Figure 4. Calculated input reflection of the waveguide modes of the damper.

Since the simulation did not include the klystron amplifier and the accelerating structure as the load, the calculated damping characteristics did not directly describe the actual damping performance. The spacing between the antennas was varied to see the optimum antenna separation. The length of the antennas was also varied. The propagation loss characteristics shown in Figure 6 for the first four modes show that the waveguide higher-order modes can be damped effectively.

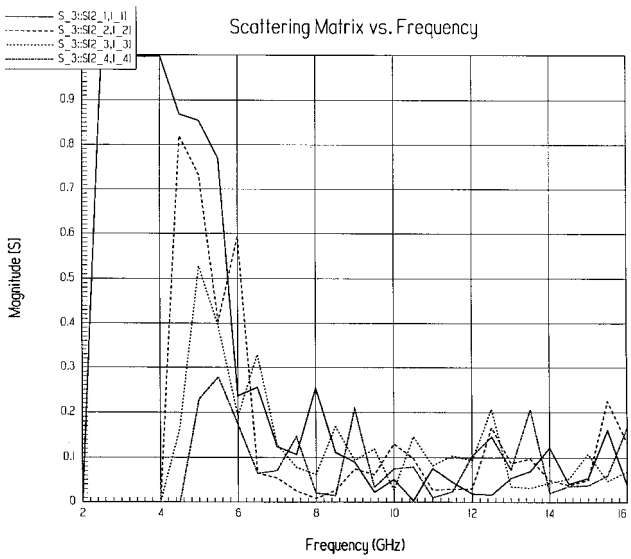

Figure 5. Transfer characteristics of waveguide modes through the harmonic damper.

The input matching and the insertion loss are good only at around 2.5-4GHz for the fundamental mode. Note that the generalized S-parameters are shown in the figures, so that the propagation loss in Figure 6 includes the waveguide cutoff loss for each mode.

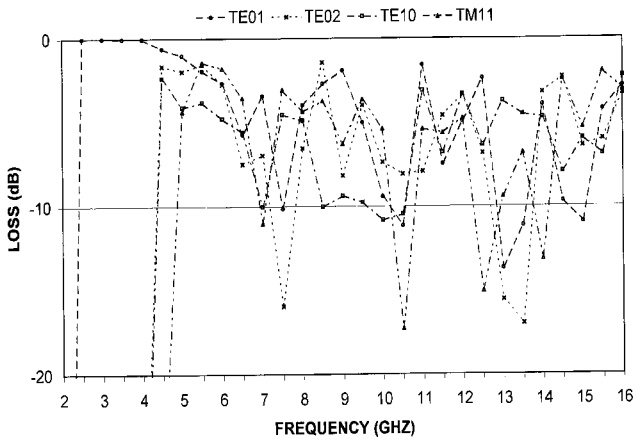

Figure 6. Propagation loss of first four waveguide modes in the waveguide harmonic damper.

4 FABRICATION AND MEASUREMENT

A prototype waveguide damper with coaxial probes has been fabricated and a low-power measurement was made. Five Ceramaseal CDP-20001 coaxial feedthroughs have been used as the probe antennas in the WR-284 waveguide. The antenna feedthroughs are welded to the copper waveguide. The fabricated damper was shown in Figure 2. The coaxial section of the antenna has a 50Ω characteristic impedance and a 50Ω coaxial termination is used in each antenna. Measurement of scattering parameters of the damper at 2.856GHz with a network analyzer confirmed good impedance matching with low insertion loss. At the fundamental frequency, the input return loss and the insertion loss were <–23dB and <0.02 dB, respectively.

The damper was to be inserted in the waveguide between the klystron and the accelerating structure. At the time the prototype was tested, the APS linac system was delivering beam to the users and, unfortunately, the damper could not be used with the actual accelerating structures. Preliminary testing of the damper between a klystron amplifier and a matched load has been planned. Since the accelerating cavity structure is a narrowband load to the klystron, measurement with a broadband resistive load may not show the characteristics of the damper. Testing with an actual accelerating structure is needed and will be performed in the near future.

5 CONCLUSION

The klystron harmonic waveguide damper employing five coaxial antennas in the narrow wall of a rectangular waveguide was simulated, fabricated, and low-power tested for the S-band linac application. The design is applicable to any system using a high-power transmitter with high harmonics content in the spectrum. The damping obtained in the design is considered adequate to protect the high-voltage connectors of the ion pumps. The design may also be useful for damping the cavity higher-order modes coupled to the waveguide.

Abstract

A 114.24-MHz sub-harmonic buncher cavity was newly developed to improve the single-bunch purity of the KEKB injector linac. The cavity was designed so as to have a high shunt impedance and a low maximum surface field at the acceleration gap. To reduce the probability of rf breakdown, the inner wall of the cavity was electrolytic-polished and a vacuum pump-out was put at the end wall of the cavity. Copper was selected as the structural material (it was copper-plated stainless steel for the old cavity) in order to improve the water-cooling capability and to reduce the resonant frequency shift by the gap-distance change when the input power increases. A cold test showed a shunt impedance of 1.2 MOhm, which is twice as large as that for the old cavity. The design, fabrication and results of low- and high-power tests and a beam-acceleration test are described.

1 INTRODUCTION

The upgraded KEKB injector linac (8.0-GeV e^- / 3.5-GeV e^+) is now at the stage of initial commissioning [1, 2]. The pre-injector of this linac has to provide single-bunch beams of 10nC in 10ps to produce intense positron beams. To satisfy this requirement, in this pre-injector, two sub-harmonic bunchers (SHB), i.e., SHB1 (114.24MHz) and SHB2 (571.2MHz) were introduced [3,4]. However, the bunch purity had not been sufficiently good; the percentage of the main-bunch current to the total current was only 80%. For this reason, we have developed a new SHB1 cavity having a large shunt impedance. Another problem of the old SHB1 cavity is low stability of the resonant frequency because of the gap-distance shift, due to poor cooling performance. Redesigns of the structural material and cooling-pipe configuration have been made.

2 DESIGN

According to the PARMELA simulation, it is possible to reduce the amount of the satellite bunch to less than 1% if the shunt impedance of the SHB cavity is increased by 1.7 times[4]. The dimensions of the new cavity was determined for this goal on the condition that the cavity can be install in the existing focusing coils (ϕ200mm).

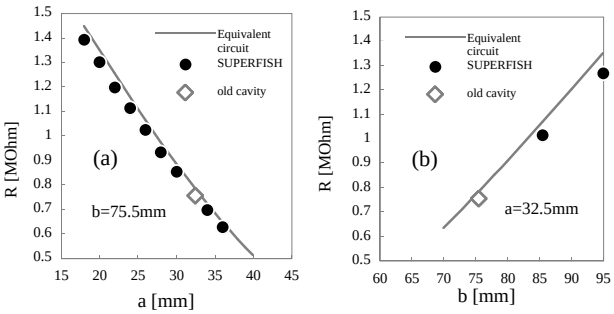

Figure 1: Dependence of shunt impedance on cavity dimensions; (a) inner radius, *a* ; (b) outer radius, *b*.

Figure 1 shows the dependence of the shunt impedance (*R*) on the inner radius (*a*) and the outer radius (*b*) of the cavity calculated by SUPERFISH and an equivalent-circuit model (quarter-wavelength-long short-circuited antiresonant transmission line). This figure shows that the required shunt impedance can be obtained when the values of *a* and *b* are selected as 30mm and 90 mm, respectively; these values were 32.5mm and 75.5 mm, respectively, for the old cavity.

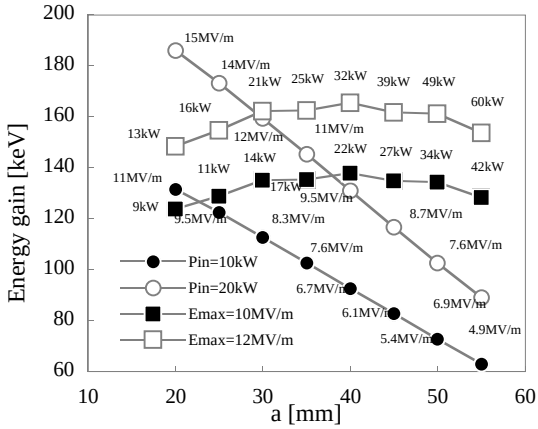

Figure 2: Relation between the energy gain and the inner radius (*a*). The numbers beside each mark show the maximum electric field for P_{in} = constant or the required source power for E_{max} = constant.

Figure 2 shows the relation between the energy gain of SHB1 and the inner radius (*a*). When the input power is constant, the smaller is *a*, the larger is the energy gain. However, when the maximum surface field is constant,

the energy gain is maximum at a = 40mm. Finally we set the value of a at 30mm because the power source available at present is limited to 10kW and beam handling would be difficult if the value of a is too small.

The distance of the acceleration gap was determined as being 40 mm (it was 18mm for the old cavity) because the longer is the gap distance, the lower is the maximum surface field. Though the shunt impedance also decreases for a wider gap distance, it is only a few percent (see Figure 3).

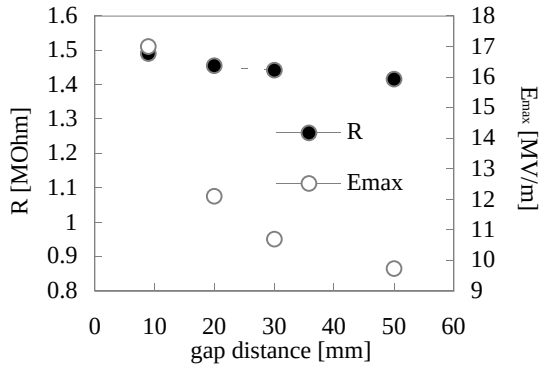

Figure 3: Shunt impedance, maximum electric field *vs* gap distance.

As the structural material, copper-plated stainless steel has been used for the old cavity. Also, only the outer conductor has been water-cooled. Consequently, the cooling performance is not good, which causes a change in the resonant frequency when the input power is changed. In the new cavity, copper (oxygen free copper) is selected as the structural material, and the inner conductor and both end plates are water-cooled.

The calculated value of the shunt impedance for the final dimensions (see Figure 4) is 1.28MΩ, which is 1.7-times that for the old cavity (0.77MΩ).

As an rf input coupler, a loop antenna of coaxial waveguide (20D) has been selected instead of that of coaxial line, which is used in the old cavity, because it has a high possibility of rf breakdown. A copper rod (ϕ24mm) is used as the tuner. According to a MAFIA calculation, a frequency change of 200kHz can be obtained by a stroke of 40mm. The tuner is remote-controlled using an ultrasonic motor

An ion pump (10l/s) is put at the end plate (see Figure 4) to improve the vacuum level of the cavity. All inner parts of the cavity were electrolytic-polished (20μm).

3 LOW POWER TEST

The resonant frequency was tuned by adjusting the length of the short nose (d_L). The sensitivity of the dimensions on the resonant frequency is given in Table 1.

Table 1: Sensitivity of the dimensions on the resonant frequency. Units of kHz/mm.

	$\partial f/\partial L_R$	$\partial f/\partial L_L$	$\partial f/\partial d_R$	$\partial f/\partial d_R$
SUPERFISH	174.18	0	210.73	36.95
Measurement	-	-	200.0	36.3

The results of a low-power test are given in Table 2. The ratio of the measured Q_0 to the calculated Q_0 (Q_0^m/Q_0^c) has increased from 0.75 for the old cavity to 0.93. This may be due to an improvement in the electrical contact because end-plates were connected using bolts and nuts in the old cavity but are connected by electron-beam welding in the new cavity.

Table 2: Results of low-power tests.

SUPERFISH	measurement				
Q_0	Q_0	Q_c	Q_L	β	Q_0^m/Q_0^c
7523	6989	6741	3433	1.04	0.93

The shunt impedance was obtained from R/Q values measured by Slater's bead perturbation method [5]. Figure 5 shows the electric-field distribution on the beam axis near to the acceleration gap.

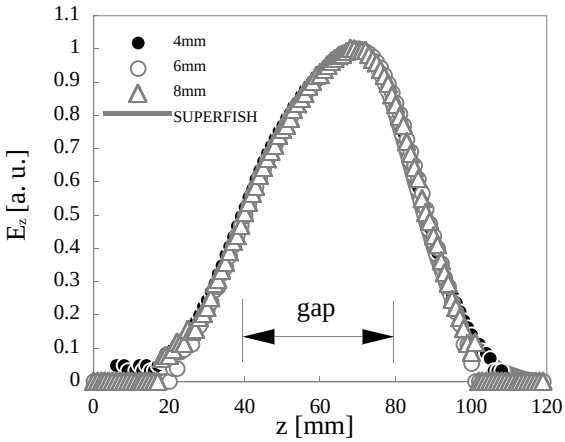

Figure 5: Distribution of the axial electric field measured by the bead-perturbation method.

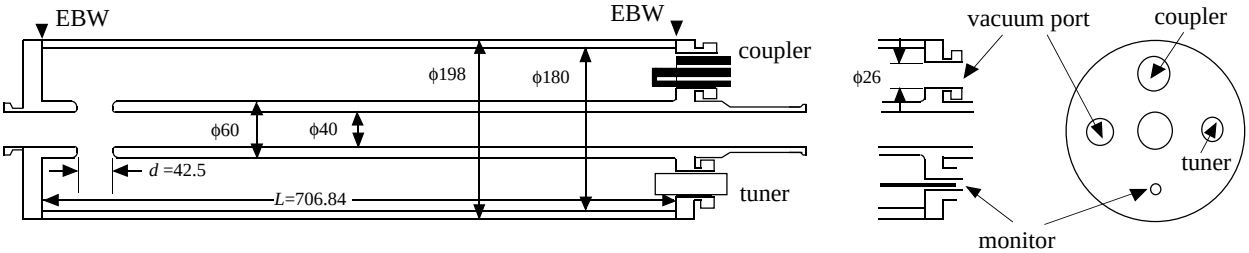

Figure 4: Cross-sectional view of the new Sub-harmonic buncher cavity.

Aluminum spheres of diameter 4, 6, and 8mm were used as perturbaters. When these values are extrapolated to the limit of zero volume, the value of shunt impedance of 1.15MOhm was obtained (see Figure 6).

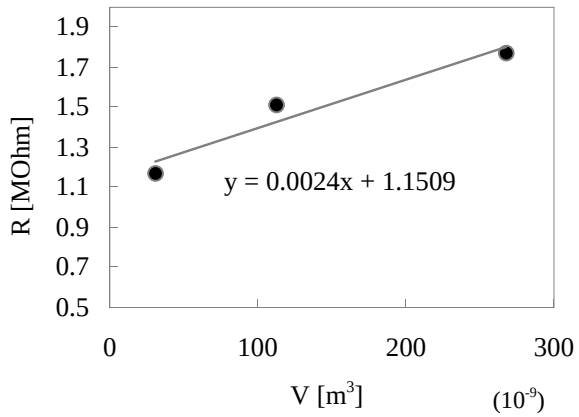

Figure 6: Relation between volume of bead and shunt impedance.

4 HIGH POWER TEST

Electric discharges by multipactoring have been observed during the initial stage of rf conditioning; it took ten days to reach an input power of 10kW without focusing coils and two days after the addition of coils. During rf conditioning, no change in the resonant frequency was observed. The pulse shapes for an input power of 10kW are shown in Figure 7. The time constant calculated from this pulse shape is about 10μs. The theoretical value is 9.6μs (= $2Q_L/\omega$).

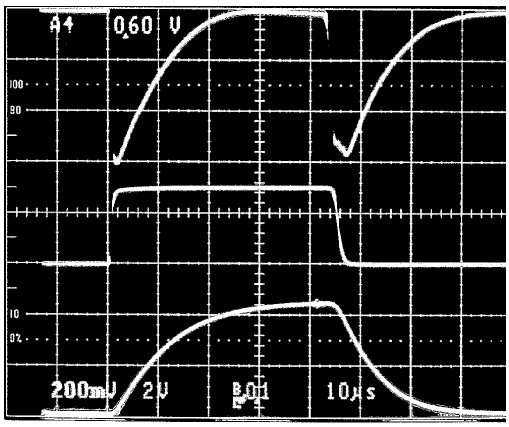

Figure 7: Photograph of rf pulses. Top trace, Reflection; Middle trace, Input; Bottom trace, Transmission. Input power, 10kW; 10μs per division.

5 BEAM ACCELERATION TEST

After installation of the SHB cavity on the beam line, a beam-acceleration test was performed. The beam charge was 12nC at the gun output. Figure 8 shows the bunch shape observed by a streak camera [6]. The bunch purity was improved from 80% to almost 100%.

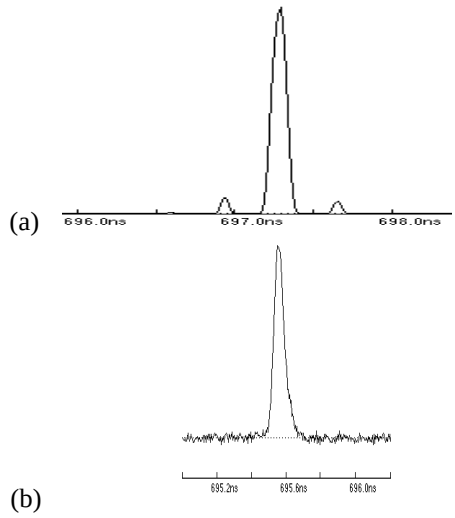

Figure 8: Shape of 12nC single bunch. (a) old SHB; (b) new SHB.

6 SUMMARY

In order to improve the bunch purity of the KEKB injector linac, a new 114.24MHz SHB cavity was designed, fabricated and tested. As a result, the shunt impedance was increased twice as large as that for the old cavity (70% came from the geometry and 20% from an increase of Q_0(measured)/Q_0(theoretical), and a bunch purity of almost 100% was obtained for a 12nC single-bunch beam. Good stability of the resonant frequency was obtained by improving the cooling performance.

7 ACKNOWLEDGEMENTS

The authors wish to thank H. Hayano for his valuable comments on the design of the SHB cavity. They acknowledge Y. Morozumi for his help in fabricating the input coupler.

DESIGN, OPERATION, AND TEST RESULTS OF 350 MHZ LEDA RF SYSTEM

D. Rees, J. Bradley III, K. Cummings, A. Regan, T. Rohlev, W. Roybal, Y.M. Wang
Los Alamos National Laboratory, Los Alamos, New Mexico USA

Abstract

The Low Energy Demonstration Accelerator (LEDA) being constructed at Los Alamos National Laboratory will serve as the prototype for the low energy section of Acceleration Production of Tritium (APT) accelerator. The APT accelerator requires over 244 RF systems each with a continuous wave output power of 1 MW. The reliability and availability of these RF systems is critical to the successful operation of APT plant and prototypes of these systems are being developed and demonstrated on LEDA. The first completed LEDA RF systems are three, 1.2 MW, 350 MHz, continuous wave, klystrons driving a radio frequency quadrapole (RFQ). This paper present the design and test results for these RF systems including the klystrons, cathode power supply, circulators, RF vacuum windows, and RF components. The three RF systems driving the RFQ use the accelerating structure as a power combiner and this places some unique requirements on the RF systems. These requirements and corresponding operational implications will be discussed.

1 LEDA RF SYSTEM DESIGN

The LEDA RF system provides RF power to an RFQ which accelerates a proton beam to a final energy of 6.7 MeV. To accomplish this acceleration the RFQ requires structure and beam power of 1900 kW. The power to the RFQ is provided by three 1.2 MW klystron amplifiers with the structure serving as the power combiner.

The LEDA RF systems utilize modulating-anode klystrons with individual power supplies to maximize operating flexibility and efficiency. Each klystron has an individual power supply, and the modulating anode voltage is derived from the cathode voltage using a regulator tube. The high-efficiency klystrons are protected from reflected power by circulators. The power from a klystron is divided into four equal parts using 3 dB hybrids to reduce the power passed through the accelerating structure vacuum windows. For the RFQ waveguide runs, the power from the three klystrons is carried in three full height WR2300 through a waveguide switch to hybrid splitters. The hybrid splitters divide the power into twelve waveguide feeds that transition to half-height WR2300 and deliver the power to the RFQ through coaxial vacuum windows.

Because the LEDA systems are, in part, meant to serve as prototypes for the APT plant, the approach to achieving high availability is also being prototyped on LEDA. Only two of the three RF systems connected to the RFQ are required for operation of the RFQ. The RFQ serves as the power combiner. Should any component of any one of the RFQ RF systems fail, a waveguide switch is used to isolate the failed system from the RFQ. The waveguide switch also reflects a short circuit at the appropriate phase to the RFQ irises associated with the failed system allowing the RFQ to continue to operate with the two remaining systems.

This approach results in some additional requirements on the RF system. With the RFQ serving as the power combiner, it is necessary to balance the output power and phase of the two or three RF systems connected to the RFQ or unwanted reflected power will result. To accomplish this, local phase control loops are implemented around each klystron and the group of klystrons is treated as if it were a single RF source by the low level control system, which modulates the amplitude and phase of the klystron drive to control the RFQ field amplitude and phase. Also, an RF arc in a window or circulator requires that all RFQ RF systems be disabled, not just the system associated with the arc, to prevent the other RFQ systems from continuing to drive the arc through the RFQ. This logic also holds true for a crowbar or interlock trip in any one of the RF systems. The other RFQ RF systems must be disabled to prevent the disabled system from being driven through the cavity by the remaining RF systems.

The low-level RF control (LLRF) system performs various functions. Foremost is feedback control of the accelerating fields within the cavity in order to maintain field stability within ±1% amplitude and 1° phase. Other functions of the LLRF control system are implementation of the local phase control loops of each klystron and RFQ resonance condition monitoring. The resonance of the RFQ is controlled by varying cooling water temperature. Because the RFQ will rapidly cool when RF is shut down, drive frequency agility in the main feedback control subsystem is incorporated to quickly restore the cavity to resonance with RF heating.

2 RF COMPONENT DESCRIPTIONS

2.1 Klystrons

The LEDA RFQ RF systems utilize 1.2 MW CW klystrons at 350 MHz. The klystron is based on the CERN klystron with one major design modification. The LEDA 350 MHz klystrons are designed to dissipate the

full beam power (1.85 MW) in the klystron collector in the steady state. This design requirement is driven by the size of the APT plant and the impact that turning off all klystrons would have on the local power grid.

The design requirements and measured performance for the 350 MHz klystron are summarized in Table 1. The 350 MHz klystrons have demonstrated all design requirements in the acceptance tests and have approximately 300 hours of operation in test stands at Los Alamos. A picture of the klystron is shown below in Figure 1.

Table 1: Klystron Requirements

Requirement	Specified	Measured
Voltage (Max)	95 kV	94 kV
Current (Max)	21 A	19.6 A
Output Power (Min)	1.2 MW	1.2 MW
Efficiency (Min)	65 %	65 %
Gain (Min)	40 dB	41 dB
Operating VSWR (Max)	1.2:1	1.2:1
1 dB Bandwidth	.7 MHz	>.7 MHz

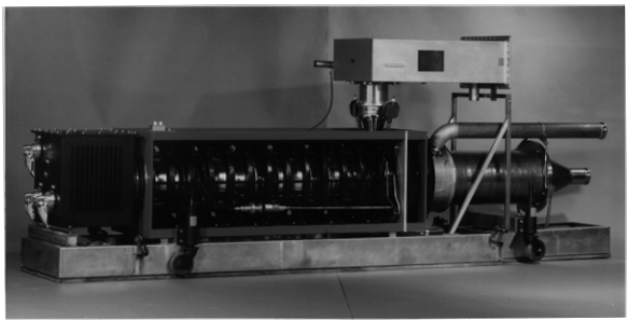

Figure 1: Picture of EEV 350 MHz klystron.

2.2 Power Supplies

LEDA is prototyping two power supply topologies that are under consideration for the APT plant: a Silicon Controlled Rectifier (SCR) center point controlled power supply and a solid state modulator power supply using Insulated Gate Bipolar Transistors (IGBTs). Both topologies provide a klystron beam voltage of up to 95 kV and a maximum beam current of 21 A and protect the klystron from excessive energy deposition in the event of a tube arc.

The SCR power supplies utilize two SCR bridges with filter inductors at the center tapped transformer primaries to produce 12 pulse rectification as shown in Fig 2. In the event of a klystron arc, the crowbar circuit protects the klystron from the filter capacitor stored energy. These power supplies must have an efficiency of ≥95%, a power factor of ≥0.93 at full power and the harmonic distortion at the input must meet IEEE Std 519-1992 requirements. Three of these power supplies have been delivered by Maxwell Labs and have met all performance requirements.

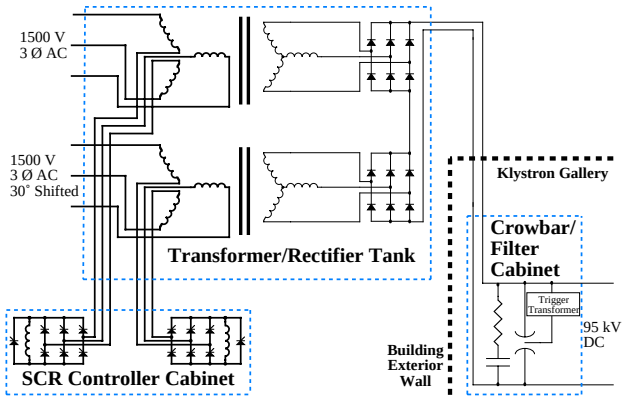

Figure 2: SCR bridges are in the center of the primaries.

The IGBT power supplies utilize 96 separate rectifying modules stacked in series. Each module is fed from an isolated secondary winding on one of four transformers. The primary windings of each transformer are phased for 24 pulse rectification at the series output. Each module uses an IGBT for current control, eliminating the need for a crowbar. Failed modules are bypassed by the control system to provide graceful degradation of operation. These power supplies must have an efficiency of ≥97%, a power factor of ≥0.98 and meet IEEE Std 519-1992 requirements. Three of these power supplies are on order from Continental Electronics and the prototype power supply has passed all acceptance tests. A picture one of the power columns containing half (48) of the 96 rectifying modules is included below in Fig. 3.

2.3 RF Vacuum Windows

The window design we have selected is a coaxial geometry. The 350 MHz window is illustrated in Figure 4. The air side is a half-height WR2300 waveguide. A T-bar is used to transition to a coaxial line. A high-purity alumina coaxial window separates the air and vacuum side of the window assembly. Another T-bar is used to transition back to half-height WR2300 which is then connected to ridge loaded waveguide to drive the iris coupled RFQ. Each RFQ window has been tested under vacuum in a back-to-back configuration to 1.0 MW of CW RF power for a minimum of four hours. In the RFQ the windows are utilized at a maximum nominal power of 300 kW. Prior to the 1.0 MW acceptance test, the windows must be conditioned to this power level. The conditioning time for each of the RFQ windows and spares is indicated in Figure 5. The average time was 18.5 hours.

2.4 Cavity Field Control

The cavity field control system controls the in-phase and quadrature (I/Q) errors of the cavity field. It consists of three VXIbus modules. The Clock Distribution Module receives a phase-stable 10 MHz reference and produces coherent frequencies needed for field signal

downconversion and I/Q sampling. The Field Control Module (FCM) houses all of the digital and analog electronics, which perform the high-precision I/Q detection and control. The Amplifier Control Module serves as an interface between the control system and the multiple klystrons driving the cavity. It takes the control signal from the FCM, splits it, and then individually modifies each output leg to compensate for the aberrations of each particular klystron. The closed-loop bandwidth of the field control system is approximately 200 kHz. A block diagram of the entire LLRF system is shown in Figure 6.

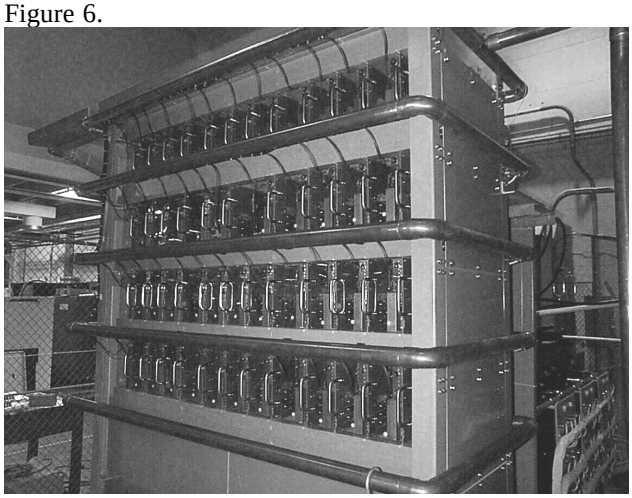

Figure 3: Power Column For IGBT Power Supply

2.5 Resonance Control

The resonance condition of the RFQ will be determined by monitoring a sample of its forward, reflected, and transmitted signals. The signals will be run through a simple algorithm in a digital signal processor on board the Resonance Control VXIbus Module to calculate the RFQ's resonant frequency. Should the resonance frequency differ from the fundamental, an error signal will be sent to the RFQ's water-cooling system indicative of the need to increase or decrease the cooling water temperature. This module also implements the frequency agile function, based on direct digital synthesis mentioned earlier. This frequency agility will be utilized only when the cavity is far from nominal resonance, not during normal operation.

2.6 RF Protection

A flexible RF Protection function has also been built into the LLRF VXIbus Control system. The RF Protect Module monitors the HPRF transmission system and turns off the drive to the klystrons should a fault occur anywhere within the system. The RF Protect function protects against arcs in the waveguide, klystron, or RFQ; high reflected power at the RFQ ports, loads on the circulator, and waveguide splitters; crowbars; and bad VSWR at the klystron output.

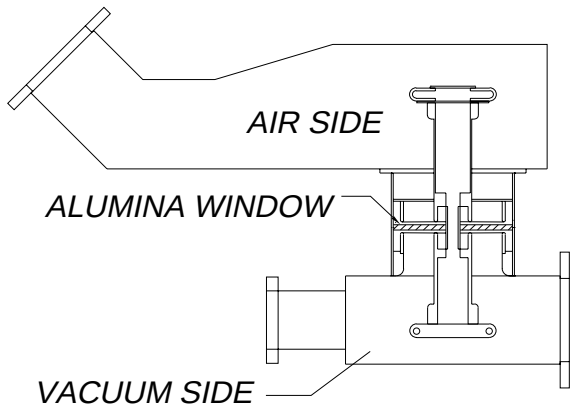

Figure 4: RFQ coaxial window.

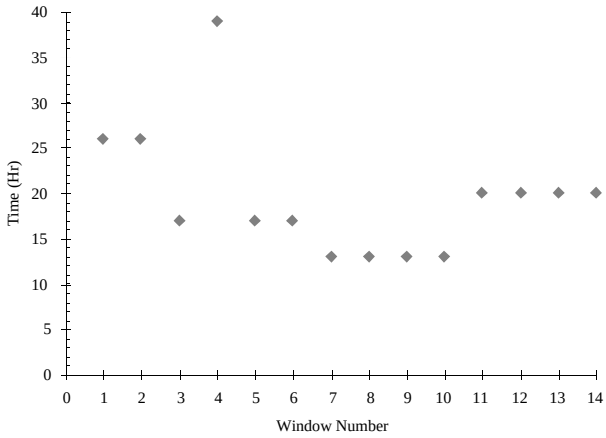

Figure 5: RFQ vacuum window conditioning time.

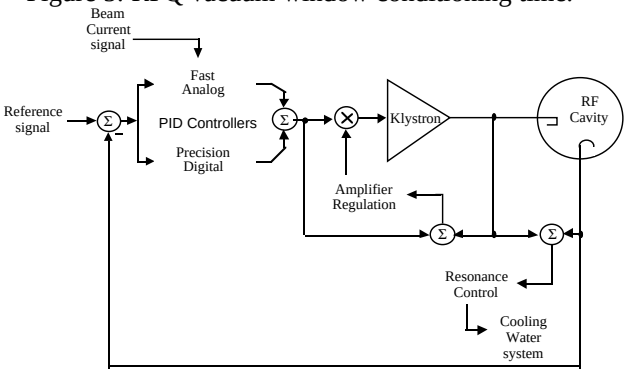

Figure 6: LLRF control system.

3 CONCLUSIONS

The RF systems for the LEDA accelerator have been installed at Los Alamos and are ready to provide RF power to the RFQ in early October. These systems have been designed as prototype equipment for the APT plant and will be used to demonstrate not only the reliability of RF equipment, but also the redundancy concepts for the APT plant that will allow for very high RF system availability. The individual RF system have demonstrated that each system meets the design requirements. The integrated testing with the RFQ in October is the next step in the validation of the APT RF system design.

THE RF POWER SYSTEM FOR THE SNS LINAC*

Paul J. Tallerico and William A. Reass
Los Alamos National Laboratory, Los Alamos, NM 87545 USA

Abstract

The initial goal of the SNS project is to produce a 1 MW average beam of protons with short pulse lengths onto a neutron-producing target. The objective of the SNS RF system is to generate 117 MW peak of pulsed 805 MHz microwave power with an accelerated beam pulse length of 1.04 ms at a 60 Hz repetition rate. The power system must be upgradeable in peak power to deliver 2 MW average power to the neutron target. The RF system also requires about 3 MW peak of RF power at 402.5 MHz, but that system is not discussed here. The design challenge is to produce an RF system at minimum cost, that is very reliable and economical to operate. The combination of long pulses and high repetition rates make conventional solutions, such as the pulse transformer and transmission line method, very expensive. The klystron, with a modulating anode, and 2.5 MW of peak output power is the baseline RF amplifier, an 56 are required in the baseline design. We discuss four power system configurations that are the candidates for the design. The baseline design is a floating-deck modulating anode system. A second power system being investigated is the fast-pulsed power supply, that can be turned on and off with a rise time of under 0.1 ms. This could eliminate the need for a modulator, and drastically reduce the energy storage requirements. A third idea is to use a pulse transformer with a series IGBT switch and a bouncer circuit on the primary side, as was done for the TESLA modulator. A fourth method is to use a series IGBT switch at high voltage, and not use a pulse transformer. We discuss the advantages and problems of these four types of power systems, but we emphasize the first two.

1 THE FLOATING DECK MODULATOR SYSTEM

The floating-deck modulator is an old technology that is well suited to pulse lengths above 0.5 ms, and pulse rates below 1 kHz. The RF duty factor, is 6.84%, since some scores of μs must be added for cavity fill time, and control loop settling time. The pulsed power duty factor is 7.5%, since the 0.1 ms rise and fall time must be added to the RF pulse length. Each 805 MHz klystron can deliver 2.5 MW of peak power into its load, and each klystron requires 120 kV and 40 A, peak. The average power into each klystron is thus 328.3 kW. We add 20% to allow for losses in the modulator, and capacitor bank slump, and arrive at 394 kW per klystron. In this floating-deck system, each power supply drives eight klystrons, so each power supply is rated at 130 kV and 3.25 MW. The current pulses are drawn from a capacitor bank. For 5 kV maximum voltage droop during the pulse, the capacitor bank must be at least 90 μF, and the bank energy is 760 kJ. A fast acting crowbar switch is used to protect the klystrons from this energy when they arc, since as little as 20 J in an arc may damage a klystron. Figure 1 illustrates the major parts of this power system.

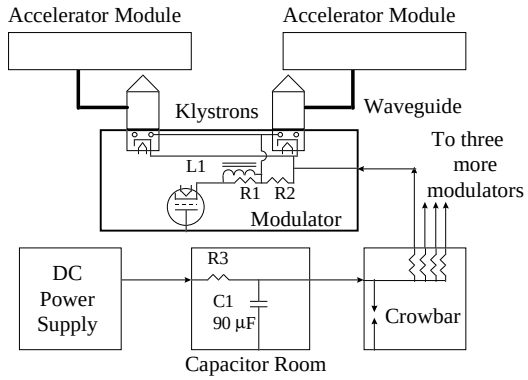

Fig 1. Block diagram of the floating deck modulator system.

With the single switch tube, rise times of 80 μs and fall times of 120 μs are typical with 100 kΩ as the sum of R1 and R2 in Fig. 1 in series with the switch tube. The efficiency of this modulator is high, since only 1.2 A flows through the modulator resistors, compared to the 75.8 A in the two klystrons. The power losses are 51.7 kW in the resistors (at 6 Ω per resistor) in the capacitor room, 43.2 kW in the modulator resistors, and only 0.6 kW in the 800 pF stray capacity in the modulators. The total energy efficiency is then 93.5% in the pulsed power part of the circuit, including the rise-time losses.

Many variations of the circuit are possible to reduce the capacitor bank droop, and Fig. 1 shows a passive compensation method. Active compensation methods are more effective, but require a higher parts count, so they usually have a reliability penalty. At voltages below 100 kV the floating-deck modulator and its klystron can be very reliable, and a Mean Time Between Failure (MTBF) of 25,000 hours for the combination of the klystron and the modulator is our estimate for those at LANSCE. However, there is dc voltage stress on the electron gun, and the MTBF decreases rapidly with voltage. The

* Work supported by the U.S. Department of Energy.

reduction in MTBF may be as high as a factor of 2 for 120 kV operation, so we look for alternative modulators. Another serious problem with this circuit is that the energy storage in the capacitor bank must be 10 times the energy in the klystron pulse to limit the droop to 5% in the klystron's voltage, and even more energy must be stored to reduce the droop below 5%. This energy must also be stored at high voltage, above 125 kV in the SNS case, and we have to deal with difficult corona control and serious safety issues.

2 THE FAST CONVERTER MODULATOR

It is possible to make dc-to-dc converters that raise a voltage to a much higher value, and many consumer products do this. A newer concept is to design a dc-to-pulsed power supply that takes power at a moderate dc voltage, and produces the 1 ms, 120 kV pulses at a 60 Hz repetition rate for the klystron. The concept is shown as a block diagram in Figure 2. The dc-to-dc converter is a multiphase chopper, operating between 10 and 20 kHz, making the high-voltage transformer very compact compared to that required for 60 Hz operation. Most of the problems with this type of circuit have been solved in the past few years by the gradual perfection of the insulated gate bipolar transistor (IGBT), that are massed produced for high-power applications, especially in motor control. The IGBT may be considered a combination of a voltage driven MOSFET coupled to a bipolar transistor. The energy left in the leakage inductance of the transformer after each pulse must be dissipated in snubber circuits, and we expect an efficiency of somewhat above 80% with this circuit.

However, it looks feasible to build such a converter that can deliver almost 10 MW pulses for 1 ms to a pair of klystrons. The dc power is provided by an inexpensive, unregulated, full wave rectifier that operates directly from a 3-phase, 4160 V source. More details on this circuit are available in [1]. Energy must be stored for the pulses, so there is a 10 kV capacitor bank on the output of the power supply.

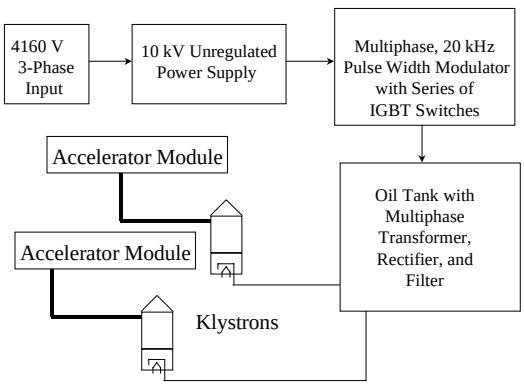

Fig. 2. Block diagram of the fast converter modulator.

Preliminary calculations are quite encouraging, and indicate that significantly less energy must be stored for this circuit than for the floating-deck modulator. Rise and fall times of 50 μs have also been calculated with a fairly detailed computer model. Another difficult component in this design is a multiphase, very tightly coupled, transformer. Measurements on a scale model of the transformer have shown that it should be possible to achieve both the high turns ratio and very low leakage inductance that we require.

3 THE BOUNCER-COMPENSATED PULSE TRANSFORMER MODULATOR

Perhaps the first method of utilizing modern semiconductor switches to drive a long-pulse, multi-megawatt klystron was the bouncer-compensated pulse transformer circuit that was developed by Pfeffer et al. [2] at Fermi National Laboratory. A simplified second version of this circuit, using IBGT's as the main switch elements, is shown in Fig. 3 below. Here the main capacitors, (C1 in Fig. 3) store only slightly more than the energy required for each klystron pulse. Normally, the voltage droop during a 1 ms pulse would be intolerable with a simple pulse discharge circuit, but the LC circuit (the bouncer) in the return leg of the pulse transformer is charged by each pulse, and the bouncer starts to oscillate before each main pulse. By appropriate design, the bouncer voltage can add to the discharging capacitor voltage to produce an output pulse that only has a few percent variation over the pulse. Earlier versions of this circuit were developed using GTO switches [3].

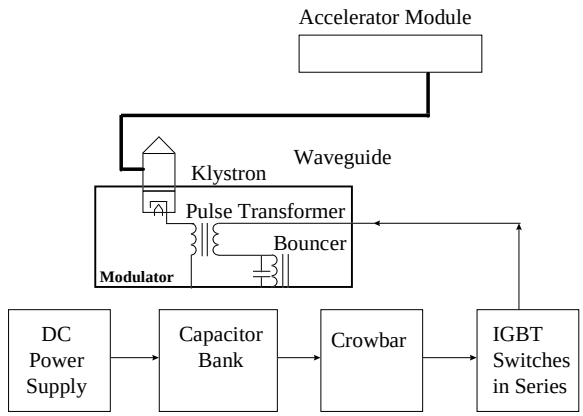

Fig. 3. Block diagram of the pulse-transformer, bouncer corrected modulator.

4 THE SERIES SWITCH MODULATOR

Rather than drive a step-up transformer, in some cases it is more economical to directly switch the high voltage between the power supply and the klystron load. Older versions of this circuit were used at the Bates linac, and in

the some Free-Electron Lasers, using electron tube technology. Solid-state versions are also possible, using IGBT switches, for example. The engineering issues are rather significant with this solution, since the switches must operate at high voltages, so isolation becomes a problem. A simplified block diagram of the series switch modulator is shown in Fig. 4. In this system, two separate switches is series, as well as many series IGBT's in each switch, are sometimes required: one chain pulses the klystron, and another provides regulation. This system has the disadvantage of storing the pulse energy at high voltage, so there are corona and safety issues associated with this energy storage.

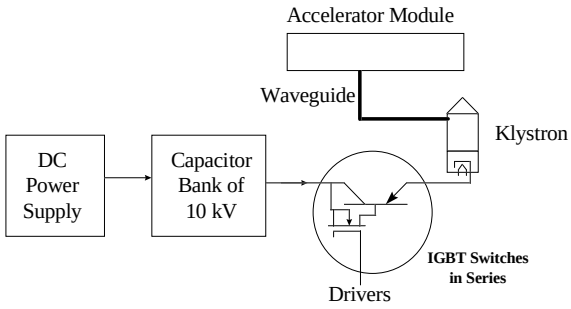

Fig 4. Block diagram of the series high voltage modulator.

5 SUMMARY AND CONCLUSIONS

Cathode pulsing is the best method for high-power, long pulse systems. The baseline RF system for the SNS is moving towards the converter-modulator option. Since all the cathode-pulsed systems do not require modulation anodes in the klystrons, the klystrons should be more reliable, and their cost should be reduced by at least a few percent. Another advantage of the converter modulator and the other new systems discussed here is that most of the electronics is out of the oil tank in these circuits, so maintenance is easier, and the environmental impact is more benign with the smaller oil tanks.

The semiconductor implementations of the power system can save capital costs by reducing the amount of energy that must be stored for the pulsed system, and some expensive or troublesome components, such as the crowbar and high-voltage capacitors, can often be eliminated.

ACKNOWLEDGMENTS

The assistance and encouragement of the SNS project management, both at Oak Ridge and at Los Alamos, has been essential in performing this work. The assistance of J. Daniel Doss of Los Alamos in performing the circuit analyses is also gratefully acknowledged.

HIGH POWER RF COMPONENT TESTING FOR THE NLC*

A.E. Vlieks, W.R. Fowkes, R.J. Loewen, S.G. Tantawi
Stanford Linear Accelerator Center, Stanford University, Stanford, CA 94309, USA

Abstract

In the Next Linear Collider (NLC), the high power rf components must be capable of handling peak rf power levels in excess of 600 MW. In the current view of the NLC, even the rectangular waveguide components must transmit at least 300 MW rf power. At this power level, peak rf fields can greatly exceed 100 MV/m. We present recent results of high power tests performed at the Accelerator Structure Test Area (ASTA) at SLAC. These tests are designed to investigate the rf breakdown limits of several new components potentially useful for the NLC. In particular, we tested a new TE_{01}–TE_{10} circular to rectangular 'wrap-around' mode converter, a modified (internal fin) Magic Tee hybrid, and an upgraded 'flower petal' mode converter.

1 INTRODUCTION

In SLAC's version of the NLC, sources, such as klystrons, transport rf power to accelerator structures primarily in circular overmoded waveguide. Various rf components—such as mode converters, 90° bends, and 3-dB hybrids (each consisting in part of single-moded rectangular waveguide)—route rf power from one circular guide to another.

In order to verify that these components can handle the required power levels of up to 300 MW, we conducted a series of tests to establish breakdown limits and to investigate mechanisms of breakdown. We present the results of experiments, which led to the identification of components capable of operating reliably at rf power levels in excess of 300 MW. In earlier tests [1], two key components of SLED-II—a $TE_{01}^{(circ.)}$–$TE_{10}^{(rect.)}$ flower petal mode converter and the Magic Tee hybrid—failed at a power level of 220–250 MW [2]. These components were modified and subsequently retested along with the newly designed wrap-around mode converter.

2 EXPERIMENT

2.1 General Layout

The general setup is shown in Figure 1. The experimental setup consists of an rf source, a SLED-II pulse compressor, and a high power load assembly. Two 50 MW klystrons operating at 11.424 GHz supply the rf power. The pulse width of each klystron is 1.05 μs running at a repetition rate of 60 Hz. Each klystron is driven by its own TWT driver which in turn is driven by a common signal generator. The power from these klystrons combine through a Magic Tee 3-dB hybrid and feed the input to the SLED-II system. The combiner was previously conditioned to full klystron power by being connected to the load assembly.

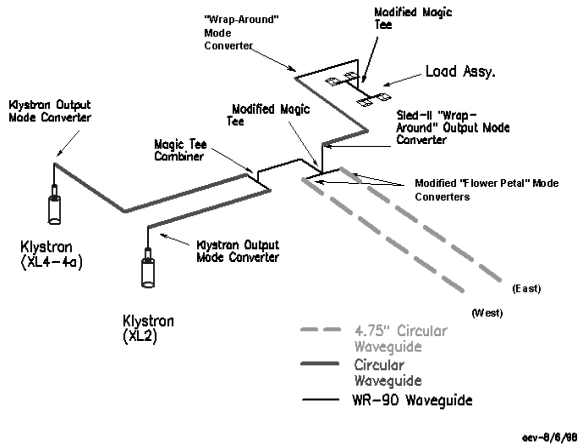

Figure 1. Schematic of the initial experimental setup.

The SLED-II pulse compression system operates with a compression ratio of 7 and a peak power gain of ≈4. Hence, this configuration can potentially yield up to 400 MW of peak power with a flat top of 150 ns. The primary components under test are the 3-dB hybrid, the two delay line mode converters, and the output mode converters.

The load assembly consists of four choked, stainless steel 'dry' loads [3] arranged in parallel. (A Magic Tee first splits the incoming power and then two additional Magic Tees divide each of the split power levels again.) In earlier tests, an individual load of this type was successfully tested to ≥100 MW at a pulse width of 150 ns.

2.2 Preparation

During all phases of the experiment, the vacuum system is baked out to approximately 150°C for at least 24 hours (plus a ramp-up/cool-down of 24 hours each). At the end of this cycle, the vacuum in the system is $\leq 1\times10^{-9}$ Torr. In addition, any new components added to the system during the course of the experiment are first high temperature baked to 400°C before installation in order to remove residual hydrogen and other contaminants.

* Work supported by Department of Energy contract DE-AC03-76SF00515

2.3 Initial Experiment

In the first phase of the experiment, two modified flower petal mode converters were installed in the SLED-II delay lines. As described in [1], these components are modified from an earlier design to alleviate the rf erosion at the bifurcation in the rectangular waveguide section. The 3-dB hybrid is a modified Magic Tee configured with the H-arm as input and the E-arm as output. The modification consists of replacing the matching post in the throat of the Tee by a broad fin with fully rounded corners and rounding the edges at the E-arm throat. (This was motivated from witnessing significant erosion of the post during previous testing). A newly designed wrap-around mode converter was placed at the output of SLED-II.[4]

Results of the initial phase of the experiment show that all components work well up to ≈240 MW. Above this power level, there were significant rf breakdown events at the SLED-II Magic Tee as well as enhanced, steady state X-ray emission. One of the two delay line mode converters—labeled the 'West' mode converter—also exhibited enhanced X-ray emission albeit far less than the Magic Tee. The wrap-around mode converter was essentially breakdown-free and radiation levels at this mode converter were about the same level as the nearby rectangular WR90 waveguide.

Figure 2 shows typical radiation levels measured at the waveguide surface of the Magic Tee by an X-ray survey meter. One curve shows a typical dose rate when the system is well conditioned. The other curve shows the effects of conditioning. Initially, at low power levels, the dose rate is anomalously high. Then, after an rf breakdown event occurs and testing is resumed, the radiation levels reduce to the typical values. These typical values did not improve or deteriorate with time.

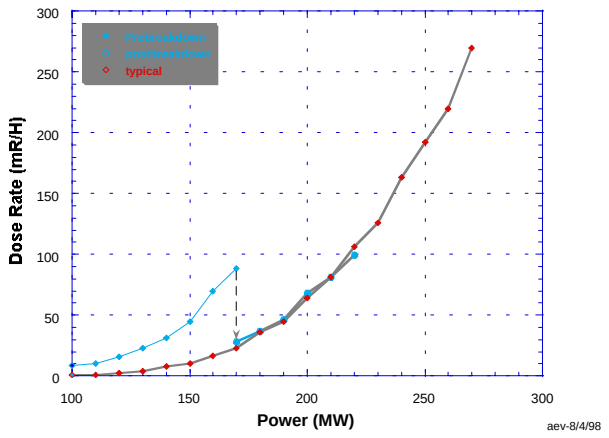

Figure 2. Radiation Intensity at the SLED-II Magic Tee.

An interesting result from radiation measurements is that the Magic Tee at the entrance of the load had much lower radiation levels than the SLED-II Magic Tee even though the peak power levels are approximately the same. It appears that the standing wave set up between the delay line iris and the SLED-II Magic Tee enhances the peak fields. Simulation verifies that the increased fields from this standing wave pattern can greatly enhance the peak fields in critical regions of the Magic Tee. It also became clear that reversing the input and output ports of this Magic Tee would significantly reduce these peak fields.

2.4 Phase Two

At the conclusion of the initial experiment, the SLED-II and load entrance Magic Tees were removed and cold tested. Their RF properties were found to be unchanged from their pre-test values although some erosion was observed in the SLED-II Magic Tee along the fin. The West delay line mode converter was also checked and found unchanged. It was decided that the positions of the two Magic Tees would be exchanged and that the new SLED-II Magic Tee would be installed with the roles of the input and output ports interchanged, i.e. now the E-arm is input and the H-arm is output. It was also decided to coat the problematic West flower petal mode converter with Titanium Nitride to try to reduce the X-ray radiation by decreasing the electron secondary emission yield.

The interchange of input and output ports of the SLED-II Magic Tee had a marked improvement on system performance. The steady state radiation level at the Magic Tee was reduced by a factor of 18. Unfortunately, the radiation levels at the West delay line mode converter remained the same with no effect due to the TiN coating. As the peak power levels approached 270 MW, it became clear that the limiting component was this mode converter. Figure 3 compares the radiation levels from the East and West mode converters and Magic Tee. It is remarkable that the radiation levels of the East mode converter are 150 times smaller than the West even though the system is apparently symmetric.

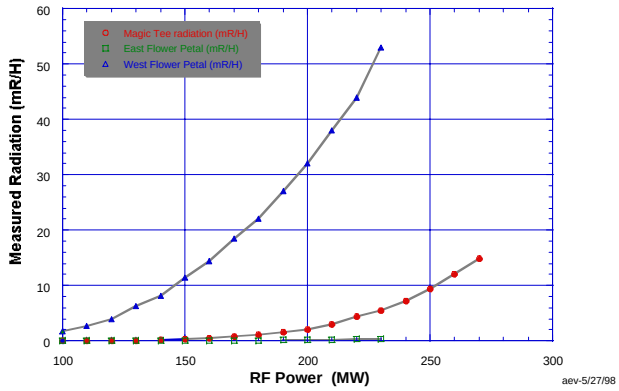

Figure 3. SLED-II Radiation levels.

To further pinpoint the location of this radiation, measurements were made through a 0.64-cm aperture of a lead-shielded survey meter in 1-cm intervals along the centerline of the mode converter (see Figure 4). The results, as shown in Figure 5, indicate that the radiation is

emanating at or behind the coupling irises (or 'flower petals').

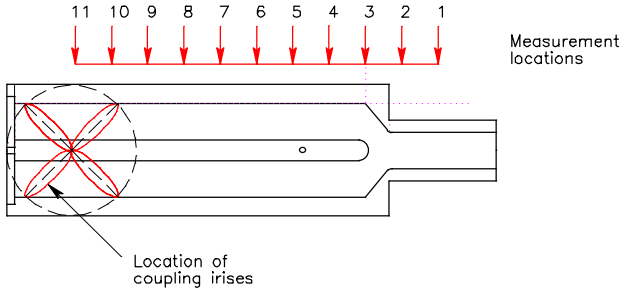

Figure 4. Location of measurement points along the rectangular portion of the mode converter. Additional measurement points are located out of the paper along the circular portion of the converter.

To estimate the energy of these X-rays, aluminum and copper absorbers of various thicknesses were used to measure the X-ray attenuation coefficient at a power level of 200 MW. Since the slope of the attenuation is quite linear (on a semi-log plot) with absorber thickness, we may assume that the walls of the mode converter selectively removed the low energy portion of the X-ray spectrum leaving only X-rays with the highest energies. Under these assumptions, we find the peak X-ray energy to be near 150 KV as shown in Table 1. For electrons accelerated from rest across the petal gap, this corresponds to a peak gradient of 510 KV/cm. This value is in excellent agreement with earlier computer simulations of 523 KV/cm at 200MW [6].

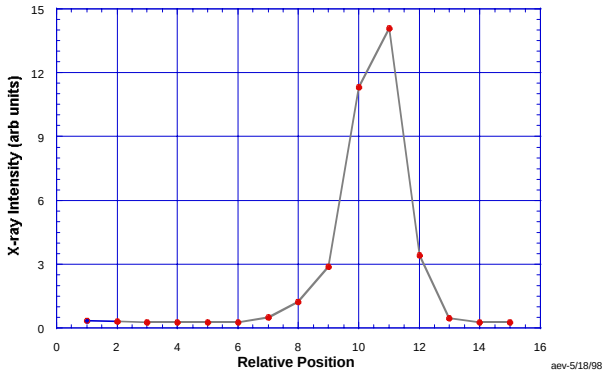

Figure 5. X-ray radiation intensity at the West flower petal mode converter at 130 MW power.

2.5 Phase Three

At the conclusion of the second phase of this experiment, both delay line mode converters were replaced with wrap-around mode converters and testing resumed.

This time we were able to drive the SLED-II system to a power level of 320 MW with no evidence that a power limit had been reached. The X-ray intensity at the Magic Tee was similar to previous measurements, and the wrap-around mode converters showed no evidence of excessive radiation (i.e. no greater than WR90 waveguide).

Table 1. Comparison of measured attenuation coefficient with tabulated values near 150 KV.

Absorber	**Measured attenuation (cm^2/g)**	**Tabulated attenuation[5]**
Copper	0.136	0.134@ 150KV
Aluminum	0.191	0.203@ 150KV 0.148@ 200KV

3 SUMMARY AND CONCLUSION

A series of experiments were performed to determine the peak power performance of various rf components. The mode converters of the modified flower petal type are adequate up to peak power levels of approximately 225 MW. Wrap-around mode converters perform well at least up to 320 MW and in all likelihood much higher. The modified Magic Tee 3-dB hybrid transmits 320 MW without difficulty but when used in applications where standing waves can enhance peak fields (such as SLED-II), the details of the installation becomes important.

At the moment, the exact reason for the heightened X-ray emission in the West mode converter is unclear. However, the measured energy of the X-rays corresponds to the expected peak field levels based on simulation.

Abstract

The electron beam which drifts through the multiple cavities of conventional induction linacs (LIA) is replaced in an IVA by a cylindrical metal conductor which extends along the entire length of the device and effectuates the addition of the accelerator cavity voltages. In our approach to radiography, the linear inductive voltage adder drives a magnetically immersed electron diode with a millimeter diameter cathode electrode and a planar anode/bremmstrahlung converter. Both anode and cathode electrodes are immersed in a strong (15-50 T) solenoidal magnetic field. The electron beam cross section is approximately of the same size as the cathode needle and generates a similar size, very intense x-ray beam when it strikes the anode converter. An IVA driven diode can produce electron beams of equal size and energy as a LIA but with much higher currents (40-50 kA versus 4-5 kA), simpler hardware and thus lower cost. We present here first experimental validations of our technology utilizing HERMES III and SABRE IVA accelerators. The electron beam voltage and current were respectively of the order of 10 MV and 40 kA. X-ray doses of up to 1 kR @ 1 m and spot sizes as small as 1.7 mm (at 200 R doses) were measured.

1 INTRODUCTION

Up to the cessation of the nuclear tests, radiography of an imploding primary (with surrogate material) was utilized to supplement the information gathered from these tests. However, this is now the only means available to probe and characterize such a device.

To radiograph very thick objects, a high-energy, high-flux, and very small spot x-ray source is required. The small spot (~ 1 mm in diameter) will provide the necessary spatial resolution while the high-energy photon flux is required to penetrate the thick object and produce a clear image of its interior. To generate those penetrating x-rays an electron accelerator is being used. The electron beam strikes a tantalum x-ray converter plate. The forward x-ray beam illuminates the surrogate primary and produces a photograph on a package of films or imaging detectors located on axis downstream from the radiographed object, similar to medical or industrial radiography.

Presently, two types of accelerators are being utilized for x-ray radiography: first, linear RF (PHERMEX) or induction accelerator (FXR); and second, single gap pulsed power devices using a high-voltage Blumlein pulse forming line (AWE). The first can produce high-energy, small-diameter (2-3 mm) electron beams relatively easily, but the current is limited to 1-2 kA yielding low photon fluences. The Blumlein pulsed power devices can produce much higher beam currents (50-100 kA), but the beam spot diameter is relatively large (~ 6 mm) and the beam energy is limited to 8-10 MV.

Our linear inductive voltage adder accelerator (IVA) coupled to a magnetically immersed foilless diode can successfully bridge the gap between the two devices. It can produce small spots (~ 1 mm), high voltages (15-20 MV), and high currents (40-50 kA) at a fraction of their cost.

In the next sections, we present first experimental validations of our technology utilizing available Sandia National Laboratories IVA accelerators.

2 SABRE EXPERIMENTS

For these experiments, SABRE was modified to increase the output voltage and proportionally reduce the current, delivering the same energy. It was, therefore, operated at 9-12 MV and 100-120 kA. The design of the MITL voltage adder and the foilless diode (Fig. 1) were validated with a large number of particle-in-cell simulations.

* Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy under Contract DE-ACO4-94AL85000.

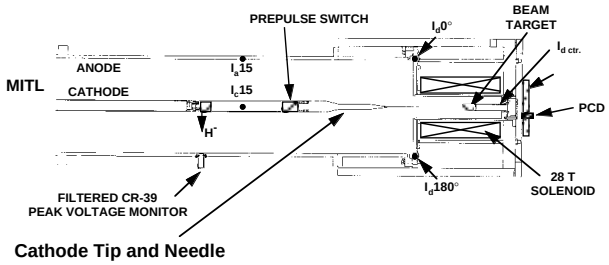

Figure 1 Schematic diagram of diode design utilized in both SABRE and HERMES-III experiments.

The intense electron beam produced by the SABRE foilless diode quickly produces an ion-emitting anode plasma. The ions are accelerated toward the cathode. The electrostatic attraction between the two beams is considerable and an ion-hose two-stream instability is excited. If left uncontrolled, this instability can cause large deflections and heating of the beam which would substantially increase the beam spot size. A strong axial magnetic field (B_z) controls this behavior. The beam offset (ε) grows until it reaches the gyrodius value. A simple model matches the simulations:

$$\varepsilon = \left(2\gamma \;\; \mathrm{I}/17 \;\; kA\right)^{1/2} \times \left(0.17 \;\; Tesla/B_z\right) \;\; cm$$

$$r_b\left(FWHM\right) = 0.83\sqrt{\varepsilon^2 + r_k^2} \;\; ,$$

where I is the beam current and r_b and r_k are respectively the beam and cathode needle radius. According to this model and IPROP simulations, a 30-T magnetic field should control the ion-hose instability and produce a 0.75-mm radius beam. The experimental results (Fig. 2) are in very good agreement with theory and simulations [1].

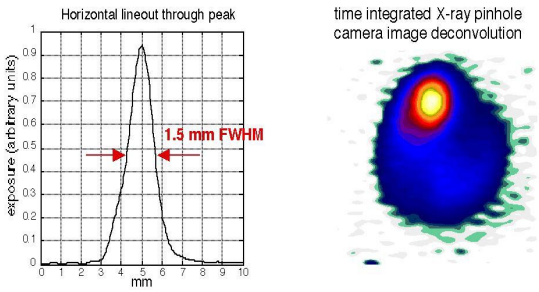

Figure 2. Time integrated x-ray image of the beam for B_z = 29 T, SABRE results. Beam size agrees with theory and simulations.

3 HERMES-III EXPERIMENTS

HERMES III is larger than SABRE, having twenty 1-MV inductively insulated cavities. It routinely produces 18-20 MV, 700-kA electron beam in normal operation, but in the present experiments, we operate it at lower voltage (12 MV), reduced current (150 kA), and longer pulse (~ 70 ns FWHM).

The outer cylinder of the extension MITL has conical sections to reduce the radius down to SABRE size. Thus, the same magnetically immersed diode (Fig. 1) assemblies are utilized with HERMES III. In addition, a smaller, 50-Tesla, cryogenic diode was designed and constructed (Fig. 3) for these experiments.

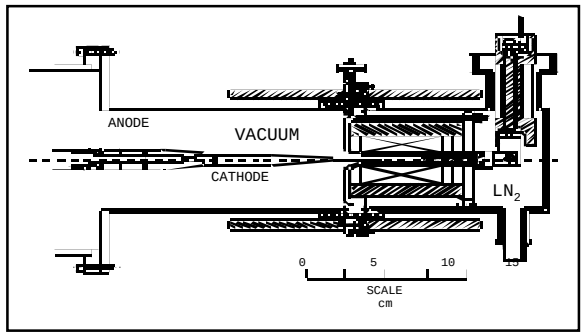

Figure 3. The 50-Tesla cryogenic diode design utilized only with HERMES-III.

During SABRE experimentation we observed a severe decrease in the diode impedance near the peak of the voltage pulse. It was attributed to a 100-kV prepulse arriving 200 ns before the main pulse. A flashover prepulse suppression switch solved the problem. The impedance remained constant during the entire duration of the voltage pulse (30-ns FWHM). In HERMES III, we installed two flashover switches in series and we made sure that no appreciable prepulse was making it into the diode. In addition, special care was taken to improve the diode vacuum to 1-3 10^{-7} torr levels. Despite all this the diode impedance still exhibited a collapse at about 10-30 ns into the voltage pulse (Fig. 4). The onset of this abnormal impedance decrease was delayed by opening the AK gap (Fig 5). While the diode impedance remained normal (~ 300 Ω) the beam spot size was small and in good agreement with numerical simulations (Fig. 6). As soon as the impedance started plummeting, the beam spot size increased and the x-ray intensity decreased. All the above are characteristic of diode shorting.

Figure 4 shows typical behavior of the diode current. At the beginning it is consistent with a monopolar flow of electrons from the cathode to the anode. About 20 ns into the pulse the expected bipolar flow sets up with a 30% increase of the total current. Finally ~ 33 ns later the current breaks away from the voltage trace and keeps increasing to 150-180 kA until the end of the voltage pulse. Analytical calculations and numerical simulation [2,3] explain the late time current behavior as due to counterstreaming heavy ions emitted from the cylindrical anode walls and the converter target. Very high-intensity heavy-ion (carbon, nitrogen, oxygen, etc.) beams, while in transit toward the cathode, suffer many electron stripping ion-ion collisions and increase their charge. When this increased ion charge density reaches the cathode, it bootstraps currents into an abnormal impedance collapse. Forty-five degree slant targets and larger anode cylindrical

walls appear to delay impedance collapse for the same AK gap (Fig. 5).

A number of impedance collapse mitigation methods have been extensively studied [4] and will be implemented in future experiments. Among them, an increase in magnetic insulation will prevent ions from the diode cylindrical walls reaching the axis. The ions emitted from the target can be reduced by utilizing a small 1-mm diameter target. Finally, the counterstreaming ions following the magnetic field lines can be prevented from striking the needle if a less-immersed cathode tip is utilized. A new 60-T diode is being designed that will offer those capabilities which, we believe, will enable us to achieve the advanced hydrodynamic radiography goals of 0.6-mm (FWHM) x-ray spot, 1-kRad dose @ 1 meter from a 12-14 MeV electron beam.

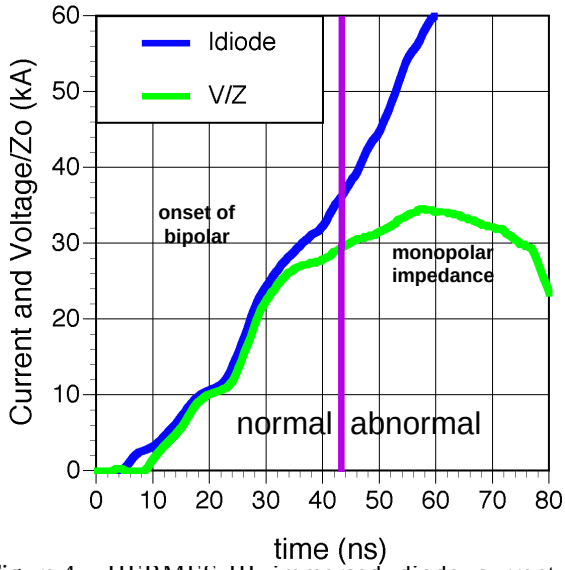

Figure 4. HERMES-III immersed diode current and voltage time behavior for a 22-cm AK gap.

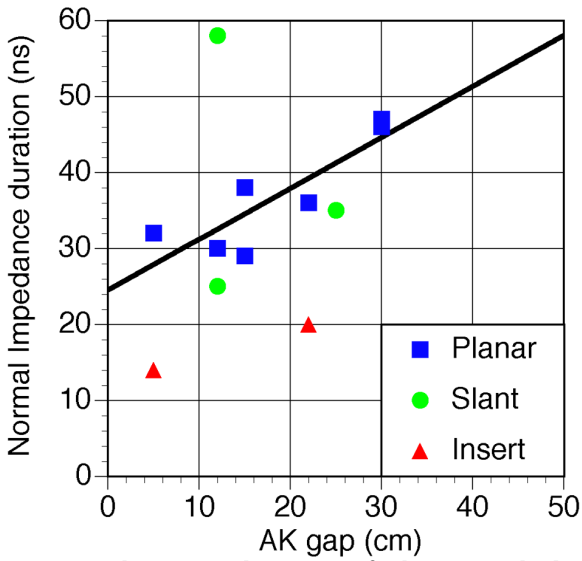

Figure 5. The time duration of the normal diode operation increases with the AK gap spacing and orientation of the converter front surface.

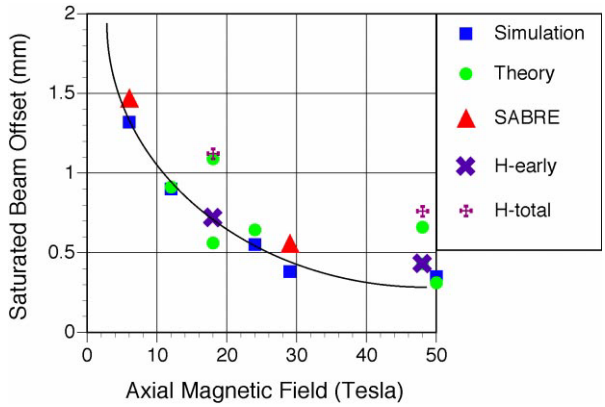

Figure 6. Measured beam offsets (ε) in SABRE and HERMES III are in very good agreement with theory and numerical simulation.

4 SUMMARY

SABRE and HERMES III experiments demonstrated that IVA/immersed diode technology can produce millimeter size x-ray sources capable of penetrating very dense objects. The observed ion hose instabilities can be controlled to acceptable levels with 50-60-T confining magnetic fields. The abnormal diode impedance behavior is well understood and mitigating diode designs are under construction for future IVA experiments. SABRE and HERMES-III results (normal diode operation) are in full agreement with theory and numerical simulations.

Abstract

An 190MW compact pulse modulator is constructed to test spare 80MW S-band klystrons(E3712 TOSHIBA) and 2 different type thyratrons(F351 TRITON, CX1937A EEV), as well as to provide R&D tool for the development of high performance modulator. Typical specifications of the modulator are 190MW peak power, 390kV peak beam voltage, 60pps pulse repetition rate, 2.2μS flat-top pulse width with less than $\pm$ 0.15% of beam voltage. Compared with conventional modulator, new technologies were used in the several points such as a 40MHz inverter power supply, a command charging, a remotely controlled tunable slug of PFN coil to improve the stability of the output voltage, to prevent a thyratron prefire and to achieve an easy adjustment of pulse flatness.

1 INTRODUCTION

The S-band injector linac of SPring-8 is 140m long, and maximum electron energy is 1.15GeV. The main high power RF components of linac are composed of 13 units of E3712 S-band klystron tube and conventional pulse modulator. Table 1 shows the specifications of E3712 klystron.The conventional pulse modulator for 80MW klystron have been operated for 11,000hr in the past two years. It is a line type pulser because of its well-established technology and reliability. In order to make a pulse modulator more efficient, the high performance modulator was designed since last years,aiming at easy maintenance, compact size, low cost, high stability. A test modulator was constructed using three inverter type HV power supplies in paralled for the charging power supply. This paper presents the circuit design, specifications and the performance data.

2 MODULATOR SPECIFICATION

Table 2 shows the main specifications of test modulator. As the 80MW klystron tube requires about 400 kV on its cathode voltage and the thyratron anode voltage should be less than 50kV, a pulse transformer with turn ratio of 1:17 was selected.Therefore, the modulator generates pulses with the peak voltage of more than 23.5kV and the peak current of more than 8160A. In order to accelerate an electron beam with the pulse width of 1μsec, the flat-top of klystron beam voltage is required to be more than 2μsec. The long-term regulation and the pulse flatness of the klystron beam voltage is decided to be less than $\pm$ 0.15% to prevent RF phase modulation and microwave power fluctuation.

Table 1: Specifications of E3712 S-band Klystron

1. Direct constant current charging by three inverter power supplies.
2. Without De-Qing circuit.
3. Command charging.
4. Improvement of maintenance due to reduction of several high voltage components,for example IVR,charging choke,hold-off diodes,etc.

In addition to these points , we designed as follows :

1. Remote control for tunable slug of PFN coils.
2. Counter circuit to detect thyratron misfire.

The modulator cabinet size (involved power supplies rack) is 2700(W) × 2300(H) × 1500(D), this is 57% of the current cabinet volume of the SPring-8 modulator. Table 3 shows the specifications of major parts in test modulator.The inverter power supplies are state of the art switch mode power supply,designed primarily for use in pulsed power applications such as laser system and capacitor charging.The voltage reversal which is cause by mismatching a PFN characteristics impedance and klystron tube impedance forces a large surge current to flow through the output rectifiers in the inverter power supply. Therefore,the protection circuit with series terminating resistors and freewheeling diodes was carefully designed.

4 ACHIEVED PERFORMANCE

A preliminary test of new modulator was started in April and initial data have been obtained. Fig.2 shows the one cycle of charging voltage profile of PFN capacitors, as set a PFN voltage of 20∼35kV at 5kV step. The time added charge time to dwell time is fixed 15ms, and the charge time was varied linearly along with PFN charging voltage. In the case of change a pulse repetition rate, only the dead time is changed. Fig.3 shows the typical waveform of klystron beam voltage and its flat-top(Beam voltage and current are 396kV,480A). In this case, the test modulator was operated at repetition rate of 30pps and a PFN charging voltage of 51.1kV. After carefully adjusting tunable slug of PFN coils, the flat-top pulse width of klystron beam voltage was achieved the 2.2μs with $\pm$0.15% which is designed values. The long-term(30hr)operational characteristics of klystron beam voltage was investigated in condition at repetition rate of 30pps, a PFN charging voltage of 40kV, two inverter power supplies. As a result, test modulator has achieved the

output voltage fluctuation of less than $\pm 0.15\%$.

5 DISCUSSION

We have fabricated a test modulator and tested its performance. This modulator have not yet satisfied with full operation, which is to be used three inverter power supplies, a repetition rate of 60pps and a PFN voltage of 50kV. Speculated causes of the problem are as follows,

1. The deficiency of cooling water capacity supplied for inverter power supply

   The high voltage parts of inverter power supply is mounted in Freon liquid, and the cooling method which is condensed evaporated Freon by cooling water was adopted. In case of repetition rate of 60pps and a PFN voltage of 50kV, inverter power supply was stopped by internal temperature interlock after 40 minutes operation.Our cooling water system is able to supply at a rate of 8ℓ/min. and 32$\sim$34°C water through three inverter power supplies. Even thought these values are within the upper limit of required cooling water specifications, the cooling water deficiency may be a main reason to stop long-term operation.

2. The power factor of inverter power supply

   It is described that the power factor of inverter power supply is 0.9 in instruction manual. But in present, the power factor was measured to be about 0.67 in case of repetition rate of 40pps and a PFN charging voltage of 50kV. It is necessary to improve the power factor of inverter power supply by way of reconsidering both the choke coil inductance in smoothing circuits and the charging time of PFN.

6 CONCLUSION

High performance modulator for 80MW klystron was designed and fabricated,good performance which the flat-top width of klystron beam voltage with $\pm 0.15\%$ flatness was 2.2μs and voltage regulation was less than $\pm 0.15\%$ for long-term operation has achieved. To operate continuously the test modulator for full operation, the deficiency of cooling water capacity and the power factor of inverter power supply should be improved.

7 ACKNOWLEDGMENTS

The authors would like to express their thanks to Messrs. H.Misawa, K.Nishio and H.Kouzu of TOSHIBA Co. for the fabrication and adjustment of the test modulator and to operators of SPring-8 service corporation for the useful support.

Abstract

The Separated Drift Tube Linac (SDTL) structure was proposed for medium energy range of proton linacs. The accelerating cavity consists of several SDTL units with focusing lenses between sections. To drive several SDTL sections from single RF source, application of both RF power dividers and coupling bridge cavities seems feasible. Through bridge couplers, the field distribution, in both amplitude and phase, is automatically stabilised among connected sections in the lowest order. Additional rf power dissipation of an order of several percents is inevitable in the bridge coupler because of its standing-wave operation. In this paper particularities and limitations for coupling bridges in the SDTL tanks are considered. Well known cylindrical bridge cavities (CBC) may be used. To maintain features of the SDTL structure as the easy-to-do low-cost one, Rectangular Directly Coupled Bridges (RDCB) look more preferable. Developed and realised in Moscow Meson Facility linac, RDCB operates in TE_{10N} mode and originally has no mode mixing problem. To simplify manufacturing procedure, RDCB design is based on parts of standard waveguide. The philosophy of SDTL-RDCB tank and results of preliminary consideration are presented.

1 INTRODUCTION

Attractive features of the bridge coupled system are well known and have been proved experimentally for Coupled Cells accelerating Structures (CCS) at high frequencies ≈ 1000 MHz in several laboratories. The bridge coupling cavities can also be applied for SDTL structure [1], taking into account SDTL particularities. The consideration of bridge coupler in SDTL structure has been performed [2] as one option possible for 200 MeV linac accelerating structure. Two concepts of coupling bridges are possible. Both CBC and RDCB have been considered. Below we summarise results of consideration [2] and results of further investigations for SDTL-RDCB tank.

2 CONCEPTS OF COUPLING

2.1 Coupling with intermediate coupling cell

Application of CBC for high frequency (700 MHz) SDTL was considered in [3]. Following the well known concept [4], a CBC is attached to the SDTL section through intermediate coupling cell (Fig.1a). In the chain of coupled cells, which describes total tank, bridge cavity is equivalent to modified accelerating cell which is displaced from beam axis. In order to reduce the rf losses in the bridge cavity one should provide asymmetrical coupling in intermediate cell $k_2 > k_1$. If total tank has M SDTL sections, $M-1$ bridges

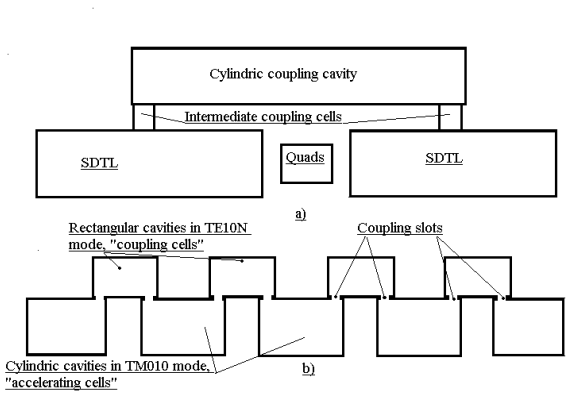

Figure 1: A sketch of the tanks coupled by CBC (a) and RDCB (b).

and $2(M-1)$ coupling cells, there will be $4M-3$ modes in the TM_{010}-like passband. Central operating mode is the $\pi/2$ mode, position of nearest modes mainly depends on k_1 value, the bandwidth of the passband - on k_2 value. Additional rf losses for such option were estimated as 3.3% for $k_2/k1 = 4$, k_2=1.8% [2]. As the result of comparison of different CBC types, the multy-cell bridge cavity [5] looks as a preferable CBC solution.

2.2 Direct coupling

Another concept of coupling bridge cavities is possible [6]. To illustrate the philosophy of RDCB, let consider bi-periodic chain of coupled cavities (Fig.1a) . First type of cavities are cylindrical ones, exited in TM_{010} mode. The second type of cavities are rectangular ones, exited in TE_{10n} mode. To simplify manufacturing procedure for rectangular cavity, let chose transversal dimensions equal to dimensions of standard waveguide recommended at operating frequency. With such choice we automatically solve mode-mixing problem for RDCB, because dimensions of waveguide are defined for single mode operation of TE_{10} wave. Both types of cavities are coupled trough coupling slots, forming the chain of coupled cavities, in which cylindrical cavities are equivalent to accelerating cells, and rectangular cavities - for coupling ones. The coupling slots are placed to couple H_ϕ component in cylindrical cavity

with H_x in rectangular one. Let define the mode in the rectangular cavity, for example TE_{10N}, and choose the length of the cavity to have the frequency of this mode equal to operating frequency of accelerating cells. We get usual chain of coupled cavities which is well known from CCS description [4]. If one match frequencies of accelerating mode (operating mode of the tank, really it is the frequency of SDTL sections taking into account effect of coupling slots) and coupling mode (the frequency of rectangular cavity also taking into account effect of coupling slots), one will have accelerating system, consisting from two types of cells, with continuous dispersion curve. If we have M SDTL sections in the tank and $(M-1)$ bridges, operating passband will have $2M-1$ modes. Central, operating mode is $\pi/2$ mode, with strong field in accelerating (SDTL) sections and weak field in coupling cells (RDCB) and with all properties of stabilisation. One should take into account that for odd N mode TE_{10N} has H_x component of different signs at the ends of the bridge. This case at operating $\pi/2$ mode phase shift between SDTL sections is 2π. For even N coupling coefficients k_c at the ends of RDCB has the same sign and phase shift between SDTL sections is π. The evident question to be answered - how can we match such directly coupled bridges with the driving waveguide, if there are no field in the bridge cavity at operating mode? This statement is only the result of our analysis based on single-mode approximation to describe RDCB. In the study of multy-mode approximation for RDCB description, one will find weak, but nonzero field in bridges at operating mode, sufficient to match with driving waveguide. For odd N the field in RDCB at operating $\pi/2$ mode can be represented as the sum over TE_{10n} modes with even n, for even N - with odd n. RDCB were proposed for high energy accelerating structures, tested at high rf power level with the Disk and Washer and Annular Coupled structures [7] and long time successfully operate in the main part of the Moscow Meson Facility linac.

3 PARTICULARITIES

If coupling bridges are attached to the ends of SDTL sections, they will couple both operating TM_{010} modes and all high order TM_{01m} modes, including nearest TM_{011} ones. With increasing of k_c bandwidths rise both for TM_{010} passband and for TM_{011} one too. If passbands will overlap, one will have mode mixing problem, leading to serious problems with the field distribution at the operating mode and reduction of the stability. There will be slope in the field distribution at operating frequency, related with TM_{011} mode influence which is especially dangerous in the transient. The frequency difference ΔF between TM_{011} and TM_{010} modes can be estimated as:

$$\Delta F \approx \frac{f_0}{8N_p^2\beta^2} \qquad (1)$$

where N_p is the number of periods in the SDTL section, β is relative velocity of particles. For particular case 5 period SDTL sections with operating frequency f_0 =324 MHz [2] TM_{011} mode is far enough for β =0.3, ΔF =17 MHz, and closer, ΔF =3.8 MHz, for β =0.55. To reduce TM_{011} mode passband influence, one should restrict the value of coupling coefficient k to keep the bandwidth of the TM_{010} passband several times less than ΔF. The coupling with TM_{011} (and all odd TM_{01n} modes too) mode can be avoided by the coupling of the bridge coupler in the middle of the SDTL cavity [3]. This [2] case CBC should have the length $7\beta\lambda$ and for f_0 =324 MHz it is equal to 1940-3560 mm, $0.3 \geq \beta \leq 0.55$. Practically we have to place in parallel additional line of cylindrical cavities, comparable in dimensions with SDTL sections. It leads to increasing of the costs for accelerating system manufacturing.

If 4, 6 or 8 sections are coupled with bridges, coupling at the ends of SDTL sections is possible, because coupling with TM_{011} mode at one end compensates such coupling at another end. If two SDTL sections are coupled with bridge couplers, coupling in the middle of the section looks reasonable.

Coupling slots decrease the frequency and we have local detuning of order $2 \div 4$ MHz in one SDTL period. This detuning is big enough and should be compensated by increasing of the gap length to avoid deterioration of the field distribution inside SDTL section.

4 THE EXAMPLE OF SDTL-RDCB TANK

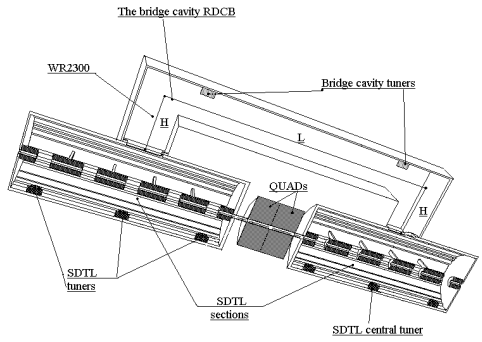

Figure 2: The sketch of SDTL-RDCB tank

Let consider two SDTL sections coupled in the middle with RDCB (Fig.2). The inter-section length is $2\beta\lambda$ [2] and RDCB should provide 0 phase shift between sections, so TE_{10N} mode with odd N should be chosen. It means, that RDCB length along 'middle line' $L+2H$ (see Fig.2) should be close to $N\Lambda/2 \approx L+2H$, where Λ is wavelength of the TE_{10} wave in the waveguide. In addition to [2], below we consider RDCB produced from standard waveguide WR2300 (Λ =151.53 cm at f_0 =324.0 MHz). To combine requirements of distance between cou-

pling slots $L = 7\beta\lambda$ and the total length of the bridge coupler $L+2H \approx N\Lambda/2$, RDCB should be formed in Π-shape (Fig.2). For the beginning of the SDTL accelerating structure β=0.314 TE_{105} RDCB mode is suitable. With the increasing of β along the structure H decreases to maintain total length $L+2H$ and when H becomes insufficient from technological requirements, TE_{105} RDCB mode have to be changed to TE_{107} one. RDCB is equipped with two plug tuners (Fig.2). With simultaneous moving of RDCB tuners we can change own frequency of RDCB, tuning position of nearest modes practically without changing of operating frequency of total cavity. With opposite moving of RDCB tuners one changes level of rf field between SDTL sections. It is very useful also to have several tuners in SDTL section. Two tuners near ends are intended to control operating frequency and field distribution inside SDTL section. It may be shown, that standard deviation of the electric field distribution σ_e in SDTL section (without post couplers) is related with standard deviation of frequencies of SDTL cells σ_f as:

$$\sigma_e \approx \sigma_f \sqrt{\frac{4}{N_p} \sum \frac{f_m^4}{(f_0^2 - f_m^2)^2}} \qquad (2)$$

where f_m are the frequencies of high TM_{01m} modes and TM011 one provides the biggest contribution into σ_e. Two tuners near ends of the SDTL section allow to compensate TM_{011} mode contribution and release tolerances for SDTL manufacturing in 3 times. Moreover, SDTL tuners in the first and last cells are useful to compensate detuning of cells due to absence of a half of stems. Central SDTL tuner is intended to compensate detuning of the middle cell due to coupling slot. If this compensation is done, the central tuner is not necessary. Numerical simulation of rf parameters has been performed for the SDTL-RDCB tank cavity for β =0.314 by using 3D code MAFIA with total number of mesh points near $1.5 * 10^6$. RDCB tuners are suggested 15 cm in diameter and 4 cm in length. SDTL tuners are supposed 10 cm in diameter and 4 cm in length. At first, reference values for SDTL section (without RDCB) have been obtained for operating frequency. RDCB tunes by adjusting H parameter (see Fig.2). The coupling slot 24 cm x 27 cm reduces the frequency of middle SDTL cell at 2.61 MHz and this reduction was compensated by increasing of the gap length at 2.4 mm. After RDCB tuning for TM_{010} mode passband were obtained - operating frequency f_0 =323.999 MHz, another TM_{010}-like modes with frequencies f_- =322.286 MHz and f_+ =325.627 MHz. The k_c value for this case is $k = \frac{f_+ - f_-}{f_0} = 1\%$. For this SDTL-RDCB options numerical calculations show no additional rf losses with respect to reference values for SDTL sections (reduction in shunt impedance Z_e is 0.16%). There are two reasons for additional rf losses - rf losses in the RDCB cavity and redistribution of rf currents at the SDTL walls due to coupling slot influence. The own quality factor Q of RDCB cavity is high ($\approx$ 48000) and comparable with Q-factor of SDTL sections ($Q \approx$ 53000). By choosing high Q RDCB cavity we decrease additional rf losses in the bridge. The dimensions of coupling slot were optimized to reduce rf currents redistribution in SDTL walls. Results of SDTL-RDCB with usual coupling slots also show [2]. tolerable decrease in Ze ≈0.5 ÷ 7% for coupling k_c ≈0.4 ÷ 3%. No significant distortions in the field distribution at operating mode in SDTL sections have been found (σ_e ≈0.1%). With increasing of the at 1 cm length of one RDCB tuner and decreasing for another the ratio of average electric field between SDTL sections changes at 1.67%, operating frequency changes at 1.5 kHz. With the removing of one SDTL end tuner (it corresponds detuning of the end SDTL cell at 650 kHz) operating frequency of the tank changes at 70 kHz (in fine agreement with averaging of frequency errors) and the change in average field level between SDTL section is 0.05%. Inside detuned SDTL section field slope 2.9% exists in good agreement with estimation (2).

5 SUMMARY

The multi-cell CBC may be used for coupling of the SDTL sections. For the operating frequency 324 MHz bridge cavity diameter is ≈ 650 mm, diameter of coupling cell is ≈ 420 mm. To avoid mode mixing in SDTL cavities, coupling coefficient should be small, leading to the reduction in the passband width and closing of the nearest modes.
RDCB may be a good option for the coupling of SDTL sections. In comparison with CBC with intermediate coupling cells RDCB have:
- better mode separation with smaller rf losses,
- smaller transverse dimensions,
- flexible tuning of rf field between SDTL sections,
- simpler manufacturing and tuning procedure.

OPTIMIZATION ON WAKEFIELD DAMPING IN C-BAND ACCELERATING STRUCTURE

N. Akasaka, T. Shintake and H. Matsumoto
KEK, High Energy Accelerator Research Organization, 1-1 Oho, Tsukuba, Ibaraki, 3050801 Japan

Abstract

Multi-bunch acceleration in the future e^+e^- Linear Collider projects requires sufficient suppression of transverse wakefield for high luminosity. The C-band accelerating structure consists of the choke-mode cavity to damp the wakefield. In order to achieve the maximum damping, optimization of wakefield absorber was necessary. After the optimization, the transverse wakefield is sufficiently damped below the desirable level.

1 INTRODUCTION

In the future e^+e^- linear colliders, multi-bunch operation is necessary for high luminosity. In multi-bunch operation, long-range transverse wakefield, which is generated by the leading bunches passing the accelerating structure with an finite offset, deflects the orbit of the following bunches. In order to prevent the degradation of the luminosity due to the orbit deflection, the wakefield must be sufficiently damped after the bunch spacing with practical alignment tolerance.

Long-range ringing of the wakefield can be shortened by broadening its spectrum. There are two promising techniques to increase the spectrum width of the wakefield in an accelerating structure: detuning and damping. In the former scheme, the distribution of the higher order mode (HOM) frequency in one or more accelerating structures is deliberately arranged to realize fast smear out of the wake field. In the latter scheme, on the other hand, the HOM's are damped and the HOM spectrum becomes broad even for one cell.

In the C-band linear collider project [1,2], choke-mode cavity [3] is adopted for the accelerator structure in the main linac. Figure 1 shows the C-band accelerating structure. The whole accelerating structure is constructed by stacking axially-symmetric cells. The wakefield generated by a bunch goes out of the cell through the radial line, whereas the accelerating field is confined by the choke. The wakefield is absorbed by the SiC ring at the outside of the choke. The choke-mode cavity is sometimes referred to as "heavily damped structure" because of its high damping performance.

The C-band accelerating structure is now under fabrication [4] to be tested at ASSET in SLAC, where the long-range transverse wakefield will be measured using a driving bunch and a witness bunch passing through the accelerating structure with an offset.

In this paper, its design procedure relating to wakefield damping is presented. First, the optimization of the wakefield absorber for a single cell is described in section 2. Next, the transverse wakefield averaged over the accelerating structure is calculated in section 3.

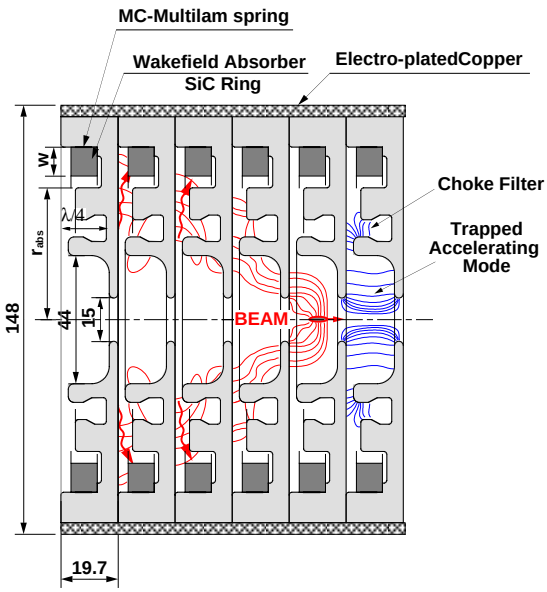

Figure 1: C-band choke-mode structure.

2 OPTIMIZATION PROCEDURE OF SINGLE-CELL DAMPING

The frequency of HOM's is not constant along the accelerating structure since it is a semi-constant gradient structure. The result of the optimization is different depending on the dimensions of the cell.

2.1 Reflection of the Wakefield by the Choke

A part of the wakefield is reflected at the choke even

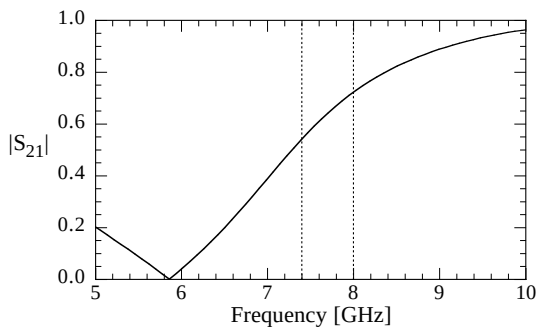

Figure 2: Dipole transmission of the choke.

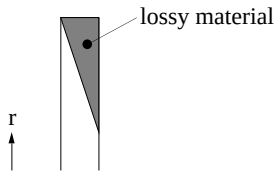

Figure 3: Dummy absorber for calculating optimum reflection coefficient.

though the radial line of the choke-mode structure effectively extracts the wakefield. This can be a serious problem when the main frequency component of the wakefield is near the dipole stop frequency of the choke. In our case, the main contribution to the transverse wakefield comes from TM110, whose peak frequency ranges from 7.4 to 8 MHz depending on the iris aperture 2*a*.

Figure 2 is the transmission coefficient of the choke for the lowest dipole mode calculated with MAFIA 2D time-domain solver (T2). The peak frequency of TM110 is in the region between the two dashed lines, which indicates that only 1/3~1/2 of the energy of TM110 wakefield is transmitted to the absorber. Because of this effect, simple matched (no reflection) absorber at the outer end of the radial line does not provide sufficient damping. This problem was solved by deliberately introducing reflection to the absorber.

2.2 Optimum Reflection from the Absorber

Before designing a realistic absorber, a simple wedge-shaped lossy material, which is shown in Fig. 3, was used in the calculation of the optimum reflection coefficient. The amplitude and phase of the reflection coefficient can be changed by the imaginary part of the permittivity and the radial position of the lossy material, respectively. Then the transverse wakefield and impedance were calculated by MAFIA T2. The optimum reflection coefficient was determined where the peak height of TM110 becomes the lowest. Typical amplitude of the optimum reflection coefficient is 0.55.

Table 1: Parameters of the C-band accelerating structure. The form $n1$ - $n2$ indicates $n1$ at upstream and $n2$ at downstream.

Frequency	5712	GHz
Phase Shift per cell	$3\pi/4$	
Field distribution	semi C.G.	
Number of cells	91	
Iris aperture ($2a$)	17.4 - 12.54	mm
Cavity diameter ($2b$)	45.3 - 43.3	mm
Disk thickness (t)	3	mm
Group velocity	0.035 - 0.012	c
Quality factor	10.7 - 10.3	10^3
Shunt impedance	53.0 - 67.3	MΩ/m

2.3 Determining the Absorber Dimensions

As shown in Fig. 1, the wakefield absorber is an ring of SiC ceramics with a rectangular cross-section. This simple shape was adopted for three reasons: (i) it is easy to fabricate, (ii) the reflection coefficient at the TM110 frequency can be easily changed by changing its width w, and (iii) the reflection coefficient above the TM110 frequency is relatively low. The width of the SiC ring is determined to realize the amplitude of the optimum reflection coefficient at the frequency of TM110. Although the reflection coefficient is optimized only at the frequency of TM110, absorbing all the field energy is sufficient for smaller peaks at higher frequency as can be seen in the next section.

The calculated transverse wakefield is shown in Fig. 4 for the most upstream cell ($2a$ = 17.4) and the most downstream cell ($2a$ = 12.54). In the figure, the thin lines are the wakefield with a matched absorber and the thick lines are with the optimized absorber. With an optimized absorber, the damping time is 2 or 3 times shorter than with a matched absorber. The damping time of the upstream cell is longer than that of the downstream cell since the frequency of TM110 is lower at the upstream cell.

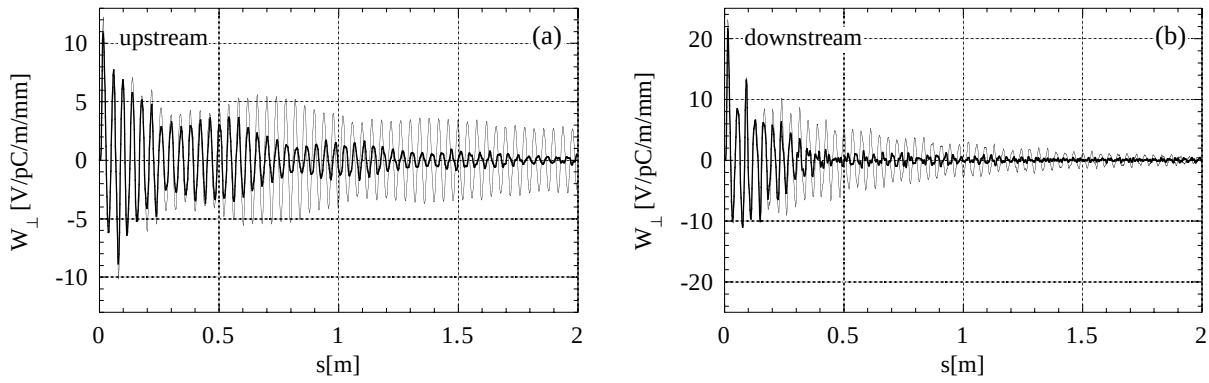

Figure 4: Dipole wakefield calculated by MAFIA T2 for (a) the most upstream cell ($2a$ = 17.40) and (b) the most downstream cell ($2a$ = 12.54). The thin lines are the wakefield with the matched (no reflection) absorber and the thick lines are with the optimized absorber.

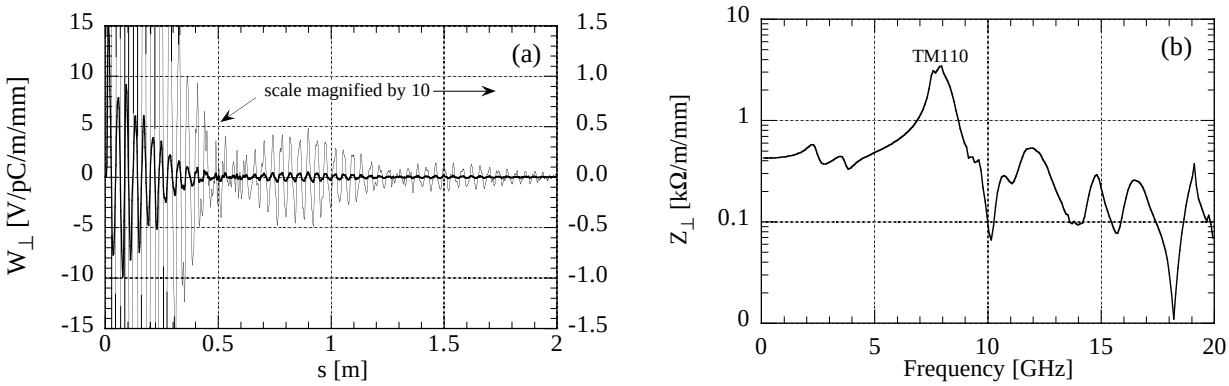

Figure 5: (a) The dipole wakefield averaged over the whole accelerating structure. (b) The impedance calculated from the wakefield.

3 DAMPING OF THE WHOLE STRUCTURE

The parameters of the C-band accelerating structure is summarized in Table 1. The iris aperture 2*a* changes linearly with the cell number from 17.4 to 12.54 and the cell diameter 2*b* also changes to keep the frequency of the fundamental mode constant. This variation of the cell structure introduces detuning of HOM's and additional spectrum broadening. All the choke dimensions including its radial position are the same for the whole structure.

3.1 Absorber Dimensions

For simplicity of the absorber design, the whole structure is divided into four regions of equal length. In each region, the absorber dimensions are determined by the optimization procedure descried above at the center cell.

Table 2: Optimized absorber dimensions. w and r_{abs} are defined in Fig. 1.

cell No.	2 - 22	23 - 45	46 - 68	69-90
w	10.0	10.0	10.0	10.0
r_{abs}	46.5	46.5	45.5	44.5

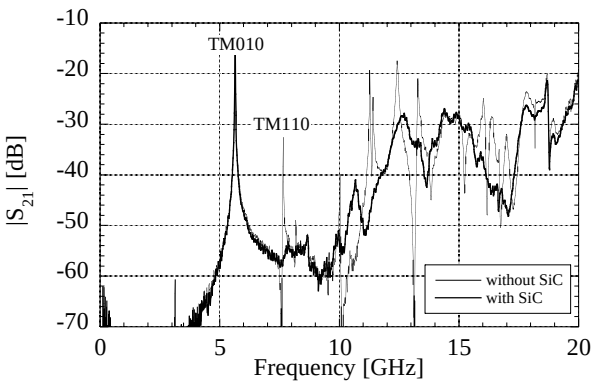

Figure 6: Measured transmission spectrum of the 44th cell.

The result of the optimization is listed in Table 2. The width of the SiC ring is decided to be constant along the accelerating structure since the optimized amplitude of the reflection coefficient was almost the same for the four regions.

3.2 Total Wakefield

The wakefield of the whole accelerating structure is obtained approximately by averaging the wakefield calculated at equally spaced 12 points. Figure 5 shows the averaged transverse wakefield and impedance. The peak of TM110 is still the highest one even after the optimization.

In the case of C-band main linac, the bunch separation is 2.8 nsec (0.84 m). The upper limit on the transverse wakefield corresponding to 30 μm alignment tolerance is 0.7 V/pC/m/mm at s = 0.84 m. From Fig. 5(a), the averaged wakefield is below this upper limit.

4 LOW-LEVEL MEASUREMENT

The transmission of a single cell was measured with two antenna-type probes on both sides of the cell. The distance of the probes from the center axis of the cell is 5 mm and their azimuth is the same. An example of measured spectrum with and without SiC absorber is plotted in Fig. 6. With SiC, sharp peaks are all damped. Further wake measurement for the whole accelerating structure will be done at ASSET.

DESIGN CONSIDERATIONS FOR MULTIPLE-BEAM RFQ STRUCTURES

V. Kapin, M. Inoue, Y. Iwashita and A. Noda
Accelerator Lab., Inst. Chem. Res., Kyoto University
Gokanosho, Uji, Kyoto 611, Japan

Abstract

There are applications, which require MeV-range multiple-beams consisting of a large number of identical highly packed beamlets. The multiple-beam RFQ (MB-RFQ) arranged as a matrix array of longitudinal rod-electrodes is appropriate candidate. A configuration of MB-RFQ resonator should ensure identical quadrupole fields in every accelerating channel. The MB-RFQ resonators based on TEM transmission lines are studied. The resonators are designed by a periodical multiplication of a 4-rod unit cell in transverse direction. To understand fields of resonator the normal mode technique is applied. The resonator field is expanded into normal modes having simple field patterns. In general case of resonator with an arbitrary number of rods and normal modes, analysis becomes difficult. To simplify problem, only normal modes composed from four normal modes of a 4-rod unit cell are selected. Similar to normal modes of a 4-rod unit cell (coaxial, quadrupole and two dipole modes), selected normal modes of multi-rod resonator have clear field patterns. Novel configurations of MB-RFQ resonators based on these normal modes are generated. The RF properties of resonators are verified with computer simulations done with MAFIA code.

1 INTRODUCTION

Several multiple-beam RFQ (MB-RFQ) structures has been proposed to accelerate a number of identical beamlets [1]. These structures consist of matrix array of longitudinal electrodes. The problem is to define a configuration of resonator, which ensures identical accelerating fields in every accelerating channel and preserves high packing of beamlets.

In this paper, MB-RFQ structures are treated as the TEM transmission line resonator. The normal mode technique is applied to decompose a complicated field resonator into fields of normal modes.

2 MB-RFQ AS THE TEM RESONATOR

Let us consider MB-RFQ resonator with N quadrupole electrodes as a resonator based on the N-conductor shielded TEM transmission lines (NCSTL). The propagation of TEM waves is described by the system of the telegraph equations. To facilitate solution of the telegraph equation the normal mode technique is usually applied. The resonator field is expanded into normal modes having simple field patterns. In the transmission line with N-conductors there are N normal TEM modes.

This technique has been applied to study 4-rod RFQ using the four-conductor shielded transmission line (4CSTL) [2]. In the case of N>4, the analytical definition of normal modes becomes difficult. To facilitate the study, let us restrict a number of considered normal modes in the NCSTL. A 4-rod configuration with known normal modes is considered as a unit cell. Normal modes of the NCSTL are composed by a periodical multiplication of a 4-rod unit cell in transverse direction.

The normal modes in the 4CSTL can be observed in the resonator shown in Fig.1. All four electrodes are grounded at the same longitudinal position, z=0 and have open ends at the another end of resonator, z=l.

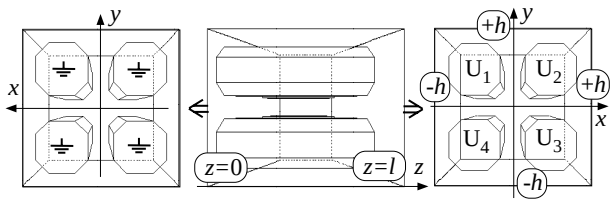

Figure 1: 4-rod RFQ allowing an observation of normal modes.

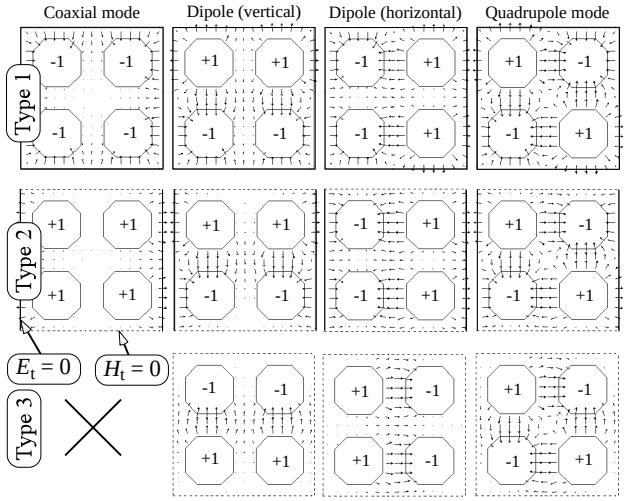

Figure 2: The E-line patterns of normal modes in the 4CSTL for three types of boundary conditions on shield.

Figure 2 shows the E-line patterns of TEM normal modes in the 4CSTL calculated with MAFIA code. Three different combinations of two boundary conditions (perfect conductor, E_t=0 or infinitely permeable, H_t=0)

on the shield are presented. The first and second type has four normal modes (coaxial, quadrupole and two dipole). The third type with H_t =0 on all four sides of the shield has only three modes, because it corresponds to opened transmission line.

The normal modes in the NCSTL can be observed by the similar way. The MB resonator with 4x4-matrix array of electrodes is shown in Fig.3. All electrodes are grounded at the same longitudinal position, z=0 and have open ends at the another end of resonator, z=l.

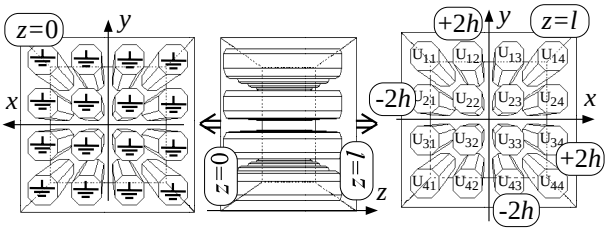

Figure 3: MB-RFQ resonator with a 4x4-matrix array of electrodes allowing an observation of normal modes.

Figure 4 shows the E-line patterns of normal TEM modes calculated by MAFIA code. Three types of boundary conditions on the shield are presented. The values of conductor potentials are shown on the conductor cross-sections.

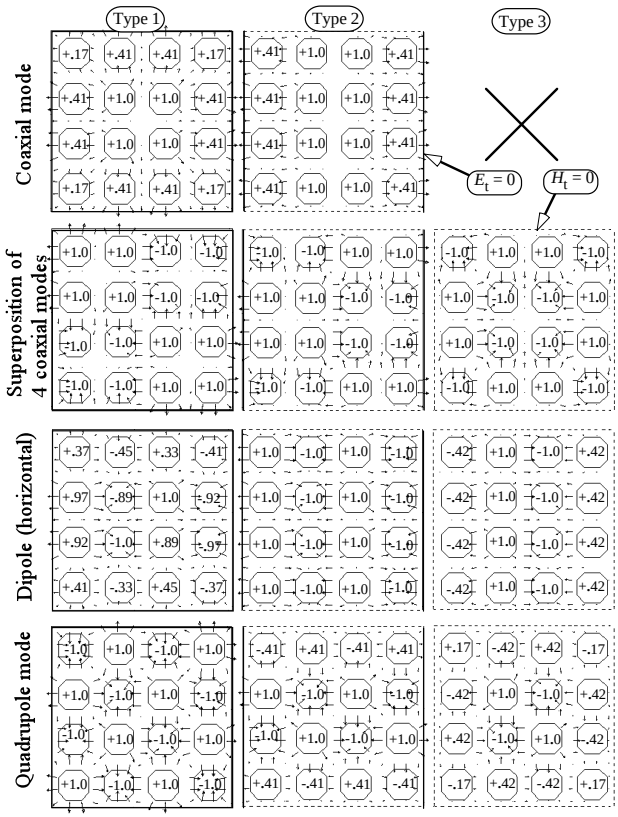

Figure 4: The E-line patterns of normal modes in the MB-RFQ resonator for three types of boundary conditions on the shield.

The quadrupole mode of the type 1 has correct-balanced quadrupole potentials for all channels. The field of the quadrupole mode increases sinusoidally along z-direction. This MB-resonator can be used as an initial matching section.

Figure 5 shows the MB resonator designed using an extension of 4-rod RFQ in the transverse direction. All electrodes are divided into two groups in a chess order. The electrodes of two groups are grounded in opposite manner.

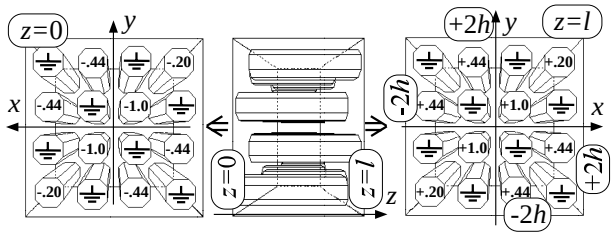

Figure 5: MB-RFQ resonator composing by an extension of 4-rod RFQ.

The field in this MB-resonator can be interpreted in terms of normal mode technique. The field of the original 4-rod resonator is described by combination of quadrupole and coaxial mode, which has been presented in [2]. In contrast to 4-rod resonator, the coaxial mode of MB-RFQ (see Fig.4, Coaxial mode of type 1) has unequal potentials of electrodes. Therefore, the combination of quarupole and coaxial modes in the MB resonator does not provide a correct excitation of the electrodes. The voltages on the electrodes surrounding RFQ-channels deviate from quadrupole symmetry.

Figure 6 shows the MB resonator designed using a periodical multiplication of 4-rod unit cell in the transverse direction. The field of the 4-rod unit cell of the resonator is described by combination of the quadrupole mode and the normal mode shown in the second row of the first column of Fig.4. The voltages on electrodes provide a balanced excitation and every second RFQ-channel can be used for an acceleration of beamlets.

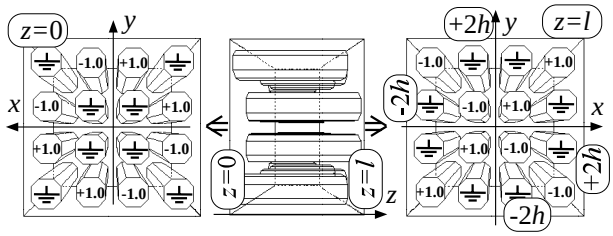

Figure 6: MB-RFQ resonator composing by a periodical multiplication of 4-rod unit cell.

Recently, a new MB-RFQ structure has been proposed [1,3]. To preserve high packing of beamlets this structure allows discrete connections of adjacent RFQ electrodes. The beam dynamics in RFQ-channels is modified. Beams perform "slalom" motions, utilizing

transverse oscillations. The Figure 7 shows the MB-resonator.

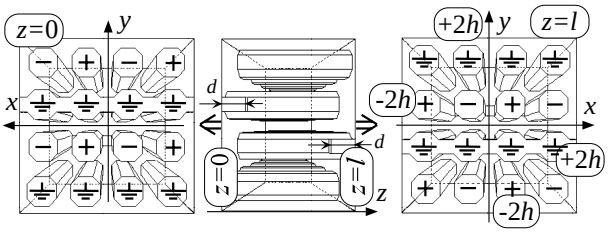

Figure 7: MB-RFQ resonator with 4x4-matrix array of electrodes.

The field of the MB-resonator with a "slalom" beam is superposition of quadrupole mode and dipole mode, which are summed at a $\lambda/4$ phase shift between each other. Figure 8 shows voltage distributions for this combination of quadrupole and dipole modes in the case of 4-rod unit cell. The result of summation is given on the right side of the Fig. 8.

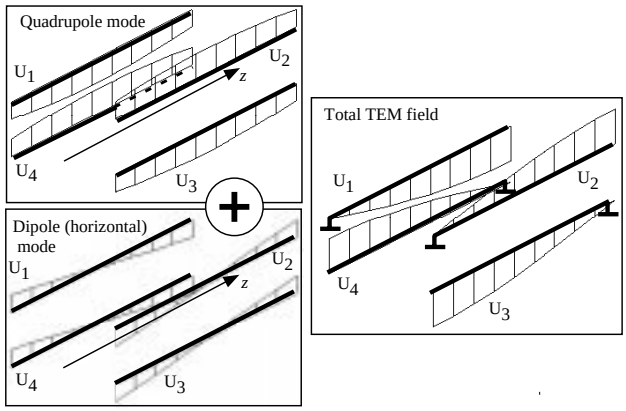

Figure 8: The superposition of quadrupole and dipole modes shifted by $\lambda/4$ to each other.

For the case of MB-RFQ, this combination is extended to the superposition of quadrupole mode of type 1 and dipole mode of type 2 (see Fig.4). For a real configuration of MB-RFQ resonator, the boundary conditions on all tank walls must correspond to a perfect conductor. The dipole mode of type 2 is replaced by the dipole mode of type 1 (see Fig. 2). In contrast to the dipole mode of type 2, potentials of electrodes surrounding RFQ-channels for the dipole mode of type 1 deviate from a correct dipole field (see Fig.4). As the result, a total field in the MB-resonator is distorted.

A difference between dipole modes of type 1 and type 2 is appeared as different boundary conditions on the shield for the upper and lower rows of 4-rod unit cells. Free frequencies of the outer cells deviate from their values for cells in the middle rows of MB-resonator. The free frequencies of the outer cells should be tuned. The free frequency of a 4-rod unit cell depends on an electrical length of conductors. For the MB-resonator shown in Fig.7, the length of conductors in the middle rows is less than the length in the outer cells on the value, d.

Fig. 9 shows the distributions of the quadrupole and dipole voltages in separate channels calculated with MAFIA code. The quadrupole voltage V_{ij} in the ij-channel is calculated from the voltages of electrodes surrounding the channel by the relation

$$V_{i,j} = (U_{i,j} - U_{i,j+1} + U_{i+1,j+1} - U_{i+1,j})/2$$

The voltages of horizontal and vertical dipole modes, Dh_{ij} and Dv_{ij} are defined by the following formulas:

$$Dh_{i,j} = (U_{i,j} - U_{i,j+1} - U_{i+1,j+1} + U_{i+1,j})/2$$

$$Dv_{i,j} = (U_{i,j} + U_{i,j+1} - U_{i+1,j+1} - U_{i+1,j})/2$$

For the case of d=0, the values of quadupole voltage, V_{ij} are different for the middle and outer channels. The phase shift between quadrupole and dipole voltages deviates from $\lambda/4$ for outer channels. For the optimal value of d=1.8cm, curves of quadrupole voltages became very similar and the required phase shift of $\lambda/4$ is restored.

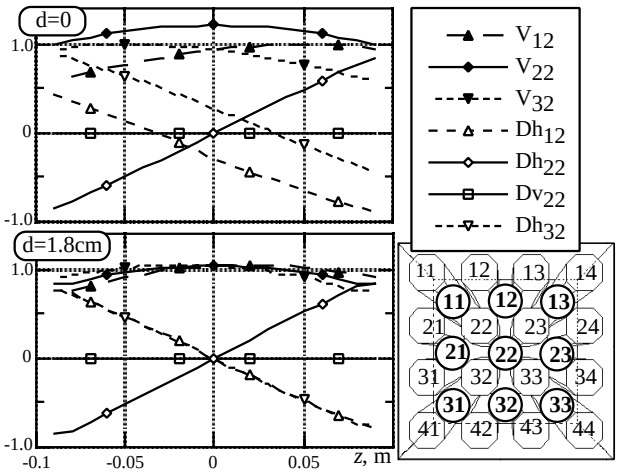

Figure 9: The distributions of the quadrupole and dipole voltages in separate channels calculated with MAFIA code.

Abstract

A high-current, cw linear accelerator has been proposed as a spallation neutron source driver for tritium production. Key features of this accelerator are high current (100 mA), low emittance-growth beam propagation, cw operation, high efficiency, and minimal maintenance downtime. A 268 MHz, cw radio frequency quadrupole (RFQ) LINAC section and klystrode based rf system were obtained from the Chalk River Laboratories [1] and were previously installed at LANL [2] to support systems development and advanced studies in support of cw, proton accelerators. A variation of the **L**ow **E**nergy **D**emonstration **A**ccelerator (LEDA) proton injector, modified to operate at 50 keV, was mated to the RFQ and was operated to support advance developments for the **A**ccelerator **P**roduction of **T**ritium (APT) program. High current, proton beam studies were completed which focused on the details of injector-RFQ integration, development of beam diagnostics, development of operations procedures, and personnel and equipment safety systems integration. This development led to acceleration of up to 100 mA proton beam.

1 INTRODUCTION

The **C**halk **R**iver **I**njector **T**est **S**tand (CRITS) was the LANL designation given to a proton accelerator designed, built, and tested at the **C**halk **R**iver **L**aboratories (CRL) in Canada. The CRITS accelerator apparatus includes a 1.25 MeV RFQ accelerator section and a prototype klystrode-based rf system for powering the RFQ. An earlier independent study at LANL, utilizing the RFQ, focussed on the high-power operation of the rf structure [2].

The LEDA program has the objective of developing a high-current, cw injector and the initial rf accelerating structures for APT. The LEDA injector is comprised of the proton ion source and a **L**ow **E**nergy **B**eam **T**ransport (LEBT) section to the RFQ. A 75 kV, cw proton ion source was developed for LEDA and has produced a proton beam with measured current and emittance meeting program requirements. A state-of-the-art LEBT was designed and built to match the ion source beam to the LEDA RFQ [3].

*Work supported by the US Department of Energy.

The functionality of an injector is best confirmed by injecting its beam into an RFQ. In preparation for installing the injector as a component of LEDA, the availability of the CRITS RFQ provided the opportunity for an initial shakedown of the injector. The modification of the ion source to 50 kV and adaptation of the LEBT exit section to the CRITS RFQ made the LEDA injector/CRITS RFQ configuration a realistic testbed for injector development. Furthermore, this configuration also supported RFQ experiments to evaluate the system modeling codes and to learn the details of cw RFQ operations. Figure 1 shows the full beamline used in this project.

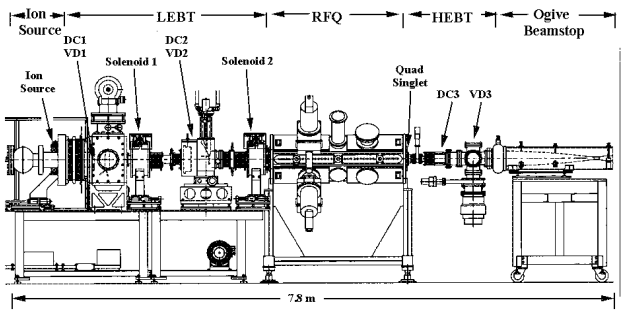

Figure 1. The LEDA Injector/CRITS RFQ experiment beamline.

In order to meet the project objectives, the RFQ specific studies focussed on verifying the RFQ field configuration, successfully operating the RFQ at high fields, verifying the accelerating fields in the RFQ, and accelerating proton beam from the modified LEDA injector.

2 RFQ FIELD DISTRIBUTIONS

Although the Q and resonant frequency of the RFQ were close to the expected values following shipment of the RFQ from CRL, the verification of the modeling codes mandated that the field distribution in the structure be confirmed. The insertion of a probe through the vacuum pumping holes in each of the quadrants gave a perturbation measurement of the cavity fields from which the dipole field contributions to the quadrupole field were calculated. The uncorrected dipole fields across quadrants 1 and 3 (dipole 1) were measured up to 14% of the quadrupole field and up to 8% across quadrants 2 and 4 (dipole 2). The dipole field distribution along the RFQ

length indicated that the vane coupling rings near the ends held the distribution close to the desired quadrupole configuration, thus, dipole field reduction at the center should achieve an acceptable field pattern in the RFQ. Adjustment of movable tuners in quadrants 2 and 4 and modification of the fixed tuner in quadrant 3 corrected the field distribution to less than 4% dipole contribution. This was considered acceptable for the beam studies. Figure 2 displays the corrected and uncorrected dipole contributions for dipole 1, the larger of the two dipole field distributions.

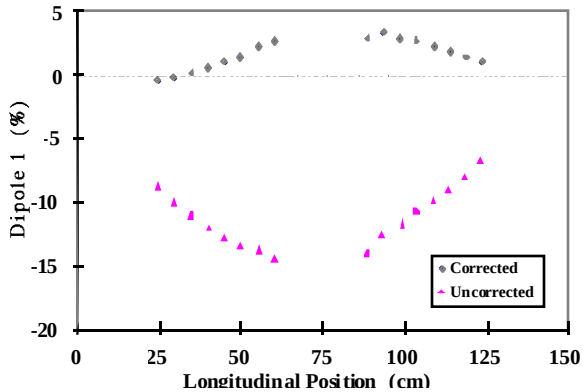

Figure 2. Dipole 1 contribution to the quadrupole field distribution.

A subsequent intervane gap measurement verified that the vanes had shifted away from their initial 1 mil tolerance and these gap differences were in agreement with the uncorrected dipole distributions.

3 HIGH-POWER FIELD LEVEL VERIFICATION

The calibration of the field sampling loops were completed using a Hewlett Packard 8753 Network Analyzer, and the rf signals from these loops at high power were monitored using power meters and oscilloscope measurements of the raw rf signals and diode rectified signals. The RFQ was conditioned to high power based on the SUPERFISH prediction of the design power level. High-power measurements of the actual field level were made using the x-ray endpoint method [4], a technique pioneered by accelerator scientists at CRL. Measurements made throughout the duration of the proton beam studies verified that the peak intervane gap voltage tracked the measured power levels according to the expected square root dependency. Figure 3 displays the gap voltage data and the curve used to project the peak intervane gap voltage as a function of measured power.

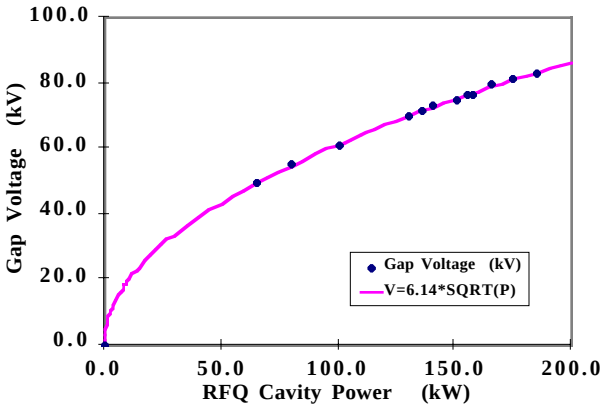

Figure 3. Peak intervane gap voltage versus RFQ cavity power.

4 SPARK RATE ANALYSIS

During the CRITS RFQ operation, the spark rate has been systematically measured and stored. Every second, the total number of sparks was read on a counter. Every minute, the raw number of sparks was stored as well as the number of seconds with at least one spark. In fact, this last information was found to be more relevant, since avalanches of sparks do not bias it. The rf power levels (forward, reflected and in cavity) were also recorded, as well as the residual vacuum pressure (Figure 4). We established that the spark rate has some influences on vacuum, but there is no evidence of any reciprocal effect.

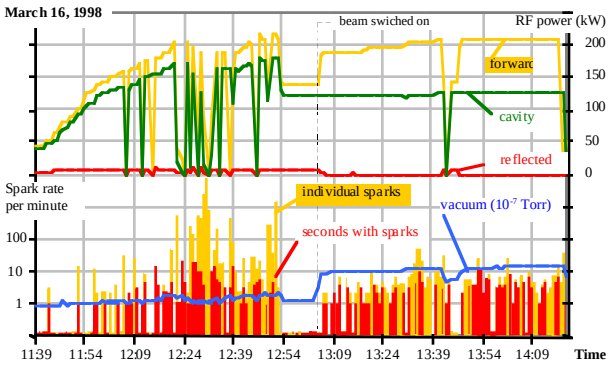

Figure 4. Example of archived rf power operations.

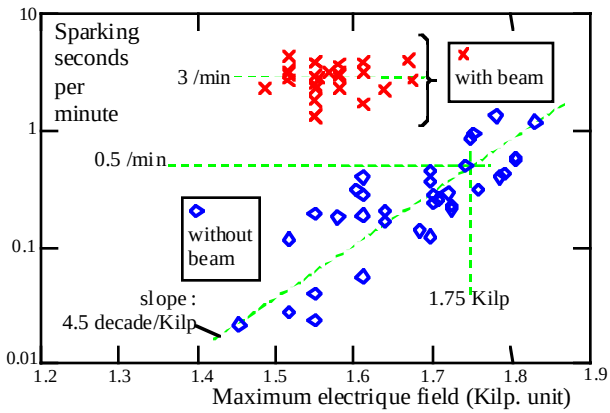

Figure 5. Average spark rates during long runs.

Within the stored data, a set of long runs (between 22 and 163 minutes long) of continuous operation have been extracted: 34 runs without beam and 24 with beam. For each run, the average rate of sparking seconds was computed. As some runs yielded no sparks at all, one spark has been added arbitrarily to each data point in order

to be able to plot the zero-spark points on a log scale (figure 5). This induces a slight bias to the data, but takes into account the fact that rates are more accurate if acquired over a long run.

Without beam, the rate is typically 0.5 per min at the design field (1.75 Kilpatrick, 77.4 kV intervane voltage, 159 kW measured in the RFQ), i.e. the average time between two bunches of sparks is two minutes. The slope shows that a 0.22 Kilpatrick decrement in the electric field lowers the sparking tendency by an order of magnitude.

During beam operations, the RFQ was run about 10% below the design field because of a peak rf power limitation. The rate jumped to 3.0 per minute, depending neither on the beam current (20 to 80 mA) nor on the field (1.5 to 1.7 Kilpatrick tested). This is about 6 times more than without beam at 1.75 Kilpatrick.

With rates such as the ones measured here, one could not hope to build an RFQ that would be free of sparks over several months of continuous operation. For LEDA proton beam operations, it will probably be necessary to deal with a spark rate which requires that the LINAC restart automatically after a short power interruption.

5 PROTON BEAM MEASUREMENTS

The proton beam studies with the RFQ proceeded cautiously by increasing current only as the injector match to the RFQ could be confirmed by the beam transmission. The desired field level for the RFQ was set from the x-ray endpoint measurement, but a measurement of beam transmission as a function of the RFQ cavity power was also used to confirm the expected behavior. As expected, a knee in the transmission curve was observed below the design field level.

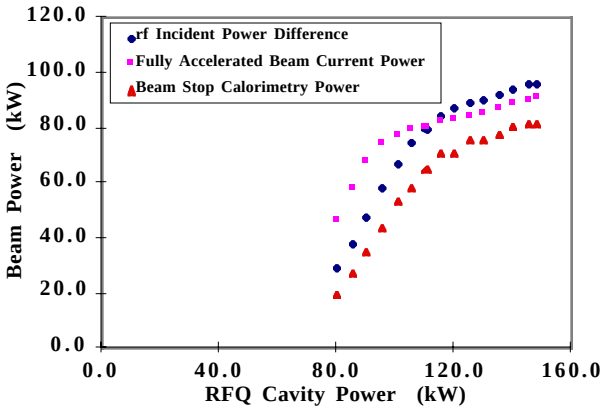

Figure 6. Beam power measurements from rf incident power difference, beam stop calorimetry, and predicted power assuming fully accelerated transmitted beam versus RFQ cavity power.

As a separate check for accelerated beam, the incident power difference and beam stop calorimetry were compared to the expected beam power under the assumption that the entire proton beam was accelerated. This assumption is known to be false but allows us to compare the beam transmission data with the two beam power measurements using the same units. These data are shown in Figure 6. The rf incident power difference and calorimetry measurements of the beam as a function of RFQ cavity power show a discrepancy in absolute calibrations, but the knee in the curve for both measurements agree. The lower RFQ cavity power correlated with the knee for beam transmission compared with the other power measurements indicates that beam is transmitted even though it is not accelerated.

6 SUMMARY

The CRITS RFQ proved to be the best test device for checking out all components of the injector. By optimizing the current through the RFQ, all injector systems demonstrated that they could operate across the required parameter space. The procedures developed in preparing the RFQ for beam and in accomplishing beam studies should expedite successful operations with the LEDA RFQ. The successful transmission of beam currents with good agreement to the simulations [5] also provides confidence in the codes as we proceed into future projects.

7 ACKNOWLEDGMENTS

We would like to thank and express our appreciation to the personnel at Chalk River Laboratories who designed, fabricated, assembled, and commissioned this accelerator section under the RFQ1 program. They provided an RFQ which met its design goals and proved to be robust enough to operate reliably through a long sequence of structure studies. Furthermore, their brilliant and innovative work provided not only the basis for the x-ray endpoint measurement which has proven so valuable at LANL, but also the underlying technical knowledge for cw, proton accelerator development which has been the cornerstone of the upcoming LEDA project.

THE MECHANICAL DESIGN AND FABRICATION OF A RIDGE-LOADED WAVEGUIDE FOR AN RFQ*

R. Valdiviez, P. Roybal, B. Clark, F. Martinez, D. Casillas, G. Gonzales, J. Tafoya
Los Alamos National Laboratory, Los Alamos, NM, 87545

Abstract

The APT/LEDA Radio Frequency Quadrupole (RFQ) accelerator has an RF power input of 2 MW and an H^+ beam output current of 100 mA at 6.7 MeV CW. The RFQ utilizes twelve nearly identical ridge-loaded vacuum waveguides to couple the RF power to the RFQ accelerating cavity. The mechanical design and fabrication of the ridge-loaded waveguides are the topics of this paper.

1 RFQ AND RF POWER SUPPLY DESCRIPTION

The RFQ linac [1] is made of eight different sections that are joined together with a flange type design. Each section is approximately one meter in length and weighs approximately 680 pounds. RF power is supplied at three different sections of the RFQ. RF feed sections have four rectangular shaped ports each that are sized to accept the nose piece of the ridge-loaded waveguide. The nose piece of the waveguide actually becomes part of the cavity wall, with the face being part of the cavity surface.

The RF power is supplied to the RFQ by three separate klystrons, each rated for 1 MW operation at 350 MHz. The output of each klystron is divided four ways to create twelve waveguide runs of nominally 167 kW each. An RF window [2] is used to separate the air and vacuum waveguide runs on each waveguide arm.

2 BASIC RF CHARACTERISTICS DESIGN OF THE RIDGE-LOADED WAVEGUIDE

The tapered ridge-loaded waveguide operates in the dominant TE10 mode, the same mode as in the half-height WR2300 waveguide used for the airside RF waveguide. The ridge in the waveguide begins at a location in the waveguide approximately twenty-four inches from the RFQ inner wall and increases in height toward the RFQ, while both the height and width of the waveguide are reduced. The RF fields have intensified sufficiently at the end of the ridged waveguide to couple the RF power into the RFQ cavity with an iris slit small enough to not perturb the tuning of the RFQ. The cutoff frequency of any cross section through the tapered ridge-loaded waveguide is equal to the cutoff frequency of the WR2300 waveguide.

3 THERMAL/STRESS ANALYSIS OF THE RIDGE LOADED WAVEGUIDE

3.1 First Ridged Waveguide Section

The waveguide arm connecting the RFQ to the RF window is actually made up of three vacuum waveguide sections. The first two sections are the ridge-loaded sections. The third section is a straight section of waveguide that includes a vacuum pumping port for pumping the waveguide arm [3].

A section view of the ridged waveguide is shown in Figure 1. The total weight of the waveguide is 97 pounds.

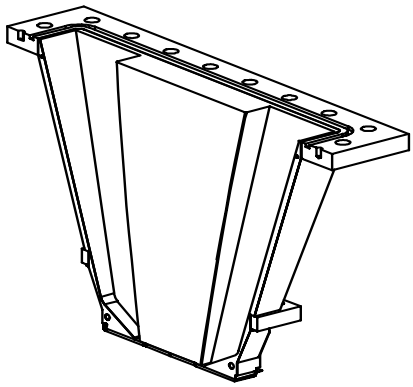

Figure 1. First Ridged Waveguide Longitudinal Section View

The first waveguide section inserts into the RFQ, and has a plate with an iris slit machined through it brazed to the bottom, rectangular face. The iris plate becomes the cavity inner wall surface. The slit aligns longitudinally with the gap between the ridges, and exposes the gap to the cavity. The Rf coupling takes place via the slit. This configuration places a considerable heat load on the waveguide. Integral coolant channels within the waveguide body are used to provide the necessary temperature control of the waveguide. Water from the

* Work supported by the US Department of Energy, Defense Programs

Resonance Control Cooling System (RCCS) [4] is used in the waveguide coolant channels. Since the waveguide becomes part of the resonating cavity wall it must be thermally controlled along with the rest of the cavity walls.

Two parallel coolant channels run down through the ridge, make six turns in a region immediately behind the iris plate, and flow up and out of the waveguide. The bulk coolant velocity is 15 ft/s in the iris region, and 12.8 ft/s in the supply and return channels in the ridge bodies. This cooling configuration allows for the power loss heat load, that ranges from 13.0 watts/cm^2 to 0.3 watts/cm^2 to be accommodated. The high thermal conductivity of the copper material allows for using only two discrete coolant channels to cover a rather wide surface area without creating substantial temperature gradients.

The thermal/stress Finite Element Analysis (FEA) model of the waveguide was created and analyzed using the program COSMOS/M, version 1.75A [5]. The waveguide geometry was obtained from the solid modeling software Unigraphics, version 11.1.3 [6] by using an IGES translation file.

To model the waveguide the thermal profile throughout the body was first predicted. The peak temperature predicted was 106 °F for normal conditions, with an inlet coolant temperature of 66 °F. This peak temperature occurs in the iris region where the peak heat load is located. This thermal profile is then used as one of the boundary conditions in a displacement and stress model. The largest displacement is predicted to be 0.0022 inch at the top of the waveguide. The peak von Mises stress is predicted to be 6540 lb$_f$/in^2 and occurs in the iris region. The iris region is locked between the lower mounting flange of the waveguide and the RF seal that the nose piece of the waveguide presses against. The RF seal acts as a very stiff spring that has some pliability, yet still offers significant resistance to the thermal growth of the nose portion of the waveguide.

Due to the value of the predicted peak von Mises stress in the waveguide the high strength copper material Glidcop AL-15 [7] was chosen as the construction material for the waveguide.

3.2 Second Ridged Waveguide Section

Figure 2 is a section view of the second ridged waveguide that connects directly to the first section. The second ridged waveguide is the section where the ridge begins, and weighs 186 pounds. One end of the waveguide matches the half-height WR2300 waveguide dimensions. The bottom-end dimensions of this waveguide match to the first waveguide to within a few thousandths of an inch.

The waveguide has four separate coolant-flow channels. The channels are located in the corner regions of the ridge. The bulk coolant velocity in each channel is 6 ft/s. The coolant water from the first section is split and sent into the second section. The power-loss heat load on the second section ranges from 0.21 watts/cm^2 to 0.05 watts/cm^2.

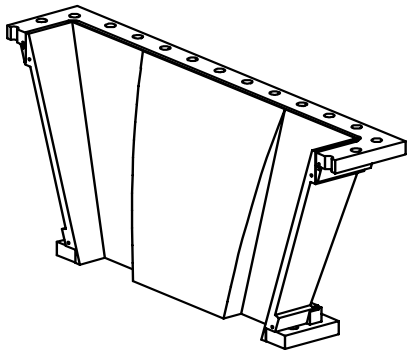

Figure 2. Second Ridged Waveguide Longitudinal Section View

The thermal/stress Finite Element Analysis (FEA) model of the second waveguide was created and analyzed using the program COSMOS/M, version 1.75A. The waveguide geometry was obtained from the solid-modeling software Unigraphics, version 11.1.3 by using an IGES translation file.

The FEA model was first used to predict the thermal profile of the second waveguide. The peak temperature was predicted to be 81 °F at a location in the lower part of the waveguide sidewall, for an inlet coolant temperature of 72 °F. This location is one of the furthest from a coolant channel in the section. The predicted thermal profile was used as a boundary condition for the displacement and stress model. The largest displacement was predicted to be 0.0013 inch at the top of the waveguide. The peak von Mises stress is predicted to be 3680 lb$_f$/in^2 located in a lower corner region of the waveguide.

The predicted von Mises stresses are not too high for the second section. For this reason OFE C10100 copper was chosen as the material of construction.

4 MECHANICAL DESIGN OF THE RIDGE-LOADED WAVEGUIDE

The mechanical design used the results of the thermal and stress analyses to determine a final design that would meet both strength and space-envelope constraints. Initial

concepts for each of the waveguide designs had been created using the solid modeling software Unigraphics, version 11.1.3.

The thermal and stress analyses of both waveguide sections predicted some areas where the initial design required some modification. The size of the coolant channel in the iris waveguide, in the region immediately behind the iris piece was changed in order to obtain the thermal/hydraulic conditions needed to achieve the desired thermal profile in this part of the waveguide body. The body of the second waveguide section was predicted as needing reinforced sections in the flange areas in order to reduce the combined stress levels.

5 FABRICATION METHODS EMPLOYED

The ridged-waveguide sections are machined copper assemblies with the individual parts joined together by brazing . The internal ridge and pocket configuration of both sections along with the tapering in two planes over the length of the section requires skillful machining. The geometry of, and the mechanical loads placed on the braze joints requires equally skillful preparation and brazing.

5.1 Machining

Each waveguide section is machined in two halves that are eventually joined together. By using this approach the internal ridge and pockets can be machined in an open-face configuration. The dimensional tolerance of the internal features was +/- 0.005 inch or less. Five three-axis machines and one five-axis machine were used to produce the waveguide bodies.

Due to the fact that the internal surfaces and features see high RF power, the surface finishes and feature sizes (such as corner radii) took on more importance than they normally would as in a non-RF power component. Sample pieces were machined out of aluminum for both waveguide sections to check for surface finish and feature sizes obtainable, and to check the machine programming. After undergoing a few iterations with samples the actual copper machining was begun.

5.2 Brazing

Gold-copper alloys are used to braze the various pieces of the waveguides together. Brazing the OFE C10100 presented no major problems due to long experience in brazing this copper material. Brazing OFE C10100 to Glidcop AL-15 presented some problems with joint sealing and joint strength. Brazing Glidcop AL-15 to Glidcop AL-15 presented increased sealing and strength problems.

In order to overcome the problem of Glidcop joint seal and strength integrity several vacuum and tensile specimens were fabricated and put through variations of the basic brazing procedure being used. In summary, the first sample investigations provided some improvement steps, but nothing that achieved consistent seal and strength integrity. Throughout this testing process other users of Glidcop were consulted about the problem. The Stanford Linear Accelerator Complex (SLAC) advised that their best success in brazing Glidcop came from first plating the surfaces to be brazed with a 0.0008 inch thick copper strike in a cyanide-copper plating process. This method of preparing the braze surface was employed on several sample pieces with very good, consistent results in sealing and strength. The preparation method was added to the fabrication sequence of the waveguide sections, and has worked well on the parts brazed to date.

6 RESULTING WAVEGUIDE HARDWARE

At the time of preparing this paper the ridged waveguide sections were still being fabricated, so no high RF power operation has been conducted yet with this ridged waveguide design. Since the desired RF design has been able to be manufactured with no major changes the waveguides are expected to perform as required.

J. Remais, J. Staples, R. Yourd
Lawrence Berkeley National Laboratory, Berkeley, CA, USA

Abstract

Prototype models that simulate components of the RFQ which is part of the Spallation Neutron Source front end injector [1] are described. The RFQ operates at 402.5 MHz, a maximum current of 70 mA H^- and 6% duty factor. The first model, made of copper plated aluminum is a full size version of one of the four sections of the RFQ and is used to perform low level r.f. measurements of frequency, r.f. tuning, field structure and power coupling port studies. It serves to benchmark the 3D computer simulation studies and to test assembly and field measurement procedures. The second model is a quarter-wave coaxial resonator is used to perform full-power tests of high current seals and joints. This model is also used to test the prototype of the RFQ tuners. The design and construction of both models are presented, as well as test results.

1 INTRODUCTION

The detailed design of the RFQ [2] requires intensive computer simulations to define the cavity shape as well as the optimal configuration of many of the components like the π-mode stabilizers (PISL) [3], tuners and power ports. While some of the work can be done with a 2D code like Superfish, whose accuracy is quite satisfactory, the lack of radial symmetry mandates the use of 3D codes like MAFIA, which are not accurate enough to determine final dimensions. A test model has been built to perform low level measurements to validate and refine the computer simulations results. A quarter wave cavity has also been built to study tuners and seals under vacuum and rf power.

2 COMPUTER MODELING

The main cavity body geometry for the SNS RFQ has been developed with Superfish. With the adoption of the PISL stabilizer scheme, the structure has also been analyzed for mode separation and stabilization. The insertion of the stabilizer bars has the twofold effect of lowering the resonance frequency of the quadrupole mode and of raising the frequency of the degenerate dipole mode. A family of MAFIA simulations, summarized in Fig. 1, shows the effect of the stabilizer rods on both the quadrupole and the dipole modes as a function of the rods' spacing.

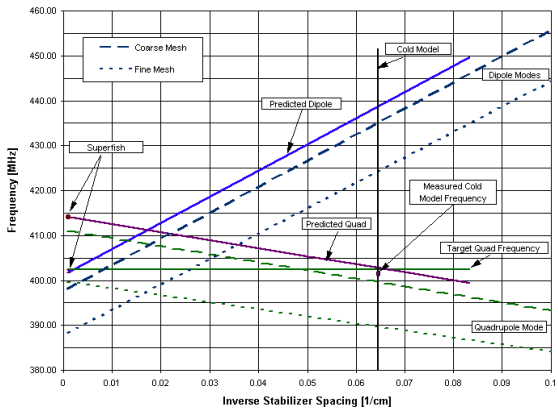

Figure 1 – Computer analyses of the quadrupole and dipole modes as a function of stabilizer spacing.

As a result of these analyses, the spacing between each set of stabilizers has been chosen to be 15.5 cm, from a horizontal pair to a vertical one (and vice-versa). This resulted in a predicted quadrupole mode shift of –11 MHz and of the dipole modes of +36 MHz. These effects were factored in the main frequency calculations performed with Superfish to determine the reference shape of the cavity. The measurements on the cold model proved the validity of this method.

3 COLD MODEL

A full size, 93 cm long RFQ cold model has been built, representing one quarter of the actual length of the full RFQ. This model is intended to validate the computer studies performed and to help defining the geometry to a better degree of accuracy than is achievable with MAFIA.

The model is made of aluminum, with a hard (acid) copper plating to guarantee a stable and strong surface to make good rf contacts between adjacent quarter sections. A picture of the cold model is shown in Fig. 2. This model has all vacuum penetrations, power coupling ports and tuner ports, but it is not built to operate under vacuum or with substantial rf power. Piston tuners are also provided,

as well as adjustable end flanges to properly define the tuning of the vane ends. A set of six π-mode stabilizers, three in the horizontal and three in the vertical plane, is installed to validate the mode separation analysis.

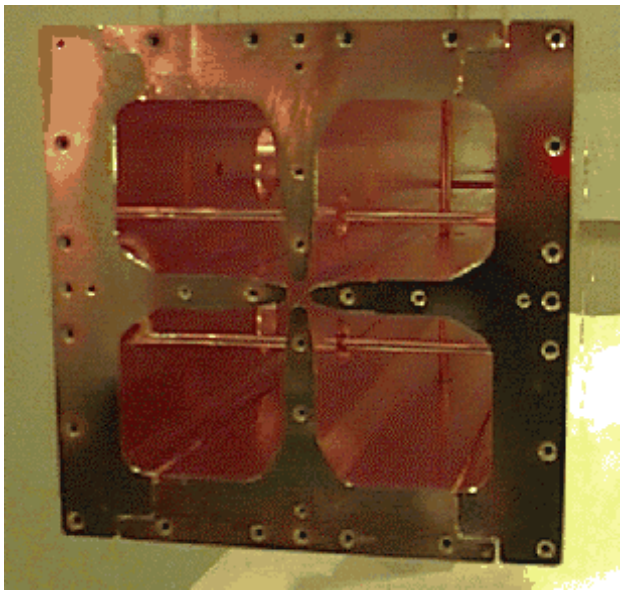

Figure 2 - The Cold Model Cavity

A computer based motion control and data acquisition system has been used to perform field perturbation measurements with the well known bead-pull method. The setup has been modified from the existing structure that was used at LBNL to map the higher order mode structure of PEP-II cavities [4]. In order to be able to observe both the H and the E fields, a set of four alumina spheres were run along the vane tips, whereas a set of four aluminum beads were run along the wall of each quadrant. To accomplish this, four motors were employed, with each motor servicing one quadrant and controlling one dielectric and one metallic bead.

The data acquisition system, based on the IGOR commercial software package running on a Macintosh platform, controls the motors via the RS232 bus. The program determines the bead positions and ensures that only one bead is inside the cavity at any given time. An HP8510 network analyzer is used to perform the S21 measurement that is used to observe the effects of the beads on the cavity. The instrument is software controlled via the GPIB bus which allows also for the transfer of the acquired data to the computer. Data analysis is later performed using separate software.

4 COLD MODEL TEST RESULTS

The perturbation measurements allowed the validation of the chosen cavity geometry. The waveguide cut-off frequency was found at 402.18 MHz, close to the required 402.5 MHz frequency. The tuners will bring the cavity to the operating frequency. This means that the cavity cross-sectional dimensions do not need to be changed, given the chosen stabilizer bars spacing. Figure 1 shows the measured quadrupole mode in comparison with the results from computer simulations.

Quadrant perturbation tests were performed using the available 12 tuners with the goal of judging the quality of the π-mode stabilization. The perturbation of one quadrant by 1.53 MHz changes the azimuthal field symmetry by less than 2.7 %. This satisfactory result finalized the current stabilization scheme.

Another important result obtained from the cold model perturbation measurements is the tuning of the end plates. The vane to end plate capacitance is balanced against the inductance of the vane undercut at a resonant frequency of 402.5 MHz that matches the cut-off frequency of the wave guide. With the help of detachable vane ends of various length it has been possible to find the optimum vane termination geometry.

The overall performance of the tuners was also verified. By moving all twelve tuners to their fully inserted and fully extracted position, a total tuning range in excess of 2 MHz was measured.

5 HOT MODEL

The hot model is designed to test rf sealing configurations on fully annealed OFE copper as well as tuner designs. To accomplish these tasks a quarterwave geometry was chosen for its simplicity and ease of fabrication. The cavity is designed to reach peak surface currents of the same density as the ones reached in the RFQ walls. This implies that the cavity operate under vacuum and be capable of taking a 6% duty factor rf high power pulse.

The cavity is powered by a tetrode-based 15 kW peak power amplifier, the components of which were provided by LANL. Using the energy stored in a capacitor bank, the system will run at a 1 ms long pulse with 60 Hz repetition rate, thus matching the operating conditions of the SNS RFQ.

The less than 1 kW average power is removed from the cavity by a spit-tube flooding the inner conductor of the resonator. The power coupling loop is also cooled in its outside wall.

The rf sealing geometry is designed to allow for testing of several types of seals. In particular, a copper-to-copper configuration was compared to sealing techniques based upon indium or tin. The hot model cavity is shown in Fig. 3.

Figure 3 - The Hot Model Cavity

The rf tuner is designed to help optimizing the piston. Clearance gap, moving rf contacts and vacuum sealing techniques will be tested under power.

6 HOT MODEL TEST RESULTS

The hot model measurement program is still underway. So far, the low level measurements have been completed.

The cavity quality factor Q has been calculated by measuring the reflection coefficient as seen on the optimally matched power coupling loop. These measurements showed no improvement in the rf performance of the cavity by adopting an indium or a tin seal. The observed values are listed in Table 1.

Configuration	Quality Factor Q
Calculated (Sfish)	4600
Cu-cu	4160
In	4140
Tin	4125

Table 1 – Rf seal measurements results.

The good performance of the copper-to-copper seal led to the decision to adopt it as the baseline in the first RFQ test module currently under design. This avoids the problems associated with using a metal seal on the fully annealed OFE surfaces and allows for the use of a rubber elastometer as the main vacuum seal.

The cavity is going to be powered soon to develop the tuner design. This phase will also allow to validate the adopted rf seal.

7 STATUS

The final dimensions of the RFQ cavity, including the vane undercuts and end plate positions have been determined and finalized aided by the measurements performed on the cold model. The bead-pull setup is now available for use to characterize the fields and assembly accuracy during the cavity manufacturing, assembly and brazing processes.

The baseline rf and vacuum sealing design has been established and will be tested in the hot model power tests that are soon to begin. These tests will also allow the conceptual development of the rf tuners.

8 ACKNOWLEDGMENTS

The authors would like to acknowledge the support received from the Beam Electrodynamics Group at LBNL, who made available the bead-pull test laboratory and provided the hardware used in the measurements. John Corlett, Bob Rimmer and John Byrd also contributed with their extensive experience in the field of cavity design and measurements.

Abstract

In the RIKEN RI-beam factory project, a Charge-State Multiplier system (CSM) is planned to be placed between the existing heavy ion linac (RILAC) and the ring cyclotron (RRC). It consists of an accelerator, a charge stripper and a decelerator. The accelerator section increases the stripping energy further and the decelerator section brings the beam energy down to the initial value. By use of this system, the charge-to-mass ratio (q/A) of the heavy-ion beams will be increased so that the ring cyclotrons can accept the beams without changing the injection radius of the RRC. For the accelerator and decelerator sections, drift tube linacs of variable-frequency type will be used, whose rf-frequency is varied from 36 to 76 MHz. The total accelerating voltage required for the accelerator section is about 26 MV and that for the decelerator section is about 13 MV. Initial design of the low energy part of the CSM, based on a quarter wavelength resonator with a movable shorting plate, is described in this paper.

1 INTRODUCTION

In the on-going RI-beam Factory project[1], a cascade of a K930-MeV ring cyclotron (IRC) and a K2500-MeV superconducting ring cyclotron (SRC) will be constructed as an energy booster of the existing K-540 ring cyclotron (RRC). The final energy will be increased up to 400 MeV/u for light ions such as Oxygen and 150 MeV/u for Uranium with this new cyclotron system. As the injector for the accelerator complex, the existing heavy-ion linac (RILAC) will be used, whose pre-injector has been recently upgraded[2]. The intended beam intensity is 1 pμA for light ions and 100 pnA for heavy ions.

For very heavy ions, a charge-stripping process is necessary before the RRC so that the cyclotrons can accept the beams by reducing the magnetic rigidity. There is, however, a significant problem that the beam energy from the RILAC is too low to provide the required charge state with the existing charge-stripper between the RILAC and the RRC.

We illustrate this problem in Fig. 1 by taking the case of Uranium acceleration as an example. If the beam is accelerated to 150 MeV/u with the SRC, the corresponding rf-frequency and the output energy of the RILAC are 27.2 MHz and 1.48 MeV/u, respectively. To be accepted in the IRC and the SRC, the charge state must be at least 58^+. The most probable charge state at this energy is, however, 42^+ and the production rate of 58^+ is almost zero[3].

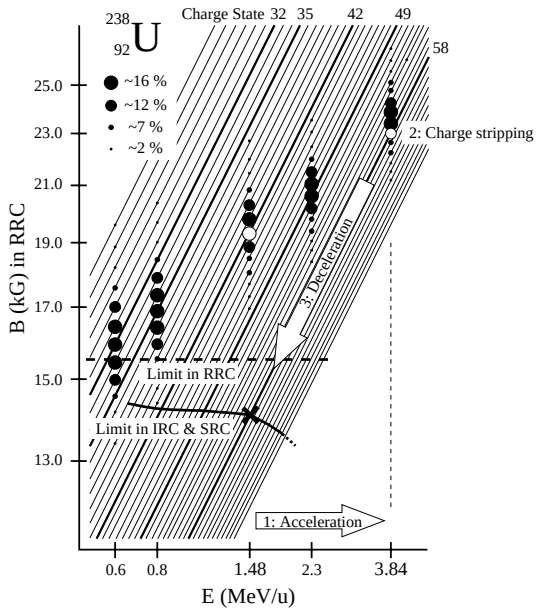

Figure 1: Principle of the CSM. The size of the dots corresponds to the production rate of Uranium ions with respective charge state at the stripping energy, E, when using a carbon foil for the stripper. The ordinate represents the necessary bending power in the RRC. The bending limit in the IRC and SRC is also indicated.

The proposed method[1] to solve this problem is also described in Fig. 1. The output beam from the RILAC is accelerated further up to 3.84 MeV/u. After charge-stripping at this energy, where the production rate of 58^+ is sufficiently high, the obtained ions are decelerated to the initial energy. It should be noticed that the injection radius of the RRC need not be changed because the input speed remains the same. This is the principle of the Charge-State Multiplier (CSM) system.

The CSM consists of an accelerator, a charge-stripper, and a decelerator as described above. Several designs have been proposed for the drift tube linacs used in the

accelerator and the decelerator sections[4,5]. In the recent design[5], four accelerating tanks and two decelerating tanks are proposed, where 16 or 18 gaps are included in each tank. The resonator is based on the Interdigital H-mode (IH) structure with a movable shorting plate, whose rf-frequency is twice the fundamental frequency. In order to put the whole CSM in a present experimental room, the maximum gap voltage is chosen to be 430 kV. However, the power consumption per tank is estimated to exceed 100 kW and the calculated current density reaches 90 A/cm on the sliding contact around the corner of the ridge of the IH structure. This design has another problem that the tank becomes too long to make the structure rigid especially in the high energy part.

2 CSM DESIGN

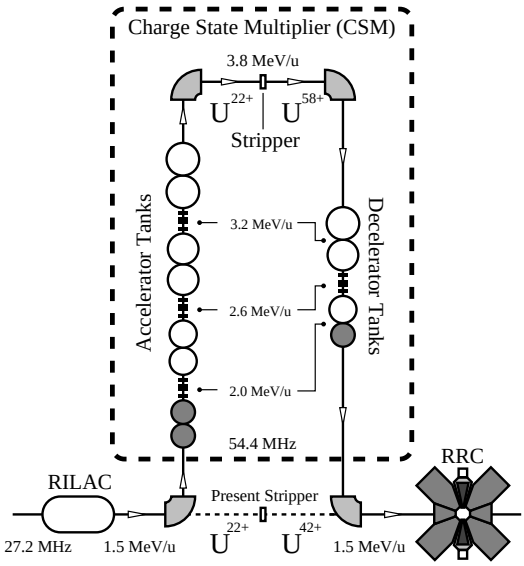

Figure 2: Schematic layout of the CSM. The energies at the fundamental frequency of 27.2 MHz are also indicated.

Figure 2 shows the schematic layout of the present configuration of the CSM. We plan to put eight tanks in the accelerator and four tanks in the decelerator. The tanks are independently operated at the doubled frequency of the fundamental one, which means that the required frequency for the CSM ranges from 36 MHz to 76 MHz. The synchronous phase of the accelerator tanks has been chosen to be -25° while that of the decelerator tanks has been 25°, in order to maintain the longitudinal focusing in the tanks. Each tank has eight gaps in it. The maximum gap voltage is chosen to be about 500 kV. The power consumption per tank will be made less than 100 kW by adopting this configuration.

The last tank of the decelerator covers the same energy-range as the first two tanks of the accelerator. In the same way, there are a pair of accelerator tanks and a decelerator tank which work in the same energy-range. Quadrupole

Table 1: Main Parameters of the Low Energy Part of the CSM

Tank	Acc.1	Acc.2	Dec.

Max. current (A/cm)**	58	61	58

* : At 54.4 MHz.
**: Maximum current density on the sliding contacts.

triplets are placed between every two tanks. The total length of the accelerator and that of the decelerator will be about 16 meters and 8 meters, respectively.

Construction of the low energy part, indicated by the hatched circles in Fig. 2, has started and the mechanical design of the resonators is under progress. The main parameters are listed in Table 1. The output energy of the accelerator section of this part is 2 MeV/u at the fundamental frequency of 27.2 MHz.

The resonator of the low energy part is based on a quarter-wavelength resonator of circular cylinder, as shown in Fig. 3. All the three resonators have the same dimensions except for the drift tubes and their stems. The resonant frequency is changed by a movable shorting plate. The rf-power is fed through a capacitive feeder. A capacitive tuner is used for the fine tuning of the frequency.

The rf-characteristic of the resonators has been studied with the MAFIA code[6]. The size of the coaxial part as well as the shape of the stems for the first and final drift

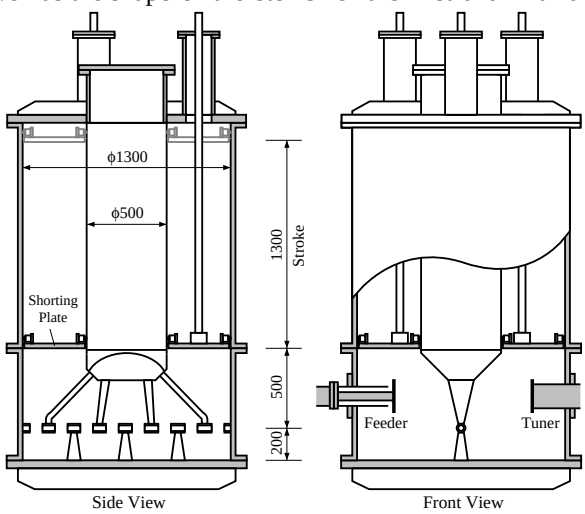

Figure 3: Schematic drawing of the resonator.

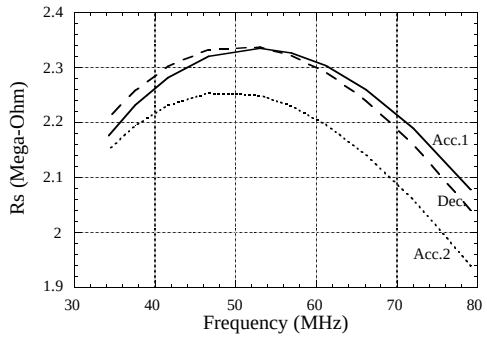

Fig. 4: Shunt impedances of the tanks of the low energy part. The solid, dotted and dashed curves represent the impedance of the first, second and the last tank of the CSM, respectively.

tubes are optimized so that the current density on the sliding contact could be as small as possible.

The calculation predicts that a stroke of 1300 mm of the movable shorting plate covers the required frequency-range from 36 to 76 MHz in the three tanks. The current density on the sliding contacts is estimated to be 60 A/cm at the maximum gap voltage of 450 kV.

Figure 4 shows the calculated shunt impedances. The shunt impedance R_s is defined in this paper by $V^2/(2P)$, where P is the rf-power consumption and V is the peak value of the gap voltage. From this result, the maximum power loss is calculated to be about 50 kW per tank. The calculated Q-values are about 30000 and they are almost constant in the frequency range.

The actual shunt impedances of the resonators will be less than the calculated ones mainly due to the sliding contacts used around the stem. Therefore, we are planning to construct the amplifiers whose maximum power is 100 kW in the required frequency-range.

Cooling is one of the most important problems in these resonators. According to the calculation, the power loss in the stem for the end drift tube is 9 kW at the maximum gap voltage. The arrangement of the cooling channels is under design based on the heat analysis.

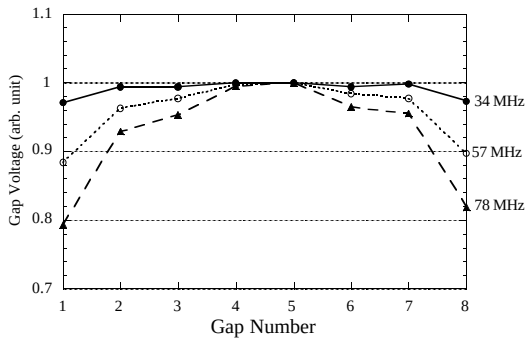

Fig. 5: Calculated gap voltage of the second tank of the CSM.

The voltage distribution is not flat along the accelerating cells in these resonators, particularly in the high frequency region. A calculated example is shown in Fig. 5 for the second tank. As shown in the figure, the gap voltage at the end cells is about 80 % of that of the inner cells at the highest frequency. The effect of this voltage distribution on the beam transmission has been estimated with a first-order calculation. According to that, the transmission will be good enough when the average gap voltage is larger than the designed voltage.

3 SUMMARY AND OUTLOOK

A design for the CSM has been proposed consisting of eight accelerator tanks and four decelerator tanks, independently operated in the frequency range from 36 MHz to 76 MHz. Three tanks of the low energy part of the CSM are under design based on a quarter-wavelength structure of circular cylinder with a movable shorting plate.

The construction of the low energy part will be completed in 1999. The three tanks will be installed and tested in the beam line between the RILAC and the RRC in the same year. The rest of the CSM tanks will be designed and constructed based on the test of the low energy part.

In parallel with the resonator design, study on the charge-stripper should be done, which can withstand the intended high intensity beams.

4 ACKNOWLEGDEMENT

The authors are grateful to Dr. M. Tomizawa at KEK for informative discussions and valuable comments on beam dynamics as well as on IH structures.

Abstract

We have started development on superconducting cavities with KEK from 1997. First, we checked out the effect of removal thickness with electropolishing (EP) . In the results, We could obtain the maximum accelerating field of 32MV/m by a repeatedly small removal thickness (30μm) up to 150 μm material removal. Next, when fabricating the second, we directly removed as much the thickness as the optimized depth by the first cavity using heavy chemicalpolishing (CP) and final light EP in sequence. We are now in the stage of fabricating the third one, 3-cell cavity. In this paper, we report on these results and activities at Sumitomo Heavy Industries, Ltd.

1 INTRODUCTION

Last year, We set up three purposes as follows. First; fabricating a single-cell L-band niobium cavity to study surface treatment, and testing it to learn many operating systems in this fields. Second; fabricating multi-cell cavities by our own technics. Third; design and fabrication of a cryo-module.

On the first step, we have acquired two important data, namely, superiority of EP [1] and hydrogen Q-disease [2]. For the former, it showed the good relationship between an amount of removed thickness and accelerating gradient(Eacc), which could be obtained with only EP as surface treatment. Finally, the cavity obtained 32MV/m of gradient. For the latter, we checked out hydrogen Q-disease with our first fabricated cavity SHI-3. This cavity surface was removed 130μm in depth with CP. Annealing was not practiced for this cavity. After the first vertical test, the cavity was kept at 100K for two hours. Before and after this process (holding 100K) , the performance almost unchanged.

On the second step, we needed to check out the proper welding condition on niobium by our electron beam welding (EBW) machine, because of the different conditions from KEK's. Then, we applied our own conditions to single-cell and 3-cell cavities .

The all fabricated cavities are named individually as shown in Table 1. SHI-1 which was fabricated at KEK was applied to study the relationship between the removed thickness by EP and maximum gradient of the cavity. SHI-2 was only used to optimize EBW condition. For SHI-3 without annealing and mechanical treatment, it was used to investigate hydrogen Q_disease. SHI-4 is a 3-cell cavity and under fabrication at SHI factory.

Table 1: List of fabricated cavities.

Name	# of cell	Factory	Remarks
SHI-1	1	KEK	Investigate effect of EP :max. E_{acc}=32MV/m
SHI-2	1	SHI	Researching only EBW condition .
SHI-3	1	SHI	Investigate anneal effect :max. E_{acc}=7.3MV/m
SHI-4	3	SHI	Not measured

2 SURFACE TREATMENT ON SHI-1

The purpose of SHI-1 cavity was to study the dependence between the cavity performance and the removed thickness with EP. A similar relationship was already studied by P. Kneisel et al. using CP [3]. First, a light chemical polishing (20μm) was carried out on this cavity to remove the contaminated surface layer, and then annealing at 760° was done to prevent the hydrogen Q-disease. After that , the performance of this cavity was measured with adding a light EP(30μm) and high-pressure water rinsing (HPR) repeatedly. The experiments were continued until 210μm removed thickness. These experimental data are shown in Figures

1~3. All tests were executed using the KEK's vertical measuring system.

X-ray was detected at the 1st, 3rd and 4th measurements in Figure 1. X-ray was observed over the higher gradients than 16MV/m at 3rd and 4th. This radiation should be due to field emission by the reason that the relative X-ray intensity is enhanced in accordance with increasing field gradient.

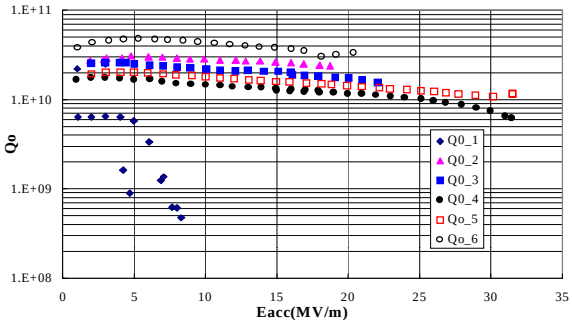

Figure 1: Q_o vs. E_{acc} at SHI-1 cavity.

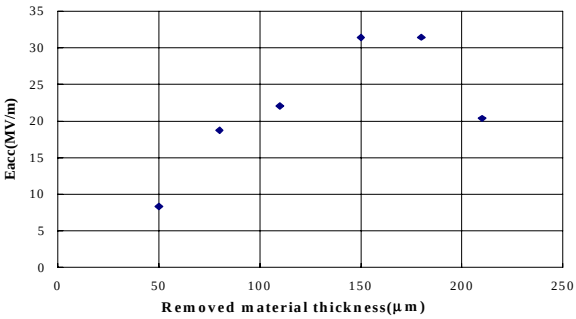

Figure 2: E_{acc} vs. removed thickness on SHI-1 cavity.

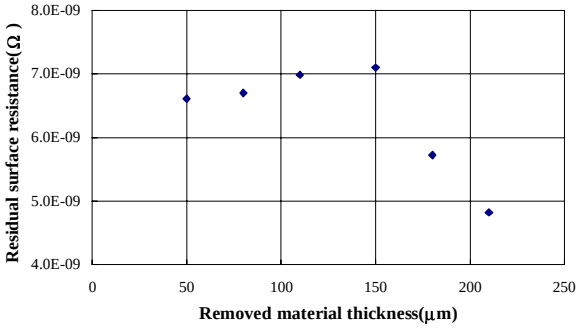

Figure 3: Residual resistance vs. removed thickness on SHI-1 cavity.

This cavity had a large pit (diameter: ~600μm) and many tiny pits (diameter: ~50 μm) on the initial stage. The tiny pits have gradually vanished with adding EP. The field gradient increased with adding 30μm EP until 150μm as shown Figure 2. At the 5th measurement (the removed thickness was in total 180μm), the performance just kept the same value as the case of 150μm removing and X-ray was not observed. After the 5th measurement, we inspected the inner surface of SHI-1 cavity and confirmed that the tiny pits have almost vanished except the large one.

Although we did not measure the temperature mapping, it is considered that the maximum performance at 6th measurements was limited by the pit. The magnetic field strength on the inner wall at 32MV/m is shown in Figure 4. At the 6th measurement (the removed thickness was in total 210μm), Eacc decreased to 20.5MV/m and X-ray was not observed. By the inspection after 6th measurement, we found the existence of many tiny pits similar to the initial stage. It might be due to EP processes.

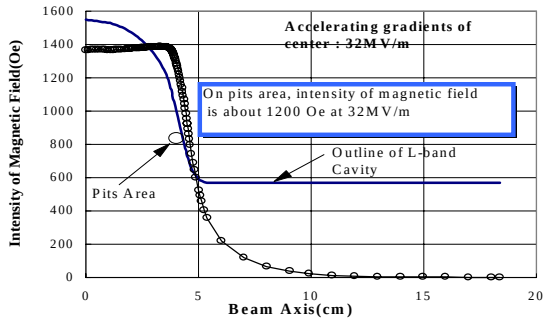

Figure 4: Distribution of magnetic field on the wall at 32MV/m on the axis.

3 SHI-3 CAVITY

3.1 Fabrication And Surface Treatment

We started fabricating a L-band single-cell cavity by our own factory while measuring SHI-1 cavity. First, we optimized an appropriate EBW condition with Nb flat sheets (thickness: 2.5mm) by our EBW machine(Table 2), and next, with beampipes (inner diameter: ϕ76mm, thickness: 2.5mm, length: 40mm). Then, we assembled SHI-2 cavity with two half-cells and two beampipes. SHI-2 got a small hole on the one iris EBW seam, because of the high electron beam currents. After modifying the EBW condition, we finished the assembling of SHI-3.

Table 2: Current condition of EBW

SECTION	VOLTAGE(kV)	CURRENT(mA)
Iris	150	14
Equator	150	16
Machine: JE-114 : Osaka henatsuki , Ltd. : Beam power-15KW (150KV- 100mA)		

Although the EBW is not perfectly optimized, our current condition is shown in Table 2. From the results of SHI-1, we decided the optimum removed thickness as 150-180μm to obtain over 30MV/m of high gradients. The subjects of SHI-3 were testing the high gradients and making sure of a hydrogen Q-disease without

annealing. The treatments on SHI-3 are shown in Table 3.

Table 3: Surface treatments on SHI-3 cavity.

No	Treatment	Method	Remarks
1	Pre_polishing	CP	130 μm
2	Final polishing	EP	30 μm
3	Cleaning 1	HWMR*	80°C / 90min.
4	Cleaning 2	HPR	8.3 MPa / 90min.

* : Hot Water with Megasonic Rinsing

3.2 Measurement Results of SHI-3

The measurements were carried out twice on the cavity. First cooling was to check out SHI-3 cavity performance after our treatment. After that, SHI-3 was kept constant temperature at 100K for two hours to make sure of a hydrogen Q-disease. From the second measurement, Q-degradation did not observed as shown Figure 5. A hydrogen Q-disease might not happen by removing sufficient amount with CP before light EP. We showed have to study the process of making Nb sheets and aging effect on the material properties.

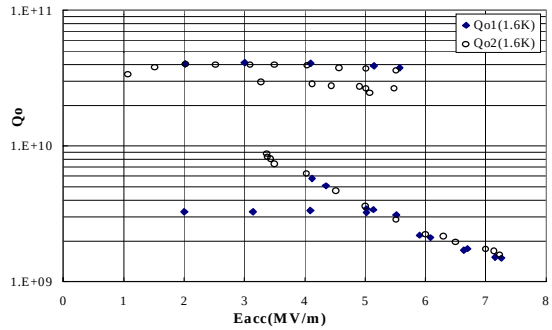

Figure 5: Q_o vs. E_{acc} at SHI-3 cavity.

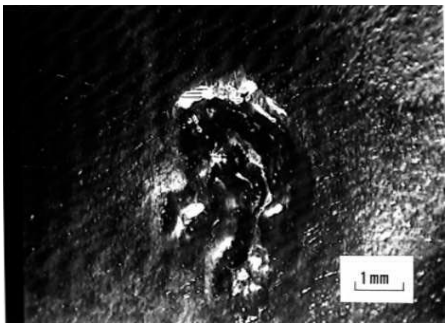

Figure 6: Equator defect found on SHI-3.

The Qo vs. Eacc curve in Figure 5, we can observe that Qo was switched to the lower level after the first quench at 5.7MV/m. The maximum Eacc was limited at 7.4MV/m. On the reverse process when decreasing Eacc from 7.4MV/m, Q jump did not appear at 5.7MV/m and kept the lower values. I suppose that this phenomenon is related to two defect. Through the inspection after measurement, we discovered a big defect on nearly the equator portion as shown in Figure 6. At the time of assembling, no such defect had been found.

4 FABRICATION OF A 3 CELL CAVITY

The manufacturing of a 3 cell cavity (SHI-4) has just been finished. Whole view is in Figure 7. This will be cold testing soon.

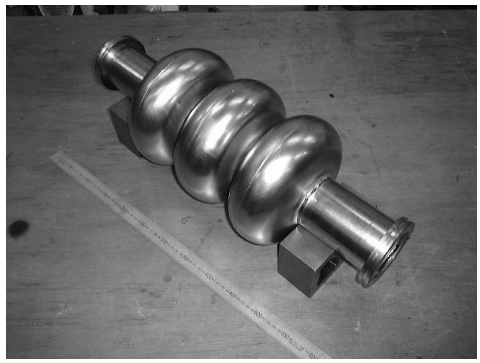

Figure 7: Overall view of 3 cell-cavity.

5 SUMMARY

We obtained the dependence of accelerating gradient upon an amount of removed thickness using EP. The optimum removal by EP to get high gradient is in over 150μm. In case of using a large amount of CP, annealing process for hydrogen degassing does not always need to avoid hydrogen Q-disease.

RF TESTS ON THE INITIAL 2.8m SECTION OF THE 8m LONG ISAC RFQ AT TRIUMF

R. L. Poirier, P. Bricault, G. Dutto, K. Fong, R. Laxdal, A. K. Mitra, B. Uzat
TRIUMF, Vancouver, B. C., CANADA

Abstract

The ISAC RFQ is an 8 meter long, 4-rod split-ring structure operating at 35 MHz in cw mode. The rods are vane-shaped and are supported by 19 rings spaced 40 cm apart. The rings are unique in that the rf surfaces have been structrurely de-coupled from the mechanical support structure to improve dynamic stability. An initial 2.8m section of the accelerator (7 of 19 rings) was installed and aligned in the 8m, square cross-section, vacuum tank to allow rf and beam tests to be carried out. The stringent, +/- 0.08 mm, quadrature positioning tolerance of the four rod electrodes was practically achieved and a relative field variation along the 2.8 meter of the RFQ was measured to within +/- 1%, using the standard bead pull method, signal level measurements gave a frequency of 35.7 MHz, a Q of 8700 and a resonant shunt impedance of 292 k Ω.m. Compared to the initial 3 ring prototype, this represents a 21% increase in Q and a 30 % increase in shunt impedance. The seven ring section has been successfully tested with beam at full power.

1 INTRODUCTION

The accelerating system of the ISAC radioactive ion beams facility consists of an RFQ and a post - stripper DTL. Ion beams with A/q $\leq$ 30 from the on line mass separator will be accelerated from 2 keV/u, to 150 keV/u through the RFQ and then to an energy up to 1.5 MeV/u through the DTL structure. The low charge-to-mass ratios of the ions dictate a low operating frequency to achieve adequate transverse focusing, and cw operation is required to preserve beam intensity. The reference design [1] for the RFQ is a four rod split ring structure operating at 35 MHz. The RFQ accelerator section is 8 meters long and is designed in 40 cm long modules with a peak potential between the electrodes of 74 kV. Full power tests on a single module [2] and on a three module assembly[3] enabled us to complete the basic electrical and mechanical design for the RFQ accelerator. The theodilite intersection method[4] was used to align two platen bases in the tank to allow 7 of the 19 rings to be installed in the first section of the 8m long vacuum tank. The alignment of the ring assemblies on the platens was accomplished by the same method. Because of the manufacturing procedures and alignment philosophy adopted [4], when the electrodes were installed on their mounting surfaces they were aligned by default with no shimming required. Figure 1 shows the vacuum tank installed on the concrete mounting pad in the accelerator building with seven rings assembled. The coupling loop, which was tested in the prototype test facility for 100 hours at 40 kW, was installed and used to feed the rf signal for calibrating the monitoring probes. The inside groove on the tank flange is for an rf spring contact.

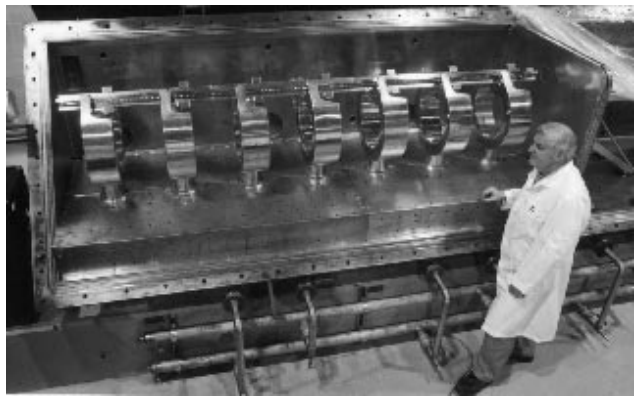

Figure 1. Seven rings assembled, installed and aligned in the bottom section of the vacuum tank

2 SIGNAL LEVEL TESTS

2.1 Frequency, Q and Shunt Impedance Measurements

The frequency and Q are measured with a network analyzer and the shunt impedance is derived from two independent R/Q measurements; ΔC method and input admittance method [5]. The input admittance of a parallel resonant circuit when plotted against frequency, produces a V-curve in the vicinity of the resonance. R/Q can be obtained from the slope of such a curve and is given by the equation,

$$R/Q = (2/f_o)*df/dy \quad (1)$$

where f_o = resonant frequency, dy = change in input admittance and df = corresponding change in frequency.
It can also be shown that R/Q is related to the change in frequency with change in capacitance and is given by the equation

$$R/Q = (1/pi*f_o)* df/dc \quad (2)$$

Results are compared to MAFIA calculations in table 1.

Table 1. Comparison of measured values to calculated MAFIA values.

Parameter	MAFIA	Measured
Frequency (MHz)	34.7	35.7
Q	15175	8700
R_{shunt} (k-ohms)	174.9	104.4
R_{shunt} (k-ohms-m)	489.9	292.3
R/Q	11.53	12.0
Capacity (pfd/m)	142	132.6

Because of the size of the mesh used in the MAFIA calculations one would expect the calculated MAFIA frequency to be lower than the measured frequency.

2.2 Bead-pull measurements

The first set of bead pull measurements were made with a set of test electrodes made of aluminum with a radius of r_o and no modulation. Because the electrodes have no shoulder to rest the dielectric bead on when measuring the lower gap, the sagging of the bead was overcome by fabricating a bead carriage from Teflon that traveled down the centre bore of the RFQ and was captured by the tips of the four electrodes. Five bead pull runs were made for each set of measurements; carriage only and four separate runs with the dielectric bead in each of the four quadrants. The carriage only run was used as the average perturbation reference and the other four runs corrected accordingly.

Both the average peak field variation and the quadrupole field asymmetry were deduced from the measurements and are shown in figure 2. The results are within the target of +/- 1% field strength variation.

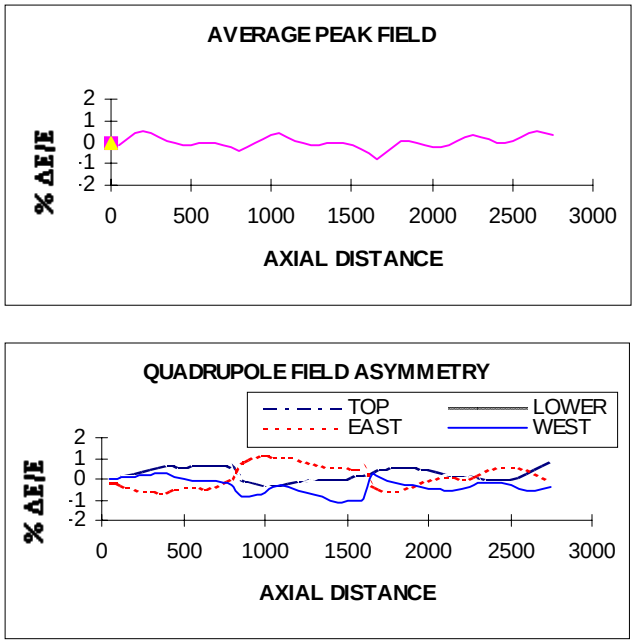

Figure 2. Average peak field and quadrupole field asymmetry for the non-modulated electrodes.

A similar set of results is shown in figure 3 for the copper electrodes with modulation. Because of the modulation, the teflon carriage for these bead pull measurements was guided by the straight edges of the electrodes. There is only one small area where the variation is slightly beyond the target of +/- 1%.

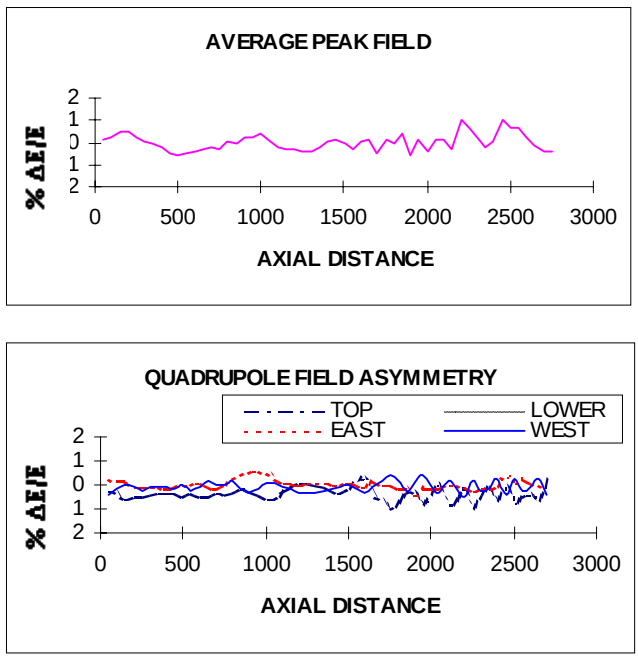

Figure3. Average peak field and quadrupole field asymmetry for the modulated electrodes.

3 FULL POWER TESTS

In preparation for full power tests the RFQ tank was baked out for three days at 60° C by uniformly mounting eighty-four 500W heaters on the tank walls, covered with a glass fibre blanket to contain the heat. At the same time 60 degree water was circulated through the structure cooling system. A base pressure of 1.4 *10-7 torr was achieved, which increased to 4.0*10-7 torr with full RF power applied. Although the bake-out temperature created a longitudinal growth of ~ 2.0 mm in the tank, the elasticity of the mounting system coped with this and the growth returned very close to zero at operating temperature. The RFQ tank went through several bake out cycles as we encountered a few water leaks. Initial tests were carried out at half voltage (36 kV) in order to do beam tests with N14 [6]. Following beam tests, 76 kV (2kV above design value) was achieved on the electrodes within four hours at the anticipated power level of 30 kW. The x-ray level during this time was 0.5 microseverts at 0.5m from the tank wall. We were able to maintain this condition for two hours before our first major amplifier overload occurred. Subsequently, we were never able to achieve the above voltage for the same power. A voltage versus power curve in figure 4 shows the power

requirement for three different days of operation, although it did remain at the lower power level for the beam tests with N28 [7]. The RFQ operated continuously for 15 hours at nominal voltage plus various runs for 5 and 10 hours before being interrupted by an amplifier trip. Automatic recovery from a high standing wave ratio is being incorporated in the RF controls to cut the RF drive rather than trip the amplifier.

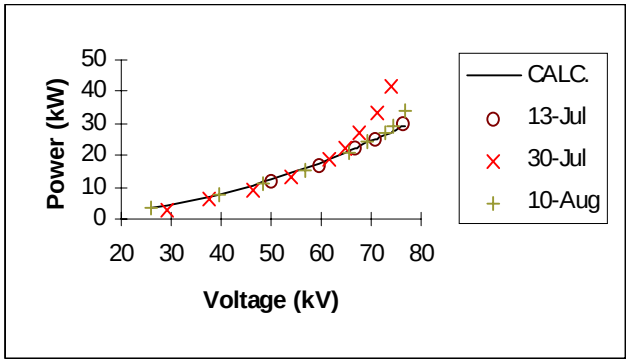

Figure 4. Voltage versus Power for the RFQ

When the lid was removed there was evidence of strong multipacting in the 7 cm gap between the RF shroud and the tank lid front wall as shown in figure 5. This could be the explanation for the additional power requirement at higher voltages. We plan to short out this gap to prevent multipacting in that region.

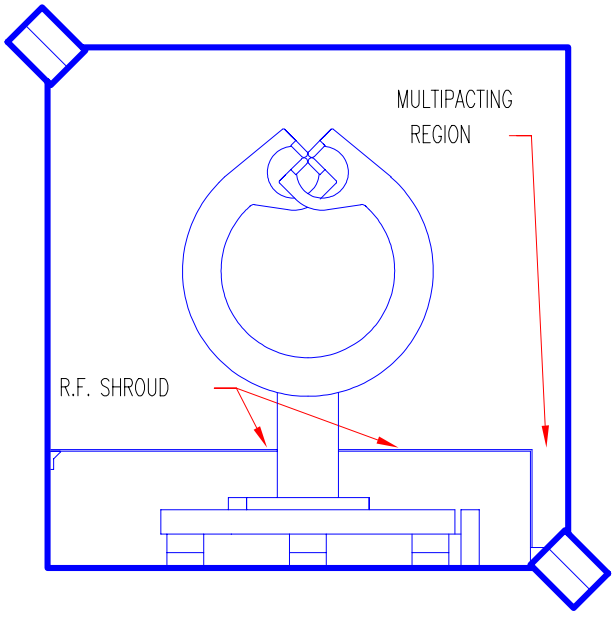

Figure 5. Cross-section schematic of RFQ tank and rings

4 CONCLUSION

Except for the increased power requirement, the RF behaved very well and agreed with the calculated predictions. The successful beam tests [7] in giving full agreement between expected and measured beam behavior (beam capture ~ 80%), indicate that the mechanical design, fabrication and alignment philosophy adopted was very successful. The remaining 12 rings will be installed in Spring 99 and commissioning of the RFQ in its final configuration by the end of 99.

5 ACKNOWLEDGMENT

We are especially grateful to Roland Roper (machine shop) who took on the responsibility of the fabrication and manufacturing details of rings, jigs and fixtures.
A special thanks to Bhalwinder Waraich for the mechanical assembly and installation of the rings, and to Peter Harmer for the organization and integration of the RFQ with all the ancillary systems.

M. E. Schulze, R. E. Shafer
General Atomics, Los Alamos, New Mexico 87544 USA

Abstract

A 1700 MeV, 100 mA proton linear accelerator is being designed for Accelerator Production of Tritium (APT). A beam expansion system is required to uniformly irradiate a 19 x 190 cm tritium production target. This paper describes a beam expansion system consisting of eight ferrite dipole magnets to raster the beam in the x- and y-planes and also describes the salient features of the design of the electronics that are unique to the expander. Eight Insulated Gate Bipolar Transistor (IGBT)-based modulators drive the raster magnets with triangular current waveforms that are synchronized using phase-locked loops (PLLs) and voltage controlled crystal oscillators (VCXOs). Fault detection circuitry shuts down the beam before the target can be damaged by a failure of the raster system. Test data are presented for the prototype system.

1 BACKGROUND

In the proposed raster-type beam expander, there will be four horizontal and four vertical raster magnets. They will be modulated so that the target is "painted" by the 1 x 2 cm proton beam in a pattern somewhat like the ones shown in Fig. 1. The pattern is achieved by modulating the vertical- and horizontal-axis magnets with triangular current waveforms at slightly different frequencies in the 500 to 600 Hz range [1]. The entire target is then irradiated in a period of approximately 20 ms.

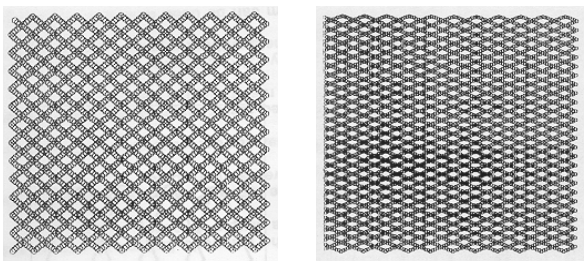

Figure 1: Sample patterns that are available by changing the ratio of the x- and y-plane rastering frequencies.

* Work supported by the DOE under contract DE-AC04-96AL89607.

An obvious requirement of using a rastered approach to beam expansion is that the beam must not be allowed to dwell on one spot of the target for very long (on the order of 0.5 ms) or else damage to the target could result. The prevention of common mode and single point failures has been a major design driver. The eight magnet systems are purposely designed to operate synchronously and independently, so that a failure of one system will not affect the operation of any other system, and therefore the beam will always be moved across the target (see Section 2.2). Fig. 2 shows the raster magnets as they fit into the high energy beam transport (HEBT) portion of the APT Linac.

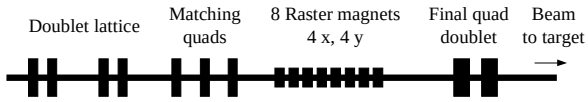

Figure 2: Raster magnets in HEBT

2 SYSTEM DESCRIPTION

The block diagram of the Raster Magnet System is shown in Fig. 3. The logical blocks of the system are the 1) Master Clock, 2) PLL/IGBT Gate Driver, 3) IGBT Modulator, 4) Raster Magnet and 5) Fault Detection Circuitry.

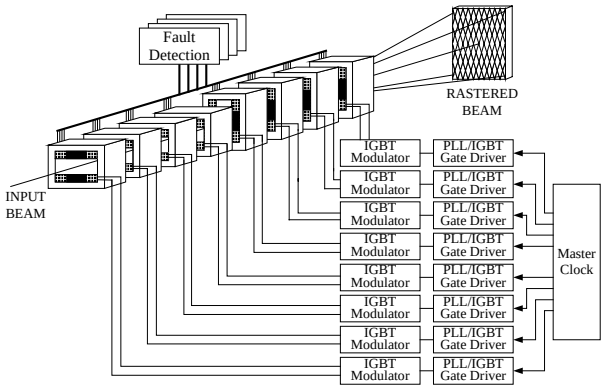

Figure 3: Raster system concept

2.1 Master Clock

The Master Clock produces two different frequencies, one for the four x-plane magnets and a second for the four y-plane magnets. The choice of frequencies is carefully made to avoid beat patterns. Important design issues of

the Master Clock are related to accurately splitting out a 1.024-MHz crystal-controlled master oscillator to two different "divide by N" circuits to drive the horizontal and vertical planes with a minimum amount of skew between the channels. The Master Clock includes on-card fault check circuitry that monitors the clocks to notify the user of a fault. The clock fault outputs are sent to four independent divisions in the Beam Enable circuitry to turn off the Linac beam before a raster system failure causes damage to the target.

2.2 PLL/IGBT Gate Driver

Each magnet gets its timing signal from the Master Clock described above. Each of the magnets has a PLL/IGBT Gate Driver that will, using a phase-locked loop, synchronize itself to the Master Clock, or else if the Master Clock fails, is able to produce its own clock so that the beam continues to be rastered onto the target. This design approach is used to preclude a common mode failure that might cause damage to the target blanket.

For this application a sequential type of phase detector, rather than an analog multiplier type, is used in each PLL to generate error signals for the VCXOs in each IGBT gate driver. The sequential phase detector results in modulator-to modulator phase errors less than about 50 ns at the rastering frequencies. The phase detector then outputs the error signal to a VCXO that varies the frequency accordingly. If the Master Clock signal fails, the VCXOs of each modulator will maintain a clock signal, although the modulators will no longer be synchronized. However, the drift is slow, allowing ample time for the fault detection circuitry to detect the problem and take action.

The PLL/IGBT Gate Driver, as the name implies, generates properly timed signals at sufficient power to directly drive the gates of the IGBTs of the modulator. Correct timing also requires that the signals sent to the IGBTs include some deadtime to ensure that two IGBTs in series are never turned on at the same time, thus avoiding shoot-through failures.

2.3 IGBT Modulator

The IGBT modulator consists of an ac/dc converter, a capacitor bank, and an IGBT H-bridge (Fig. 4). Each modulator will be powered by uninterruptible power to prevent a common mode failure due to the loss of ac input voltage. The ac/dc converter will charge up and maintain a constant voltage on the capacitor bank. Charge is drawn into and out of the capacitor bank by the H-bridge. The value of the dc output voltage of the power supply is dictated by system level requirements in that the dc voltage represents the rate of change of the current in the raster magnet inductance (V = L*dI/dt).

The dc voltage values are different for the x-axis magnets and y-axis magnets because the required peak deflections (i.e. peak B-field) differ. Final beam expansion and sizing is actually controlled by two quadrupole magnets located downstream of the raster magnets in the HEBT beamline as shown in Fig. 2. The dc capacitor bank exchanges reactive power with the magnet on a 1000 Hz timescale (twice per cycle). The IGBT H-Bridge circuit drives the raster magnets with a voltage square wave, resulting in a triangular current waveform. The timing of the IGBT gate circuit is controlled by the PLL/IGBT Gate Driver already mentioned.

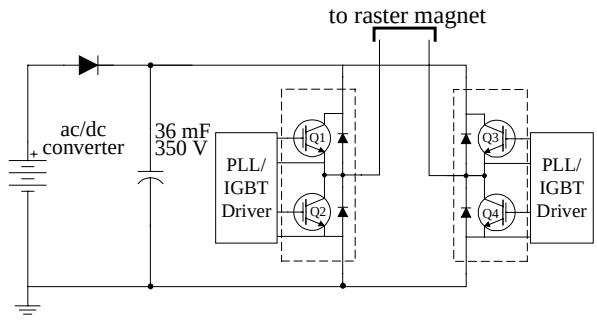

Figure 4: IGBT Modulator

The choice of IGBTs as the switches for the H-bridge was made on the basis of the operating frequency of 500 Hz and the low losses that these devices exhibit, in contrast to the choice of MOSFET switches in the system described in [2]. Freewheeling diodes are included across each switch to return the stored energy in the inductive load to the capacitor bank each half cycle, which is whenever the voltage applied to the load changes polarity. Because of this exchange of stored energy or reactive power between the capacitors and the magnet, the applied dc real power to maintain charge on the 36 mF capacitor bank is only 4% of the peak reactive power in the load, making this a very efficient system.

2.4 Fault Detection Circuit

The beam can not be allowed to stop sweeping across the target. The Fault Detection Circuit is the watchdog circuitry consisting of magnetic field and current sensors and the associated processing circuits that will check to be sure no serious failure modes exist in the Raster System. If a failure is detected, the Fault Detection Circuit removes the beam enable from the Linac, thus shutting down the beam until repairs can be made.

There are two B-dot pickup coils wound in each magnet that will have a voltage induced in them when there is a change in the magnetic field (dB/dt). Since the field is a triangular waveform, this induced voltage is essentially a square wave that can be used to detect a fault in either the magnet or the magnet drive. There are also two Rogowski current loops per magnet that will be used to measure the derivative of the triangular current. Each of these four sensors removes the beam enable signal from one of the four divisions of the Fault Detection Circuitry if it detects a fault. The beam is shut off if two or more of the four beam enable signals are missing.

2.5 Raster Magnet

The raster magnets are ferrite, 30-cm long with an 8-cm square aperture. A magnet cross-section is shown in Fig. 5. A prototype magnet has been built and tested which uses Ceramic Magnetics CMD5005 Hi-mu, low loss ferrite rather than the air core of [2]. This is a nickel-zinc material with a permeability of 4500 * μ_0 H/m at 1500 Gauss. The inductance with two 20-turn coils is 1.1 mH which produces peak fields of 640 Gauss at 100 A. From a radiation hardness standpoint, there is experience with ferrite cores as kicker magnets at Brookhaven National Laboratory that show that the ferrite material will outlast the coils.

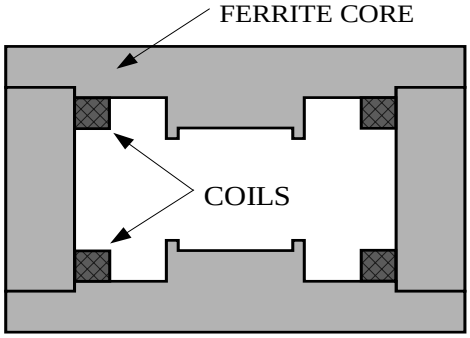

Figure 5: Raster magnet cross section

3 TEST RESULTS

A raster modulator and magnet have been successfully tested at LANL. A photo of the modulator and the resulting triangular current is shown in Fig. 6. The modulator is designed to operate at voltages up to 300 V and 1000 Hz. For this magnet with an inductance of approximately 1.1 mH, when the voltage is set to 243 V, peak operating current is +/- 100 A (59 A rms).

Figure 6: Modulator and test waveform
(+/-100 A, 500 Hz)

The output power capability of the power supply is based on the predicted losses in the load, which is the sum of the losses in the IGBT H-bridge, the cable, and losses in the magnet which include the magnet cable resistance and the magnet eddy current losses. At 243 V and 100 A peak current, the output power is essentially reactive and equal to 14,030 VARs. The measured input power (real) is only 925 Watts. With approximately 1000 joules stored in the 36 mF capacitor bank, the magnet field drops to the 1/e point in about 2 seconds if the dc charging circuit is turned off. Fig. 7 shows the raster waveforms as measured on an oscilloscope.

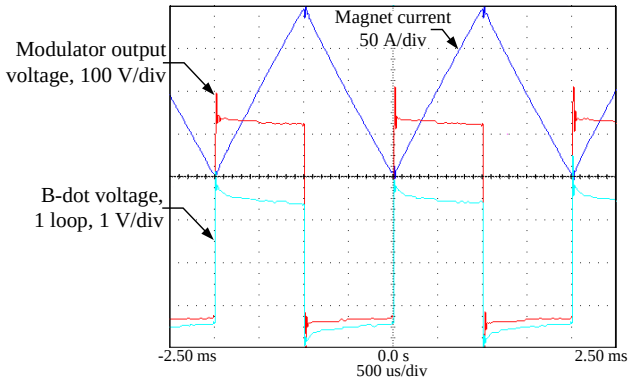

Figure 7: Measured waveforms of modulator

The spikes visible in the modulator voltage are caused by the stray inductances being switched by the IGBTs in the modulator. The peaking that is seen on the B-dot waveform, on the otherhand, has two distinguishable features:

- An overall L/R droop due to the resistance of the circuit, and
- A short overshoot of about 10% at the beginning, with a time constant of about 100 microsec. This is due to eddy currents in the coil that essentially shield part of the volume of the ferrite magnet. The voltage overshoot is thereby caused because the initial inductance is only 90% of its dc value.

4 CONCLUSIONS

A raster magnet system that is capable of safely and reliably expanding a proton beam onto the APT target has been developed and tested. Test data taken on a prototype indicate that the required ac power is about 4% of the peak reactive power in the raster magnet. The full-scale design is robust due to the application of redundancy as well as the use of independent fault detection circuitry that monitors the operation of the raster system. Based on the positive results of the prototype test, a complete system of eight magnets, modulators and fault detect circuits is currently being fabricated for full system evaluation and testing.

LOW TO HIGH ENERGY BEAMSTOPS FOR APT

D. Doll, T. Van Hagan, K. Redler, J. Tooker, A. Baxter, M. Fikani - General Atomics, San Diego CA
D. Schneider, F. Spinos - Los Alamos National Laboratory, Los Alamos, NM
W. Funk – Westinghouse Savannah River Site, Aiken, SC

Abstract

Beamstops are required for commissioning and operating linear accelerators. The family of beamstops currently being developed for the DOE-sponsored Accelerator Production of Tritium (APT) program is addressed. The operational range encompasses proton energies of 6.7 MeV at the end of the radio-frequency quadrupole RFQ to 1.7 GeV at the target/blanket, and both pulsed and cw operating modes. An additional beamstop needed on a companion test facility to validate ion injector performance has been built and operated. This was the first of the series of cw beamstops; the second is under construction and will be operational by the end of 1998. Particle stopping distance and duty factor drive the size and heat transfer capacity of these beamstops; the need for low neutron production and activation potential drives the material selection. At energies above 6.7 MeV, the preferred beamstop material is graphite with aluminum the choice for structures and helium the choice for coolant. Boronated water is the preferred shielding below about 35 MeV, but is less suitable at higher energies because of the creation of Be-7. The evolution of the low-energy demonstration accelerator (LEDA) beamstops to 11 MeV and descriptions of APT beamstops are presented with performance ramifications and the status of the hardware and testing.

1 BACKGROUND

A linear accelerator operating cw at 0.100 A has been proposed for producing tritium to replace the nation's stock-pile as it continually dwindles due to natural decay. The APT program addresses this need and is being implemented by Burns and Roe, General Atomics (GA), and Los Alamos National Laboratory (LANL) in a facility to be located at the Savannah River Site (SRS). In support of this program, an Engineering Design and Development (ED&D) program is on-going simultaneously at LANL. The baseline APT facility will produce tritium at a rate of 3.0 kg/year. A two-phase approach now under consideration would accommodate an intermediate stage whereby a 1.5 kg/year production rate could be achieved and be upgradable with minimal schedule impact. The linac uses a rf driven ion injector that feeds into the RFQ at 75 kV. The RFQ accelerates the beam to 6.7 MeV; this is followed in ascending energy levels by a CCDTL (96 MeV), CCL (211 MeV), and high energy cryo-cooled (HE) linac (1700 MeV). In the two-phase program, the first-phase facility would have the proton beam turned 90^0 at 1032 MeV and directed to the target/blanket switch-yard instead of going to 1700 MeV, turning 180^0, and returning to the same switch-yard.

Beamstops are being designed and built to accommodate each stage of the linac assembly as well as on-line tune-up operation. This began with the ED&D [1] program which requires three beamtops, two of which have been built and operated; a third is being designed. This paper gives an overview of all these beamstops outlining the key requirements, basic approach to the designs, and a summary of the work completed.

2 REQUIREMENTS AND KEY CRITERIA

The obvious prime requirement for any beamstop is to stop the accelerated particles. Not so obvious is the need to do so in a manner that addresses both the linac operation and the need to minimize the effects of nuclear interactions produced. Above a few MeV, protons will activate a target as well as produce neutrons that escape the target and activate the surrounding materials. Since proton energies up to 1700 MeV will be produced, the APT beamstops will see the full range of nuclear reactions well into the spallation regime. The object is to select the solid target material that produces the fewest neutrons. A comparison of three candidates is shown in Fig. 1. Carbon is the clear winner throughout all energies. In the same way, the vacuum vessel and structures are aluminum because of its low production of long half-life isotopes; helium is the coolant because it is transparent to the neutrons.

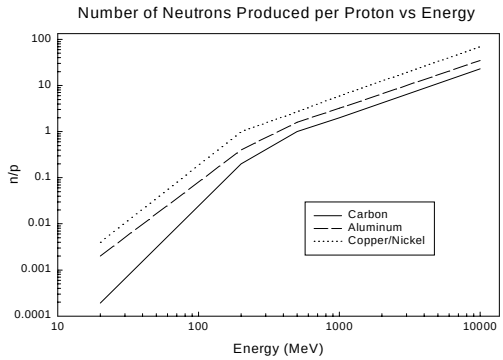

Fig. 1 Comparison of beam absorber materials

Spallation reactions with carbon produce a wide range of daughter isotopes but only Be-7 (0.48 MeV gamma, 53 day half-life) seriously affects shut-down access for

maintenance or replacement. The cross section for this reaction is shown in Fig. 2. The low and intermediate energy beamstops will not accumulate much Be-7 at 0.1 % duty unless long operating times (>>6 months) are used in linac commissioning. The 1700 MeV beamstop will build up 5.4 Curies (gamma-producing) over the projected 1000 initial hours of operation at 2% power. Man-access for repair or replacement will be affected.

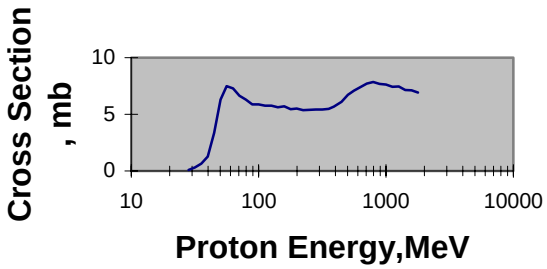

Fig. 2 Cross section for $^{12}C(p,n)^{7}Be$ reaction rises sharply above 32 MeV.

As the proton beam enters the graphite, it will penetrate as far as the initial energy will carry it. This stopping distance and the concomitant power deposition are the remaining key factors in the beamstop design. At energies up to 20 MeV, the heat deposition is essentially on the surface (2.75 mm); above this energy, the power is deposited into an ever increasing volume and depth until at 1700 MeV, 4.6 m of 1.8 g/cm^3 graphite is required to stop the beam. Fig. 3 shows the radial and axial power distributions for a 1 σ, 2.66 cm beam at 1700 MeV. This is used to design the array of cooling passages in the graphite target.

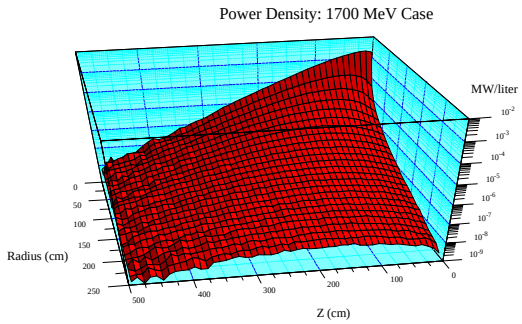

Fig. 3 Power density in graphite from a 1 σ = 2.66 cm 1700 MeV proton beam

Beamstop shielding requirements vary widely over the linac, driven by the effects of increasing proton energy. The neutron spectrum produced comes from three sources: 1) cascade neutrons that are produced from proton energies >20 MeV and can be as energetic as the incoming proton, 2) evaporation neutrons whose energies are <5 MeV, and 3) thermal neutrons arising from degradation of the cascade and evaporation neutrons. While the evaporation neutrons have an isotropic angular distribution, the cascade neutrons are forward scattered and become more so as the proton energy increases. Yields (n/p) range from $2x10^{-4}$ at 20 MeV to 2 at 1700 MeV with mostly evaporation neutrons at low energy and about half-and-half at high energy. One meter of water or concrete (4π) is adequate for neutron shielding for proton energies up to 20 MeV; it is also adequate at higher proton energy transverse to and upstream of the beam. Above 150 MeV, 6-8 m of concrete are required on the down-stream end to capture the high energy spallation neutrons. The latter may be made thinner by substituting an inner layer (20–30 cm) of steel. Unfortunately, this layer would become quite activated making it a solution of last resort.

3 COMMISSIONING BEAMSTOPS

The preliminary linac commissioning plan [2] calls for five beamstops. The first three will be used for commissioning and stored in shielded alcoves off the main tunnel after the linac has been built and tested to that point, i.e. 6.7 – 20, 211, and 470 MeV. The last two beamstops located at the end of the linac (1700 MeV. 0.1 %) and adjacent to the target/blanket (1700 MeV, 2%) are permanently integrated into the linac facility. The graphite targets of the three commissioning beamstops are cooled by thermal radiation to the respective vacuum vessels, thus eliminating the need for a window. Although larger, the 0.1% HE beamstop at the end of the linac is cooled similarly. The 2% 1700 MeV beamstop requires direct cooling of the graphite with helium and a window also cooled with helium.

The low energy beamstop will be used to commission the RFQ and as many CCDTL modules as practicable limited primarily by the increased forward scattered cascade neutrons (Fig. 4). The graphite beam target is located in the center of the shield tank and radiates the heat to the cylindrical housing which is in turn cooled by natural convection of the shield water. Air convection on the outside of the tank cools the shield water, resulting in completely passive thermal management.

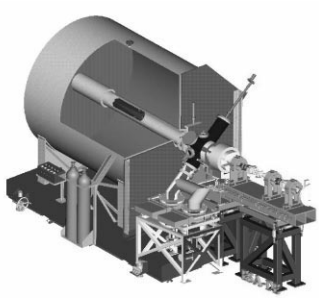

Fig. 4 Low energy beamstop to be used for commissioning at several energies starting at the RFQ

The preferred coolant is helium since it does not activate, has good heat transfer properties, and can heat-exchange to conventional cooling systems. The arrangement for the 470 and 1700 MeV (0.1%) beamstops will be designed similar to the low energy beamstop except elongated to accommodate the increased proton range and the vessel is cooled with helium. In all beamstops above 200 MeV, the shield will be concrete about 1 to 2 m thick radially to capture evaporation neutrons and 6 to 8 m thick downstream to stop the cascade neutrons.

The high energy beamstop is the final tune-up target before the beam is switched into the target/blanket. It is designed to absorb 2% of the 1700 MeV beam, or 3.5 MW. The graphite is arranged as vertical hexagonal blocks with coolant holes running transverse to the beam and spaced to keep the temperature as uniform as practicable. Helium is circulated through the blocks starting at the bottom (up-flow) with a large plenum that also acts as a support and terminating at the top where orifices are used to balance the flow through the differently heated zones. The heat is exchanged at a remote location with water to a conventional facility cooling system. The window separating the vacuum from the pressurized helium is aluminum, used to minimize the long-term activation products. It is cooled with helium through holes running transverse to the beam. The concrete shielding is similar to the intermediate energy beamstops except that special provisions are made to replace the window remotely should that become necessary.

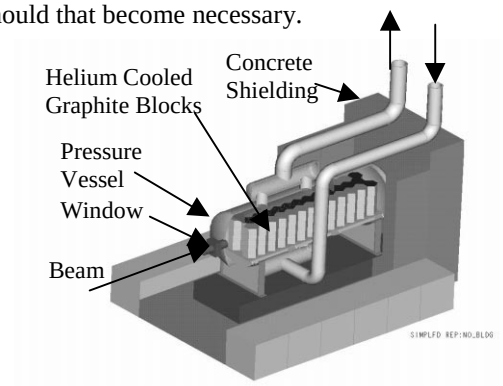

Fig. 5 High energy beamstop – 1700 MeV

4 ED&D BEAMSTOPS

Two beamstops [3] have been built in support of the ED&D program at LANL. Both use the same basic design approach to stopping the proton beam and dissipating the thermal energy, which is to use concentric thin-wall ogive (pointed arch) shapes with high velocity water flowing in the gap between them. The first one was built of copper and operated successfully in the Chalk River Injector Test Stand (CRITS) facility (Fig. 6 upper left) which reached 0.085 A at 1.2 MeV, the highest power cw beam yet achieved. The second was fabricated from electroformed nickel, chosen over copper because of the lower n/p at 6.7 MeV. This ogive is integrated into a cartridge that fits into a central chamber in an aluminum tank filled with boric acid saturated water which acts as a neutron and decay gamma shield (Fig. 6, lower right).

5 CONCLUSIONS

The development and commissioning plans for the APT linac have created unique requirements for the beamstops. These have been met with an array of designs that have taken advantage of graphite as the absorber, aluminum for structures, and helium for coolant. These materials minimize the production of neutrons and activation products which reduces the effects on worker safety and the need for remote handling. These designs give the greatest flexibility to the facility design and commissioning activities.

LOW-STORED-ENERGY 100-kV REGULATOR FOR ION SOURCES AT LANSCE *

E. G. Jacobson, R. L. Haffner, W. B. Ingalls, B. J. Meyer, J. E. Stelzer
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

At Los Alamos Neutron Science Center (LANSCE), as elsewhere, it is desirable to minimize the available stored electrical energy for the H^- ion sources to minimize accelerating column damage caused by uncontrolled energy release during arc-downs. The stored energy includes, in addition to the charge in the power supply output capacitance, the charge on the electronics racks. The racks are supported and insulated from ground by PVC pipe and have a capacitance to ground of approximately 900 pf. In 1988 LANSCE personnel designed a high-voltage current source using a low-stored-energy power supply and planar triode with the goal of eliminating uncontrolled release of charge stored in the power supply. Construction and testing were performed intermittently as resources permitted until 1993. When work on the Short-Pulse Spallation Source (SPSS) [1] started on the LANSCE Ion Source Test Stand (ISTS), it was recognized that a higher current power supply would be needed and work resumed on the regulator circuitry. A 120-kV power supply having low output capacitance and a planar triode have been used to supply 40 mA, 120-Hz, 12% duty-factor current for the ISTS beam. The triode's cathode current is controlled by circuitry operating both at power-supply voltage level and at ground level via a fiber optic link. Voltage droop is approximately 600 V during the 1 ms beam pulse. We present the status of the regulator and its special challenges.

1 BACKGROUND

Requirements for a low-stored-energy power source supplying 50 mA at 100 kV at 12% duty were defined a decade ago. A 120-kV, 25 mA power supply was specified and acquired. The power supply's output capacitance was to be charged during the 7.3 s periods that beam was not being extracted from the source, and its output voltage was to decrease during the 1 ms periods when H^- ions were being extracted. The tube would be controlled, if possible, such that plate voltage, relative to ground, would decrease 1 V for each 1 mA of increase in load during a beam pulse. One goal was to have the electronic circuitry, including the fiber optic components, have a frequency response of 1 MHz in order to minimize droop at the beginning of a pulse. Circuitry was also designed to turn the tube off quickly in case of an arc to ground at the output. Several operational amplifier configurations were tried, and by the spring of 1993, the electronics response was flat out to approximately 300 kHz, the components destined for oil immersion had run in air with an output of 7.5 kV for an input voltage of 10 kV, and preparations were made to test the regulator with a pulsed load.

When the supply and regulator were tested in preparation for use on the ISTS at LANSCE, the only detectable component failure resulting from the 4 years of storage was physical damage to one optical fiber conductor. The fiber optic transmitters were relocated from the ground level electronic chassis to the top of the oil tank to prevent recurrence. Approximately 5 m of optical fiber were replaced by copper. No performance degradation was detected when duplicating pre-1993 measurements in the fall of 1997.

The regulator and power supply were placed in service on the ISTS late in 1997 and they operated satisfactorily with a pulsed beam current (H^- plus electrons) up to 40 mA with droop of 600 V (15 V per mA). At current above 40 mA, droop was no longer linear due to operation of the current-limiting feature of the circuitry associated with the field-effect transistors (FETs). At some total beam current level above 60 mA, probably over 100 mA, operation of the power supply became erratic, and then the power supply failed.

All components of the regulator have been subjected to the transients associated with ion source arc-downs on the test stand and there have been no failures. The tube has an amplification factor of 1300 and with 120 kV across it, it is cut off with a grid-to-cathode voltage of –110 V, more than a factor of 3 below the rated drain-to-source voltage of the FETs. The high gain of the tube permits the FET circuitry to limit plate current during normal operation, including arcing to ground (through the source or otherwise) of the output.

2 SIMPLIFIED REGULATOR DESCRIPTION

A 0 to 10 V reference is supplied to the control circuitry located at ground and compared with the feedback voltage developed by the compensated divider Fig.1. The magnitude of the signal provided to the fiber optic transmitter is varied as necessary to make the magnitude of the feedback voltage equal to the reference. Tube cathode current is controlled by varying current in the

* Work supported by the U. S. Department of Energy

FET. For plate-to-cathode voltage of greater than 3 kV and plate current of less than 150 mA, grid-to-cathode voltage is negative and grid current is zero. Within those constraints, plate current is equal to FET current.

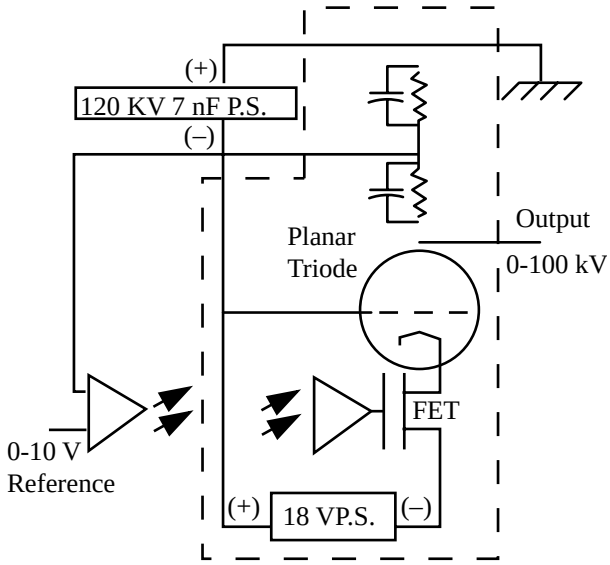

Figure 1: Simplified circuit diagram. Components represented by symbols inside the dotted line are in an oil-filled tank. The double arrows represent fiber optic transmission and detection.

3 COMPONENTS AT GROUND LEVEL

Reference to the summing junction of the regulator amplifier is provided by a 10.000 V, +/- 2.5 mV precision reference chip and a 10-turn potentiometer. The regulator amplifier is followed by three stages of amplification of gain seven each. The operational amplifiers used for these stages have a gain-bandwidth product of no less than 45 MHz. They are followed by a buffer amp of gain 0.9 which drives the fiber optic transmitter. The transmitter is mounted on the top of the oil tank.

4 COMPONENTS IN THE OIL TANK

Devices located in the tank filled with electrical insulating oil are mounted on a plate that is supported by rods connected to the removable tank top. All components are accessible when the tank top is lifted. A 120:24 V isolation transformer rated 120 kVDC and the compensated voltage divider are mounted on the plate. Also attached to the plate is a phenolic support structure on which is mounted:

- A printed circuit card holding the fiber optic receiver and three stages of amplification, FETs which provide on-off switching and cathode current control, and 18- and 23-V voltage regulators
- A 24:6 V filament transformer
- A planar triode and heat sink
- Light-emitting diodes that indicate circuit components' status outside the tank via light fibers

5 FIBER OPTIC LINKS

The printed circuit board in the oil tank has two fiber optic inputs from ground level. The analog control signal originates in the regulator module. A digital on-off signal comes from a transmitter that receives its input from an arc-down recovery card module that has several permissive inputs. The FET depicted in Figure 1 represents both the FET associated with the analog signal and the FET associated with the arc-down recovery card. Figure 2, though still simplified, is an expansion of the FET circuitry.

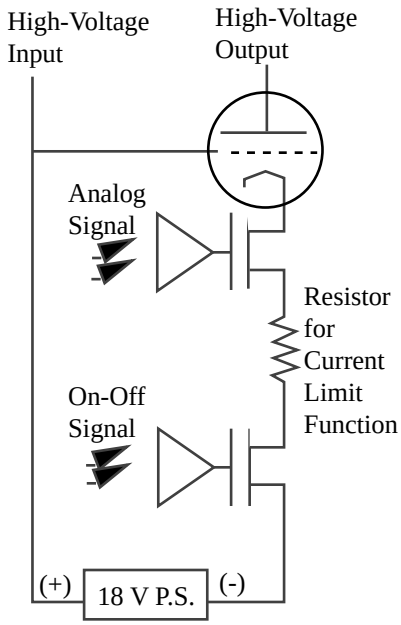

Figure 2: Simplified circuit diagram. Analog amplifier represents a detector diode and three stages of amplification. On-off amplifier represents a detector diode and a comparator.

The output of a comparator on the card in oil ensures that the FET associated with the permissive signal from the arc-down recovery card is either fully enabled or disabled. When enabled (effectively a short circuit), control of current in the FETs, and consequently the planar triode, is provided by the FET whose gate signal is a function of the output of the ground-level regulator circuitry.

6 CONTROL RESPONSE

The open-loop gain, from the reference input of the regulator to the gate of the controlling FET, is approximately 1600. Time to peak following an input step small enough not to cause any amplifier saturation,

2.5 mV through 1 kΩ into the summing junction, is approximately 850 ns. Time to reach steady-state is approximately 2.25 μs. Because of the limitations of the compensated divider, measurement of closed-loop response has been difficult due to the magnitude of the noise on the divider signal. Use of a commercial divider having a half-power frequency response of 5.7 MHz has been used to observe what we think is a truer representation of voltage applied to the ion source on the ISTS. The regulator has supplied 40 mA, 1 ms pulses at 120 Hz with a droop from 80 kV of 600 V.

7 COMPENSATED DIVIDER

The divider which generates the voltage feedback signal consists of three 300 pF vacuum capacitors and one 1 μF polystyrene capacitor in series that are in parallel with seventy-eight 1.283 MΩ resistors and one 10,001 Ω resistor in series. The 1.283 MΩ resistors are wound spirally around a phenolic tube that encloses the 300 pF capacitors. The first resonance of the vacuum capacitors, measured individually, in air, occurs at 33 MHz. The first resonance for the polystyrene unit occurs between 0.5 and 0.6 MHz.

The change in effective capacitance when the assembly is submerged in oil is not known. However, total capacitance of the three vacuum capacitors before submersion in 1990 was 116 pF. After the resistor, capacitors, and phenolic tube had been submerged in oil for 4 years, measured total capacitance was 256 pF. Measured individually, the increases were 70 to 80 pF per resistor-capacitor section. The effects on regulator performance of the variation from ideal have not been determined.

8 FUTURE WORK AND CONCERNS

The initial requirement of supplying a 50-mA pulsed load has changed to 100 mA and may be increased to 200 mA or more. A nonstandard power supply capable of 200 mA at 12% duty has been ordered. It is possible to add power supplies in parallel.

The manufacturer's experience with the planar triode indicates that, as operated in this application, it is capable of peak current of 350 mA without exceeding the anode dissipation capability of the tube or the tube's emission capability. Due to consequences of consolidations within the vacuum tube industry, tube procurement lead time has been long.

Considerable time was spent before 1992 in the effort to build a good high-frequency voltage divider. The original goal for frequency response had been 1 MHz for the electronics and 10 MHz for the divider. Although operation using the divider has been satisfactory, the signal it provides is noisy and needs to be improved. A chip capacitor whose first resonance is at 1.1 MHz is a possible replacement for the polystyrene capacitor if the chip's relatively inferior stability would not be a problem. Although short, 4 cm, the connection between the plate, made on the heat sink bolted to the triode, and the top of the divider is inductive, and the effect of varying the length has been investigated only briefly.

9 CONCLUSIONS

Regulation of -80 kV using a planar triode and a low-stored-energy power supply whose output droops from –120 kV during the time charge is being extracted from an ion source on the ISTS has been demonstrated. The capacity of the high-voltage supply has been exceeded with no apparent damage to the regulator components.

With an adequate power supply and modifications to the FET current limit circuitry, which floats at high voltage, it is anticipated that up to 350 mA at 12% duty could be supplied by the regulator using the present planar triode.

Future work will include investigation of the response time of on-off FET circuitry, reduction of compensated divider noise, determination of the cause(s) of the higher-than-designed-for droop, and testing with the new power supply.

ACKNOWLEDGMENT

Andrew A. Browman was the initial designer of the regulator, provided solutions to circuit limitations as they became apparent as portions were constructed and tested, and has continued to provide valuable suggestions when requested.

Abstract

Two vacuum systems were designed and built for the RFQ (Radio Frequency Quadrupole) cavity in the APT/LEDA (Low Energy Demonstration Accelerator) linac. The gas load from the proton beam required very high hydrogen pump speed and capacity. The gas load from the high power RF windows also required very high hydrogen pump speed for the RF window vacuum system. Cryopumps were chosen for the RFQ vacuum system and ST185 sintered non-evaporable getter (NEG) cartridges were chosen for the RF window vacuum system. Hydrogen pump speed and capacity measurements were carried out for a commercial cryopump and a NEG pump. This paper will discuss the test procedures and the results of the measurements.

1 INTRODUCTION

Cryopumps and NEGs are known for their high hydrogen pumping speed and capacity and are used widely in accelerators applications. Cryopumps were selected for the RFQ cavity due to the very high hydrogen gas load from the proton beam loss. A cost analysis showed that for the same cost, cryopumps could provide twice the pumping speed compared with turbomolecular pumps. NEGs were selected for the RF windows because in addition to the high hydrogen pumping speed, they are relatively small in size and lightweight. Size and weight were important requirements in the RF window vacuum system since space in the waveguide area was very limited.

The Ebara ICP200 cryopump was selected for the RFQ vacuum system because of its reasonable cost, very large hydrogen capacity and its flexible interface for remote operation. The SAES CapaciTorr B1300 NEG cartridge pump utilizing the sintered ST185 blades was selected for the RF window vacuum system. The manufacturer claims that the sintered ST185 blades has increased pump speed and capacity at room temperature over other types of NEGs.

Since LEDA is a demonstration facility for APT, beam availability must be high to prove that APT production goals can be met. Therefore, it was important to verify the performance of the cryopumps and NEGs to ensure they would support the operational requirements for LEDA.

2 TEST SETUP

The pump speed and capacity for the cryopump and the NEG pump were measured using test domes built to American Vacuum Society Standard 4.1 [1]. The pumps were tested using only hydrogen, since it is the primary gas load in APT. A schematic of the test setup is shown in Figure 1.

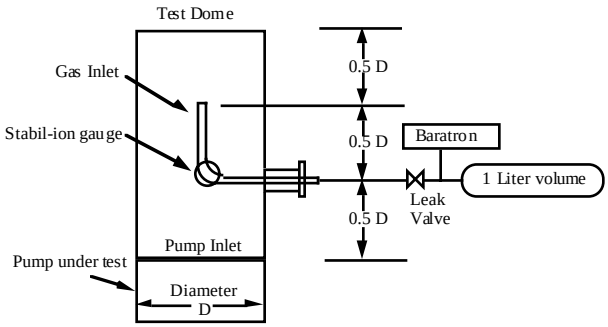

Figure 1. Test setup for pump speed measurement.

The pressure in the test dome was measured using Granville-Phillips 370 Stabil-ion gauges. These gauges were supplied with individual calibration data on memory modules that were downloaded into their controller. Granville-Phillip claims the measurement uncertainty is 3%. The gauges were calibrated at the factory for Nitrogen. All measurements were taken using the factory calibration and then corrected for hydrogen.

Gas flow into the test dome was established by charging a known volume to a set pressure, then measuring the change in pressure with respect to time. The gas flow into the test system was controlled by a Varian variable leak valve. The pressure in the known volume was measured using an MKS Baratron. The Baratron is a capacitance manometer with an accuracy of 0.5%.

The measurement of pump speed was similar to the flowmeter method as outlined in AVS Standard 4.1. However, this method varies from AVS Standard 4.1 in that the flow rate drops off as the pressure in the known volume drops. The LabView data acquisition system

*Work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract W-7405-Eng-48

measures the pressure change in the known volume via the Baratron and the vacuum pressure via the Stabil-ion gauge at prescribed time intervals. For a given short time interval, we assume that the flow rate is constant. The pump speed can then be calculated using the equation $S = Q/(P - P_0)$ where the throughput Q is the change in pressure in the known volume during the sample time interval and P is the Stabil-ion gauge pressure in the test dome. P_0 is the base pressure in the test dome before the test gas is introduced.

For the pump speed measurements, a certified 1 liter volume was used as the known volume. By substituting the 1 liter volume with a larger volume and changing the Baratron to a higher range we used the same LabView system to measure pump capacity. LabView then calculated the total Torr-Liters of gas sorbed versus pump speed.

3 RESULTS AND DISCUSSION

Pump speed and capacity were measured for both the cryopump and the NEG. LabView recorded a timestamp, pressure in the test dome, and pressure of the test gas in the 1 liter volume.

3.1 Cryopump Data

The cryopump reached a base pressure of 1.78×10^{-10} Torr in the test dome. The pump speed was measured at over 2700 liters/sec. The pump speed test was repeated 5 times after the pump was conditioned as stated in the AVS Standard 4.1. (Pump Conditioning = pump speed x 0.03 Torr-liters. Using the manufacturer's specification of 2200 liters per second [2], the pump was conditioned after 66 Torr-liters.) See Figure 2 for a typical plot of cryopump pump speed versus sorption. The measurement shows that the manufacturer's specification is very conservative.

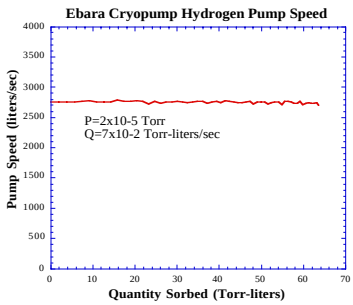

Figure 2. Measured Cryopump Pump Speed Versus Sorption.

The hydrogen capacity of the cryopump was measured to be over 30 standard liters at an operating pressure of 1×10^{-4} (H_2) Torr and a throughput of 2×10^{-1} Torr-liters/sec. This flow rate is over two orders of magnitude higher than the predicted gas load in APT/LEDA. Figure 3 shows the sorption plot at the high flow rate. At this very high flow rate the test took 33 hours.

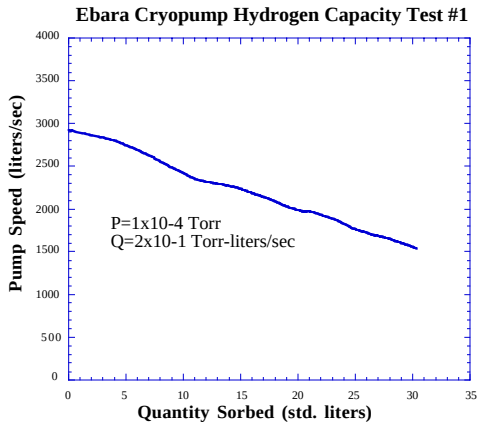

Figure 3. Measured Cryopump Capacity at High Flow.

The cryopump was then regenerated and after regeneration the cryopump reached a base pressure of 1.90×10^{-10} Torr. The hydrogen capacity of the cryopump was re-measured and found to be 32 standard liters at an operating pressure of 1.0×10^{-5} (H_2) Torr and a throughput of 2.0×10^{-2} Torr-liters/sec. This flow rate was still at least an order of magnitude higher than the predicted gas load in APT/LEDA. Figure 4 show the sorption plot at the lower flow rate. At this flow rate the test took 12.8 days and the results agreed very well with the previous test at the high flow rate.

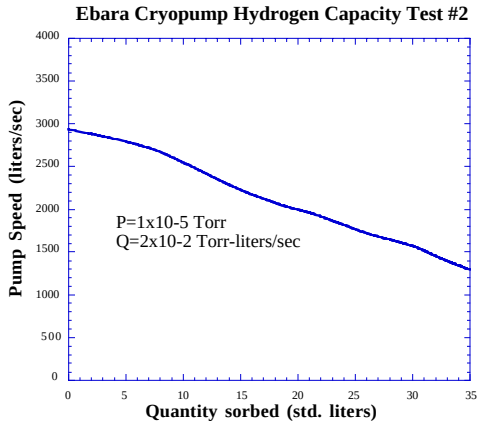

Figure 4. Measured Capacity at the Lower Flow Rate.

3.2 NEG Data

The ST185 NEG, like all NEG pumps, does not pump inert gases, therefore a small turbo pump was added to the system. The turbo was a Varian V70LP and has a specified hydrogen pump speed of 45 liters/sec. The hydrogen pump speed was measured in the test dome before the NEG cartridge was inserted and found to be 51 liters/sec.

The NEG cartridge pump was mounted in the optional 6" diameter body rather than the standard 4" body. According to SAES, this would increase pump speed from about 700 liters/sec to 1200 liters/sec [3].

It was observed during installation of the cartridge pump in its heater assembly that the thermocouple used by the NEG regeneration controller to control the heater was mounted very near the heater element and free standing. There was concern that the actual temperature of the NEG pump would not be what the thermocouple was reading since the ST185 blades are mounted radially outward and the view factor of the blade to the heater is small. It was felt that a thermodynamic analysis was not in the scope of this study, but it would have been interesting to mount thermocouples directly on NEG blades and measure the temperature gradient. Pump speeds could probably be further optimized by knowing this temperature gradient.

After the initial activation recommended by SAES of 500 C for 45 minutes, several pump speed measurements were made, followed by a regeneration. It was found that by increasing the regeneration to an indicated 550 C for 90 minutes produced higher pumping speeds. This agrees with tests performed by others [4]. Subtracting the pump speed of the turbo, the average speed of the NEG was 1380 liters/sec. Figure 5 shows a typical sorption plot for the NEG.

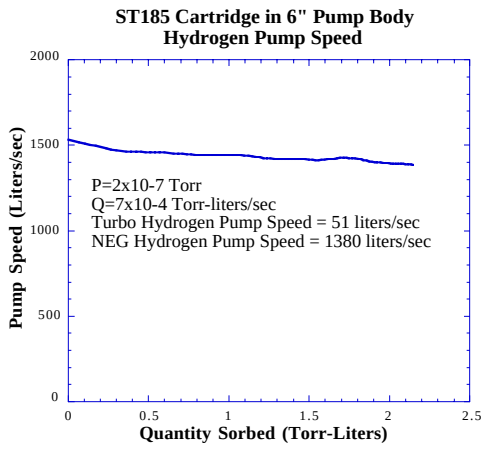

Figure 5. Measured Speed of ST185 Cartridge Pump.

A test of the hydrogen capacity of the NEG pump was performed after a regeneration. The objective of this test was to show that the NEG pump was capable of sorbing one standard liter of hydrogen at the rated pump speed. One standard liter was an arbitrary value that represents several months of normal RF window operation. As the data shows in Figure 6, the pump speed was 1150 liters/sec after 700 Torr-liters.

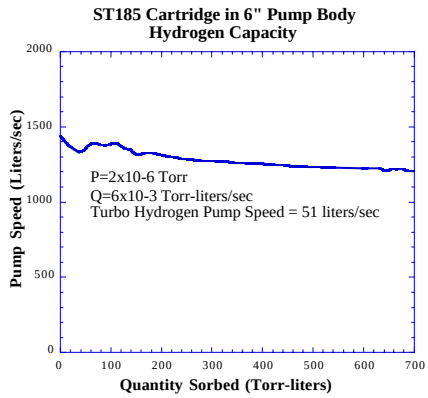

Figure 6. Measured Capacity of ST185 Cartridge Pump.

4 SUMMARY

We have measured the pump speed and capacity of the cryopump and NEG that are proposed for use in the RFQ vacuum system for APT/LEDA. The results verify the manufacturer's specifications and gives us confidence that these commercial pumps will provide the necessary vacuum performance for the operation of LEDA.

Abstract

Electron linacs have been widely used in medical applications. Most of these linacs use S-Band (about 3 GHz) microwave technologies. Recently, however, several new ideas in radiation therapy have been proposed that require new, higher power, higher gradient accelerators. In this paper, we propose the application of C-Band (5 to 7 GHz) technology for radiation therapy. Also, we describe the possible design of a new standing wave accelerator structure and R&D of C-Band technology in KEK.

1 INTRODUCTION

Cancer is the major cause of death in most developed countries, where approximately one in every four persons will develop a cancer at sometime in his or her lifetime. Modern society has recognized the immense value of linear accelerator technology as a powerful tool in medical technology. Today more than 5500 electron linacs are used for medical purposes, mainly for the treatment of cancer, in the world.

2 MEDICAL ACCELERATORS

Linacs play such an important role in radiation therapy because of its treatment efficacy and cost efficiency. One of the difficulties in treating cancer is targeting the treatment at the cancerous cells only, without putting the rest of the body at possible or certain risk, as does often surgery and chemotherapy.

Radiation therapy is a preferable alternative to chemotherapy and surgery, although it is often used in conjunction with both. Nearly half of all cancer patients in developed countries will receive radiation therapy, as definitive therapy, for palliation, or as an adjunct to surgery, and more than 50% will be cured by radiation therapy [1]. Linear accelerators direct the x-ray dosage at the target volume, the cancerous tumor cells, and control their reproduction capabilities. Radiation therapy offers these benefits:

1. It localizes the treatment to the tumor
2. No cuts or abrasions are made on the body
3. The process is moderately tranquil, not traumatic for patients
4. Patients usually do not suffer side effects from radiation therapy
5. Most patients do not need expensive hospital care
6. Smaller medical staff is involved in treatment

However, the x-rays are “equal opportunity destroyers,” killing healthy tissue while traveling to, and through, the target volume. The goal of new radiation therapeutic technology, therefore, is eradication of the tumor with minimal radiation damage to the surrounding healthy tissue while maintaining a high quality of life for the patient.

3 CURRENT RESEARCH IN RADIATION THERAPY

Tomotherapy [2] and stereotactic [3] radiotherapy are new radiation treatments that offer advanced solutions to this enduring problem. Currently, simulator and CT (computer tomography) imaging technology allowing radiation physicians the ability to precisely locate the tumor position before treatment. Modern medical accelerators utilize the most updated computer technology, which has allowed radiation to be delivered to the tumor as a function of time, space and dose rate. The time dependent dose delivery is called "physiological gating," wherein the beam is delivered only over certain time intervals in order to account respiration and heart motion. For space dependence, the multileaf collimator "MLC," which utilized a number of beam absorbing leaves to produce an irregular beam shape in order to "conform" the treatment beam to the prescribed 3-D treatment volume. However, these advanced techniques are still not based on real time tumor monitoring and treatment concurrently. Tomotherapy and stereotactic radiotherapy will allow physicians to locate the tumor position *during* treatment as well, and are able to make modifications to the beam based on real-time analysis, thus making the treatments more proficient and yielding a higher cure rate for its patients. Advances in the ratio of computational power to computer cost are now making

this form of therapy economically practical. Between 1970 and 1980, significant advancements in CT and MRI technology made radiation oncology a precise and predictable modality. As a result, the cure rate by radiation therapy has increased dramatically

Figure 1 shows the tomotherapy concept. Tomotherapy combines the precision of a helical CT scan with the potency of dynamic radiation therapy. Using an intensity-modulated fan beam, rotational radiotherapy delivery is achieved by moving multiple collimator vanes in and out of the beam path with speed and precision. By rotating the beam source around the patient, the beam is able to enter the patient from many different angles and to deliver more doses of lesser potency, thereby exposing the healthy tissue to a significantly lower dosage of radiation.

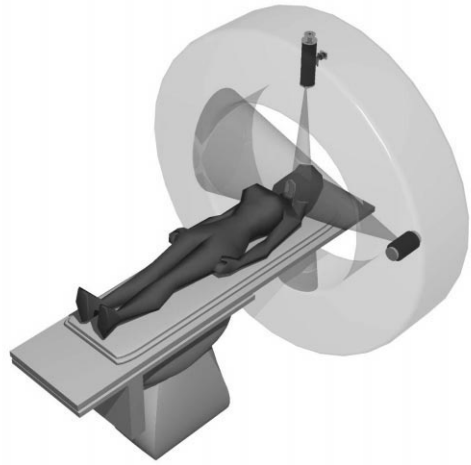

Figure 1: Tomotherapy concept

Thus, tomotherapy accurately controls the location and intensity of the radiation entering the patient with the joint advanced technology of the MLC system and helical CT imaging technology, and delivers highly conformal dose distributions. When using such a capable dynamic modulator, however, one must pay special attention to possible inaccuracies such as leaf transmission, leakage and alignment.

Stereotactic radiotherapy is often prescribed for brain tumors, using extreme precision and a finely focused radiation dosage to the target volume. By directing finely collimated beams of radiation from thousands of angles, the x-rays converge at one small spot, the tumor, while the healthy non-targeted tissue receives very little radiation.

This technique currently requires the use of a head ring, CT scan often in conjunction with magnetic resonance imaging or angiography, and 3-dimensional simulation and computerized dosimetry as well as treatment using a linear accelerator. Figure 2 shows a new concept of stereotactic radiotherapy, which utilizes two rotary joints that are placed on the side of the gantry and the top of ceiling. These provide all the necessary electrical powers and coolings to the accelerator and the X-ray source, which are free to rotate around all angles of the target volume.

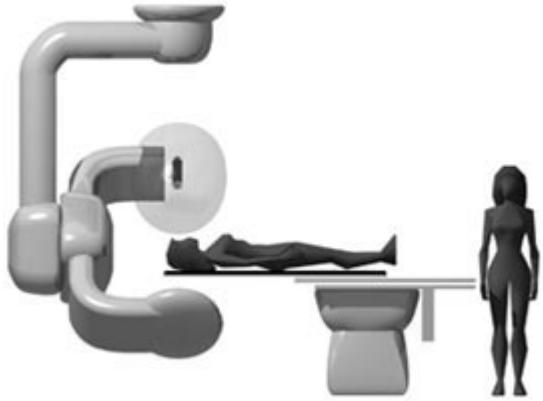

Figure 2: Stereotactic therapy concept

4 MEDICAL ACCELERATORS IN THE FUTURE

Even today's most sophisticated linear accelerator systems for radiation therapy still have many shortcomings. Both tomotherapy and stereotactic treatments require more advanced accelerators that can produce much more x-ray radiation and at a more stable rate, in time and space. They need:

1. A dose rate of 1 Gy/sec or higher
2. X-ray treatment beam position accuracy of 0.1 mm
3. Compact size of the linear accelerator
4. 100% temporal and spatial control of the x-ray beam.

In today's treatment, however, there is not 100% temporal and spatial control; tumor position monitoring is not done in real-time. Simulation is done in another room during the treatment, and what results is bombardment without knowing the exact target. A second issue is the undesirable shift of organs during the radiation treatment, where organs may potentially move 2 cm and thus interfere with the line of radiation.

Advanced equipment such as CT can be used merely for sending and storing information through the network in a sequential manner. What we need is interactive equipment that can produce real time imaging and can feed back immediately (to the degree of a millisecond) to the linear accelerator and deliver the dose at once, thereby eliminating bombardment without knowing the exact target location. This image-directed therapy modifies the radiation source so that the intended target is in the beam line instead of modifying patient position to align with the radiation source. Taking into account natural organ shifts, it is also necessary to deliver the dose in a very short time,

requiring a much higher dose rate and a more powerful linear accelerator.

5 C-BAND ACCELERATOR RESEARCH AND DEVELOPMENT

Hence, we propose high-power C-band accelerators to fit the requirements of the accelerators of future radiation therapy. The following summarizes the general description of these C-band accelerators:

1. Compact
2. High gradient
3. High current
4. Stable
5. Mechanically tolerant
6. More efficient

There are many advantages to using higher frequencies for compact accelerators, i.e. higher shunt impedance per unit length, smaller diameter, shorter filling time, and a higher breakdown threshold. Most electrical parameters can be scaled with frequencies but not for mechanical and thermal parameters. As a result, the shunt impedance can not be increased with the rate of $f^{1/2}$ as we wish. The filling time τ will decrease with a frequency of $f^{-3/2}$, which is the advantage for short pulse operation. The voltage breakdown threshold increases roughly by the square root of the frequency [4].

Meanwhile, there are currently several shortcomings in using a much higher frequency, such as a tighter mechanical tolerance, higher power density, and higher power transmission loss. These are true not only for the accelerator itself, but also for RF power sources such as klystrons and magnetrons. Because of tighter tolerance and higher power density, these microwave sources are difficult to make operating reliable at higher peak power.

The High Energy Accelerator Research Organization (KEK) in Japan has developed C-Band components and accelerators that bring solutions to the above-mentioned problems. Among their advanced solutions include:

1. C-Band klystron
2. Pulsed modulator for C-Band klystron
3. C-Band accelerating structure

KEK's C-Band 50MW klystron uses $\pi/2$ mode traveling wave structure in the output circuit in order to enhance the power-conversion efficiency and to reduce the electric field gradient in the output circuit. Operating at about 5700 MHz, the beam voltage reaches about 360 kV. Various tests have demonstrated that the KEK design is powerful and reliable for the multi-cell output structure.

The pulse modulator uses an inverter-type power supply, which eliminated the massive charging-transformer and also the de'Q-ing circuit from the traditional design. KEK's compact modulator design produces test output voltage of 23.4 kV, and a pulse width of 3.9 microseconds. Having followed the concept of the "Smart Modulator," this one tries to satisfy demands that it be reliable, simple, cheap, efficient, and easy to operate.

The C-Band accelerating structure is under development. Table 1 summarizes the design parameters of a proposed compact high power accelerator for medical applications, which utilizes the hybrid standing wave structure (patent pending).

This structure will be able to deliver a much higher dose rate (1Gy/sec) than currently used in the S-band accelerator, provided the successful operation of the new X-ray target concept.

Table 1: Specifications for C-Band accelerating structure

ACCELERATOR LENGTH (cm)	23
STRUCTURE	Hybrid Standing Wave
NUMBER OF ACC. CAVITIES	9
FREQUENCY (MHz)	5712
ENERGY (MeV)	10
BEAM CURRENT (mA)	600
BEAM PULSE WIDTH (μsec)	4
REPITION RATE (PPS)	240
RF PEAK POWER (MW)	11
SHUNT IMPEDANCE (MΩ/m)	140
LOAD LINE (MeV)	15-8 i

6 CONCLUSION

Electron accelerators have been key contributors to the success of radiation therapy. The medical community is always looking for new linac technologies that are more effective and can save more lives. C-Band frequency technology could be the best choice for future applications in radiation therapy.

Abstract

The 60 MeV cyclotron at Clatterbridge operates as the UK centre for proton therapy, concentrating on treatment of eye tumours; the accelerator is a Scanditronix model MC60PF fixed energy isochronous cyclotron with a high current ion source. Although possible energy upgrades have been previously considered interest has now been reawakened by the activities of the Italian TERA Foundation, which has proposed a compact high frequency booster linac as a potential solution to achieve the 200 MeV needed for a broader therapy programme. The paper reports progress on studies to assess if the Douglas cyclotron is suitable for a test of such a prototype booster linac. The results demonstrate that a cyclotron beam pulse of about 25 microseconds can be achieved by application of amplitude and phase modulation to its RF system. The most recent measurements of output emittance and energy spread of the accelerator are presented and compared with the normal CW values. Compatibility with the acceptance of the proposed linac is discussed.

1 INTRODUCTION

An overview of the use of accelerators for medical applications has been given by Amaldi [1]; this includes the important technique of hadron therapy using a variety of particles. Of these the potential for proton therapy in the treatment of a broad range of cancers is now widely accepted and has already been identified by an EU Working Party as deserving of priority support [2]. It is already used effectively for eye melanomas in the range 60-70 MeV but for deep seated tumours requires energies of at least 200 MeV. Few hospitals have such higher energy facilities and most patients have had to be treated at nuclear physics laboratories, a less than satisfactory situation. What is needed is a compact, economical solution for provision of these 200 MeV proton beams.

One route proposed by the Italian TERA Collaboration [3] is the production of a novel 3 GHz protontherapy linac, using an injector followed by two side-coupled linac structures with energies respectively of 70 MeV and 200 MeV; this challenge has been taken up by the Frascati team in its TOP project [4].

An attractive option is to exploit the same economical technology to boost the energy of existing therapy facilities, especially those in medical centres. Many are intermediate energy cyclotrons and it is necessary to assess whether their extracted proton beams can be successfully matched into the small physical aperture and restricted longitudinal phase space of a high frequency linac structure. In particular the Italian design has an acceptance of about 10π mm-mrad and 0.1 % rms energy spread [5]. Beam intensities for treatment need only be 10-20 nA average current and the linac is assumed to have a typical duty cycle of about 0.1 %, leading to an instantaneous cyclotron current of a few 10ís of μA. Especially in a hospital environment it is crucial to minimise beam losses in the transfer between the two accelerators so that it will be important to develop pulsed operation of the cyclotron matching that of the linac (~10μs) as closely as possible.

The initial studies of the suitability of extracted beam characteristics of one such cyclotron, at the Clatterbridge Oncology Centre in the UK, were recently reported at the EPACí98 conference in Stockholm [6]; updated studies are reported in this paper. It may be possible for this accelerator to be used as a test bed for the proposed concept, perhaps in collaboration with the Italian project [7]. A suggestion to boost the energy of the Clatterbridge accelerator with a linac, albeit of somewhat lower frequency, had previously been made in an earlier study by AEA Industrial Technology [8].

2 THE CLATTERBRIDGE CYCLOTRON

The Douglas Cyclotron Unit at Clatterbridge has operated a cyclotron for proton therapy since 1988. However for several years before that tests were carried out on the efficacy of neutron therapy, necessitating an accelerator with exceptionally intense proton currents of at least 50-100 μA to produce the required neutron fluxes from its beryllium target. A large switching magnet steered the protons into a neutron area and this separate beam line still exists, providing a useful facility for test purposes.

The commercially supplied isochronous cyclotron is a Scanditronix model MC60PF, whose principal parameters are summarised in Table 1.

Table 1. Principal Cyclotron Parameters

Energy	(MeV)	62
Current	(μA)	50+
Emittance/1σ	(π mm-mrad)	2-3
Energy Spread	(%, FWHH)	0.25
Radiofrequency	(MHz)	25.7
Harmonic Number		1
Dee Voltage	(kV)	40
Bunch Length	(deg)	13

These are notional parameters, as specified by the manufacturer, and in some cases are probably conservative. The current rating reflects the earlier utilisation as a neutron source and in recent years the accelerator has rarely exceeded 50 nA in CW mode. Emittances were measured at the factory and the energy spread and phase length are assumed to be equal to that of another Scanditronix model (MC35). The energy has been estimated from transmission through aluminium foil absorbers and for this type of cyclotron is fixed.

The intense ion source is a cold cathode (PIG) discharge type. Extraction is by utilising a radial integer resonance, together with an electrostatic deflector and focusing magnetic channel. This makes it difficult to predict the exact properties of the output beam.

3 MODIFIED PULSE DURATION

The obvious and most straightforward method of modulating the beam in a cyclotron would be to pulse the source of ions whilst they are at low energy. Unfortunately the ion source of the Clatterbridge accelerator, as with the majority of medical cyclotrons, is positioned at the centre of the dees and is very inaccessible. Furthermore, no modifications to the cyclotron could be considered which might reduce its availability in its primary function as a source for therapy. For these reasons an alternative approach to achieving a pulsed output beam was selected, that is to modulate the RF accelerating voltage.

If the RF accelerating voltage is not optimum, the first few orbits of ions which have been emitted from the ion source are perturbed, resulting in them colliding with collimators which are critically placed near the centre of the dees. Running the cyclotron with reduced RF amplitude and pulsing the RF up to the correct level when the beam pulse is required will produce a pulsed output beam. In practice this technique must be constrained by the need to keep the RF within certain limits so that the auto-tuning loops remain functional.

An alternative technique is possible in cyclotrons of the type used at Clatterbridge where there are two pairs of dees used. Adjusting the relative phase of the drive to the separate RF amplifiers feeding the dee pairs can alter the RF accelerating voltage effectively seen by the ions. This has the advantage of not disturbing the tuning loops. A highly simplified block diagram of the RF system is given in fig 1, showing how the amplitude and phase modulating signals are applied. The Clatterbridge system was modified to allow the two types of modulation and a series of tests were made in which short rectangular pulses of both amplitude and phase shift were applied at a repetition rate of 50 Hz and synchronised to the electricity main.

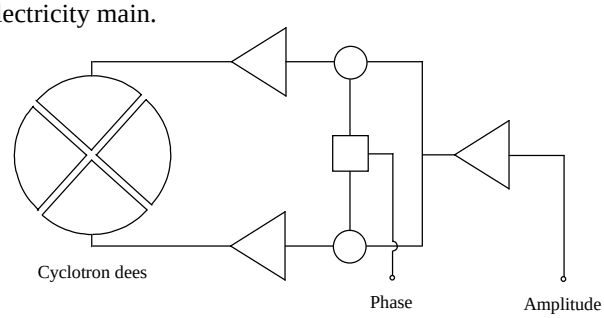

Figure 1: Block diagram of the modified RF system

The results showed that both modulations were fully effective in producing a pulsed output beam, which was detected from a faraday cup signal. The amplitude modulation was limited to the rise time of the RF system and gave a beam pulse of about 100 μs half width. Shorter pulses of about 25 μs were obtained by driving the RF rapidly through the optimum level, but this of course gave rise to 2 beam pulses, on the upward and downgoing edges of the drive pulse. The phase modulation system gave slightly shorter beam pulses of about 20 μs, as shown in fig 2, but a measurement of the basic system response to step phase changes has not yet been made so that it is not clear what the ultimate shortest pulse would be. At present it is likely that the best technique for generating a single short beam pulse is to apply shifted, overlapping, phase and amplitude modulations.

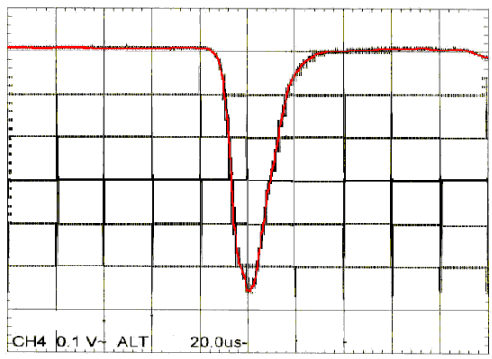

Figure 2. Successful RF pulsing of the cyclotron beam

4 EXTRACTED PROTON BEAM TESTS

The extracted beam properties have been assessed in an experimental programme making use of the beam line

previously devoted to feeding the neutron target. This line has quadrupole triplets before and after a 55^0 dipole magnet and the latter allows a large dispersion to be set if required. The available diagnostics in the experimental beam line has been quite limited; a fluorescent screen at the downstream end supplements spinning wire profile monitors at two fixed locations. Viewing the screen image with a CCD camera the beam sizes were estimated by fitting to Gaussian profiles using framegrabber and image analysis software written with LabVIEW [9].

Systematic scans of single quadrupoles with the beamline set to give both high and low dispersion at the screen [6] gave a range of data that was then fitted to a linear model of the beamline written using Microsoft EXCEL [10]; quadrupole field gradients were calibrated using a Hall plate. Although the predicted beam sizes are only weakly dependent upon the model energy spread an upper bound of 0.1% rms can be given for this cyclotron parameter; Twiss functions and emittances have also been estimated, the latter being consistent with those given in Table 1. An example is shown in Figure 3 where the horizontal beam size is compared with model energy spreads of 0.1%, 0.05% and 0.01%.

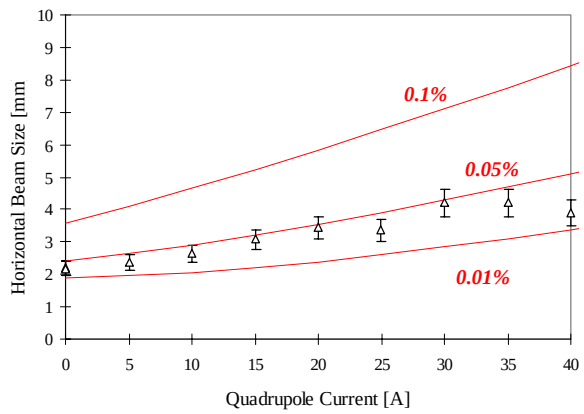

Figure 3. Typical fit of cyclotron parameters

5 CONCLUSIONS

The first phase of assessment of the properties of the extracted proton beam from the 62 MeV Clatterbridge cyclotron has been successfully completed. Emittances in both planes have been confirmed to be at or even below the expected values of about 2-3 mm-mrad and the energy spread appears to be exceptionally good, with an upper value (rms) of 0.1 % and probably considerably lower. Pulsed beam operation has been commissioned by modification to the RF drive circuitry and a pulse width of 20 μs at 50 Hz demonstrated; since the modulation is effectively onto the low energy beam acceptance in the accelerator it is not expected that the high energy beam properties will be adversely affected, but this has yet to be confirmed experimentally. Nevertheless it is clear that the cyclotron could be a suitable injector into a high frequency proton linac booster. The possibility of testing this with a real accelerating structure will now be pursued, perhaps in an international collaboration.

6 ACKNOWLEDGEMENTS

We wish to thank E. Wilson (CERN) and U. Amaldi (CERN and TERA Foundation) for helpful encouragement and advice. L.-O. Arlasjo (Scanditronix Medical AB) provided important technical advice on the cyclotron.

Abstract

Several hospitals and laboratories possess proton cyclotrons with output energies of 60 to 70 MeV. A high frequency (3 GHz) booster linac (LIBO) is proposed to upgrade the cyclotron beam to an energy of 200 MeV, sufficient to treat deep seated tumours. LIBO is a side-coupled linac which can produce beams with a variable output energy. This paper presents the feasibility study of such an accelerator, together with the milestones planned for 1998-1999, including the machining of a part of LIBO and testing it with full RF power on a test stand at CERN.

1 INTRODUCTION

The design of a novel high-frequency proton linear accelerator of 200 MeV for medical purposes was proposed by the TERA Foundation in 1996 [1]. Such an accelerator has been further studied at ENEA, Frascati, Italy, and the low energy part of it is now under construction [2]. Reference [1] briefly describes a study of a booster linac, LIBO, intended to upgrade a cyclotron beam energy from about 60 MeV (already available in several hospitals and research institutions) to 200 MeV in order to treat deep seated tumours. In an earlier proposal [3] a similar but lower frequency upgrade was considered for the 62 MeV cyclotron of the Clatterbridge Centre for Oncology, UK. LIBO studies are also based on the Clatterbridge cyclotron, but the operating frequency has been pushed into the S-band in order to reduce the accelerator size and increase its breakdown limit.

LIBO is a side-coupled linac (SCL) operating at 2998 MHz. It is composed of 36 tanks, separated by permanent magnetic quadrupoles (PMQs). Four tanks are grouped into a module, an RF unit, fed by its own RF chain.

The average output beam required from LIBO is of the order of 10nA, and it must be possible to vary its energy from about 130 to 200 MeV. This constrains both the number of tanks in a module and their length.

The 3 GHz klystrons used to power the tanks operate in the pulsed mode with pulse lengths of up to 5 μs, but it is the average power a klystron can deliver that limits the LIBO duty cycle. The energy spread in the LIBO beam should be narrow enough to limit the distal fall off of the dose given to the patients to ≤ 2 mm. A beam pulse repetition rate of 400 Hz has been chosen to suit an active beam scanning method (e.g. pixel scanning). Preliminary tests have been performed to pulse the Clatterbridge cyclotron beam [4] to study its use as a LIBO injector

2 BEAM OPTICS

Beam optics studies have been made in order to find a suitable layout of LIBO. A high average axial accelerating gradient E_0 (15.3 MV/m) has been selected to limit the accelerator length and care has been taken to avoid synchro-betatron parametric resonances. The cyclotron beam will be matched transversely to LIBO by focusing elements placed between the two accelerators and the aperture radius of 4 mm will make the transverse acceptance A_t such as to contain the cyclotron beam emittance ($A_t \cong 12\ \pi$ mm mrad).

Longitudinally the situation is different. Only part of the low frequency cyclotron beam falls into the short LIBO buckets and many particles remain outside. This effect has been analysed by simulating the cyclotron beam, which appears continuous in phase when referred to the LIBO frequency of 2998 MHz, and dividing it into many thin phase slices which span 360 degrees. Each slice is followed through the linac with a beam dynamics program, and LIBO is optimised in a preliminary way, assuming no misalignments. It is then found that about 50% of the continuous beam can be transmitted and about 25% of the transmitted beam is fully accelerated. Thus the accelerated beam is about 12.5% of the input beam. Most of the rest of the beam leaves with energies below 70 MeV.

Misalignments of PMQs and linac tanks, and other errors, such as quadrupole gradient errors, can reduce the intensity of the accelerated beam. One can estimate the effect of quadrupole misalignments on the transmission by making a Monte Carlo optics calculation.

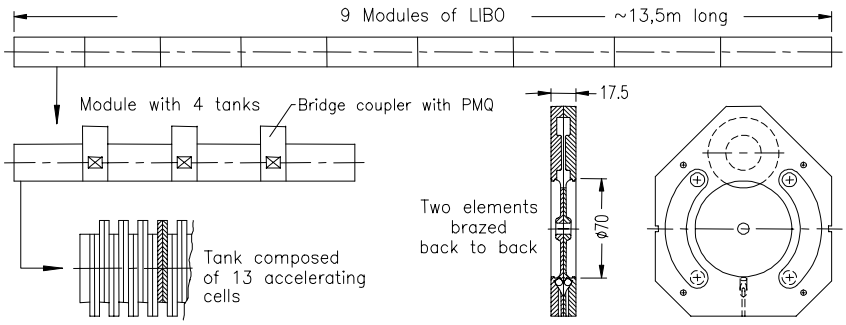

Figure 1: Schematic layout of LIBO

Four types of error have been analysed: quadrupole displacement errors of ±0.1 mm; tank displacement errors of ±0.1 mm; quadrupole rotation errors of ±1°; and quadrupole strength errors of ±1%. The only error that produces any significant reduction in the transmission is quadrupole displacement. For a displacement error tolerance of 0.1 mm there is a 90% probability that the transmission will be greater than 10%, and about a 50% probability that the transmission will be greater than 11%. With a 10% transmission and a beam duty cycle of 0.0018 (400 Hz and 4.5 μs) the LIBO trapping efficiency will be 1.8×10^{-4} and hence, in order to have an average output current of 10 nA, the peak intensity in the cyclotron beam pulse should be about 55 μA.

3 LIBO STRUCTURE

A schematic layout of LIBO is shown in Figure 1. Nine modules, each comprising four tanks, are mechanically coupled together to form the 13.5 m long accelerator. A tank has 13 accelerating cells, which are formed from 24 basic elements and from 2 half end cells. Each basic element consists of half of an accelerating cell and half of a coupling cell. The tanks of a module are resonantly coupled together via three bridge couplers. The central coupler is connected to the RF feeder line and the remaining two to a vacuum system. An RF pick-up is installed at either end of each tank and PMQs, placed between the tanks, form a FODO focusing lattice. The soft copper linac will be precisely aligned by fixing it on a rigid support with pre-adjusted keys.

The shape of the cells has been studied using the program SUPERFISH. Investigations have included, among other things, the effect of the accelerating cell diameter D and of the web thickness w (wall between two accelerating cells) on the effective shunt impedance ZT^2 and peak surface field E_{peak}. The shunt impedance includes the effect of slots for 3% coupling. The upper curve in Figure 2 shows that at the high energy end of LIBO (β=0.56), the chosen diameter D of 70 mm is optimum with respect to ZT^2. The lower curve shows that at the low energy end (β=0.35) there is little to be gained in ZT^2 by reducing D and that E_{peak} would increase rapidly. With D=70 mm, E_{peak} is limited to a conservative value of 1.6 times the Kilpatrick limit E_k.

Figure 3 shows that a thin web thickness w is preferable, as one might expect from the short cell lengths of LIBO. A 4 mm web has been chosen for a good mechanical rigidity of the pieces during machining and it has been decided to braze two basic elements back to back before the final machining of the accelerating cells. However, the really delicate issue is whether cooling channels are required in the web or whether circumferential cooling alone is sufficient. Cooling channels would necessitate a relatively thick web, which spoils the electrical characteristics and complicates the mechanical design, adding an extra risk and cost.

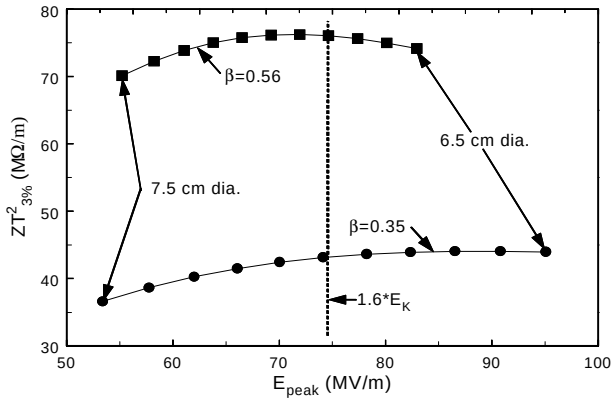

Figure 2: The points show the shunt impedances and the peak surface fields for 11 different cell diameters D, at the input (β=0.35) and output (β=0.56) energy. The web thickness w is 4 mm.

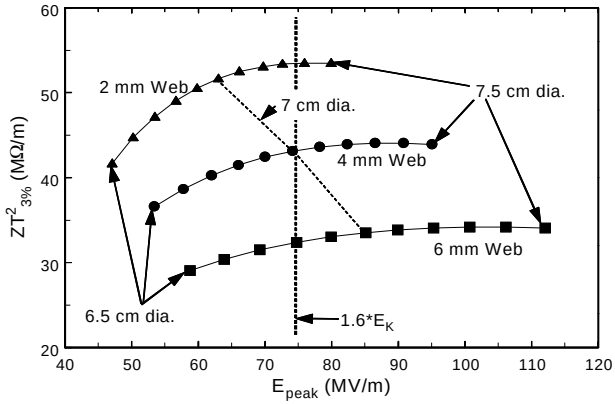

Figure 3: The points show the shunt impedances and the peak surface fields for 11 different cell diameters D and for 3 web thicknesses w, at the input energy (β=0.35).

The cooling problem has been studied assuming an RF duty factor of 0.2%, for which 150 W are dissipated in each accelerating cell of tank 1. Very little power is dissipated in the coupling cells because LIBO operates in the $\pi/2$ mode. The study has proceeded as follows:

- A table of surface coordinates of an accelerating cell and of the power density distribution on its walls is generated by SUPERFISH.
- The table is read by a finite element engineering code ANSYS, together with the specifications of the cell material. In our model this material extends to a radius of 40 mm, where a thermal boundary is defined. Simple cooling is simulated by fixing the sink temperature, T_{sink}, at this radius, where one may reasonably expect the temperature to be uniform. ANSYS computes the temperature distribution, the thermal stresses and the mechanical deformations of the cell. In our case, there was a temperature gradient between the nose (centre of the cell) and T_{sink} of about 7° C.
- A special code has been written to compute the frequency of distorted cells. The code reads the coordinates of the deformed cell surface from ANSYS, compares them with the original ones and computes the frequency detuning Δf by using Slater's perturbation theorem. The detuning is found to be about –250 kHz if T_{sink} is held at its ambient value.
- By lowering T_{sink}, the original cavity can be mechanically deformed in the opposite sense. Using ANSIS and the special code, it was found that changing T_{sink} by –5° C brings the cell back on tune; see Figure 4.

The conclusion is that circumferential cooling will be adequate for LIBO and that by controlling T_{sink} with the frequency feedback loop, it will be possible to keep the accelerator on tune.

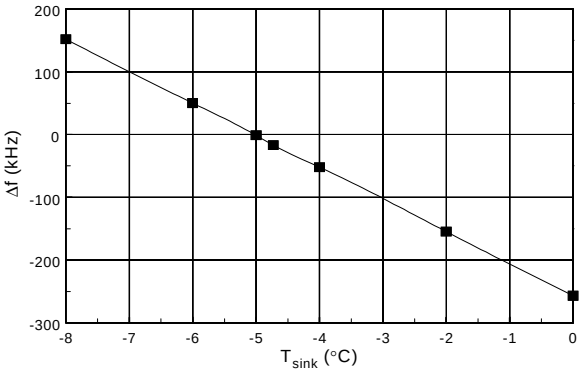

Figure 4: Detuning Δf as function of the lowering of the sink temperature T_{sink}.

The effects of coupling slots between cells have been studied with the 3-D program MAFIA. The PSPICE program, dealing with coupled circuits, has been used to assess the importance of various errors in the presence of incompletely closed stop bands. Cold RF measurements on a few cells of an aluminium model at CERN completed the studies of LIBO.

4 FEASIBILITY TEST

The SCL type of structure is usually used with lower frequencies or with higher β values than those foreseen for LIBO. It is therefore important to carry out a feasibility test prior to the construction of a complete medical booster linac. In a collaboration with High Vacuum Process (HVP), Parma, Italy, the following milestones have been set:

- Construction of a model of the first LIBO tank in copper (at HVP) in order to master the delicate parts of the production (machining, tuning, assembling, brazing, cooling etc). It should be completed in the second half of 1998.
- Construction of the complete first LIBO module (at HVP) to be tested with full RF power at CERN; the module will be pumped, water cooled and powered by a spare 3 GHz chain of LIL, and it will also contain pick-ups for RF feedback. The tests at CERN are planned for the end of 1999.

5 ACKNOWLEDGMENTS

Our CERN collegues, L. Bassi, P. Bourquin, A. Millich and R. Zennaro participated in several studies presented in this paper; A. Catinaccio, in particular, dealt with the deformations of the structure and the resulting detuning. J. Lipp of RAL assisted in this analysis. K. Hübner, D. Simon and the PS division of CERN supported this project in many ways and rendered, together with S. Ferrari (HVP), the fixing of our milestones possible. To all of them go our deepest thanks.

The financial support of the Price Foundation is gratefully acknowledged.

1 INTRODUCTION

In order to meet US tritium needs to maintain the nuclear weapons deterrent, the Department of Energy (DOE) is pursuing a dual track program to provide a new tritium source. A record of decision is planned for late in 1998 to select either the Accelerator Production of Tritium (APT) or the Commercial Light Water Reactor (CLWR) as the technology for new tritium production in the next century. To support this decision, an APT Project was undertaken to develop an accelerator design capable of producing 3 kg of tritium per year by 2007 (START I requirements). The Los Alamos National Laboratory (LANL) was selected to lead this effort with Burns and Roe Enterprises, Inc. (BREI) / General Atomics (GA) as the prime contractor for design, construction, and commissioning of the facility. If chosen in the downselect, the facility will be built at the Savannah River Site (SRS) and operated by the SRS Maintainance and Operations (M&O) contractor, the Westinghouse Savannah River Company (WSRC), with long-term technology support from LANL. These three organizations (LANL, BREI/GA, and WSRC) are working together under the direction of the APT National Project Office which reports directly to the DOE Office of Accelerator Production which has program authority and responsibility for the APT Project.

2 DESCRIPTION OF APT

The APT, which is shown schematically in Figure 1, is made up of four major subsystems which are described briefly below[1].

2.1 Accelerator System

The Accelerator System consists of the following subsystems:

- Proton injector to develop and maintain a continuous 100-mA current.
- Radio Frequency Quadrupole (RFQ) to focus and accelerate the proton beam to 7 MeV (kinetic energy)
- Coupled-cavity Linac (CCL) to accelerate the proton beam to 211 MeV.
- Superconducting Linac (SCL) to accelerate the proton beam to its final energy of 1700MeV. The design is modular so that the portion of the accelerator up to 1030 MeV can be completed to produce 1.5 kg/yr of tritium and then a decision can be made as late as 2002 to add the last section if the START I production level is still required.

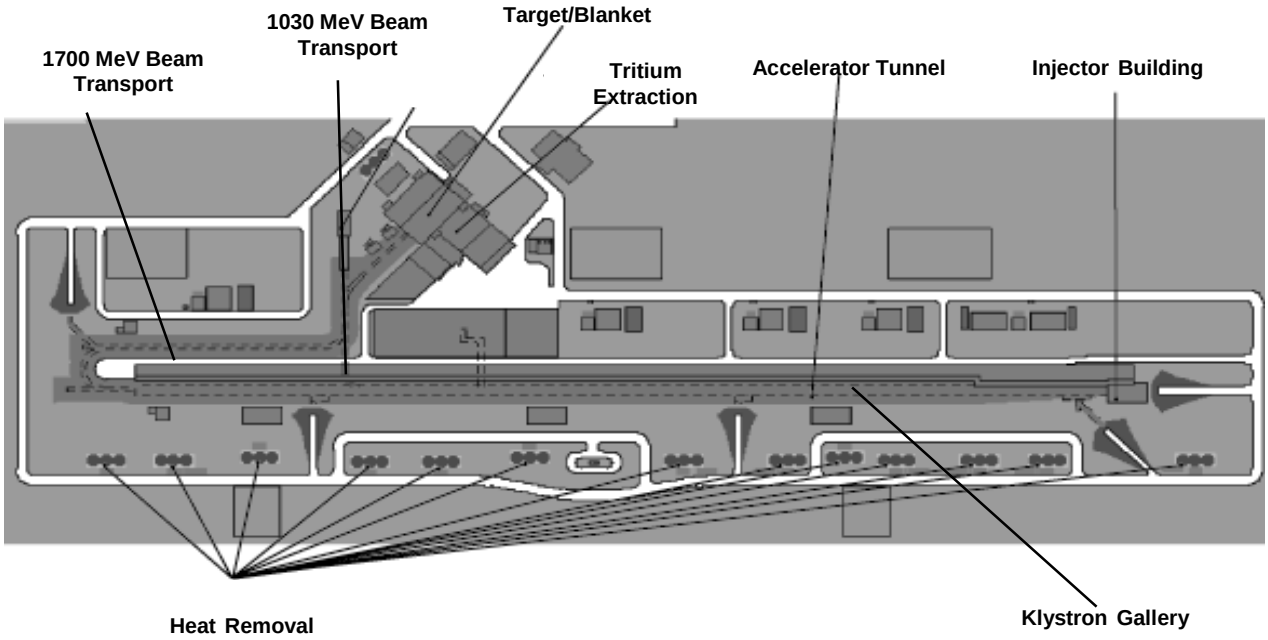

Fig. 1 APT Plant Layout

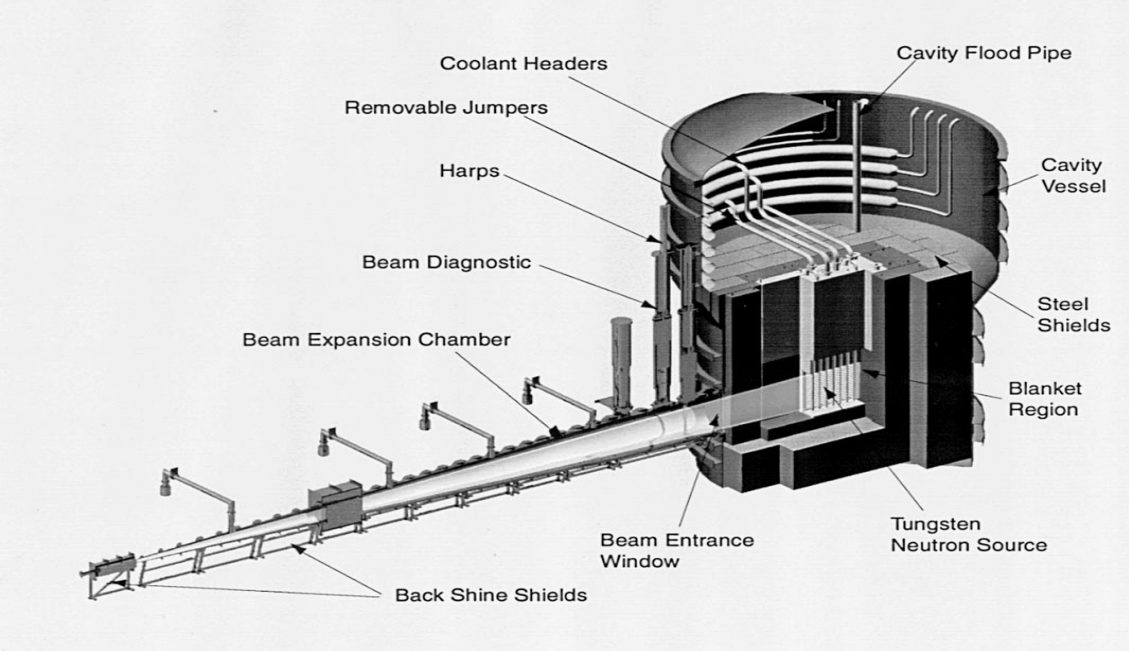

Fig. 2 APT Target/Blanket

2.2 Target/Blanket (T/B) System

The Accelerator System provides a proton beam that is expanded and directed to a T/B assembly shown in Figure 2. The T/B assembly consists of a tungsten clad target in which neutrons are produced by spallation surrounded by a blanket in which additional neutrons are produced in lead. The neutrons are thermalized by collisions in the lead and in light-water and are subsequently captured in He-3 to produce tritium.

2.3 Tritium Separation Facility (TSF)

The TSF operates by extracting tritium from a tritium, hydrogen, and He-3 mixture returned from the T/B System in a recirculating He-3 loop. The He-3, hydrogen and tritium mixture also contains impurities such as water, methane, ammonia and small quantities of radioactive materials. Hydrogen isotopes are separated from the He-3 and sent to an Isotope Separation System where the tritium is separated from hydrogen. The He-3 is purified and recycled to the T/B assembly.

2.4 Balance of Plant (BOP) Systems

The BOP Systems support the integrated operation of the accelerator, T/B, and TSF, and provide the facility buildings that house them. The BOP System designs are driven by the required electric power input, the generated waste heat to be removed throughout each facility and the need to handle radioactive materials remotely.

3 MEDICAL ISOTOPE PRODUCTION WITH APT

The APT T/B will produce a high energy, high flux proton and neutron irradiation environment that is unique in the field of isotope production[2]. In addition to converting He-3 to tritium, it can be used to create isotopes for medical applications. Although the primary mission of the APT is to create tritium for the nuclear weapons deterrent, an ancillary isotope production mission is possible without significantly impacting tritium production. Because of the unique irradiation environment, and the large volume of space available, the APT has the potential to provide a significant source of research, diagnostic, and therapeutic isotopes to the medical community.

The capability for the irradiation of medical isotope targets is feasible within the scope of the T/B material surveillance program. The centerpiece of this program is a “rabbit” system that allows the insertion and removal of material surveillance coupons directly into several (up to seven) locations within the T/B assembly. Double wall tubes with a continuous flow of water provide a cooled environment for small (approximately 1.4 cm diameter by 6.3 cm long) target capsules. These capsules are moved in and out of the irradiation positions using hydraulic pressure. The design of the tungsten neutron source in the APT T/B allows for a large volume of potential irradiation positions directly in the high proton and neutron flux regions.

A small hot cell located nearby in an adjoining room is used to remove the capsules from the ”rabbit” tubes and load them into shipping casks for transfer to a processing facility. Location of a private processing facility at the site boundary is a possibility. As an option to shipping casks, it is also possible to use pneumatic transfer tubes from the hot cell to the processing facility to speed the transfer.

Radioisotopes production in the APT target/blanket was analyzed to determine production rates and radiopurity of several isotopes that are of interest to the medical community. These include Cu-67, Ge-68, Sr-82, In-111, Re-186, Sm-153, Pd-103, P-32, Sc-47, and Ga-67. The isotopes were produced by nuclear spallation of natural (non-enriched) target materials by high-energy protons and neutrons. Significant production rates, high radiopurity and specific activity were achieved for most of the isotopes. In addition, the calculations showed that for 11 liters of target volume placed directly in the proton beam the decrease in tritium production was less than 2%.

4 THE POTENTIAL IMPACT OF APT ON MEDICAL ISOTOPE NEEDS

Leaders of the biomedical science community met recently in Dallas[3] to discuss the importance of developing an adequate supply of radionuclides to support clinical practice, research, education and training, and new treatments. The group acknowledged that the present supply of radionuclides is insufficient to meet current and projected future needs.

As an example, the recent development of specific delivery agents such as monoclonal antibodies that can target specific tumor cells and carry radiotherapeutic materials to those cells has led to a major advance in radiotherapy. Other healthcare areas with great potential include bone pain palliation, brachytherapy applications in inoperable tumors, nuclear cardiology and positron emission tomography (PET) procedures. For these to become available in routine practice there must be a supply of reasonably priced, high purity radionuclides

The proposed APT facility has the potential to supply the much-needed radionuclides. Although the charter for APT does not include radionuclide production, the facility has the potential to make a significant contribution with little impact on tritium production. The biomedical community leaders learned of preliminary calculations of production yields, specific activities and radionuclidic purities for the nuclides listed above. This wide variety is possible from APT because, unlike reactor facilities, both energetic protons and neutrons are available in quantity.

Working as a team, the group developed the following statement in support of including radionuclide production in the APT charter:

“The APT facility will provide a unique resource for the production of substantial quantities of high specific activity radionuclides resulting in enormous scientific, research and education opportunities. These radionuclides will be especially useful in advancing healthcare for diagnosis and in the rapidly growing area of radionuclide therapy. We therefore support an expansion of the APT project charter to include designing into a biomedical radionuclide production capability. This initiative should not draw from existing radioactive materials research or production programs, as it is fundamental to the overall DOE mission, extending rather than replacing existing efforts, with downstream benefits which are vast for the nation.”

There was general agreement within the group that any new opportunity for radionuclide production and development gained by construction of the APT facility should be jointly pursued by the National Institutes of Health (NIH), DOE, and the Department of Defense (DOD), with NIH being the lead agency.

5 CONCLUSIONS

The APT will produce a high energy, high flux proton and neutron irradiation environment that is unique. Medical isotope production in APT has the potential to provide downstream benefits which have been judged by the biomedical community to be “vast for the nation”. Although the primary mission of the APT is tritium production, significant medical isotope production is possible with little impact on tritium production.

OPERATION OF HIGH-POWER 8.6 AND 17.1 GHz COAXIAL GYROKLYSTRONS*

W. Lawson, B. Hogan, M. Castle, V. L. Granatstein, M. Reiser, X. Xu
Institute for Plasma Research, University of Maryland, College Park, MD 20742

Abstract

At the University of Maryland, we have designed, constructed, and tested a number of gyroklystron tubes operating from X-Band to Ka-Band over the past several years [1]. The purpose of this effort is to examine the suitability of gyro-amplifiers as drivers for advanced accelerator applications such as the Next Linear Collider. We are currently conducting a series of experiments with coaxial tubes which are designed to produce peak powers in excess of 100 MW in X- and Ku-Band, increasing the state-of-the-art by a factor of 3-5. Preliminary results have indicated peak powers in excess of 75 MW at 8.6 GHz in a three cavity first-harmonic gyroklystron tube with a gain near 30 dB and an efficiency near 32%. In this paper we will detail the experimental results of this tube and discuss designs and preliminary cold test results of a 3-cavity second-harmonic device, which is expected to give comparable results at 17.14 GHz.

1 INTRODUCTION

At the University of Maryland, we have been investigating the suitability of high power gyro-amplifiers as drivers for linear colliders for over a decade. [1] To this end, we have designed, constructed, and tested a variety of gyroklystron and gyrotwystron tubes operating from X-Band to Ka-Band. With a 440 kV, 160-260 A beam, we were able to produce about 30 MW of peak power in 1 μs pulses near 9.87 and 19.7 GHz with first- and second-harmonic gyroklystron tubes, respectively. The peak efficiencies were near 30% and the large-signal gains were 25-35 dB. Circular electric modes were used in all cavities and the average beam velocity ratio was always near one. Efficiency was limited by instabilities in the beam tunnel preceding the input cavity and beam power was limited by the electron gun.

The focus in the past few years has been to upgrade the system to achieve peak powers approaching 100 MW in X- and Ku-Band. The increase in power results from a larger beam current, which is achieved by maintaining the same current density, but enlarging the average beam radius. Subsequently, the tube cross-sectional dimensions are increased and an inner conductor is required to maintain cutoff to the operating mode in the drift regions. To date, we have hot-tested a 2-cavity and a 3-cavity first harmonic tube and we are about to test a 3-cavity second harmonic tube.

In this paper we first discuss the experimental test facility. Then we discuss the computer simulations before describing the experimental results from our X-Band tubes. Finally, we mention our Ku-Band progress before closing with our near and long term goals.

2 EXPERIMENTAL TEST FACILITY

The voltage pulse is generated with a line-type modulator which is capable of producing 2 μs flat-top pulses at up to 2 Hz with voltages and currents up to 500 kV and 800 A, respectively. A capacitive voltage divider and a current transformer are used to measure the time evolution of the voltage and current. Our single-anode MIG is

capable of producing a 500 kV, 720 A beam with an average orbital-to-axial velocity ratio of $\alpha = 1.5$ and an axial velocity spread of $\Delta v_z/v_z < 10\%$. The beam parameters are given in Table I for the operating point where maximum amplification occurs. The voltage and current are measured quantities; all other values come from the EGUN simulations and are based on the MIG geometry and the magnetic field profile. The actual theoretical fields at the centers of the three cavities are given in Table I. The axial field is detuned by -3.5% in the input cavity, -8.8% in the buncher cavity and -15.4% in the output cavity.

The 3-cavity microwave circuit is shown in Fig. 1 and the key dimensions are given in Table I. The inner conductor is supported by two thin tungsten pins and forces the drift tubes to be cutoff to the TE_{01} mode at 8.6 GHz. The inner conductor only extends a few centimeters into the downtaper and is rapidly terminated after the output cavity. Lossy ceramics are placed in the drift regions to suppress spurious modes. The rings on the inner conductor generally alternate between carbon-impregnated alumino-silicate (CIAS) and 80% BeO-20% SiC. Two layers of lossy ceramics are placed along the outer conductor in the drift regions. The outer layer is BeO-SiC and the inner layer is CIAS. The 2-cavity circuit omits the buncher cavity and has a longer drift region.

The input cavity is defined by a decrease in the inner conductor radius. The cavity loss is roughly evenly divided between the coupling aperture and a CIAS ring on the inner conductor which is placed adjacent to the cavity. The power to the input cavity is supplied by a 150 kW coaxial magnetron. The buncher cavity has identical dimensions for the metal components. However, the Q is determined entirely by CIAS ceramics.

The output cavity is defined by radial changes on both walls and the lip radii are equal to the drift tube radii. The quality factor is dominated by the diffractive Q which is adjusted by changing the length of the coupling lip.

3 THEORETICAL AND EXPERIMENTAL RESULTS

3.1 First-Harmonic Results

A partially self-consistent large-signal code is used to design the circuit and magnetic field configuration and to estimate the performance of the tube at the actual operating point. A small-signal start-oscillation code is used to determine the stability properties of the cavities and set limits on the cavity quality factors. The solid line in Fig. 2 shows the expected performance of the tube as a function of velocity spread for α=1.5. The simulation predicts a zero-spread efficiency of 43%, and an efficiency of 34% for 10% spread. For the 6% spread predicted for a 500 A beam, the simulated interaction efficiency is about 40%. All microwave cavities are expected to be stable at the design operating point for the quality factors indicated in Table I. The theoretical efficiency for the 2-cavity tube is slightly less, but the predicted gain is significantly lower. Consequently, the 2-cavity tube was gain-limited and produced less than 1 MW of output power.

The optimal parameters and experimental results have been listed in Table I. The values are all taken from anechoic chamber measurements. The time dependence of

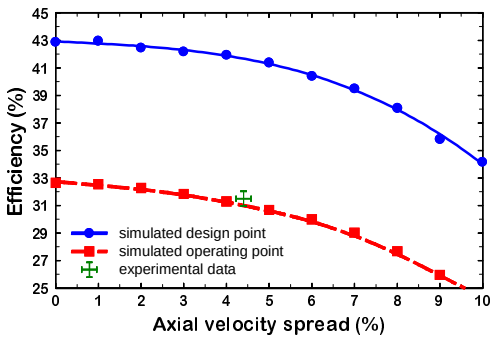

Figure 2. Efficiency versus velocity spread.

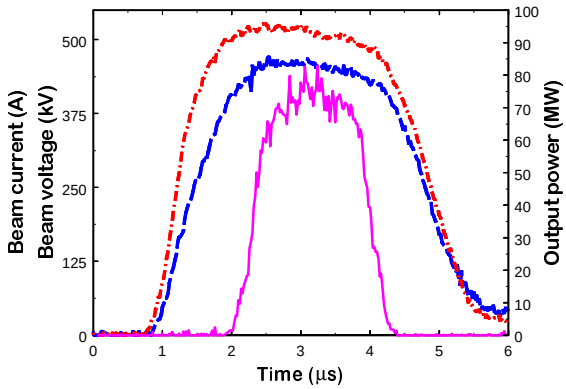

Figure 3. Time dependence of the output pulse.

the beam voltage (dashed line), beam current (dot-dashed line), and the amplified signal (solid line) are shown in Fig. 3. There is a slight droop on the flat top due to mismatches in the modulator. The peak values indicated in Table I represent the average value of the signal in the flat top region. The peak power is about 75 MW, which represents an efficiency of nearly 32%. The corresponding gain is almost 30 dB and the pulse width is 1.7 μs (FWHM). Attempts to increase the peak power further by raising the beam's velocity ratio result in a sharp cut in the output signal near the maximum value which is usually indicative of an instability (though none were detected by the microwave diagnostics).

An EGUN simulation using the parameters of the operating point indicate that the beam's velocity ratio at the entrance to the circuit is near one. There is a reasonably large uncertainty in this ratio due to the neglect of the self-axial magnetic field in EGUN and the uncertainty in the applied field at the cathode. In a previous experiment at the University of Maryland, for example, the measured average velocity ratio was consistently higher than the simulated ratio by about 15%. [2] Simulations of the amplifier performance at the operating point are given by the dashed line in Fig. 2. The simulated cathode magnetic field is adjusted slightly to produce the best match between the theoretical efficiency and the measured efficiency, which is indicated by the cross. The required field is about 20 G lower than the calculated ideal field and well within the uncertainties of the experimental data.

3.2 Second Harmonic Tube

The second harmonic tube is realized by keeping the first harmonic tube's input cavity but replacing the buncher and output cavities with ones that resonate at twice the drive frequency in the TE_{021} mode. Such cavities

Table II. The second harmonic design.

Beam voltage (kV)	500
Beam current (A)	770
Velocity ratio	1.51
Input cavity Q	50
Buncher cavity Q	389
Output cavity Q	320
Gain (dB)	49
Efficiency (%)	41
Output power (MW)	158

are normally difficult to realize, because the cavity's end walls generate other radial modes due to the beam tunnel opening. For cavity isolation, the fields must not leak substantially into the drift regions, yet the operating frequency is well above the cutoff of the TE_{01} mode. In circular waveguide systems, the usual way to avoid this problem is to introduce smoothly-varying wall radii, but the added length of these transitions is usually unacceptable. Fortunately, in coaxial tubes, making the radial wall transitions that define the TE_{021} cavity approximately

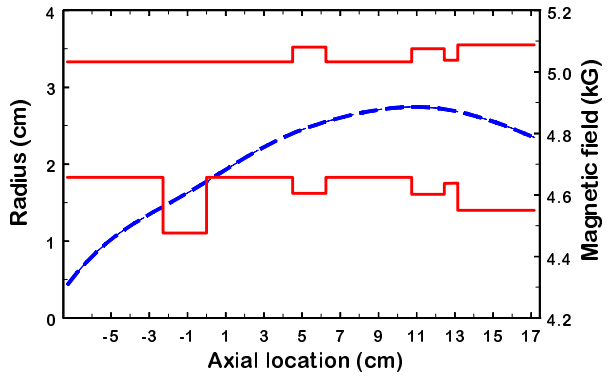

Figure 4. The shape of the second harmonic tube and the simulated optimal magnetic field profile (dashed line).

equal on the inner and outer walls naturally leads to a mode with very little conversion to the TE_{01} modes and subsequent leakage fields.

The principal design parameters for our three cavity second harmonic tube are given in Table II along with the simulated performance estimates. The cavity profile is shown in Fig. 4. The overall length is very similar to the first harmonic tube. At this point, the tube components have been constructed, the cavities have been adjusted to achieve the required frequencies and quality factors, and the tube is installed in our test facility. Hot testing should commence in the next few days.

4 SUMMARY

In summary, we have developed an X-band coaxial gyroklystron which has increased the state-of-the-art in peak power for gyroklystrons by nearly a factor of 3. In the near future we will test our 2nd harmonic tube, with the goal of obtaining about 100-150 MW of peak power at 17.136 GHz. We will investigate the limitations on velocity ratio in greater detail and attempt to increase the nominal velocity ratio to the original design value. In the long term we expect to build and power a 17.136 GHz accelerator structure with an accelerating gradient near 200 MV/m.

1 INTRODUCTION

As part of the A0 Photo-injector collaboration at Fermilab [1, 2] and the TeSLA collaboration [3], a high brightness, low emittance electron source has been developed. In the process, a system was constructed for coating molybdenum cathodes with a layer of cæsium telluride (Cs_2Te), a photo-emissive material of high quantum efficiency (QE). The use of Cs_2Te was first investigated at CERN [4] and LANL [5]. The development of the systems for the TeSLA Test Facility Linac and the Fermilab Photo-injector was done in Milano [6]. The system at Fermilab incorporates manipulator arms to transfer a cathode from the preparation chamber into a 1.3 GHz photo-electron RF gun while it remains in an ultra-high vacuum (UHV) environment, in order to avoid the deleterious effects of residual gases on the QE. A first prototype electron gun has been operated with a photo-cathode for several months [1]. This paper describes preliminary results obtained with the first 2 photo-cathodes and the first gun.

Some of the desired parameters for the TeSLA Test Facility beam are given in Table 1. The desired characteristics for the photo-cathodes include (i) high QE, (ii) high current density ($>$500 A/cm^2), (iii) long lifetime, and (iv) low field emission. The choice of Cs_2Te is a compromise between long lifetime, rugged metal cathodes with low QE (typically between 10^{-6} and 10^{-4}) and semiconductor cathodes with high QE ($>$10%), which generally have a short lifetime because of their sensitivity to contamination.

2 PREPARATION CHAMBER

To minimise the poisoning by residual gases, the cathodes must be coated under UHV conditions and remain in UHV throughout their useful lives. Thus, all components of the cathode preparation chamber (Figure 1) are compatible with UHV. The chamber is baked at 150 to 200°C after exposure to ambient air. The vacuum is maintained by 2 ion-getter pumps and a titanium sublimation pump. Ionisation gauges and a residual gas analyser (RGA) are used to monitor the pressure. The chamber can accommodate up to 5 cathodes, which could in principle all be used in turn without the need to bleed up the chamber. A cathode is moved from the coating chamber to the RF gun via one mechanical actuator and 2 magnetically-coupled actuators. The electrical contact between the cathode and the wall of the gun is made with a toroidal Be/Cu spring.

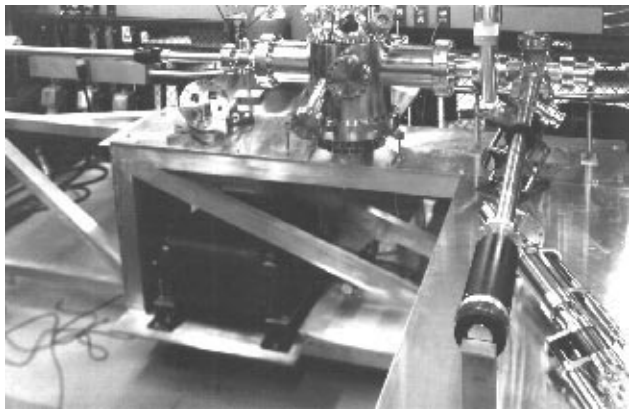

Figure 1. Cathode preparation chamber.

3 COATING OF THE CATHODES

Prior to coating, the sources are degassed by flowing a small amount of current through them. In the mean time, the molybdenum cathode is heated with a halogen lamp to encourage the evaporation of surface contaminants: the temperature is ramped up to 350°C and held at 350°C for 30 to 60 minutes. The cathode is then allowed to cool to 120°C and held at that temperature for the duration of the coating. A quartz crystal thickness monitor is inserted momentarily to calibrate the evaporation rates for the Cs and Te sources. Ultra-violet (UV) light from a mercury lamp (λ = 254 nm) is focussed onto the cathode and the photo-current is monitored during the deposition, as shown in Figure 2. Te is deposited for 10 minutes at a rate of 1 nm/minute, and then Cs is deposited at the same rate for 60 to 120 minutes. The pressure typically increases to between 1 and $4 \cdot 10^{-9}$ torr during evaporation of Cs or Te. The colour of the photo-emissive film was orange for the first cathode (Cs deposited for 63 minutes) and blue for the

second cathode (Cs deposited for 110 minutes).

4 QE MEASUREMENTS

The UV beam from the mercury lamp is used to measure the QE while the cathode is in the preparation chamber. The QE is defined as

$$\mathrm{QE} = \frac{\text{Number of Emitted Photo-electrons}}{\text{Number of Incident UV photons}} .$$

The UV power is measured with a photo-diode. A bias of 200 V is applied between cathode and its surroundings to capture the photo-electrons. The photo-current is measured with a picoammeter; the background current (obtained by blocking the UV light) is subtracted. The DC QE is deduced from the ratio of the photo-current to the UV power. The UV spot size is typically about 5 mm during the DC measurements.

While the cathode is in the RF gun, the UV pulses from the laser (λ = 263 nm, 1 to 10 ps pulse length) are used to measure the QE. The UV energy per pulse is measured with a photo-diode. The photo-electron bunch produced by a laser pulse is accelerated by the gun. The charge per bunch is measured with an integrating charge transformer at the exit of gun. The pulsed QE is deduced from the ratio of the charge per bunch to the UV energy per pulse. As can be seen in Figure 3, there is a decrease in the measured pulsed QE at high charge per bunch. This might be due to space charge or an actual dependence of the photo-electron yield on UV intensity.

The QE measurements on the 2 cathodes are summarised in Figure 4. The initial QE of both cathodes exceeds 10%, but the QE after removal from the RF gun is less than 1%. The maximum charge extracted from the cathode was 30 nC for a single bunch and 15 nC per bunch for trains of 9 bunches.

5 GAS EXPOSURE

Exposure to residual gases, O_2, CO_2, and H_2O in particular, causes the QE to decrease with time. The base pressure in the preparation chamber was of order $5 \cdot 10^{-10}$ torr or lower; RGA measurements indicated that the dominant gas was H_2, with other species typically down by at least a factor of 4. The pressure in the gun without RF was about $2 \cdot 10^{-9}$ torr when the first cathode was inserted; it had fallen to $\leq 5 \cdot 10^{-10}$ torr by the time the second cathode was removed. The pressure with RF on was significantly worse; it got as high as $5 \cdot 10^{-8}$ torr initially, but did improve with time. Actuator motion inside the vacuum system also produced some short-term increase in pressure.

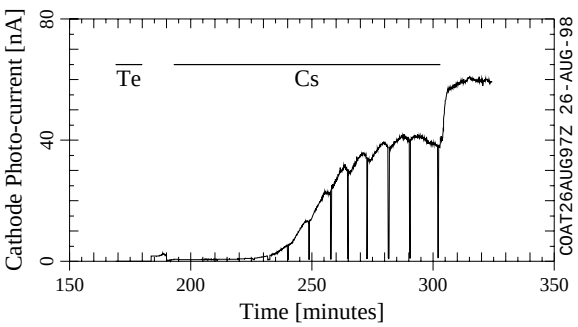

Figure 2. Photo-current as a function of time during the coating of the second photo-cathode. The times during which Te and Cs were being evaporated are indicated by the bars along the top. The downward spikes correspond to the UV light being blocked momentarily to check the background current.

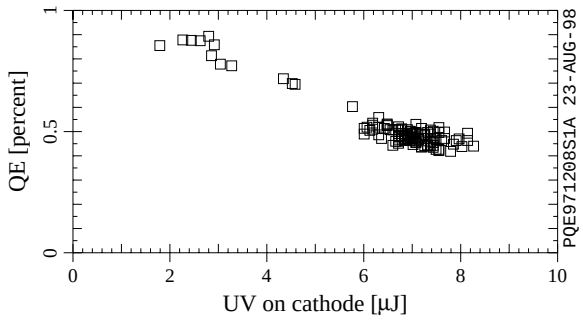

Figure 3. Dependence of the QE on the energy per laser pulse.

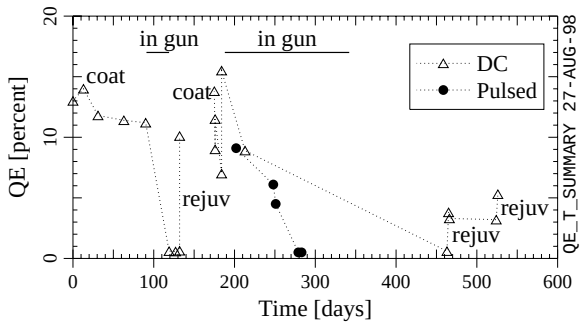

Figure 4. Time dependence in the QE.

6 REJUVENATION

The decrease in QE due to gas exposure can be partially reversed with a combination of heat and UV light [5, 7]. UV light from the mercury lamp is focussed onto the cathode with a spot diameter of about 10 mm; the UV power is between 6 and 40 μW. The cathode is heated to 230°C. The combination of heat and light causes improvement of the QE. The exact process is not yet clear; it may be desorption of residual gas from the surface or diffusion from the surface further into the photo-emissive layer.

Figure 5 shows the increase in photo-current during the rejuvenation of the first cathode. From time t = 30 minutes to t = 90 minutes, the cathode temperature was ramped up to 230°C; the temperature was held at 230°C until t = 190 minutes, at which time the temperature was ramped back to room temperature. As can be seen in Figure 5, the photo-current increases the most rapidly as the temperature is ramped up; it still increases by almost a factor of 2 as the temperature is ramped down (the latter increase was

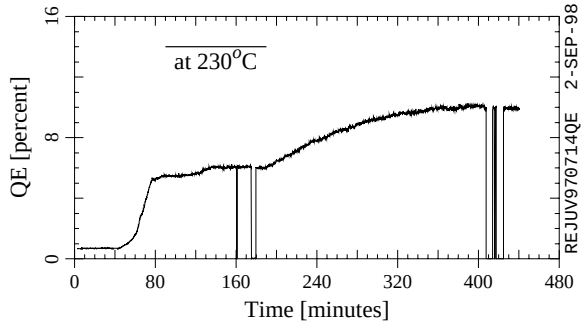

Figure 5. QE as a function of time during the rejuvenation of the first cathode. As before, the downward spikes correspond to the UV light being blocked momentarily.

not observed during the rejuvenation of the second cathode, however). The pressure was highest (between 1 and $2 \cdot 10^{-9}$ torr) while the temperature was ramped up.

As indicated in Figure 4, the QE of the first cathode increased from 0.65% to 10% during rejuvenation. The QE of the second cathode increased from 0.6% to 5% in 2 iterations.

7 MUTABILITY

After coating the second cathode, we observed an increase in the QE with time in the presence of UV light at room temperature, presumably due to the same mechanism as the rejuvenation at elevated temperatures. The QE increased from 7% to 15.5% in about 150 minutes. Much less mutability in the QE was seen after rejuvenation: the QE remained between 2.9 and 3.3% over 130 minutes. The time dependence in the QE is compared in Figure 6.

8 QE SCANS

Maps of the QE as a function of position on the cathode were obtained by focussing the UV light from the lamp to a small spot (about 1.25 mm diameter) and scanning the spot over the photo-emissive surface. A mirror on a kinematic mount (allowing us to translate and rotate the mirror reproducibly) was used to divert the UV spot onto a piece of graph paper in order to determine the location of the spot.

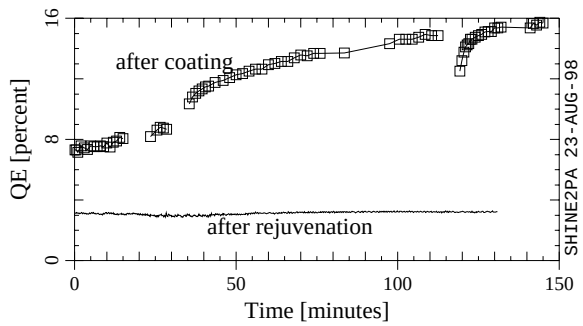

Figure 6. Comparison of the QE versus time before insertion into the gun and after rejuvenation for the second photo-cathode (UV power = 10 μW, spot size = 5 to 10 mm).

Visible light was used to determine the location of the cathode in the coordinate system of the graph paper. A QE map taken after the coating of the second cathode is shown in Figure 7. As can be seen, the QE is not uniform over the entire photo-emissive layer (15 mm diameter).

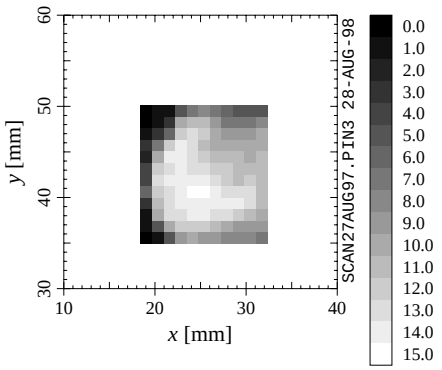

Figure 7. Map of the QE as a function of position on the surface of the second cathode the day after coating. Each pixel represents one QE measurement; the legend on the right indicates the QE values in percent.

9 CONCLUSION

We have coated and used two Cs_2Te photo-cathodes in the first prototype RF gun of the Fermilab photo-injector. We have extracted 30 nC from a single bunch and 15 nC per bunch from trains of 9 bunches. Under operating conditions, the QE falls from $\geq$8% to $<$1% over one or more months. Our QE measurements with DC and pulsed light are reasonably consistent, although we see a reduction in the pulsed QE at high UV intensity. Rejuvenation allows us to restore the QE to $\geq$5%, although we have not yet used a rejuvenated cathode in the gun. It would be desirable to improve the spatial uniformity and lifetime of the cathodes.

ACKNOWLEDGEMENTS

We thank our colleagues, especially E. R. Colby, M. J. Fitch, and C. Gesmundo for their help with this work, which would not have been possible without the support of H. T. Edwards and C. Pagani.

A HIGH CHARGE PHOTOINJECTOR FOR THE PULSED RADIOLYSIS FACILITY - ELYSE*

J.C. Bourdon, T. Garvey, J. Le Duff,

M. Gaillard,
Laboratoire de Photophysique Moléculaire, Université de Paris-Sud, CNRS, Orsay, France.

Abstract

The Physical Chemistry Department of the CNRS at the Université de Paris-Sud and the Laboratoire de l'Accélérateur Linéaire (LAL) will collaborate on a dedicated radiolysis user facility named ELYSE. The irradiation of users' samples will be performed using electron beams of energies varying from 4 to 9 MeV, produced from a laser triggered RF gun. The accelerator group at LAL, benefitting from the experience gained with their experimental RF gun (CANDELA), are responsible for the design and construction of the accelerator. The nominal beam requirements for ELYSE are 1 nC pulses of 5 ps width (FWHM). However there is a strong scientific interest in obtaining bunch charges of 10 nC for the same pulse width. The need to extract such high charges necessitates the use of Cs_2Te photocathodes with their high quantum efficiency. An essential user requirement is to keep the charge of the integrated dark current during the RF pulse width (3 microseconds) below 1% of the charge of the main beam. We will present the status of our studies aimed at construction of an RF gun and its associated transport optics capable of achieving these challenging goals.

1 INTRODUCTION

The ELYSE project is aimed at providing the French physical chemistry community with a facility for the study of fast chemical reaction dynamics. The increasing interest in such facilities has resulted in their study and construction elsewhere [1,2]. Irradiation of chemical samples will be possible with both electron beams (radiolysis) and laser beams (photolysis). A "probe" laser, synchronised with the excitation source, will then be used to examine the induced reactions. The Laboratoire de l'Accélérateur Linéaire has the responsibilty for the design and construction of the electron accelerator for the radiolysis experiments. Our design will benefit from the experience we have gained with our experimental RF gun project, CANDELA [3]. In this paper we will present the requirements of the accelerator and illustrate the status of our studies towards its design.

2 SPECIFICATION

The desired beam parameters for ELYSE are shown in table 1 below.

Table 1: Specification of the ELSYE Accelerator

Energy	4 - 9 MeV
Bunch charge	> 1 nC
Bunch duration	< 5 ps (FWHM)
Energy spread (RMS)	2.5%
Normalised RMS emittance	60 mm-mrad
Repetition rate	> 10 Hz
Beam diameter on target	2 - 20 mm

In addition to the above requirements there is a strong interest in pushing the bunch charge to 10 nC for the same bunch length and in having machine operation at frequencies up to 100 Hz. As the project requires a probe laser synchronised with the electron beam it seems natural to consider a laser triggered RF gun as the electron source. Following our previous experience with S-band structures we have opted for a 3 GHz RF gun. Good experimental conditions require the level of dark current charge incident on user samples to be less than 1% of the charge from the main electron pulse. As the RF pulse width will be typically 3 μs long it is clear that the dark current arriving in the experimental area must not exceed several μA and this condition is certainly one of the principal challenges of the machine.

3 THE ACCELERATOR

3.1 The Electron Gun

We aim to benefit as much as possible from existing RF gun experience and therefore we base our choice of gun on the one developed for the CLIC Test Facility (CTF) at CERN [3]. This 1-1/2 cell structure provides a beam of 4.5 MeV for a nominal electric field of 100 MV/m. As it is known that the dark current is a strongly increasing function of the cathode field (E_C) we aim to slightly modify the CERN geometry so as to permit operation at reduced fields. Calculations with the SUPERFISH code show that the introduction of a chamfer around the cathode plane can reduce E_C with respect to the maximum axial field by 17% [4]. With this modification we can envisage running the cathode at fields of typically 65 - 75 MV/m (79 - 91 MV/m peak axial field). In order to allow clean transmission of the beam for these reduced fields we open the iris diameter of the structure from 20 mm to 30 mm. PARMELA simulations indicate that such a gun should produce a

beam of 3.6 MeV for E_C = 65 MV/m (4.2 MeV for E_C = 75 MV/m).

The additional energy needed to reach 9 MeV will be provided by a "booster" cavity which will be identical to the one employed on the CTF. This is a four-cell standing wave structure operated in π mode. As the 10 nC bunch leaving the gun will be strongly affected by space charge forces a solenoidal focusing coil, placed at the gun output will be used to focus the beam through the booster. Table 2 shows a summary of the beam parameters as calculated by PARMELA at the exit of the booster. A schematic drawing of the RF gun and the booster is shown in figure1.

Table 2 Beam parameters as calculated by PARMELA.

	9 MeV/1nC	9 MeV/10 nC	4 MeV/1 nC	4 MeV/10 nC
RMS Bunch length (ps)	1.1	2.4	1.2	2.8
RMS energy spread (%)	0.8	2.6	1.7	6.0
RMS Norm Emittance (mm-mrad)	14	67	15	70

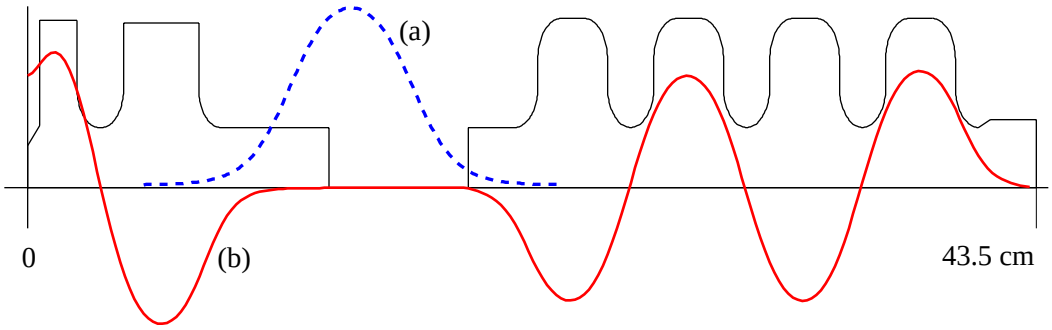

Fig. 1 Schematic of RF gun and booster showing (a) solenoidal magnetic field and (b) RF accelerating field.

The desire to have 10 nC bunch charges implies the use of Cs_2Te cathodes. Such cathodes have demonstrated quantum efficiencies in excess of 1% with life-times of several hundred hours [4]. We propose to use a 10 mm diameter cathode irradiated at near normal incidence by a 266 nm wavelength laser beam. A commercially available Titanium-Sapphire laser (800 nm) produces the UV light after frequency tripling. The UV pulses are typically of 1 ps RMS width and have an energy of 70 μJ.

3.2 The Transport Line

The beam from the booster can be delivered to any of three different experimental stations with the aid of two 30° bend dipole magnets (Fig.2). It is hoped that the dispersive nature of the dipoles will serve to reduce the level of dark current arriving at the targets of those users for whom this effect is particularly troublesome. Collimating slits between the two dipoles can be used to select a narrow energy band around the nominal beam energy. Until now we have checked the transport through the magnet elements with the TRANSPORT and TRACE-3D codes. Input to the codes was provided by outputs from PARMELA runs calculated from the cathode up to the exit of the booster cavity. PARMELA gives the distribution of the particles on the 2-D phase-space projections; x-x', y-y', and δφ-δE/E, where these symbols have their usual meaning. However, as TRACE-3D has no notion of particle distribution we make the following approximation; the elliptical phase-spaces used to start the TRACE-3D runs are chosen such that the values of the beam parameters are equal to the RMS values calculated by PARMELA (for which the 2-D projections are not necessarily enclosed by an elliptical contour).

As the arc, composed of the two dipoles, has a non-zero momentum compaction we have the possibility of bunch compression due to energy-dependent path length effects. Initially we run TRANSPORT to find settings for quadrupoles Q4 and Q5 which yield $R_{51} = R_{52} = 0$, where R_{51} and R_{52} are the φ-x and φ-x' elements of the transport matrix (calculated from the entrance of the first dipole to the exit of the second). We then run TRACE-3D to add the effects of linear space-charge forces and finally optimise the settings of Q4 and Q5 to obtain a minimum in the bunch length at the exit of dipole 2. In the absence of space charge forces the final phase width of the beam, $\Delta\phi_f$, is given by,

$$\Delta\phi_f = R_{56}\delta p/p + \Delta\phi_i$$

where $\Delta\phi_i$ is the initial length and R_{56} is the φ-δp/p element of the transport matrix. We have seen signs of such bunch compression from the TRACE-3D runs and experimental observations of this effect have been obtained recently using a two-dipole arc similar to the one which we propose [1].

Calculations indicate that compression is possible for all energies and charges of interest when the beam is transported to experimental area 3. In contrast we note that, for the case in which the space-charge is strongest (4 MeV, 10 nC), the bunch delivered to experimental area 1 is longer than the bunch which exits the booster. The PARMELA simulations indicate that the 4 MeV-10 nC beam exiting the booster has transverse phase space ellipses which are strongly distorted by non-linear space

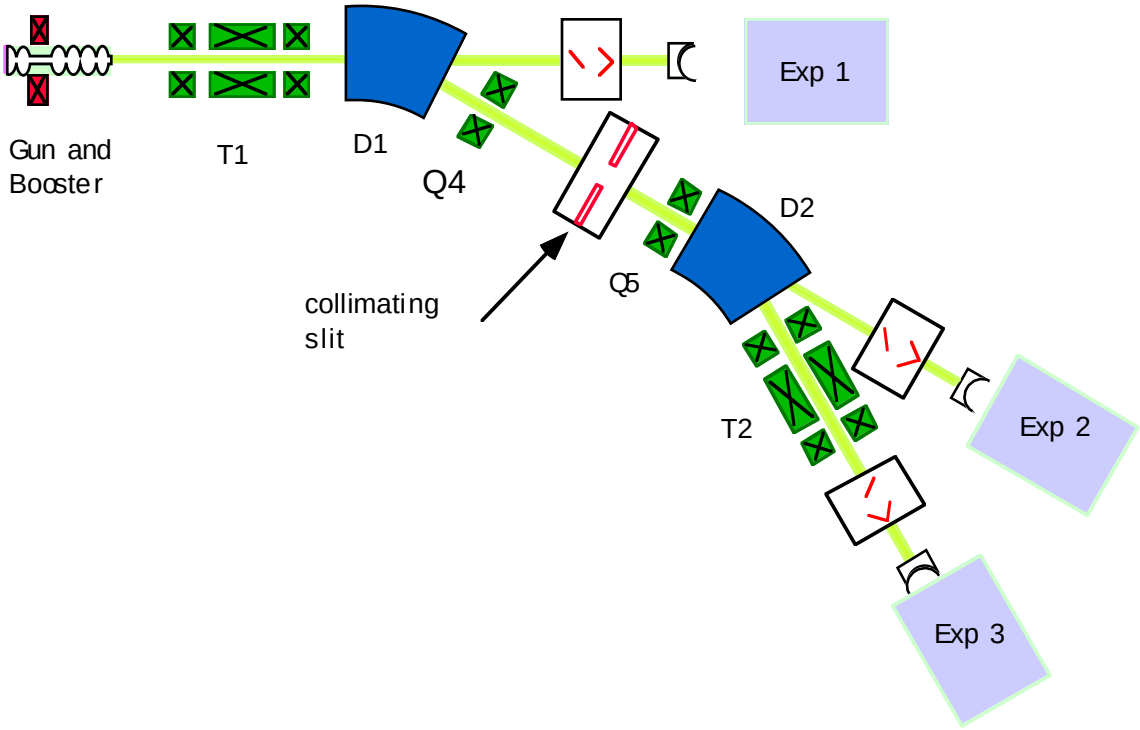

Fig.2 Schematic of the ELYSE accelerator showing the gun, booster, triplet magnets (T1, T2), dipoles (D1, D2), quadrupoles (Q4, Q5) and experimental areas (Exp 1, Exp 2, Exp 3).

charge effects. However, the input phase spaces for TRACE-3D simulations are ellipses with Twiss parameters which correspond to the RMS emittance, size and divergence of the PARMELA outputs. Therefore, the results of the TRACE-3D runs should be regarded with some caution. Now that we have some idea of the necessary quadrupole strengths required to confine the beam we intend to perform PARMELA simulations throughout the entire accelerator to verify the results of the TRACE-3D calculations.

ACKNOWLEDGEMENTS

We are indebted to R. Bossart and J.C. Godot of CERN for all the information they have provided us with concerning the CTF gun and booster cavity. The various simulation runs described above were performed by H. Monard and Y. Thiery with the aid of B. Mouton. The modifications to the CTF gun were suggested by J. Rodier. We thank P. Dufresne for the preparation of figure 2.

* Funding for ELYSE is provided by the CNRS, the MENRT, the Universite de Paris-Sud, the Conseil Regional Ile-de-France and the Conseil General de l'Essonne.

FIRST PERFORMANCE OF THE RFD LINAC STRUCTURE*

D.A. Swenson, K.R. Crandall, F.W. Guy, J.W. Lenz, W.J. Starling
Linac Systems, 2167 N. Highway 77, Waxahachie, TX 75165

Abstract

Our "Proof-of-Principle" prototype of the RFD linac structure is fully assembled, tuned, and under vacuum, awaiting the delivery of the rf power system, which is now 15 months late and scheduled for delivery at the end of this conference (September 1998). Hence, we have no linac beam or full power performance to report. Nevertheless, we have some ion source beam, prototype assembly, and low-power linac performance to report.

1 THE RFD LINAC PROTOTYPE

A "Proof-of-Principle" prototype of the new RFD linac structure has been installed in the Linac System's laboratory in Waxahachie, TX. The purpose of this prototype is to demonstrate the validity of this new format of rf electric focusing and the practicality of using this new linac structure for a variety of scientific, medical, and industrial applications. The prototype is fully assembled, tuned, and under vacuum, awaiting the delivery of the rf power system, scheduled for delivery in the near future.

This prototype, comprising a 25-keV duoplasmatron ion source, a short two-element einzel lens LEBT, a 0.65-m-long, 0.8-MeV RFQ linac section, and a 0.35-m-long, 2.5-MeV RFD linac section, is shown in Fig. 1. The left-most section of the prototype, as shown in the figure, contains the ion source and LEBT, the middle section contains the RFQ linac, and the right-most section contains the RFD linac. The linac structures were designed to operate at 600 MHz; they both are currently tuned to 596.48 MHz.. The entire length of the prototype is 1.5 meters; the total length of the two linac structures is 1 meter.

The ion source, on loan from Los Alamos, is a scaled down version of the LAMPF ion source, designed and built for the PIGMI program in the late 1970s. It still produces more than 15 mA of proton current, which is more than adequate for this application. The ion source/LEBT vacuum enclosure is pumped by a single 400 l/s turbo pump and operates, under normal hydrogen gas flow, at a vacuum pressure of about $2x10^{-4}$ Torr.

The LEBT incorporates a small amount of electrostatic steering, a two-element einzel lens, and a small amount of beam diagnostics near the entrance to the RFQ linac. An excitation of 24.5 kV on each einzel lens element produces a small, well-centered beam spot at the entrance to the RFQ linac, without the use of any beam steering. A four-quadrant beam collection plate followed by a beam current transformer completes the Ion Source/LEBT portion of the system.

*Supported by National Inst. of Mental Health (NIMH).

The RFQ linac structure was fabricated as four separate pieces of OFE copper; two major pieces (the top and bottom vanes) and two minor pieces (the side vanes). The vane tips were contoured with a special, fixed-radius cutter, with a very small (3.5 mm) throat radius. The intent was to bolt the four pieces together for low power testing and to furnace braze them together for operation. However, for expedience, we chose to eliminate the final furnace brazing step.

For want of a proper machining fixture, the precision of the four RFQ pieces was not as high as expected. In spite of its short length, the RFQ tuning process was quite difficult. In the end, we found considerable help from the dipole-mode tuning rods developed by Los Alamos. Figure 2 shows the resulting mode spectrum and the field distribution at three places in each of the four quadrants. The quadrant fields appear to have an rms deviation of about 2.2%.

The RFQ vacuum enclosure is pumped by a single 400 l/s turbo pump. It typically operates at a vacuum pressure of $1x10^{-6}$ Torr. The RFQ assembly incorporates an ultra-thin (6.35 mm) beam line vacuum valve to provide vacuum isolation between the ion source/LEBT region and the RFQ region for maintenance purposes.

Fig. 1. 2.5-MeV RFD Linac Prototype.

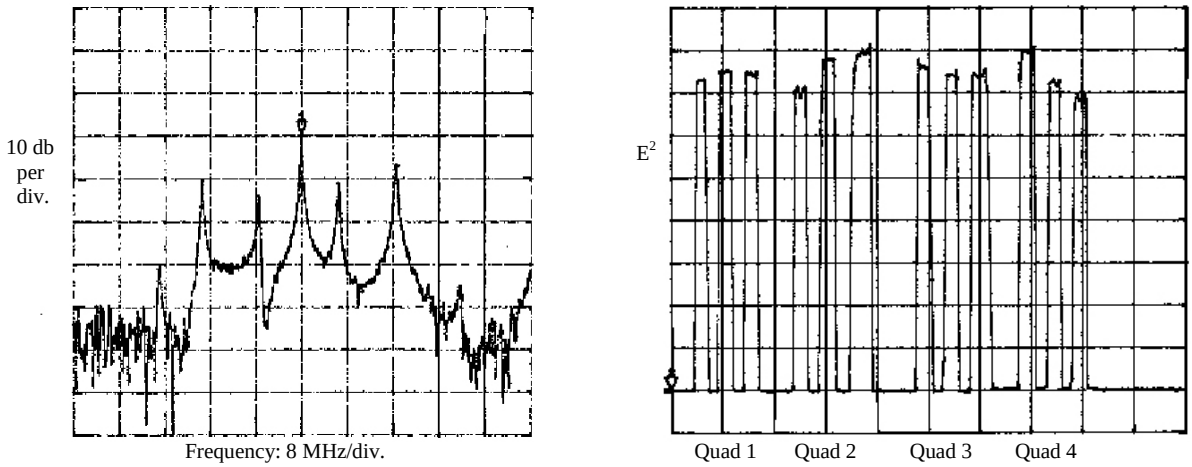

Fig. 2. Mode Spectra and Field Distribution in the RFQ Linac Structure.

The RFD linac structure is essentially a simple water-cooled cylindrical tank, loaded with RFD drift tubes. The RFD drift tube body and stem design comprises two half-body electrodes, with a total of four fingers to create the rf quadrupole field along the axis, supported on two water-cooled support blades that emanate from a single stem that mounts in a single hole through the linac tank wall. Both the drift tube and the hole are precision machined and no provision for additional alignment is planned.

The stem/blade assembly is a 4-layer stainless steel sandwich requiring two hydrogen-furnace braze cycles for completion. A portion of this assembly was machined to a circular cross section and precision ground to a cylindrical surface for installation into a reamed hole in the tank wall. The stem and hole is keyed to control the angular orientation of the drift tube. Fig. 3 shows two views of the RFD drift stem prior to adding the two half drift tube bodies. Several views of an RFD half drift tube body are shown in Fig. 4.

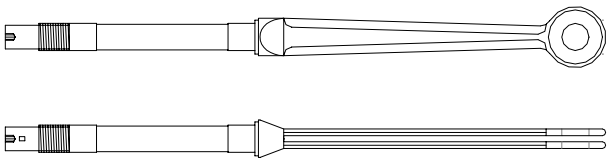

Fig. 3. RFD Drift Tube Stem.

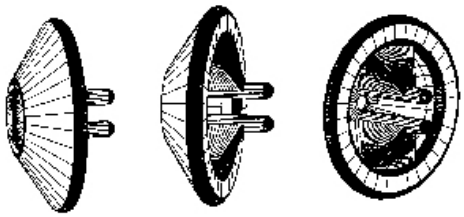

Fig. 4. Several Views of an RFD Half Drift Tube Body.

Soon after receiving the RFD drift tubes, we installed them in the RFD tank and checked the resonant frequency. It turns out to be about 595 MHz. As the RFQ frequency is about the same, we accepted 596.48 MHz for the Proof-of-Principle (POP) prototype.

We developed a way to measure the RFD lens excitation. By pulling a small "copper sponge" (diameter ~ 2.4 mm) along the axis of the linac, stopping inside each RFD drift tube, we shorted each RFD lens in succession, resulting in a frequency perturbation to the structure in proportion to the electrical stored energy in each lens. Initially, we employed the usual phase shift technique used for bead pull measurements. However, as the perturbation was larger than the Q-width of the structure, it was better to simply measure and record the resulting resonant frequency. The results are presented on the upper half of Fig 5. Next, we proceeded to measure the drift tube body gap, which has a direct effect on the expected lens excitation. The results are presented on the lower half of Fig. 5. Note the correlation! After inspection and adjustment of the RFD Drift Tube geometry, the uniformity of excitation was very good.

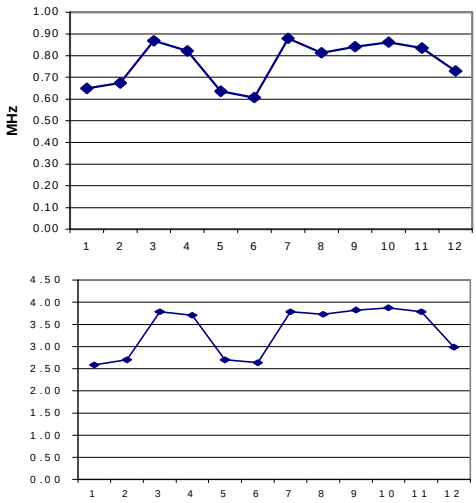

Fig. 5. RFD Lens excitation (upper) and Physical Misalignment (lower).

A resonant coupler, designed to couple the excitation of the two linac structures by locking their fields in phase and amplitude, is being employed. The resonant coupler extracts precisely the right amount of rf power from the RFD structure to excite the RFQ structure. It has the form of a quarter-wave stub in a cylindrical can as shown in Fig. 6. Slots near the base of the quarter-wave stub provide coupling to the fields of both the RFQ and RFD structures.

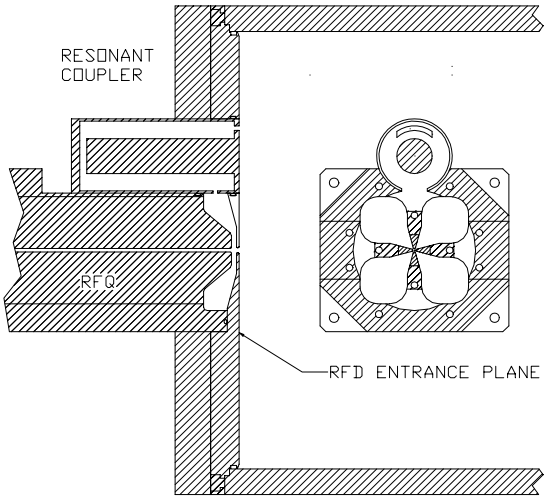

Fig. 6. The Geometry of the Resonant Coupler.

The two linac structures together with the resonant coupler form a chain of three coupled resonators that, when properly tuned, can be excited in three different modes corresponding to 0, $\pi/2$ and π phase shift between adjacent resonators. These three modes can be seen in the mode spectra of our coupled linacs shown in Fig. 7.

Our system is tuned to use the $\pi/2$ mode, which is well known for its ability to lock the phase and amplitude of the fields in adjacent cavities with great accuracy.

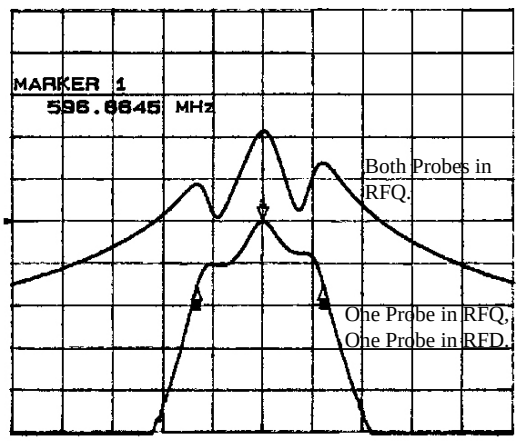

Fig. 7. Mode Spectra of the Coupled Linacs.

The rf power system is based on a multiplicity of high power YU-141 planar triodes. It is designed to produce a peak power of 240 kW at a pulse duty factor of 0.5%. It will consist of a chain of two intermediate power amplifiers (IPAs) and one final power amplifier (FPA). The IPAs will be rack mounted, while the FPA will be mounted directly above the RFD linac section, as shown in Fig. 1. The IPAs will use a total of 3 of the planar triodes. The FPA will utilize an all new single cavity configuration of 12 planar triodes in parallel.

This rf power system is nearing completion at JP Accelerator Works, Inc. It features easy tube replacement (individual cathode assemblies), a broadband cathode circuit (no tuning required), a light weight cavity assembly, built-in phase and amplitude control, a PC based control system with fiber-optically isolated control modules and professional controls software. The system is scheduled for delivery next month (September 1998).

We hope to demonstrate successful performance of this new linac structure in the very near future. The status of this effort will be reported promptly on our web pages at: **www.linac.com**

THE PERFORMANCE OF THE 1.3 GHz SUPERCONDUCTING RF CAVITIES IN THE FIRST MODULE OF THE TESLA TEST FACILITY LINAC

Wolf-Dietrich Möller for the Tesla collaboration
Deutsches Elektronen Synchrotron DESY, 22603 Hamburg, Germany

Abstract

The design goal of the 1.3 GHz 9-cell superconducting RF cavities for the Tesla Test Facility (TTF) is a gradient Eacc ≥ 15 MV/m at a quality factor of Qo ≥ $3 \cdot 10^9$. The cavities are operated in pulsed mode: 0.8 ms constant gradient with 10 Hz repetition rate.

After the vertical acceptance test and prior to the assembly in the linac the cavities are tested in a horizontal cryostat fully equipped with helium vessel, high power input coupler, higher order modes coupler and tuning system. After installing module 1 the first 120 MeV beam has been delivered successfully.

We report about the measured results in vertical and horizontal tests, the processing of the superconducting cavity system in the first module and the performance of the cavity system before, during and after operating the linac.

1 INTRODUCTION

In order to prove the technical basis of TESLA[1] the TTF (Tesla Test Facility)[2] was established at DESY within the frame of an international collaboration. In May 1994 the infrastructure was ready to prepare and test superconducting cavities. Twenty-seven 9-cell cavities, manufactured by four different European companies have been processed and measured so far.

9 cavities from the first production are operating in the TTF linac and 8 more cavities are now being installed. In end of 1997 26 more cavities were ordered which are now under fabrication or final processing. Two of them have been measured already.

2 CAVITY TREATMENT

The standard cavity preparation before the vertical test consists of the following steps: 80 µm removal from the inner surface by buffered chemical polishing (BCP), a 2 h heat treatment (HT) at 800 ˚C, a 4 h HT at 1400 ˚C with titanium getter and additional 100 µm removal by BCP. The cavity is then rinsed with high pressure (100 bar) deionized ultra pure water. After welding the He-tank and prior to the horizontal test a 20 µm BCP and a high pressure water rinse takes place.

3 VERTICAL TEST RESULTS

The average gradient of the 27 cavities tested so far is 19.5 MV/m. The average gradient of the last 13 cavities measured is even 24.6 MV/m, 3 of them showed gradients Eacc > 28 MV/m (see Fig. 1). The main limitation now is field emission. It is remarkable, that all 4 manufacturers delivered cavities with gradients higher or close to 25 MV/m.

However at the time of selecting the capture cavity and the 8 cavities for module 1, only 4 cavities were available with gradients > 15 MV/m. 5 cavities were limited by quench below 15 MV/m in the vertical test (see table 1). The reasons for this limitation were found as foreign inclusions in the material and improper cleaning of weld area before welding[3,4]. In the future this type of defects will be excluded by eddy current scan of all niobium sheets and by the current fabrication method.

Table 1: Cavity performance during vertical and horizontal tests and after installation into the linac. The numbers are the gradients in MV/m. The 1. linac test was done before and the 2. test after 3 month of linac operation. At the vertical test the dissipated power is set to 100W in order to compare the cw measurement in the vertical test with the pulsed measurement (duty cycle 1%).

4 HORIZONTAL TESTS

13 cavities for module 1, injectors and first for the module 2, equipped with all auxiliary components (helium-vessel, high-power-coupler, HOM-couplers, tuning mechanism and magnetic shielding) were tested in a horizontal cryostat. Because of the low Q_{ext} of the high power input coupler only measurements in the pulsed mode were

possible (500 μs rise time and 800 μs constant gradient at a repetition rate of 10 Hz)

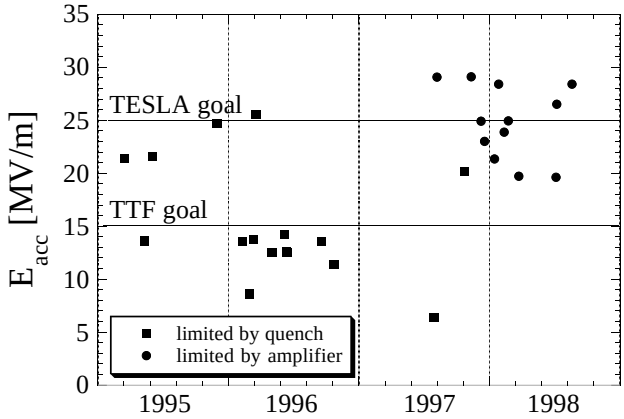

Fig. 1: Result of vertical cavity tests. The gradients below 15 MV/m before mid '97 are due to fabrication errors.

These 13 cavities reached an average gradient of 19.7 MV/m in the horizontal test compared to an average gradient of 20.3 MV/m in cw mode in the vertical test stand. In the horizontal tests, field emission has been observed higher intensities. The reason is probably particle contamination due to the more complicated assembly and the processing of the main power coupler. The higher field emission loading is responsible for the slight degradationin performance.

The performance of the cavities selected for module 1 are listed in table 1. Three cavities (D2, S8, S11) showed a higher field in the horizontal test under pulsed conditions than in the vertical cw test. This is most likely caused by the slow thermal development of the quench as compared to the rf pulse length. The other cavities sufferedfrom higher field emission or stayed constant.

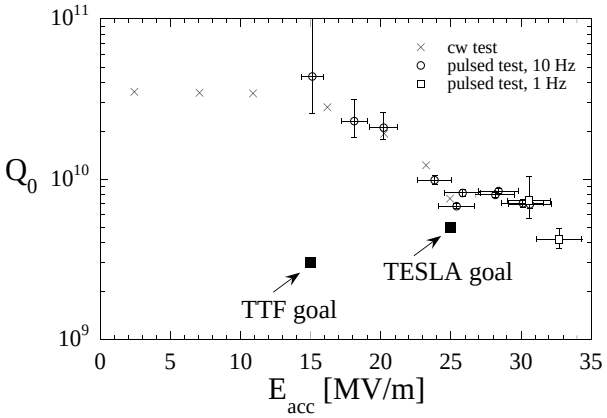

Fig. 2: The best horizontal test so far. The Q values during the pulse tests are calculated from the cryogenic losses. The cw measurement from the vertical test is given for comparison.

The best cavity tested so far in the horizontal test cryostat reached33 MV/m with a quality factor $Q = 4 \cdot 10^9$ (Fig. 2). At 34 MV/m a quench occurred. In the vertical test, this cavity reached25 MV/m, limited by available power.

Cavities showing strong field emission can be further improved by applying HPP[5]. For this purpose, short pulses of high instantaneous power (≤500 μs, up to 1 MW) are applied to destroy field emitters. The power coupler has to be carefully processed up to 1 MW, which may take several days. Due to a tight time-schedule HPP was not always applied during the horizontal test.

5 PROCESSING OF THE MODULE 1

5.1 High power input coupler

The two types (Fermilab and DESY design) of high power couplers[6] consist each of two RF vacuum windows. The coaxial window near the cavity at 70 K and the room temperature window in front of the wave-guide (Fermilab) or as a part of the wave-guide to coax transition (DESY) outside the cryostat. The coupler vacuum of all eight couplers on the module is connected and pumped by a common ion getter pump.

All 8 cavities in module 1 are driven by one 5 MW klystron. A linear RF distribution system is branching off identical amount of power for each cavity by directional couplers.

5.2 Processing couplers and cavities

The TESLA design parameters call for a transfer of 206 kW peak RF power per cavity to the beam with a pulse length of 1.3 ms and a repetition rate of 5 Hz. In addition it is also foreseen to apply HPP to the cavities in situ which requires1 MW at a maximum pulse length of 500 μs and at a repetition rate ≤ 1 Hz. Therefor the couplers have to be conditioned to this limits.

The coupler processing procedureat TTF starts with the cavity and coupler at room temperature. Therefor gases released by RF stimulated desorption can be pumped away. In the beginning of the conditioning the cavity is off resonance. The first power rise (dependent from the vacuum pressure and e^- and light in the vacuum) is done with a pulse length of 20 μs, then the pulse length is doubled for the next power rise and so forth. At the full pulse length the power is sweeped for some hours. After this the cavity and coupler are cooled down and the same processing procedureis carried out again. The last part of processing is done with the cavities on resonance.

5.1. Processing results on module 1

Due to limited time the processing of couplers in module 1 was restricted to 200 kW and 600 μs. The processing of the coupler on the module at room temperature was done at two couplers at a time in order to distinguish the vacuum reactions in the common coupler vacuum. It was always observed, that initially it is possible to rise the power very quickly without being

limited by outgassing, electron signals or light. After a sudden burst of outgassing on the coupler side of the cold window at a typical power level of 50 - 100 kW many hours are needed to once again reach the earlier achieved power level. Once the maximum power of 200 kW is reached for the shortest pulse length the power rises for longer pulses are straight forward. After about 48 to 72 h only one multipacting level at 125 kW is visible at the charged particle detectors. But the signals are smaller by a factor of 10 compared to the first processing hours. A second multipacting level at 65 kW is processed away.

When the module was cooled down to the operating temperature of 1.8 K the same processing procedure took place. All multipacting levels were processed after 30 h. The temperatures of the Fermilab cold window increased due to dynamic losses by about 5 K. Due to a fabrication failure during brazing metallization of the cold DESY windows occurred. This causes a much stronger temperature rise of about 100 K which does not effect the coupler behavior but creates higher losses at the 70 K shield circuit of the module.

When the cavities are on resonance the field distribution in the coupler differs from the off resonance full reflection condition. An additional processing is necessary. After only a few (1-5) more hours the couplers were fully operational without limiting the cavities. No interlock events were observed up to the TTF operating power of 125 kW during the first 30 days of operation time. After a few days power off time no new processing was needed to operate the module again.

6 OPERATION OF THE CAVITIES IN THE LINAC

After installation in the linac the cavities were measured again individually under pulsed conditions. Here the capture cavity C19 showed a reduced performance due to field emission loading (Tab. 1). The 8 cavities mounted in the module 1 reached almost the same results as in the vertical tests. One cavity D2 showed a slightly higher, one cavity D3 a slightly lower gradient, caused by field emission.

Operating all cavities with one klystron and a uniform power distribution the module performance is limited by the worst cavity. Therefor the quench of cavity S7 limits the maximum gradient of the module 1 to 12 MV/m at the full pulse length of 800 µs flat top and 10 Hz repetition rate. For shorter RF pulses of 300 µs rise time and 100 µs flat top at 2 Hz repetition rate acceleration gradients of 16.7 MV/m were obtained.

7 CAVITIES FOR MODULE 2

In Fig. 3 the vertical test results of the 8 cavities forseen for the module 2 are shown. The module 2 will be installed in the linac by end of September '98. The expected average gradient for this module is ≥20 MV/m.

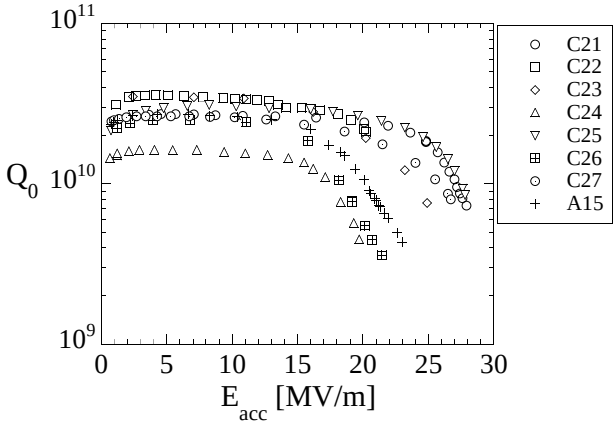

Fig. 3: Vertical test results of the 8 cavities selected for module 2.

8 CONCLUSIONS

Gradients well above 20 MV/m have been demonstratedwith 9-cell TTF cavities. Excluding only the cavities with a well identified fabrication error, the average gradient of 13 cavities is 24.6 MV/m.

The highest gradient in the horizontal cryostat with a fully equippedcavity was 33 MV/m.

The main limitation is field emission, indicating the high standardof niobium quality and fabrication methods. Further progress in gradient can be expectedby improving cleanliness during final treatment and assembly.

The first beam of 8 mA has been successfully accelerated. The average gradient of the first 8 cavity module is limited by one of the above mentioned cavity. Further improvement of the gradient is possible by optimizing the RF distribution.

A slight reduction in gradient from horizontal test to module operation was observedand is causedby high field emission loading. It shows that improvements in clean assembly and coupler handling is still necessary.

SIMULATION OF BEAM DYNAMICS INCLUDING SPACE CHARGE IN PROTON LINAC WITH ERRORS*

D.V.Gorelov** and P.N.Ostroumov
Institute for Nuclear Research of the Russian Academy of Sciences, Moscow, 117312 Russia

Abstract

The LANA computer code (Linear Accelerators Numerical Analysis) has been modified in order to study the effect of random errors on beam dynamics in proton or heavy ion linacs. The standard well known set of different errors of the accelerating and focusing channel including geometry misalignments in all directions, magnetic and electric field imperfections and accelerating field instabilities are simulated. Partial as well as cooperative effects of the errors are analyzed. The LANA code includes space charge forces in the beam, using certain approximations. A comparison of the errors effect on the beam parameters with and without space charge in the 30 mA proton linac is presented. As was found the error effect on beam dynamics is a main contribution on halo formation as well as on beam losses.

1 INTRODUCTION

The present research has been done as part of the conceptual design of the 400 MeV proton linac for JHF at KEK, Tsukuba [1]. The linac includes an RFQ, MEBT, DTL and CCL. The errors study has been performed for the MEBT-DTL-CCL part of the whole linac – from 3 MeV up to 400 MeV. The CCL operates at the third harmonic of the fundamental frequency of 324 MHz, and a transition from the DTL to CCL occurs at 70 MeV. The structure of the linac has been designed for beam intensity of 30 mA.

This research has been done using LANA code [2], that has been developed in INR, Moscow since 1991. This code has been extensively used during the commissioning and operation of the Moscow Meson Factory linac [3]. LANA was also used during the commissioning of the Fermilab linac upgrade in 1993 [4]. Presently this code is being used at TRIUMF for the ISAC project [5] and at CERN for SPL design [6].

* Research was done in frames of the collaboration between INR, Moscow and KEK, Tsukuba and as part of the agreement between these institutions.

** At present time author has temporary position at NSCL, MSU

2 MODEL

The errors which influence the beam dynamics in linacs can be divided into three groups [7]. Beam related errors, e.g. displacements of the beam with respect to the accelerator axis, mismatched beam in phase space, energy shift and spread, etc, compose the first group. Only errors of the displacements of the beam were considered in this study, taking into account the periodical steering of the beam position.

The second group of errors include time-independent (slow) errors - misalignments, e.g. tanks and drift tubes length and positioning, quads gradients, length and positioning, accelerating field flatness and setting of the amplitude and phase during the tune-up procedures, etc. A full set of this kind of errors is considered in this work.

The third group of errors consists of time-dependent (fast) errors – instabilities, e.g. amplitude and phase from the rf source, mechanical vibrational errors, field distortion due to transient beam loading, etc. This group of errors is responsible for the jitter in the beam. Only the accelerating field amplitude and phase instabilities were considered during this study as the major errors of this kind.

A simplified space charge model of the beam is used in LANA. This is a model based on the analytic relations between the charge density and the space charge electric fields for a distribution with 3-D ellipsoidal symmetry in real space [8]. Therefore this model can be applied to bunched beams only.

When doing error studies LANA provides the following values at the end of every accelerating cell in the cavity or every intertank element, e.g. drifts or quads: the transverse coordinates and derivatives of the beam center; the longitudinal average phase and energy of the bunched beam; the maximal radial extent of the beam; vertical and horizontal maximal and rms sizes of the beam; phase and energy maximal and rms spreads; the normalized rms emittances and the normalized emittances containing 99% particles in all 3 dimensions; and a number of other quantities of interest. A well known set of different errors in the linac were simulated during this study. Table 1 shows the tolerance limits for all simulated errors which are the maxima of the allowed deviations of the corresponding variables, uniformly distributed around its design value. The rms value of errors is 3 times less than the values listed in the table 1.

Table 1: Maximal tolerances limits

Error Type	Tolerance Limit
1. Transverse beam displacement	500 μm
2. tilt	1 mrad
3. CCL section length	100 μm
4. alignment	100 μm
5. Drift tube length	100 μm
6. alignment	100 μm
7. Quadrupole gradient	1.5 %
8. Length	100 μm
9. Alignment	100 μm
10. Displacement	50 μm
11. Tilt	0.5 mrad
12. Rotation	10 mrad
13. Field difference between CCL sections in amplitude	1 %
14. in phase	1 °
15. Non-flatness of the accelerated field in the cavity	3 %
Average accelerating field amplitude over DTL or CCL tank:	
16. tune-up	3 %
17. instability	1 %
Phase difference between neighbor cavities:	
18. tune-up	3 °
19. instability	1 °

The errors of the first group (1. and 2.) were applied at the entrance of each section where the steering of the beam is provided after the centering the actual position of the beam.

3 COMPARISON OF THE PARTIAL CONTRIBUTION OF DIFFERENT SETS OF ERRORS

Five different sets of errors were considered in this study:

1. All errors listed in Table 1.
2. All errors, except the 17th and 19th – the instability errors.
3. RF system errors only, i.e. from 13th to 19th.
4. RF system errors except instabilities errors.
5. Geometry misalignments, quad errors and beam mismatches, i.e. from 1st to 12th.

All these simulations were performed both with and without space charge effects taken into account.

Figs. 1, 2 and 3 presents the results of the 1st set of error simulations, listed above. It could be seen in Fig. 1 that the space charge effects have a smaller impact on the maximal beam radius growth compared to the error effect. The error effect for the beam without space charge gives approximately a factor of 4 in the maximal beam radius growth, but the space charge effect gives approximately a factor of 3 for the beam without errors and a factor of 2 – with errors for the simulated number of particles ~1200.

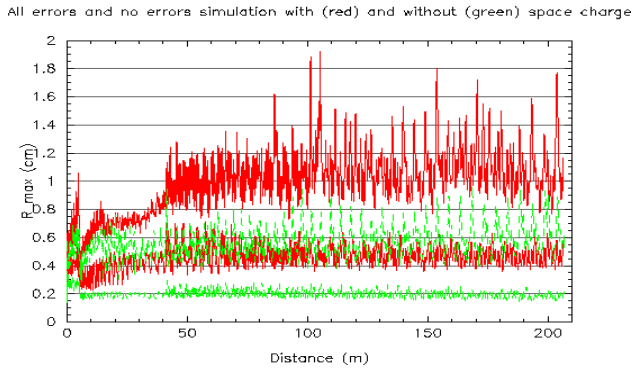

Figure 1. Evolution of the maximal beam radius along the linac with errors (upper lines) and without errors (i.e. design linac) with space charge (solid lines) and without space charge (dashed lines).

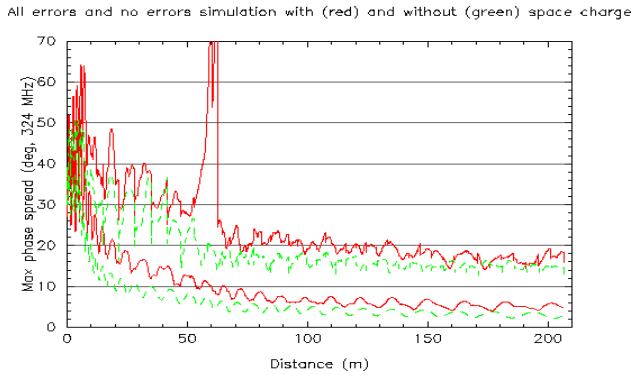

Figure 2. Evolution of the maximal phase spread along the linac with errors (upper lines) and without errors (i.e. design linac) with space charge (solid lines) and without space charge (dashed lines).

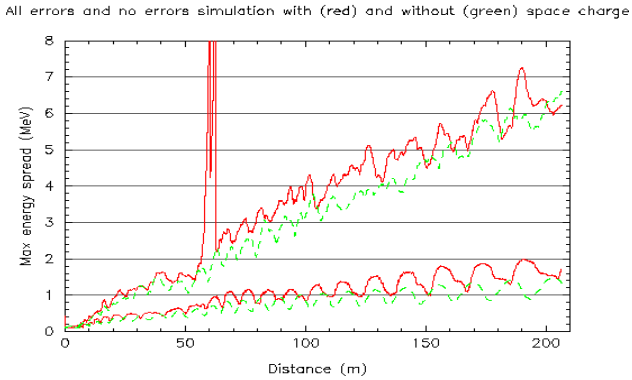

Figure 3. Evolution of the maximal energy spread along the linac with errors (upper lines) and without errors (i.e. design linac) with space charge (solid lines) and without space charge (dashed lines).

The interesting result is that the relative effect of the errors is smaller in the case of a charged beam (~3 times growth of the maximal beam radius) compared to the case of a non-charged beam (~4 times growth of the same parameter).

The halo formation process could not be studied in detail because of the limited number of particles used for the statistical simulations. But in some cases of charged beam simulation where the field instabilities were included a few particles were lost. These losses indicate intensive halo formation induced by instabilities of the accelerating field.

4 PROBABILITY ANALYSIS

The probability distributions of the maximal beam radius and the longitudinal effective emittance, containing 99% of particles, are presented in Figures 4 and 5 respectively. These figures show the probabilities for simulations without space charge for 400 and 100 random errors samples. Also the probability distributions of the simulations with space charge for 100 errors samples are shown on the same figure in a different scale.

The detailed consideration of the probability distributions, which could not be discussed here because of the limited space, show that the statistics of 400 errors samples is good enough for the transverse beam parameter study and reasonable for the longitudinal ones. The 100 errors samples analysis shows good qualitative results, but insufficiently reliable quantitative ones.

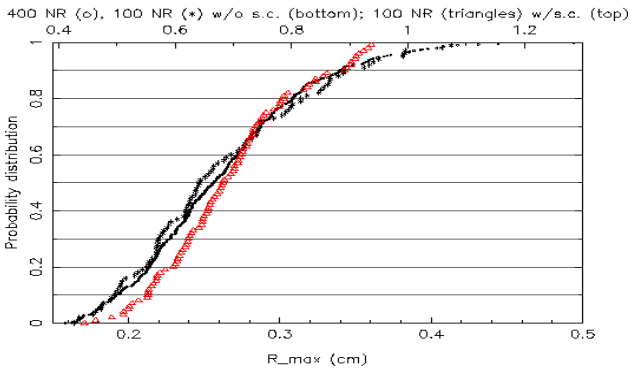

Figure 4. Probability distribution of the maximum beam radius from 400 NR (dots), 100 NR (asterisks) without space charge; and from 100 NR (triangles, upper scale) with space charge.

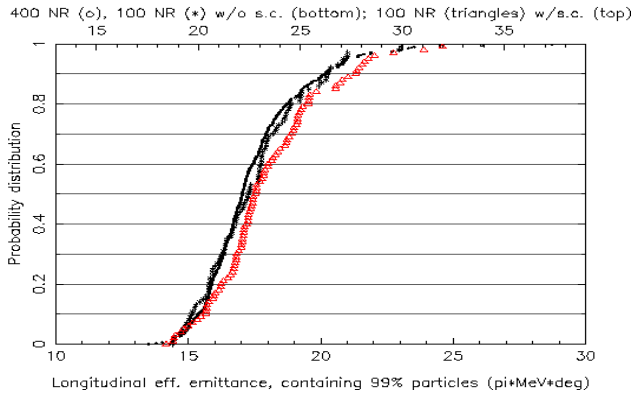

Figure 5. Same as in Figure 4, but for the longitudinal effective emittance, containing 99% of particles.

5 CONCLUSIONS

The time-consumptive calculations that were done for the statistical analysis of the errors influence on the charged beam dynamics provide interesting results and emphasizes the problem of halo formation which is not the subject of the present article. Though in the conclusion of this study we would like to state that the halo formation takes place in the regions of the non-adiabatic changes of the linac main parameters and is induced by the instabilities of the accelerating field.

The probability distributions study confirms that the number of samples for such a study could be chosen to be about 200-300 for the transverse beam dynamics and about 400-500 for the longitudinal ones.

These studies show that the given values of the tolerance limits (table 1) could be recommended in order to meet the requirements of low losses in the linac.

While the most sensitive error for the transverse emittance growth is quad rotations, the one for the longitudinal dynamics is the accelerating field instability.

The relative increase of the maximum beam radius is smaller in the case of the charged beam simulation compared to the relative growth of this quantity in the non-charged beam simulation. Nevertheless the cooperative effect of space charge and the errors could lead to halo formation if no special care is provided to control this process.

BASIS FOR LOW BEAM LOSS IN THE HIGH-CURRENT APT LINAC

Abstract
The APT linac has been designed for very low beam loss. This important aspect of the design is supported by three main bases: 1) an understanding of the performance of the 800-MeV LANSCE proton linac at Los Alamos using measurements and simulations, 2) a theoretical understanding of the dominant halo-forming mechanism in the APT accelerator from physics models and multiparticle simulations, and 3) a conservative design approach for APT aimed at maximizing beam quality at low energies and providing large apertures at high energies to reduce beam loss to a very low value.

1 BEAM LOSS AND ACTIVATION

The APT accelerator [1] is a cw medium-energy proton linac with a design beam current of 100 mA, a number of particles per bunch equal to 1.8×10^9, and a final energy of 1030 MeV or higher, depending on the desired tritium production rate. It has been designed to operate with extremely low beam losses to avoid radioactivation of the machine components. It is important to achieve hands-on maintenance capability along the machine in order to meet overall plant availability requirements, although remote maintenance techniques could be employed at a few high-beam-loss locations without major impact.

The maintenance criterion limits post-shutdown activation levels to a few mrem/hr at the beamline. The corresponding beam loss rate that can be tolerated, as a function of beam energy, has been estimated in Ref. [2]. Expressed in beam power, the loss above 100 MeV is limited to a few tenths watt per meter, a value that is consistent with experience at the LANSCE linac, which operates with hands-on maintenance. LANSCE is the highest power operating proton linac in the world. It is a pulsed machine with multiple beam operation that includes a 6%-duty-factor 1-mA average current 800-MeV output beam. For LANSCE the average fractional H^+ loss rate above 100 MeV is about 10^{-6}/m. Excluding two hot spots at focusing transitions lowers this value to about a few times 10^{-7}/m. The number of particles per bunch in APT is only about 3.4 times greater than for LANSCE, and the beam focusing strength in the APT design is greater so that the beam-physics regimes of the two linacs are nearly the same. The APT peak beam current of 100 mA is by no means a record for proton linear accelerators; the Brookhaven and Fermilab injector linacs have operated with H^+ beams at peak proton currents near 300 mA. Nevertheless, the challenge for the APT linac is to deliver an average current 100 times higher than LANSCE in the same energy range, while achieving a beam-loss rate that is no larger in absolute terms. This scales for APT to an acceptable average fractional loss rate of about 10^{-8}/meter, or a total of about 10^{-5} fractional beam loss above 100 MeV. The design objective for APT is a factor of 10 smaller than these numbers.

2 APT BEAM-LOSS THREAT

Our evaluation of the beam-loss threat in APT and its impact on the linac design are based on a combination of operational experience, and theory plus simulation. The approach we have used has several aspects and components:

- Use of measurements of beam performance and activation levels in the LANSCE linac combined with computer simulations to determine the causes of beam loss in that accelerator.
- Choice of the APT linac design architecture and parameters to avoid the halo-generating and loss-mechanisms seen in LANSCE.
- Use of analytic modeling and computer simulation to understand the remaining physical mechanisms responsible for generating halo, and the amplitudes of particles projected into the halo.
- Confirmation of the predicted beam performance (at low energies) by measurements on the Low Energy Demonstration Accelerator (LEDA) now being built at Los Alamos. In the present schedule, initial data should be available in late FY99.

3 BEAM LOSS AT LANSCE

LANSCE routinely achieves hands-on maintenance at all locations in the accelerator and beam transport. Typical H^+ loss rates after the major focusing transitions in the linac are very low; the integrated fractional loss along the high-energy linac is normally less than 5×10^{-4} and never more than 10^{-3}. Simulations of the LANSCE linac [3] have shown several causes of beam loss. The main cause is the incomplete bunching action of the 2-cavity 201.25-MHz bunching system in the low-energy beam transport. This system, which pre-dates the development of the RFQ, produces a beam with an extended tail in longitudinal phase space, leading to poor longitudinal capture. A significant beam loss occurs downstream from the frequency jump at 100 MeV, where the 201.25-MHz drift-tube linac (DTL) transitions to the 805-MHz coupled-cavity linac (CCL); here both the transverse and the longitudinal acceptance decrease substantially, and the beam is also poorly matched longitudinally. Near 200 MeV, there is a sudden reduction in the transverse focusing strength, which leads to additional losses downstream.

Several other effects are believed to contribute to beam loss in LANSCE. First, the dual beam (H^+ and H^- accelerated together) operation of the accelerator limits the effectiveness of beam steering and other corrections.

In practice, beam steering is restricted to the low-energy beam transport and the transition region between the DTL and CCL, where the two beams are separated. Second, LANSCE is a pulsed linac, and as much as 40% of the beam loss occurs during the beam-turn-on transients. This loss can be caused by several factors, including beam-neutralization variations in the low-energy transport, and the beam-induced transient in accelerating-cavity fields, uncorrected by feedforward signals. Finally, the aperture radii in the LANSCE focusing elements and accelerating structures are relatively small, 1.6 to 1.9 cm in the high-energy linac, and the transverse focusing is relatively weak, because of the large spacing of quadrupole magnets. These two factors taken together result in a small "aperture ratio" (the ratio of physical aperture radius to rms beam radius), which varies from about 4 to 7 in the high-energy linac.

4 LANSCE LINAC AND APT DESIGN

How are the beam-loss mechanisms identified in LANSCE addressed in the APT linac design? First, the dominant loss mechanism in LANSCE, longitudinal tails caused by incomplete bunching, is almost completely eliminated in APT by the use of the RFQ, the modern replacement for the LANSCE injection and bunching architecture. Second, only one charge species, H^+, is accelerated in the APT linac, allowing uncompromised beam steering and matching. Third, APT is a cw linac with no pulse structure during normal operation, so there are minimal losses due to beam-turn-on transients; these should be managed to a greater degree than in LANSCE by the rf control loops planned for this system with feedback and feedforward. Fourth, APT is designed with much larger apertures than in LANSCE and with stronger transverse focusing. In the APT high-energy linac, the aperture radius is 8 cm. Combined with the stronger focusing in APT, the resulting aperture ratio ranges from 13 at 100 MeV to about 50 at 1030 MeV, compared with those given above for LANSCE. The very much larger aperture ratios in APT mean that beam halo is much more easily contained within the aperture. The large aperture ratios at high energies, where the activation threat is greatest, are a major benefit of using superconducting cavities for the high energy linac. Finally, improved longitudinal phase-space margin for APT is provided by conservative choice of the accelerating gradient in the superconducting linac. A 10% field increase above the design value is possible in most of the linac, which produces a 27% increase in bucket phase width and a 14% reduction in longitudinal beam size.

Improved matching is also addressed in the APT linac design. Beam-current-independent matching is obtained by maintaining the same transverse and longitudinal focusing strength across accelerating structure transitions, and focusing-strength changes are made adiabatically wherever possible. Operational setting errors that would lead to mismatch are reduced by providing adjustable focusing and appropriate beam diagnostics.

5 BEAM HALO IN APT

Given that the LANSCE beam-loss mechanisms have been addressed in the APT design, what remains as the main potential cause of APT beam loss? The beam spends only a short time transiting the linac (a few microseconds) and effects common in circular machines, such as intrabeam scattering from single Coulomb collisions have insufficient time to develop. Far more important are collective space-charge forces due to the beam as a whole. Numerical-simulation studies predict that the most important potential cause of beam loss is that associated with space-charge-induced halo caused by beam-optics mismatches [4]. These mismatches produce density oscillations of the beam core that can resonantly drive particles to larger radial amplitudes. Theoretical and numerical studies of halo formation show particle amplitudes resulting from single mismatches that extend well beyond the Debye tail of a matched beam, but not growing without limit.

Particle-core models of mismatched beams such as those in Refs.[5-14] have been constructed to provide quantitative estimates of the characteristics of halo-particle amplitudes caused by a single mismatch. In these models, the space-charge field from the oscillating beam core in a uniform linear-focusing channel is obtained from an oscillating density distribution. The amplitude of the core oscillation is directly related to the magnitude of the rms mismatch of the beam. The behavior of halo particles is studied by representing them with test particles that oscillate through the core and interact with it. A parametric resonance occurs [6] when the particle oscillation frequency is half the core frequency. The amplitude growth for the resonant particles is self limiting, because outside the core the space-charge force falls off and the net restoring force increases nonlinearly with radius, producing a dependence of frequency on the particle amplitude such that the particles drop out of resonance as their amplitudes grow. A simple scaling formula has been derived [11] from the transverse halo models that shows how the maximum amplitude for an rms mismatched beam decreases with increased focusing strength. Halo formation from the particle-core model has also been studied in 3D bunches with self consistent stationary distributions [14] with bunch parameters close to the APT case. Results for the transverse halo are similar to those from 2D models; the relative extent of the longitudinal halo has been found to be smaller than that of the transverse halo. The halo models have provided a basic understanding of the underlying physics of the most important beam-loss mechanism expected in the APT linac.

6 NUMERICAL-SIMULATION STUDIES

Numerical simulation studies are an important tool for the analysis of the beam behavior in APT. Simulations using several codes have been carried out to support the basic design of the linac. The forces acting on the particles in

the simulations include the external focusing fields and the direct space-charge fields; nonlinear force terms are included. Two-dimensional cylindrical-beam simulations with a single beam mismatch, initiating a breathing-mode core oscillation, were carried out for comparison with the particle-core halo models; these have shown remarkably good agreement in terms of maximum radial amplitude as a function of mismatch[11, 13].

End-to-end (from injector to linac output) simulation studies of the LANSCE accelerator have also been carried out for comparison with beam measurements [3] and loss estimates. The simulations agreed with measured rms quantities to within 10% to 15%. The major loss locations in the high-energy linac were correctly indicated by the simulations, but the loss magnitudes were overpredicted by about an order of magnitude. This discrepancy was not unexpected because of the sensitivity of the beam losses to the details of the particle distribution in the beam tails formed during the LANSCE bunching process, and the lack of longitudinal phase-space measurements, which are very difficult to make.

Both 2D(r-z) and 3D particle-in-cell space-charge routines have been compared and are in excellent agreement for APT, which suggests that 3D effects that account for x-y differences are not important. Nevertheless, precise calculation of the details of the particle distribution at the edges of the beam may be beyond our capabilities. Even assuming that the simulation code contains all the correct beam physics, and if sufficient numbers of particles could be run to eliminate artificial statistical fluctuations, as a practical matter the exact configuration of the machine errors can not be precisely known, nor can the initial phase-space distribution of the particles in the beam be precisely known. Because of these uncertainties, the numerical simulation studies can only make probabilistic predictions and at best have statistically validity. Given the expected statistical distributions of the errors, many computer runs are needed to predict statistical distributions of the beam parameters.

Supercomputers using massively-parallel processing are now being applied to these simulations. Some preliminary simulations looking at beam halo using up to 10^7 particles per run have already been done, and have shown the potential of applying increased computing power to the halo problem. Unlike the LANSCE simulations, the APT simulations for a linac with realistic errors produce zero beam loss above 100 MeV when using 10^7 particles per calculation. If the total fractional loss above 100 MeV was equal to 10^{-5} (an acceptable loss level), these simulations would yield an integrated loss of about 100 particles along the high energy APT linac. The absence of particle loss above 100 MeV is an encouraging result, and is positive evidence for a successful design.

At present, no direct measurements of beam-halo amplitude distributions are available for comparison with the codes, although such measurements will be carried out on LEDA. Such measurements are not trivial, and to be definitive must be carried out with careful characterization of the input beam in all six phase-space dimensions, and using precision beam diagnostics capable of taking measurements over a large intensity range.

7 BEAM-LOSS CONTROL

We believe that the practical approach to achieving very-low beam loss in the APT linac is to produce a strongly-focused well-matched high-quality beam in the low-energy normal-conducting linac, including an RFQ, and inject this beam into the large-aperture high-energy superconducting linac. Throughout the linac, rf phase and amplitude (feedback) control loops must keep the beam well centered within the longitudinal bucket, and beam steering must be provided to keep the beam well centered in the aperture. The beam halo observed in simulations with realistic errors does not extend radially beyond 5σ for a well-matched beam, or beyond about $10\,\sigma$ for a beam with mismatches; the maximum particle amplitudes are well within the apertures of the high-energy linac.

DESIGN SIMULATION FOR SPOT SIZE STABILIZATION IN ITS/DARHT*

Thomas J. T. Kwan, David C. Moir, Barbara G. DeVolder, Charles M. Snell, and Michael Kang
Los Alamos National Laboratory

Abstract

In high resolution flash x-ray imaging technology the electric field developed between the electron beam and the converter target is large enough to draw ions from the target surface. The ions provide fractional neutralization and cause the electron beam to focus radially inward, and the focal point subsequently moves upstream due to the expansion of the ion column. A self-bias target concept is proposed and verified via computer simulation that the electron charge deposited on the target can generate an electric potential, which can effectively limit the ion motion and thereby stabilize the growth of the spot size. A target chamber using the self bias target concept was designed and tested in the Integrated Test Stand (ITS). We have obtained good agreement between computer simulation and experiment.

1 INTRODUCTION

The stable propagation of a relativistic electron beam in vacuum requires balance between the electric and magnetic forces. For a charge unneutralized relativistic electron beam, the difference between its Coulomb repulsive force (radially outward) and its self magnetic force (radially inward) scales as $1/\gamma^2$, where γ is the relativistic factor. The Coulomb force always dominates slightly so the beam will diverge as it propagates in vacuum. However, if there is fractional charge and/or current neutralization of the electron beam, the dynamics of propagation can be quite different. For example, if the fractional charge neutralization is η, the net force acting on the beam scales (η - $1/\gamma^2$). For a highly relativistic electron beam, a small fractional charge neutralization can cause the magnetic force to dominate, resulting in radial pinching and the subsequent divergence of the beam after the pinch point. In x-ray radiography, the electron beam generates x-rays via the bremsstrahlung process in a converter target. For high resolution radiography, the energy density of the electron beam is sufficiently intense that an electric field can develop near the converter target such that ions can be extracted from its surface. Typical ions species are from contaminants such as hydrocarbons, water vapor, oxygen, etc. Among the various species, hydrogen is the most mobile and most prone to cause radial focusing of the electron beam. In our study, we assume hydrogen ions in all of our calculations. Once the ions are created, they are drawn toward the potential well near the axis of the electron beam form by its space charge. Such an ion column provides fractional neutralization of the electron beam locally and thus causes the beam to focus radially inward. Furthermore, as the ion column expands in the upstream direction, the location of the pinch point also moves in the same direction. The divergence of the beam immediately after the focal point causes the beam spot on the target to grow. The temporally increasing radiographic spot size is detrimental to high-resolution radiography. This dynamical phenomenon of the electron beam has been predicted in computer simulations[1] and confirmed by experiments at the Integrated Test Stand (ITS)[2] at Los Alamos National Laboratory

2 CONCEPT OF SELF BIAS TARGETS

In this paper, we present a novel idea of establishing an electrical potential between the target and ground that would overcome the space charge potential of the electron beam to confine the ions near the converter target. When an electron beam is incident on a target, a certain fraction of the charge will be deposited in the target in addition to the forward transmitted and the backward reflected components. The partition among the three components depends on beam energy, target material (atomic weight and mass density) and thickness (path length). In addition, there are low energy knock-on electrons coming off the surfaces. Through the variation of target thickness, one can achieve a charged state of the target ranging from positive to negative depending on the balance between the charge carried away by knock-ons and the charge deposited by the electron beam. If the target is charged negatively, an electric field will develop to attract the ions toward the converter. This can be an effective method to control the ion column, leading to the stabilization of the beam spot size. We have performed Monte Carlo electron transport calculations of the ITS electron beam and the DARHT electron beam in targets of different materials and thicknesses. The beam parameters for the ITS beam are 5.5 MeV, 3.8 kA, and 60 ns pulse length. The beam parameters for the DARHT beam are 20 MeV, 4.0 kA, and 60 ns pulse length. The target material used in the experiments was either copper or tantalum. To estimate the charge buildup and the resulting electric field in its vacinity, we will take the 1.5-mm-thick copper target as an example. From our Monte Carlo calculation, the fractional charge deposited on the target is 0.241. During the 10 ns rise of the ITS electron beam pulse, the electron energy is lower and fractional charge deposition will therefore be higher. From a rough estimate of the charge buildup on the target, we find that after approximately 3.5 ns into the rise of the electron beam pulse, an electric potential of 400 kV would be developed. At that time, excess charge needs to be drained from the target to avoid electrical breakdown between the target and the surrounding grounded conductors.

2 TARGET ASSEMBLY DESIGN

One of the major concerns of the target chamber design is field breakdown resulting from the bias potential across the collimator and the target assembly. The final design of the target chamber assembly is shown in Fig. 1. The critical surfaces are shaped in such a geometry to minimize electrical field stress. The design is aimed at a bias potential of 360 kV. The minimum distance between the target and the collimator was 2.0 cm. The diameter of the collimating aperture was chosen to be 2.0 cm. The finite element code FLUX2D was used to obtain the electric field profile in the target chamber. The maximum field strengths were found to be –175 kV/cm at the target holder position and 240 kV/cm at the tip of the collimator. In addition, the code calculated the capacitance of the target chamber to be 29.2 pF. Note that the resistance of the radial liquid resistor between the Rexolite can be varied easily by changing the salt concentration.

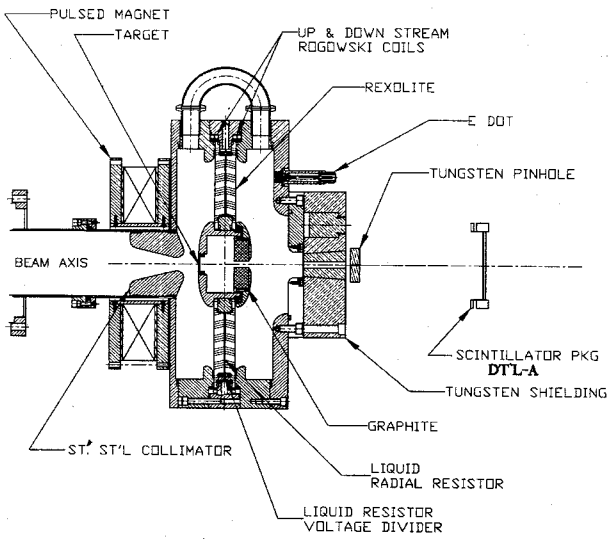

Figure 1 Experimental layout of the target chamber

3 PHYSICS DESIGN SIMULATION

The design of the target chamber was numerically simulated by using the large-scale, time-dependent, two-dimensional fully electromagnetic and relativistic particle-in-cell code MERLIN. An electron beam with the ITS parameters was injected at the left boundary and was focused on the target with a spot size of 1 mm in radius. The electron beam current was chosen to be 3.0 kA, corresponding to the experiment in which an emittance selector was inserted upstream in the beam pipe resulting in reduced current but higher beam quality. The transmitted and reflected electrons have the proper momentum and angular distributions determined by prior Monte Carlo calculations. The hydrogen ions are emitted from the target foil according to the space-charge-limited emission model. The liquid radial resistor was modeled in our simulation by a vacuum diode with its impedance determined by a properly chosen anode-cathode (AK) gap. In Fig. 2, we show the real space diagram of the target chamber assembly from our simulation. At this time, the beam current has achieved its full value of 3.0 kA. The bias potential has reached a steady state value of 360 kV after the rise time of the electron beam. We note that in Fig. 1, the axial length of the hydrogen ion column is clearly limited by the self bias potential. The ions execute vortex motion in the potential well, which limits its axial excursion. In the case where the ion column is not significantly larger than the betatron wavelength of the electron beam, the spot size on the target will not increase. The quarter betatron wavelength of the electron beam is estimated to be 3.3 cm for the parameters in our simulation. As a result, the spot size is expected to be stable. In Fig. 3, we show from our computer simulation the root-mean-square(rms) radius of the electron beam on the target plane. After the transient state due to the rise of the beam current (i.e., the development of the bias potential), the rms radius achieves a steady state value of about 0.5 mm. Note that the root-mean-square value is weighed by the beam current.

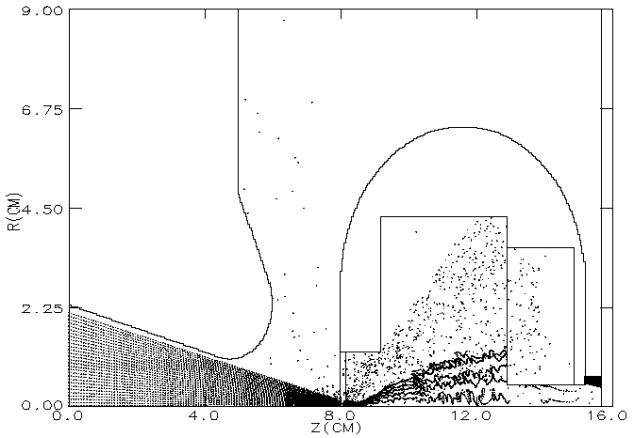

Figure 2 Physics simulation of the target chamber

4 EXPERIMENTAL COMPARISON

Experiments to validate the concept of a self bias target and the design of the target chamber were carried out at the ITS. Emittance selectors were used in the beam pipe to increase the quality of the electron beam and reduce the beam halo phenomenon. The experiment reported here had a beam current of 3.0 kA and a voltage of 5.6 MV. The radiographic spot size was monitored as a function of time. Its measured radius versus time is shown in Fig. 4. It is clear that after some transient behavior consistent with the development of bias potential, the spot size is stabilized. Besides the difference in a scaling factor due to normalization, the comparison with the simulation result in Fig. 3 is found to be quite favorable.

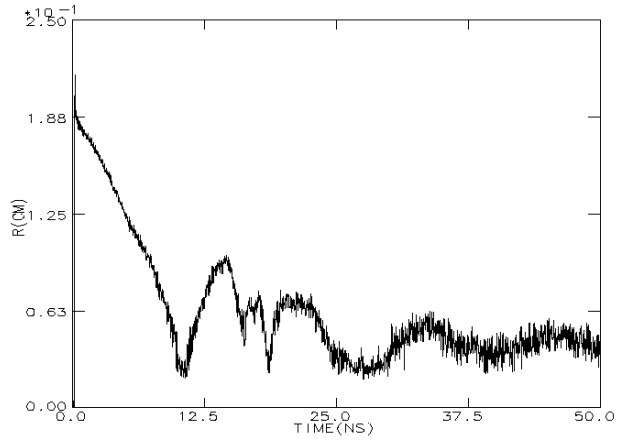

Figure 3 The rms radius of the electron beam at the target plane from the simulation

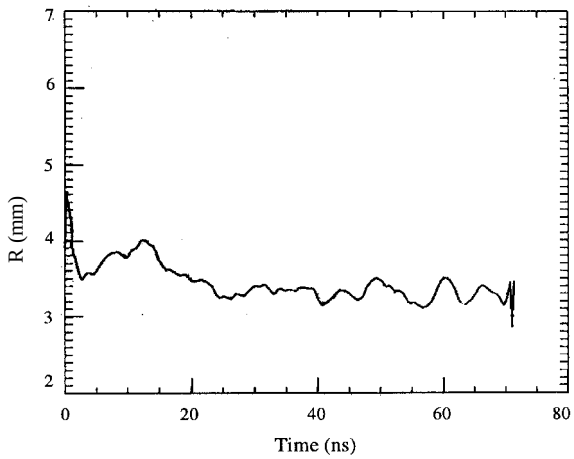

Figure 4 The radius of the radiographic spot obtained from the experiment

5 CONCLUSIONS

We found good agreement between experiment and simulation of the target chamber. The self bias potential between the target and the collimator is shown to be able to maintain the radiographic spot size in high dose radiography.

MODELING BEAMS WITH ELEMENTS IN PHASE SPACE*

E. M. Nelson
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

Conventional particle codes represent beams as a collection of macroparticles. An alternative is to represent the beam as a collection of current carrying elements in phase space. While such a representation has limitations, it may be less noisy than a macroparticle model, and it may provide insights about the transport of space charge dominated beams which would otherwise be difficult to gain from macroparticle simulations.

The phase space element model of a beam is described, and progress toward an implementation and difficulties with this implementation are discussed. A simulation of an axisymmetric beam using 1d elements in phase space is demonstrated.

1 INTRODUCTION

Conventional particle codes represent beams as collections of macroparticles. This representation is adequate for many applications, but there are situations where relatively subtle details of the beam distribution are studied, and discretization noise in the macroparticle representation of the beam may obscure these details. Simulations of beam halo and emittance growth in space charge dominated beam transport are two examples. Algorithms which model a subset of the beam distribution have been successful. These include the δf algorithm[1, 2] and an algorithm[3] which employs a form of domain decomposition in phase space. Another approach is to model the Vlasov-Maxwell equation on a grid[4, 5]. Efforts using massively parallel computing paradigms with $\sim 10^8$ macroparticles are also providing significant advances in beam simulation[5].

This work discusses another model. In this model the beam is represented by a collection of elements in phase space instead of point-like macroparticles. Current is distributed over elements instead of being localized in macroparticles. This phase space element model of the beam represents a smooth phase space distribution better than a macroparticle model. Thus, this model might provide for beam transport calculations with less discretization noise. The motivation of this work is to develop improved models of emittance growth in DARHT[6].

2 PHASE SPACE ELEMENT MODEL

An element in phase space is a d dimensional simple shape embedded in a $2n$ dimensional phase space. The shapes are simplexes such as line segments, triangles or tetrahedra. Quadrilateral and hexahedral shapes may also be viable, as are shapes of four or more dimensions. Test particles at the element's vertices (and perhaps edges and faces) define the element's shape and location in phase space. Local coordinates are assigned to each point of phase space inside the element. There is a simple map from the element's local coordinates to global phase space coordinates.

Each element carries a number (or charge or current) density which is expressed in the element's local coordinate system. A number is obtained by integration of this density over the element's domain. In the jargon of differential geometry, the number density is a pseudo-d-form. This density is different from traditional densities where one integrates the density over a volume of configuration space to obtain a number.

The test particles evolve (e.g., over time) according to their equations of motion. The elements move with the test particles because each element's shape and location is defined by its test particles. The number density expressed in local coordinates on each element does not change. It is simply carried with the element. Collision-like effects are not being treated. The validity of this model depends on the interpolation of the evolved test particles being close to the evolution of an interpolated initial particle. Such tests can be performed to assess the accuracy of the model, and perhaps to adaptively refine the phase space elements which represent the beam.

3 AN IMPLEMENTATION

A code is being developed to model the transport of an intense steady-state axisymmetric beam in the presence of axisymmetric static fields. The phase space is $(x, y, ct, \gamma\beta_x, \gamma\beta_y, \gamma)$. The relativistic equations of motion for the particles are integrated in z. No paraxial approximation is used. Coordinates (x, y) are used instead of radius r to avoid potential difficulties pushing particles near the axis. Points (x, y) with the same radius r are equivalent. One can imagine revolving the phase space elements and particles about the axis in order to visualize the beam's particle distribution. Coordinate ct is computed for each particle, but this coordinate does not influence the particle motion.

The phase space elements are one dimensional line segments connecting two test particles. A local coordinate u, with $0 \leq u \leq 1$, labels points on each element. One test particle is $u = 0$ and the other is $u = 1$. The map from local coordinate u to global phase space coordinates is linear interpolation of the two test particles' phase space coordinates. Note that radius r is not linearly interpolated. It is computed from the interpolated values of x and y. This scheme better represents the beam's particles near the axis.

* Work supported by W-7405-ENG-36.

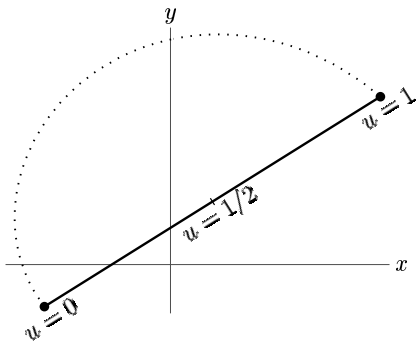

Figure 1: A one dimensional element (solid line) near the axis. Two test particles (filled circles) define the location and shape of the element. Local coordinate u identifies points on the element. The dotted line shows the effective element location if interpolation were performed in radius r instead of (x, y).

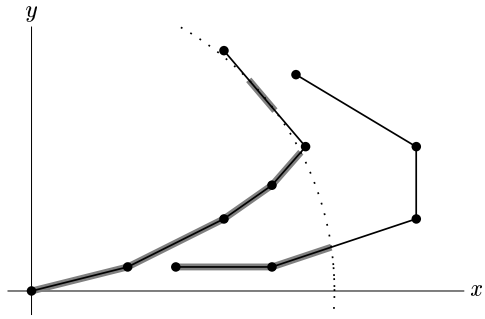

Figure 2: A collection of one dimensional phase space elements. For the self field calculation at the radius of the dotted circle, the current density is integrated over the region outlined in gray.

Fig. 1 illustrates a one dimensional element and the distinction among interpolation schemes.

An element's current density $\mathcal{J} = dI/du$ is a linear function of u. That is, the pseudo-one-form current density is $\mathcal{J} = (j_1 u + j_0)du$ with constants j_1 and j_0. This form for the current density $\mathcal{J}$ enables good representation of a uniform current density (traditional sense) beam.

The fields acting on the particles are external focusing fields, accelerating fields, and self-fields (including a flux conserving diamagnetic field). The self-fields are computed using Gauss' and Ampere's laws assuming the beam is uniform with respect to z. For example, Ampere's law gives

$$H_\theta(r) = \frac{I(r)}{2\pi r} = \frac{1}{2\pi r} \sum_i \int_{\mathcal{U}_i(r)} \mathcal{J}_i \qquad (1)$$

where $I(r)$ is the current enclosed by a circle of radius r, and i is a phase space element index. For the ith element, the domain of integration $\mathcal{U}_i(r)$ is the portion of the element inside of radius r,

$$\mathcal{U}_i(r) = \{u : 0 \le u \le 1, r_i(u) < r\}. \qquad (2)$$

The radius at u in the ith element is $r_i(u)$. An example is shown in Fig. 2. Notice that an element may have two intersections with the circle of radius r. The implementation splits elements into subelements during each self field calculation so that each subelement has at most one intersection with a circle.

Algorithms have been developed for higher dimensional phase space elements. Elements are first split into subelements so that intersections with circles are simple. A circle splits a triangle subelement into a triangular piece and a quadrilateral piece. The possibility that the triangle element encloses the axis has also been considered. A tetrahedral subelement splits into a tetrahedral piece and a prism piece, or into two prism pieces.

The motivation for using Gauss' and Ampere's law is to employ the simplest algorithm at this stage of the investigation. The integration in Gauss' and Ampere's law does not scale well with increasing number of phase space elements and test particles. However, the integration requires calculation of the intersection of elements with only one circle at a time. A better implementation will use a grid for the computation of self-fields, but such an implementation will have to deal with intersections of an element with two circles instead of just one. This adds complexity to the code.

Accelerating fields are treated crudely at this time. A fixed $\Delta\gamma$ is added to each test particle as it passes through a gap. The magnetic field on-axis is computed from a rational function approximation. Off-axis fields are computed using a four term Taylor's expansion. The equations of motion for the test particles are integrated using a fourth order Runge-Kutta algorithm.

4 AN EXAMPLE

An example is shown in Figs. 3-5. Nominal DARHT-I parameters are employed except for the beam's initial emittance. The beam is not matched with the accelerator. The initial beam is a laminar (zero emittance), uniform current density beam. The particle energies are corrected for space charge depression and all particles have zero canonical angular momentum. The initial beam is composed of 100 elements equally spaced in radius on the positive x-axis.

The example illustrates two issues. First, the beam model is wrapping itself around the axis. This will ultimately ruin the effectiveness of the element's interpolation scheme. The wrapping has two sources. One is the tune shift due to the beam's self-fields. The other is the non-conservation of canonical angular momentum, p_θ, introduced mainly by the self-field calculation scheme.

The assumption of uniformity with respect to z in the self-field calculation leads to errors in p_θ. The error for particles near the axis are opposite in sign from the error for particles near the beam edge. Using an improved self-field calculation or particle pushing scheme will reduce this effect, but the tune shift must still be dealt with when the

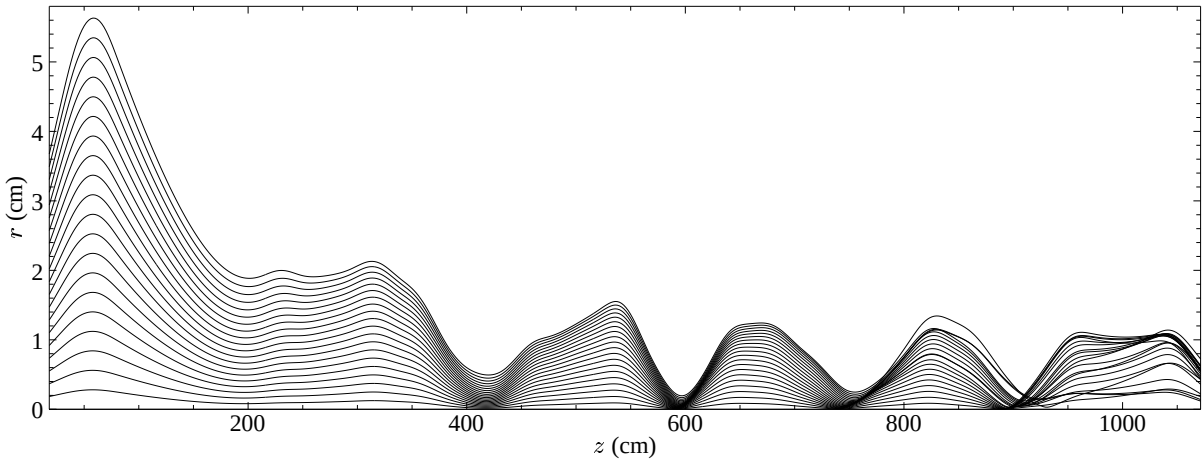

Figure 3: Trajectories of 20 particles (every 5th particle) of a mismatched laminar beam in the first 10 m of DARHT-I.

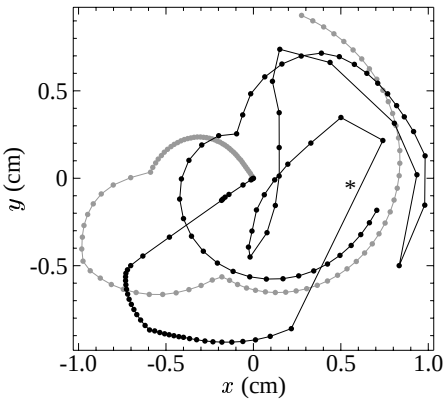

Figure 4: Configuration of the phase space elements of the beam at z=8.1 m (gray) and z=10 m (black). The gray curve clearly shows the beam model wrapping around the axis. The black curve shows that the model becomes very convoluted.

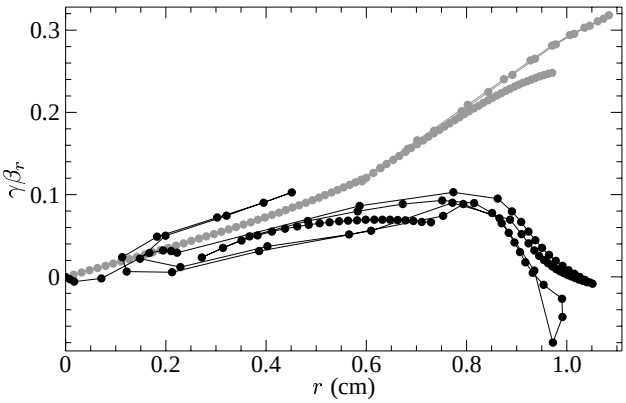

Figure 5: The beam model at z=8.1 m (gray) and z=10 m (black) projected onto the r-$\gamma\beta_r$ plane.

full accelerator is modeled.

One might modify the equations of motion to cancel the tune shift. Recall that the test particles in this axisymmetric simulation represent an equivalence class of particles at the same radius, so it is not absolutely necessary for their trajectories to coincide with real particles.

This leads to the second issue. The configuration of the beam at z=10 m (see Fig. 4) is quite convoluted. This casts doubt on the validity of the beam model. In fact, refinement of the model (i.e., more elements) shows that it is surprisingly good except near the large phase space element labeled *.

5 CONCLUSION

Some progress has been made in developing a phase space element model for a beam. More work is needed before this model's viability can be demonstrated concretely, but there are promising indications that the model will yield some improved beam simulations.

SURVEY TALK - NEW LASER AND OPTICAL RADIATION DIAGNOSTICS*

W. P. Leemans
Center for Beam Physics, Accelerator and Fusion Research Division
Ernest Orlando Lawrence Berkeley National Laboratory, Berkeley, CA 94720

Abstract

New techniques are reported for electron beam monitoring, that rely either on the analysis of the properties of wiggler radiation (from static magnetic fields as well as from laser "undulators", also referred to as Thomson scattering) or on the non-linear mixing of laser radiation with electron beam radiation. The different techniques reviewed are capable of providing information on femtosecond time scales and micron or even sub-micron spatial scales. The laser undulator is also proposed as a useful tool for non-destructive measurement of high power electron beams. An example is given of measuring electron beam energy and energy spread through spectral filtering of spontaneous wiggler radiation [1]. A novel technique based on fluctuational characteristics of radiation is described, for single shot, non-destructive measurement of the electron beam bunch length [2,3]. Thomson scattering based beam monitoring techniques are discussed which, through analysis of the radiated beam properties, allow non-destructive detailed measurement of transverse and longitudinal distributions of relativistic electron beams [4]. Two new techniques are discussed which rely on non-linear optical mixing of laser radiation with electron bunch emission: differential optical gating (DOG) [5] and electron bunch length measurement in a storage ring based on sum-frequency generation [6].

1 INTRODUCTION

Measurement of the transverse and longitudinal phase space properties of electron bunches produced in present and future high performance linacs [7-9], requires development of beam diagnostics with high spatial (micron or sub-micron) and temporal (femtosecond) resolution. Measurement of beam properties of high current, high power linacs [10] requires non-destructive diagnostics to be developed. Several diagnostics will be discussed, which rely on direct measurement of the properties of electron beam radiation, or on the interaction of that electron beam radiation with a laser beam. In each of the techniques discussed in this paper, the electron beam radiation is generated through interaction of the electron beam with static magnetic fields (e.g. wiggler radiation) or with electromagnetic radiation from a laser (Thomson scattering). Most of the techniques can be applied more generally to other types of radiation sources, except when the unique property of a one-to-one correlation between observation angle and wavelength of the emission is used, such as in radiation originating from the interaction with magnetic fields.

Wiggler radiation (from permanent magnets, electromagnetic undulators and lasers) has been used for diagnostic purposes [1-3, 11-13] in a wide range of beam energies, as the radiation contains the full signature of the electron beam. In Section 2, a technique for measuring energy and energy spread through spectral filtering of spontaneous emission of a wiggler will be discussed [1] as well as a technique for bunch length monitoring through fluctuational interferometry of the incoherent light [2,3]. In Section 3, experiments using radiation from laser Thomson scattering [4] (i.e. electromagnetic undulator) for beam characterization will be reviewed. In Section 4, non-linear optical mixing of laser radiation with radiation from electron beams for longitudinal bunch profile measurements [5,6,14] will be discussed.

2 WIGGLER RADIATION

2.1 Beam Energy Diagnostic

The wiggler emission cone contains information about the electron beam mean energy and energy spread [15,16]. A series of proof of principle experiments [1] have been carried out at the Accelerator Test Facility (ATF) at Brookhaven National Laboratory, demonstrating wiggler-based beam diagnosis in single shot mode, both for single micropulses and single macropulses. The experiments were performed using a high precision (0.08% peak amplitude rms) pulsed electromagnetic microwiggler from MIT, with a wiggler period of 8.8 mm. The high microwiggler field quality simplified the interpretation of the spectra defined by the convolution over many parameters: energy spread, divergence, spot size, matching, beam pointing and wiggler field errors. For a beam energy of 44-48 MeV, the wiggler emission was in the visible, where a wide range of optical diagnostics are available.

The wiggler emission profile was studied at the fundamental (532 nm). A narrow (1 nm) bandwidth interference filter was used to spectrally filter the radiation cones, and the full transverse far field pattern was recorded using a CCD camera. For a fixed wavelength, determined

* Work supported by the US Department of Energy under contract No. AC03-76SF00098.

by the filter, the cone radius depends on beam energy and wiggler field strength, and the cone width contains information of divergence and energy spread. Analytic expressions were derived, showing that for energy spreads realistic for the linac (0.5% FW) at 48 MeV, divergence dominates over both energy spread and natural linewidth at sufficiently large angles [1]. For small cones, both effects are important. The far-field profile provides an advantage over the spectrum in divergence sensitivity. A systematic set of experiments was carried out to study cone response to beam energy, energy spread, wiggler field strength, electron beam misalignment and filter central wavelength. An electron beam divergence of 0.25 mrad was extracted in a single shot measurement. Examples of spontaneous emission cones are shown in Figure 1. Note that with a wiggler length of 70 periods, sensitivity to as little as 0.5% change in central beam energy was demonstrated.

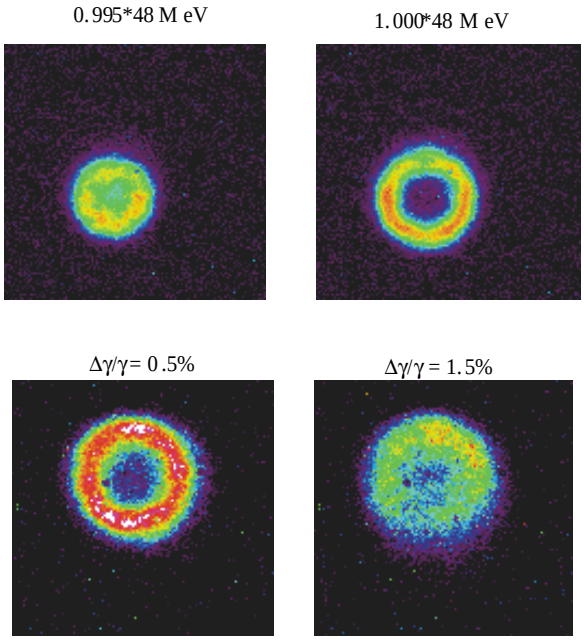

Figure 1. CCD images of a 1 nm portion of the far field wiggler spontaneous emission profile, showing sensitivity to beam energy (top pair – 48 MeV and 48*0.995) and energy spread (bottom pair – 0.5% and 1.5% FW). From Ref. 1.

2.1 Fluctuational Interferometry

In 1995, a fluctuational interferometry technique relying on the incoherent contribution to the radiation was proposed [2]. For a radiation pulse to be longitudinally incoherent, the spectral bandwidth $\Delta\omega$ must be much larger than the inverse of the pulse duration τ_p, i.e. $\Delta\omega\tau_p >> 1$. Using a bandpass filter, centered around ω_0 and with spectral width $\delta\omega$, temporal coherence can be imposed with an associated coherence time $\tau_{coh} \propto \delta\omega^{-1}$, effectively breaking the pulse up in N independent portions where $N = \tau_p / \tau_{coh}$. From shot-to-shot, the intensity will vary on the order of $1/\sqrt{N}$. Measurement of the variance of the intensity fluctuations will then give a measure for N and hence $\tau_p \approx N / \delta\omega$.

A proof of principle experiment was carried out at the ATF, in which the single shot spontaneous emission spectrum of the MIT microwiggler, was studied for a range of bunch lengths (1-7 ps) [1,3]. The microwiggler provided high brightness visible wavelength emissions for an electron beam energy of 44 MeV. A typical measured spectrum is shown in Figure 2a, revealing nearly 100% modulation and the presence of random spikes of a characteristic width, from which a bunch length of 2 ps was extracted. For comparison, a simulation for a similar bunch length including the measured instrumental resolution is shown in Figure 2b. The important features of the experimental data, the characteristic spike width and the level of modulation, are reproduced by the theory. Quantitative agreement has also been obtained between bunch length extracted from fluctuations and independent calibrations of beam bunch length [3].

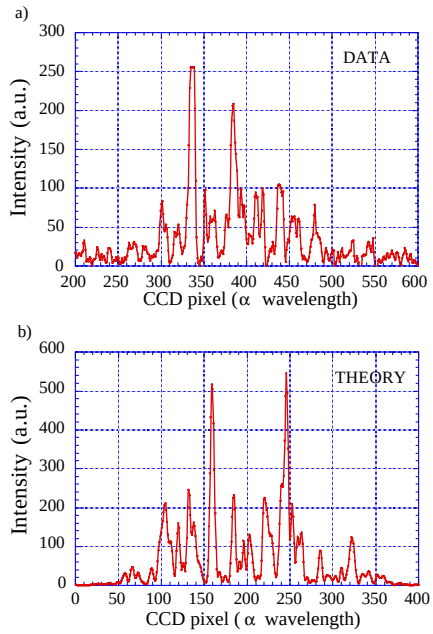

Figure 2. a) Single shot spontaneous emission spectrum from a microwiggler at 632 nm, showing nearly 100% modulation of the spectrum. Beam bunch length was extracted in a single shot measurement from the spectral fluctuations. b) A simulation for the same bunch length reproduces both the qualitative and quantitative features of the data.

3 LASER SCATTERING DIAGNOSTICS

A different approach to generating radiation from particle beams for beam monitoring is to use the interaction of the beam with high intensity laser fields. In effect, the laser acts as an electromagnetic undulator and the

properties of the emitted radiation can be accurately predicted using an equivalent undulator model [17]. The scattered radiation contains information on energy as well as on transverse and (for short laser pulses) longitudinal distributions of the electron beam.

At the Final Focus Test Beam (FFTB) at SLAC, transverse e-beam sizes as small as 70 nm were measured, by scanning a 50 GeV e-beam across the intensity fringes of an optical standing wave [7] produced by crossing two laser beams. The gamma ray yield depends on the number of photons with which the electron beam interacts and is therefore much larger at the peaks than at the valleys of the standing wave. Such resolution is beyond usual optical (e.g. optical transition radiation or synchrotron radiation) based methods.

A laser based beam diagnostic [4] which relies on analysis of the properties of the scattered radiation has been developed and used at the Beam Test Facility (BTF) [18] of the Center for Beam Physics at Lawrence Berkeley National Laboratory (LBNL). Some of the results of this experiment are discussed next.

3.1 Orthogonal Thomson Scattering Diagnostic

The experiment [4] was conducted at the BTF and used the 50 MeV (γ = 98) linear accelerator (linac) injector of the Advanced Light Source in conjunction with a high power (40 mJ in 100 fs) short pulse laser system operating at 800 nm wavelength. Electron bunches were transported using bend magnets and quadrupoles to an interaction chamber where they were focused and scattered against the laser beam. After the interaction chamber, a 60˚ bend magnet deflected the electron beam onto a beam dump, away from the forward scattered x-rays. A 75 cm radius of curvature mirror was used to focus the S-polarized amplified laser pulses to about a 30 μm diameter spot at the interaction point (IP) (measured by a charge coupled device (CCD) camera at an equivalent image plane outside the vacuum chamber).

To measure the spot size (and position) of the electron beam at the IP, an image of the electron beam was obtained by relaying optical transition radiation (OTR) [19] from a foil onto a 16 bit CCD camera or optical streak camera using a small f-number telescope. Electron beam spot sizes as small as 35 μm rms have been measured.

During the interaction of an electron beam and laser beam, scattered x-ray photons are produced with energy U_x, given by (for $\gamma >> 1$)

$$U_x = \frac{2\gamma^2 \hbar\omega_0}{1+\gamma^2\theta^2}(1-\cos\psi), \qquad (1)$$

where ω_0 is the frequency of the incident photons, ψ is the interaction angle between the electron and laser beam ($\psi=\pi/2$ in our experiments) , and θ is the angle at which the radiation is observed and assumed to satisfy $\theta << 1/\gamma$. In the experiment, x-rays with a maximum energy of 30 keV (0.4 Å) are generated.

To measure the transverse electron beam distribution for a given slice of the electron beam, we scanned the laser beam transversely across the electron beam in steps of 10 μm, by changing the tilt of the focusing mirror. and monitored the x-ray yield on the phosphor screen. It was found (Fig. 3) that the laser based technique and the results from OTR were in good agreement and give a half-width half maximum (HWHM) vertical size of 66 μm. However, the measurements for the beam edges differed and were both non-Gaussian. From the OTR data an HWHM horizontal size of 47 μm was obtained.

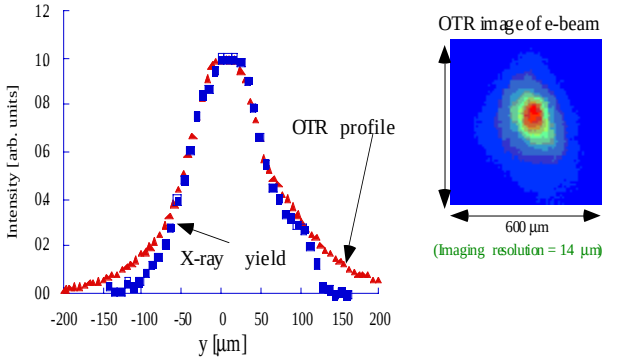

Figure 3: a) OTR image of the focused electron beam and b) triangle - vertical line-profile through the OTR image of the electron beam; square - x-ray yield vs. vertical laser beam position.

Measurement of the electron beam divergence for a fixed longitudinal location (i.e. fixed delay time between the laser and electron beam) of a time slice of the electron beam, with a duration equal to the convolution of the transit time of the laser pulse and the laser pulse duration, was done by monitoring the spatial x-ray beam profile on the phosphor screen using the CCD camera (see Fig.4). The scattered x-ray energy flux contains information of the angular distribution of the electron beam. By convoluting the single electron spectrum with a Gaussian distribution for the horizontal and vertical angles ($\sigma_{\theta x}$ and $\sigma_{\theta y}$ are the rms widths of the angular distribution of the electron beam in the horizontal and vertical direction respectively) and integrating over all energies and solid angle, the energy flux can be written as [4]:

$$\frac{dP}{d\theta_x d\theta_y} \propto \int_0^{2\pi} d\phi \int_0^1 d\kappa F(\kappa)\kappa\left[1-4\kappa(1-\kappa)\cos^2\phi\right]$$

$$\exp\left[-\frac{(\theta_x - \gamma^{-1}\sqrt{\frac{1}{\kappa}-1}\cos\phi)^2}{2\sigma_{\theta x}^2}\right]$$

$$\exp\left[-\frac{(\theta_y + \gamma^{-1}\sqrt{\frac{1}{\kappa}-1}\sin\phi)^2}{2\sigma_{\theta y}^2}\right] . \qquad (2)$$

Here dP is the radiated x-rays intensity in a solid angle $d\theta_x d\theta_y$, ϕ is the azimuthal angle, $F(\kappa)$ is an x-ray energy dependent function modeling the detector sensitivity and x-ray vacuum window transmission. Also, $\kappa = U/U_{max} = (1+\gamma^2\theta^2)^{-1}$ and $U_{max} = 2\gamma^2\hbar\omega$ and a single incident laser frequency is assumed.

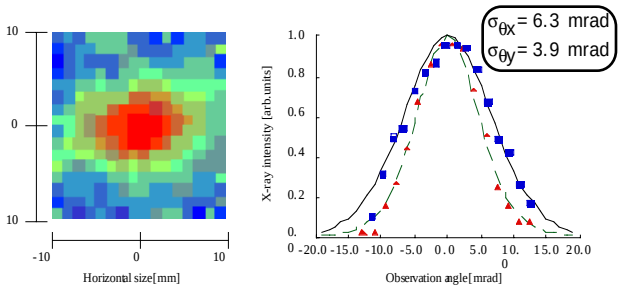

Figure 4. a) False color CCD image of the spatial profile of a 30 keV x-ray pulse on the phosphor screen, which is located 80 cm from the IP; b) square- horizontal line-profile and fitting curve (solid line), triangle -vertical line-profile and fitting curve (dashed line) from Fig. 4 (a). The scale has been converted into angular units.

By fitting the data (see Fig. 4) using Eq.(2), an electron beam divergence of $\sigma_{\theta x}$ ($\sigma_{\theta y}$) = 6.3 ± 0.2 (3.9 ± 0.2) mrad was found. F(κ) was adjusted to account for the spectral dependence of the x-ray window transmission. The difference between $\sigma_{\theta x}$ and $\sigma_{\theta y}$ is due to a combination of the electron beam being focused astigmatically at the IP, resulting in a tilted phase space ellipse (y, y′), and a laser spot size much smaller than the vertical electron beam size. As the laser beam crosses the focal volume of the electron beam, the complete horizontal (direction of propagation of the laser) phase space (x, x′) is sampled by the laser beam. However, only electrons occupying the region in the vertical phase space defined by the spatial overlap with the laser beam will contribute to the x-ray flux. As opposed to the transition radiation based detector, the laser beam therefore acts as an optical microprobe of a finite region of the transverse phase space. This value of the electron beam divergence is also consistent with an effective angular divergence of the electron beam of 3.5 - 4 mrad obtained from analyzing the x-ray spectra. Of course, the main difference is that measurement of the spatial profile is a single shot technique as opposed to measuring the x-ray spectra which requires accumulation of thousands of shots.

Finally, since the x-ray yield is sensitive to both the longitudinal bunch profile and the degree of transverse overlap between the laser and electron beam, time-correlated phase space properties of the electron beam can be studied. When an electron bunch, which exhibits a finite time-correlated energy spread (chirp), is focused at the IP with a magnetic lattice which has large chromatic aberrations, different temporal slices of the bunch will be focused at different longitudinal locations. The transverse overlap between e-beam and laser will therefore strongly depend on which time slice the laser interacts with. This in turn will lead to a time dependence of the x-ray yield varying faster than the actual longitudinal charge distribution. To illustrate this, the x-ray flux was measured as a function of the delay between laser and e-beam, for two different magnetic transport lattices. In both lattices, the magnet settings were optimized to obtain a minimum electron beam spot size in the horizontal and vertical plane (as well as zero dispersion at the IP), but chromatic aberrations were about 5 times larger in the second lattice. Result of a 60 ps long scan (time step of 1 ps) and time-resolved OTR from the streak camera for the lattice with low and high chromatic aberrations is shown in Fig. 5(a, b).

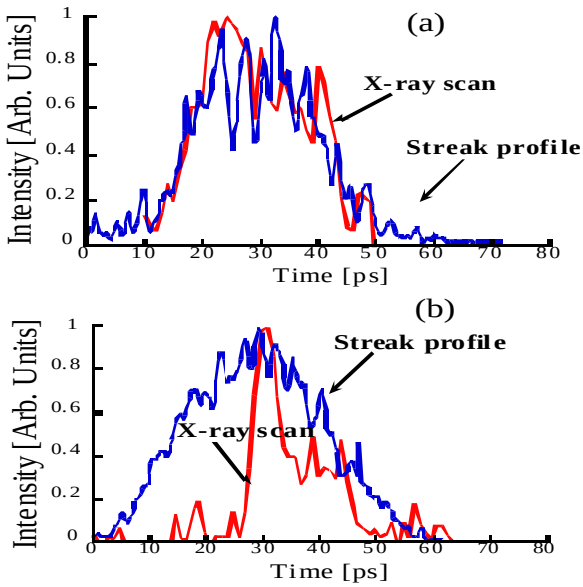

Figure 5: x-ray yield vs. delay time between laser and electron beam and profile of time resolved OTR image from a streak camera for a lattice with a) small and b) large chromatic aberrations.

Whereas the temporal scan for the lattice with low chromatic aberrations (Fig.5a) is in good agreement with the time-resolved OTR measured with a visible streak camera, the scans taken for the second configuration (Fig.5b) typically showed a 2-3 times larger amplitude 5 ps wide peak sitting on a 20 ps wide pedestal. This is to be compared to the time resolved OTR from the streak camera which typically showed a 25-30 ps wide electron beam without any sharp time structure. From lattice calculations, it is found that an energy change on the order of 0.25 % would increase the vertical spot size by a factor two at the IP, compared to best focus, resulting in a proportional reduction in vertical overlap between the laser and electron beam, and hence in x-ray yield. These measurements indicate the potential of the laser based Thomson diagnostic to measure time-correlated energy changes of less than a percent, with sub-picosecond time resolution.

It is important to note also that, due to the non-destructive nature of the Thomson scattering technique, it might prove to be a useful tool for the diagnosis of high current, high power electron beams, such as for the DAHRT project [10].

4 NON-LINEAR MIXING

Another new direction being pursued for developing beam diagnostics, is the non-linear mixing of laser radiation with radiation from electron beams [14]. Two recent

examples of the application of non-linear optics for bunch length monitoring are discussed next: one in which a tightly synchronized laser pulse is used to perform a cross-correlation measurement and one in which the laser pulse is loosely synchronized with respect to the electron beam.

4.1 Laser Correlation with Synchrotron Pulses

Experiments at the Advanced Light Source have recently shown [6] that a synchronized laser pulse can be used to measure femtosecond synchrotron pulses via frequency up-conversion. Visible synchrotron radiation from the ALS at 2 eV was sum-frequency mixed in a BBO crystal with 1.55 eV radiation from a short pulse (<100 fs) Ti:Al_2O_3 laser. By scanning the laser pulse in time with respect to the electron bunch, a 16.6 ps rms bunch length was measured, which is in good agreement with streak camera measurements. Furthermore, the technique was shown to detect sub-picosecond structure of the electron bunch, purposely imposed on the bunch by co-propagating an intense short laser pulse with the electron beam inside a wiggler. The laser beam, in the presence of a wiggler field, causes an energy modulation of a slice of the bunch via a FEL-like interaction. The energy modulation depth is determined by the wiggler and the laser pulse strength, and the duration of the slice is equal to the laser pulse length. By propagating the modulated electron beam through a dispersive section, this short slice can be separated from the main bunch, leaving a small density depression in the main bunch. The cross-correlation technique detected this few 100 fs long depression [6].

4.2 Differential Optical Gating

The second example relies on the use of a loosely-synchronized laser pulse as a gate in a non-linear medium for pulse length measurement in a technique which is called differential optical gating (DOG) [5]. DOG uses two non-linear media as gates and two detectors (A and B). The gate pulse and the electron beam radiation are optically split in two parts. The laser reaching gate B is delayed by a time δ with respect to the one reaching gate A. Under the assumption that the gate pulse is much shorter than the radiation pulse (and an instantaneous gate response), the signal seen by each detector can be written as [5]

$$\begin{aligned} A(t_1) &\propto E_G I_S(t_1) \\ B(t_1+\delta) &\propto E_G I_S(t_1+\delta) \end{aligned} \qquad (3)$$

where E_G is the energy of the laser gate pulse and $I_S(t)$ is the instantaneous intensity of the radiation. From this measurement, both the instantaneous intensity and its time derivative are then known, which allows bunch shape reconstruction. Through the loose synchronization, the laser pulse randomly "walks" across the bunch, much like interleaved sampling on digital oscilloscopes. In recent experiments at Stanford University, the technique has been applied to the pulse shape measurement of a picosecond free electron laser source, using both an instantaneous gate and a step function gate [5].

5 ACKNOWLEDGEMENTS

I would like to thank Palma Catravas for kindly contributing to the section on the fluctuational interferometry and wiggler radiation measurements, R. Schoenlein and M. Zolotorev for information on the non-linear mixing, C. Rella and T. Smith for the DOG information, as well as my collaborators on the laser based probing work. I also want to thank E. Esarey for many useful conversations.

HIGH GRADIENT SUPERCONDUCTING RF STRUCTURES

H.Weise
Deutsches Elektronen-Synchrotron DESY, 22607 Hamburg, Germany

Abstract

Superconducting (s.c.) RF structures for the acceleration of electrons have been known for over 30 years (HEPL, Stanford). More than 10 years after their successful start a new generation (i.e. standing wave, π-mode cavities), made from niobium and operated at frequencies between 352 MHz and 3 GHz, was established at accelerators being operated for high energy physics (CERN, DESY, KEK) as well as nuclear physics (CEBAF, Darmstadt) experiments. Although the HEPL s.c. cavities were limited to a 10% duty cycle and the 2nd generation now allows continuous wave operation, the increase of the accelerating gradient was remarkably small with respect to the > 50 MV/m limit given by the physics of RF superconductivity.

Thirty years ago HEPL cavities reached about 2 MV/m; 15 years later DESY cavities achieved 4 MV/m. And the large 338-cavity CEBAF installation is based on a 5 MV/m gradient, the commissioning of the accelerator being less than 10 years ago. Since 1992 the TESLA (TeV Energy Superconducting Linear Accelerator) collaboration has studied the fundamental problems in cavity fabrication as well as operation. Last year an 8 mA electron beam was successfully accelerated in a 15 MV/m module containing 8 s.c. 9-cell cavities. Two more modules (20 to 25 MV/m) will be installed. From recent cavity tests a gradient of 25 MV/m can be taken as state of the art. Cavity production, preparation, and installation was remarkably improved, a prototype linac (TESLA Test Facility Linac) for a large linear collider shows good performance.

1 RF SUPERCONDUCTIVITY AND LINEAR ACCELERATORS

In 1961 Banford and Stafford [1] at Harwell proposed the feasibility of a superconducting proton linac, and have carried out experimental measurements on lead and niobium at 400 MHz using quarter-wavelength hairpin resonators. Similar measurements were started by Susini [2] and others at CERN and the University of Lausanne on lead and niobium surfaces at 300 MHz using a capacitively-loaded coaxial resonator. Here the interest was in building a s.c. separator. Also in 1961, a program was started at Stanford University to measure the properties of superconductors in a microwave cavity at 2856 MHz [3]. This program started the pioneering work for the application of superconducting RF structures for the acceleration of electrons.

The Stanford cavity was about 14 cm in diameter by 14 cm in length and was resonant at 2865 MHz in the TE011 mode. In this mode there is no current flux across the joints between the cavity side wall and the two end plates, so that the quality factor Q is independent of these joints. Several types of tin and lead surfaces were measured. Electroplated surfaces gave the highest Q's. A residual resistivity was always observed as T approached zero. Today we know from the theory of RF superconductivity that this is not due to improper cavity fabrication but can be explained by the BCS theory of superconductors. Nevertheless, material properties are limiting the achievable accelerating gradient. We characterize the state of the art material by the so-called RRR (residual resistivity ratio) which is a direct measure of the thermal conductivity.

At the 1963 International Conference on High Energy Accelerators in Dubna the Stanford group published a very preliminary design of a 20 GeV - 10% duty cycle superconducting accelerator. This at a time at which no real cavity has ever been built. The remarkable numbers were an assumed length of 3000 m corresponding to about 10 MV/m (active/total length ratio of 66%), and a power dissipated in the walls of the structure of 200 kW average, i.e. 100 W/m; the forward power was claimed to be 2 MW average, so that the total beam power of 1.8 MW average corresponded to almost 100 μA average electron beam current. Ref. [4] can be used to compare this design with the actual TESLA design [5] for a 500 GeV c.m. linear collider.

Based on the TE011 measurements the Stanford group designed and built the first two accelerating cavities, one TM010 and one 2 π/3 mode cavity. In 1965 an accelerating gradient of 3.7 MV/m was reached at an unloaded Q_o of $2.5 \cdot 10^8$ [6]. The cavity was electroplated with lead and operated close to 2856 MHz. Radiation exceeding 100 mR/h provoked the optimistic statement *The radiation provides indirect evidence of strong accelerating fields*. The explanation for the field emission limit was a possible local enhancement of the electric field by a factor 200 caused by sharp projections on typical surfaces [7]. Today we use enhancement factors of

100 to 1000 to explain the level of field emission using Fowler-Nordheim theory.

During the discussion of a LINAC 64 conference paper [8] the author felt that *the present state of knowledge of RF superconductivity was sufficiently discouraging to abandon further work on a superconducting proton linac.* Suelzle from Stanford wrote almost 10 years later *lower-than-expected accelerating gradients have necessitated the re-evalution of the energy objectives* [9]. The hope for getting roughly 14 MV/m in a 6-meter long, 1300MHz accelerating structure was not fulfilled. By the end of 1972 the 1300 MHz structures were limited to 3 MV/m. But the first superconducting electron linac was commissioned. It produced an 8 MeV, 250 μA beam with 12 keV · deg (FWHM) and a transverse emittance of less then 1 π mm mrad. Today the HEPL accelerator is used to drive different undulators and produce Free Electron Laser radiation in the infrared.

2 S.C. CAVITIES FOR STORAGE RINGS

The somewhat disappointing results from Stanford certainly have de-emphasized the search for high gradients. But in the late 70's the use of s.c. cavities in storage rings was considered. Here gradients of a few MV/m were sufficient. Important were instability thresholds - an adequate damping of higher order modes (HOMs) for multiturn operation was needed. Tests in existing storage rings led to promising results as reported [10-11]. Today we can find 352-MHz cavities in LEP as well as 500-MHz cavities in HERA. The first Workshop on RF Superconductivity, organized in 1980 by the Kernforschungszentrum Karlsruhe (KfK), summarized all activities aiming for the use of RF superconductivity for acceleration of ions as well as electrons.

While all first β=1 cavities were of cylindrical symmetry, i.e. a pill box with slightly smoothed out edges, one can find the first spherical resonators around 1980. According to [12] the Genoa / Italy 3-cell C-band structure was built in spherical geometry because of easier manufacturing. The result was amazing, the comparison of the maximum accelerating field shows the remarkable gradient of 8 MV/m. Somewhat later the spherical geometry was found to be the best in order to avoid multipacting. The high radiation levels in the HEPL tests were not only caused by simple field emission but by resonant electron emission, i.e. multipacting.

Within a short time the five laboratories being the driving forces towards high gradient β=1 structures, CERN, Cornell, DESY, KEK, and Wuppertal, concentrated on the spherical geometry. The E_{peak}/E_{acc} ratio was optimized to be about 2 for any geometry. Some cavities had a wall section being exactly perpendicular to the cavity axis (remains of the old pill box). Later the elliptical geometry was found to be best because of easier chemistry and water cleaning. The resonator frequencies and the number of cells varied from 352 MHz / 4-cell (CERN) to 3 GHz /5 & 20-cell (Cornell; Wuppertal - for the S-DALINAC / Darmstadt).

A significant frequency dependence of the maximum obtainable accelerating field could not be found. The choice of frequency was determined by the need to combine the cavity operation with other normal conducting structures or by the existence of klystrons. For most of the listed cavities the maximum number of cells was chosen from HOM calculations. The need to damp HOMs and to have sufficient coupling between the input coupler and the cavity led to slightly different designs.

3 HIGHER GRADIENTS, LOCALIZED DEFECTS, AND HIGHER RRR

For many years the design goal for superconducting structures was about 5 MV/m. This was based on experience with multicell cavities. Nevertheless, the goal of high gradients was never forgotten since the BCS theory predicted maximum gradients of almost 50 MV/m at 2 K. Considerable effort has been devoted to the understanding of surface defects. Larger defects could be localized and sometimes even eliminated by grinding. In 1979 the technique of temperature mapping was developed at CERN and it was demonstrated that well localized defects were one of the prime causes of quenching [13]. Over the years these temperature mapping devices have been improved, and more diagnostics like X-ray diodes and RRR measuring devices using eddy current induced by small coils have been introduced.

Cornell pointed out that the threshold for thermal instabilities could be increased if the thermal conductivity, i.e. the RRR of the cavity wall is improved. In a close collaboration with industry the RRR value for the used Nb material was raised from typically 40 (corresponding to a heat conductivity λ = 10 W/(m·K) at 4.2K) to values between 150 and 200. To increase the RRR even further yttrification at about 1250°C was used at Cornell. Later the use of 1400°C UHV baking in the presence of titanium vapor was established.

The combination of eliminating defects and using higher RRR has guaranteed a more reliable way towards accelerating fields of 5 to 10 MV/m in multicell cavities. As examples one can quote results from CEBAF prototype cavities which reached 6-8 MV/m, a single cell KEK 500 MHz cavity (RRR 80) with 7.6 MV/m, the first CERN LEP prototype cavity (4-cell, 352 MHz) with 7.5 MV/m, and last but not least one 20-cell 3GHz cavity for the S-DALINAC which reached 7.8 MV/m after the preparation at Wuppertal. Cornell was able to reach really high gradients in 1.5 GHz single cell cavities: 22.5 MV/m. Wuppertal followed with 23.1 MV/m for a 3 GHz single cell structure.

A few years later the standard material for s.c. cavities was RRR 280. The first multicell cavities reached again higher gradients but shortly after the installation of the first 20-cell cavity in the S-DALINAC the enthusiasm was damped by a new phenomenon. After keeping the cavity at temperatures just above nitrogen temperature (70 - 100K), which can happen in a linac installation, the quality factor dropped, the cryogenic losses were increased by a factor of 10. Darmstadt and DESY found the Q-degradation (sometimes also called Q-disease) at about the same week. Months later it was clearly identified as a clustering of hydrogen and therefore creation of normal conducting niobium hydride areas [14]. For increasing the RRR of the Nb material the oxygen was removed with the disadvantage that the hydrogen is not chemically bound anymore. A cooling of the acid during chemical polishing is necessary to avoid high hydrogen concentration in the niobium. Otherwise Niobium hydride areas start to grow. Baking at temperatures above 750°C can cure the problem.

4 THE STATUS BEFORE TESLA

At the LINAC 92 Conference R. Sundelin presented a good overview about the state of the art in s.c. cavity production [15]. Assembly in clean rooms was standard, the Cornell group had improved gradients using high peak power processing, and CERN used high pressure water rinsing to suppress field emission in the LEP cavities which are made from copper but sputter coated with Nb. The number of superconducting cavity operating hours in larger installations increased substantially.

Table 1:
S.c. cavities in operation as known at the time of the LINAC 92 Conference, i.e. before the start of the TESLA program. The CEBAF installation was ongoing at a rate of 16 cavities per month.

	Nbr.	of Cav.	MHz	m	MV/m
MACSE	5	5-Cell	1500	2.5	6.5
S-DALINAC	10	20-Cell	3000	10.0	5.9
HERA	16	4-Cell	500	19.2	3.6
HEPL				30.8	3.0
TRISTAN	32	5-Cell	508	47.2	6.6
CEBAF	106	5-Cell	1497	53.0	7.6
LEP	12	4-Cell	352	20.4	3.7

The achieved accelerating gradients of the different machines are listed above. The CEBAF installation was ongoing at a rate of 16 cavities per month.

5 CEBAF AND LEP INSTALLATION

The CEBAF recirculating superconducting electron linac at Jefferson Lab went in full operation and is now using 330 s.c. cavities operating at 2.0 K. The operation frequency is 1497 MHz. Four pairs of the 0.5-m-long cavities are contained in one cryomodule but each cavity is separately powered by one 5 kW klystron. According to [16] the distribution in the accelerating gradients has its maximum at about 7.5 MV/m with a spread of 5 MV/m FWHM. The principal limitation of the installed cavities is electron field emission and associated phenomena, such as X-ray production, charging and arcing at the cold ceramic RF window, and anomalous 2 K heat load. This affects about 80% of the cavities. Only 12% of the cavities are limited by quench. The average quench limit is at 13 MV/m.

The cavity operation in CEBAF has been quite stable and reliable. In 1997 the maximum energy delivered to the nuclear physics experiments was 4.4 GeV at a beam current of 115 μA. The RF could have supported 5.6 GeV with a five pass beam delivery. In-situ RF-helium processing of the cavities was tested and yielded an additional 41 MeV/pass. Jefferson Lab intends to upgrade the machine to the 6-8 GeV region by this method. Further steps towards higher electron beam energy are described elsewhere [17]. The Jefferson Lab Free-Electron Laser installation can operate above 10 MV/m.

In 1997 CERN operated 240 s.c. cavities in LEP. Out of the 240 cavities 16 were made from solid niobium and 224 were sputtered Nb/Cu cavities. The operation frequency is 352 MHz, the nominal operating field 6 MV/m. Eight cavities are grouped each and driven by one klystron. Two klystrons are connected to one HV power converter. According to [18] the overall performance of the s.c. RF system was good during the 1997 operation period. The average operational gradient of the 224 Nb/Cu cavities was 5.9 MV/m even though some cavities were limited at lower gradients. The four solid Nb modules were running at about 3.6 MV/m (nominal gradient 5 MV/m).

6 THE TESLA R&D EFFORT

Since 1991 the international TESLA collaboration [19] is following an approach to a 500 GeV linear collider using superconducting accelerating cavities. Altogether 35 institutes from nine countries are developing linac components as there are s.c. accelerating structures, couplers, cryostats, RF sources, beam diagnostics etc. The TESLA Collaboration tries in a joint effort to increase the usable accelerating gradient to more than 25 MV/m. A test facility, located at DESY with major components flowing in from members of the collaboration, is going to establish a well-developed collider design. The status of this design work is described elsewhere [5].

The TESLA Test Facility (TTF) includes cavity preparation and testing as well as the final test of cavities in a linac installation [20]. About 25 standard 9-cell 1.3 GHz structures operating in the pi-mode have been prepared and tested. Out of the first production series eight cavities were taken for the assembly of one TESLA cryogenic unit, the TTF module #1.

The goal for the accelerating gradient was set to 15 MV/m average (to be compared with the 1992 state of the art given in table 1) at an unloaded quality factor $Q_o=3\cdot10^9$. This goal was reached with module #1. Although some cavities are limited below 15 MV/m the maximum achieved electron energy was 125 MeV in short macropulses and 105 MeV in 800 µs long macropulses. The overall performance is limited by the weakest cavities since all eight cavities are driven by one common klystron and the RF forward power is equally split. Details about the operation can be found in [21].

7 THE FIRST TTF CAVITY PRODUCTION

About 25 cavities from 4 different manufacturers were tested in a vertical test cryostat. The average gradient was 19.2 MV/m at $Q_o > 3\cdot10^9$. 14 cavities showed $E_{acc} > 20$ MV/m, 3 cavities showed $E_{acc} > 28$ MV/m. The last 9 cavities delivered and tested had a clearly increased gradient of 24.3 MV/m at $Q_o > 3\cdot10^9$. Figure 1 shows the test results as a function of time. Maximum gradients are plotted as well as the usable gradient defined by the onset of increased cryogenic losses. Some of the very first cavities had maximum acceleration voltage being almost high enough for TESLA 500 but the strong field emission limited the usable gradient.

During 1996 the first group of cavities was tested. High pressure rinsing with ultraclean water reduced the field emission but most of the tested cavities were limited around 13 MV/m. The reason was found to be an insufficient cleaning after the preparation for electron beam welding of the equator. Since summer 1997 another 11 cavities were tested. The average maximum gradient is almost 25 MV/m. Field emission is still an issue and limits the usable gradient to roughly 22 MV/m. Nevertheless, all four manufacturers were able to produce cavities with gradients above or close to 25 MV/m. The gradient of the best TESLA 9-cell cavity is above 30 MV/m. Figure 2 shows the horizontal test result. This cavity is going to be used in the second cryogenic module.

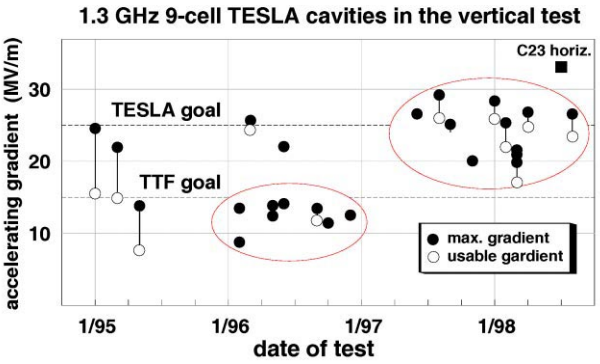

Fig. 1: Vertical test of 1.3 GHz 9-cell cavities.

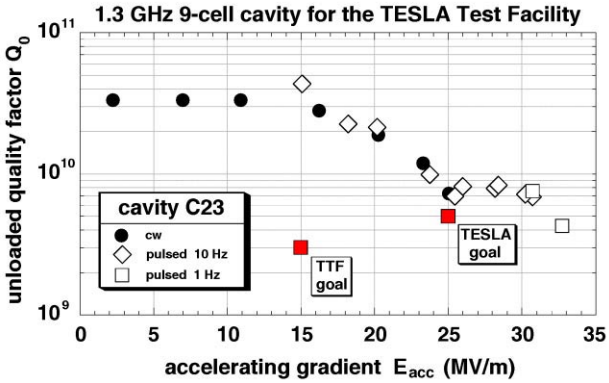

Fig. 2: The best TESLA 9-cell cavity measured in a horizontal test cryostat. For this test the cavity is equipped with the main RF input coupler and the HOM couplers.

8 OUTLOOK

The goal for the second TTF Linac module being just in the assembly phase is 20 MV/m. The third module is expected to reach 25 MV/m. All three modules will be used for a Free Electron Laser experiment in the UV [22]. Further modules will be built to finalize the design of accelerating units of the large TESLA machine [23]. Being installed in the TTF Linac they will finally drive a VUV free-electron laser. Therefore a new cavity production was started. A total number of 26 cavities is expected to be at DESY by end of 1998. The material for all cavities was scanned for inclusions of other metals. A special eddy current scanning apparatus was developed.

Single cell cavities have reached 40 MV/m accelerating field [24]. The members of the TESLA collaboration and also Jefferson Lab as well as KEK are still improving the gradients of resonators made from solid niobium. Electropolishing is studied again in order to smoothen the inner surface. High pressure water rinsing is the most successful method to decrease field emission. Nevertheless, the installation procedure of all RF couplers seems to be a main issue.

With the aim to decrease the cavity production costs two new fabrication methods are studied. Spinning of cavities is described elsewhere [25]. Hydroforming of multicell cavities is also under investigation. Both methods allowed the production of L-band single-cell cavities with accelerating gradients above 20 MV/m. A slightly decreasing Q vs. E_{acc} is not understood. Multicell-cavities are underway and will be measured next.

Abstract

The design and fabrication of a four-vane RFQ to deliver a 100 mA CW proton beam at 6.7 MeV is described. This linac is an Oxygen-Free Electrolytic (OFE) copper structure 8 m in length and was fabricated using hydrogen furnace brazing as the joining technology.

1 INTRODUCTION

The linear accelerator for the Accelerator Production of Tritium Project (APT) [1] will include a 6.7 MeV Radio Frequency Quadrupole (RFQ) linac. The first phase of this project, the Low Energy Demonstration Accelerator (LEDA) [2] consists of this RFQ plus a 20 MeV Cavity-Coupled Drift Tube Linac (CCDTL) [3]. The technical specifications for the APT/LEDA RFQ are given on Table 1.

Table 1: APT/LEDA RFQ Specifications

PARAMETER	VALUE
Frequency	350.00 MHz
Particle	H^+
Input Energy	75 keV
Input Current	105 mA
Input Emittance, trans./norm.	0.020 π-cm-mrad rms
Output Energy	6.7 MeV
Output Current	100 mA
Output Emittance, trans./norm. longitudinal	0.022 π-cm-mrad rms 0.174 deg-MeV
Transmission	95%
Duty Factor	100 %
Peak Surface Field	1.8 Kilpatrick
Average Structure Power	1.2 MW
Average Beam Power	0.7 MW
Average Total Power	1.9 MW
RF Feeds	12 Waveguide Irises
Average Heat Flux	11 W/cm^2
Maximum Local Heat Flux	65 W/cm^2
Resonant Segments	4 @ 2.0 m each
Brazed Sections	8 @ 1.0 m each
Slug Tuners	128 total
Length	8.0 m
Weight	5000 lb
Inlet Coolant Temperature	50°F
Operating Temperature	85°F

* Work supported by the US Department of Energy

These requirements presented significant challenges for the beam dynamics, cavity design, and thermal management. This was further exacerbated by the scarcity of similar devices which have been built and the limited operational experience. Indeed, none have been operated continuously for as long as one year. A comparison of CW RFQs is given in Table 2 on the following page. The CRNL1 RFQ, which has been moved to LANL and is now in operation as the CRITS (Chalk River Ion Source Test Stand), is the only device to have amassed significant operational time [4].

The original concept design for the APT RFQ was carried out in 1993 [5]. That concept incorporated a cavity that was segmented longitudinally as four resonantly-coupled cavities [6].

Because of the high output energy and current, there are some significant new features in the APT RFQ. Some of the issues and their resolution are:

- Long Electrical Length - This is possible through use of the segmented resonantly-coupled cavity [6]
- High Power - The use of a non-uniform vane-skirt width [7,8] reduces the peak and total cavity power.
- High Average Power Density - The average surface power of 11.4 W/cm^2 is a factor of four higher than CRNL1. Use of 24 longitudinal coolant passages in the cross section is required to dissipate the heat.

2 FABRICATION CONCEPT

The original fabrication concept [5] was based upon the electroformed joint which was developed by LANL, Northrop-Grumman, and GAR Electroformers for the BEAR RFQ [9] and later used for the CWDD [10] and SSC [11] RFQs. This method produces a monolithic cavity which has high structural efficiency and serves as an integral vacuum vessel. Electroforming is a room-temperature process and thus there is no concern regarding the maintenance of dimensional integrity. These advantages are largely offset by the high cost and long process duration.

Following completion of the conceptual-design study for the APT RFQ, LANL began an investigation of other manufacturing technologies in an attempt to reduce both cost and schedule. The primary focus was the joining technology. Welding, dip-brazing, plasma-spray, and hydrogen-furnace brazing were investigated. LANL has

extensive experience in hydrogen-furnace brazing of linear accelerators. The brazed joining concept was tested on a 525-MHz, 0.48-meter-long engineering model [12].

The brazed RFQ linac concept has the advantages of using OFE copper for its high thermal and electrical conductivity while facilitating the attachment of high-strength copper (C15715 GLIDCOP [13]) for high-stress areas such as flanges.

The 8-meter long APT RFQ cavity was fabricated as eight one-meter long "sections." A cross section of the cavity of the APT RFQ is shown on Fig. 1 with a schematic of the entire 8-meter structure shown on Fig. 2. The cavity is a major/minor vane arrangement. Each vane is fabricated as a vane tip brazed onto a base. This allows coolant passages to be machined in and located very near the vane tips. Plugs are brazed over the coolant passages. The brazed-on vane tips are the only water-to-vacuum braze joints in the structure. An alternative would have been to deep-hole-drill the passages and plug the ends by brazing.

The manufacturing plan allowed for each one-meter-long section to be mechanically aligned and for the RF-field distribution and resonant frequency to be measured prior to brazing. The alloy used to form the longitudinal joints, Cusil (AWS BAg-8), flows freely over copper surfaces and these joints could be assembled metal to metal. The alloy was supplied from wire placed into grooves. Thus it was not necessary to compensate for the thickness of the alloy in the mechanical alignment and RF measurements. After brazing, it was determined that the mechanical alignment had not changed more than 0.001 in and the resonant frequency had changed less than 75 KHz.

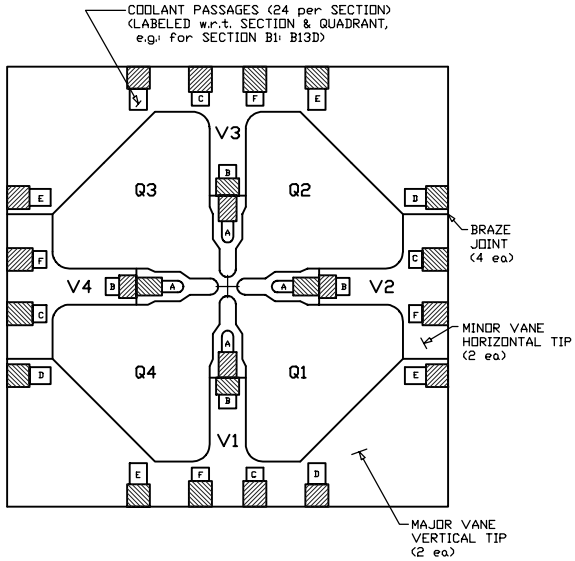

Figure 1: APT/LEDA RFQ Cross Section

Table 2: Comparison of CW RFQs

Parameter		**FMIT**	**CRNL**	**CRNL1 CRITS**	**CWDD**	**APT**
Particle		H_2+	H+	H+	D-	H+

* The CWDD RFQ was designed to operate at 35 K. The stated copper power includes the effect of enhanced surface electrical conductivity.

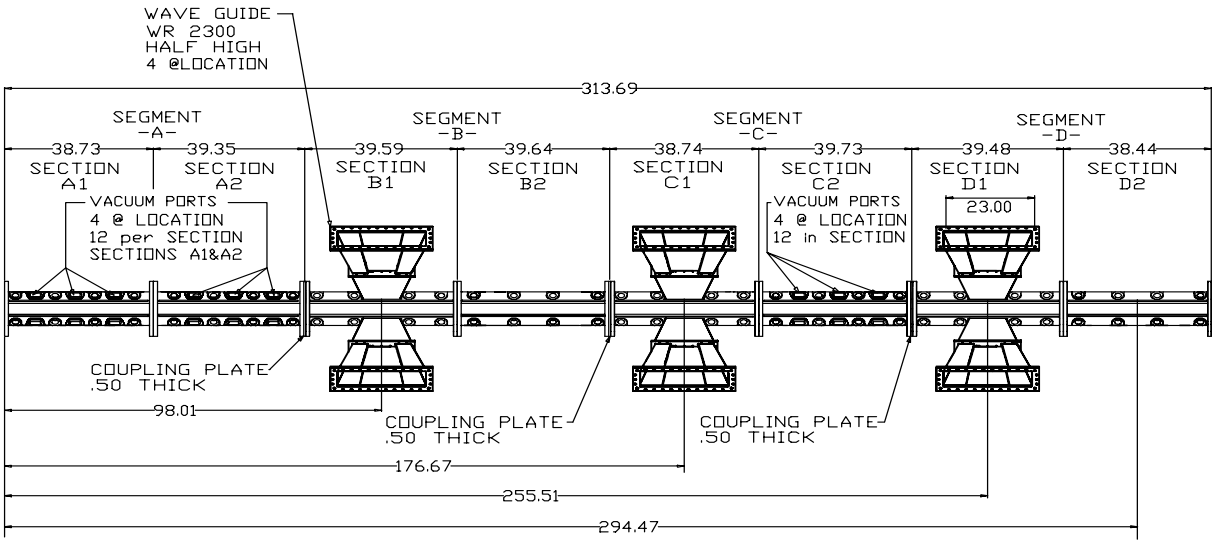

Figure 2: APT/LEDA RFQ Schematic

3 THERMAL MANAGEMENT

A total of 1.2 MW must be removed from the APT/LEDA RFQ cavity. With the average surface-power density being a factor of four higher than any earlier CW RFQ, thermal management was the major concern for the engineering analysis and design. The coolant passages were sized such that the bulk velocity did not exceed 15 ft/s to minimize flow erosion. The coolant passages were sized and located such that the heat gain per unit length in each passage was equal in the cross section. This was necessary in order to assure symmetric thermal distortion of the cavity.

A requirement that the longitudinal tilt of the local cavity frequency not exceed ±20 KHz in each one-meter long section established the number of cavity coolant passages (24 longitudinal passages in each section) and their locations. The "small" (350 MHz) cavity cross section did constrain the number, sizes, and locations of the coolant passages.

The RF field is ramped along the linac. The RF power in each of the four resonant segments is significantly different (A = 188, B = 318, C = 361, & D = 398 kW). In order to simplify manufacture, all segments have the same number and arrangement of coolant passages. The differences between the segment cooling requirements are addressed by having separate flow loops (including pumps and mixing valves) for each of the four resonant segments [17].

The resonance-control scheme provides coolant (360 GPM total) at a constant 50°F into the tip passages ("A" & "B" as identified on Fig. 1) while the temperatures of the coolant (1160 GPM total flow) fed to the cavity wall passages ("C," "D," "E," & "F") are modulated to maintain the cavity on resonance. The inlet coolant temperatures to the cavity walls of each segment are predicted to be 71, 65, 63, and 61°F respectively. Modulating only the cavity-wall-coolant temperature gives a positive derivative of the frequency with respect to the coolant temperature in the cavity-wall passages ($\partial f/\partial T = 1.7X10^4$ Hz/°F).

Each slug tuner (128), vacuum pumping port (36), RF iris/waveguide unit (12), coupling plate (3), and both end-walls are also supplied with coolant. There are 424 coolant passages.

The 50°F coolant temperature was selected in order to reduce the peak temperature of the cavity wall to about 100°F. (The highest temperatures, ~150°F, occur in the end undercut regions where the surface heat flux is 65 W/cm^2.) This serves to minimize longitudinal thermal expansion as well as cavity power which would have increased at higher surface temperatures. The 50°F inlet temperature requires the coolant water to be refrigerated rather than supplied from a cooling tower. A cooling tower would provide 105°F inlet water in the summer which would raise cavity-wall temperatures and power consumption significantly.

4 VACUUM SYSTEMS

The vacuum pumping system for the RFQ is designed to provide a cavity-vacuum level of better than $1X10^{-6}$ Torr. As much as 10 mA of the H^+ input beam will not be captured. This will form $1.0X10^{-3}$ Torr-l/s of H_2 in the first resonant segment. There is an additional $0.5X10^{-3}$ Torr-l/s of other species (H^+, H_2^+, H_3^+, & O_2) from the injector that must also be removed. There are 36 vacuum pumping ports, 12 each in Sections A1, A2, and C2. Each pumping port has local heat fluxes up to 40 W/cm^2 and therefore they must be actively cooled.

The vacuum-manifolding concept is based on that used for the SSC RFQ [11]. Five 8-in cryopumps are used. These are connected via manifolds to allow for operation during regeneration and to provide installed redundancy [18].

There are 12 RF windows [19] connected via ridged waveguide [20] to the quadrants of Segments B1, C1, and D1. Each window will transmit 250 kW thru a small (0.063 in wide by ~3.5 in long) iris. Because the vacuum conductance through these irises is very small (< 16 l/s) and the outgassing of the window and ridged waveguide assemblies is high (>$5X10^{-9}$ Torr-l/s), separate vacuum pumping units are required for each assembly. Direct-mounted non-evaporable getter (NEG) pumps will be used in these locations [21]. These have the advantages of being passive (no mechanical vibrations) and oil free. The selected units (SAES "CapaciTorr") have greater than 1000 l/s speed for H_2 and the predicted time between regenerations exceeds one year. There is no installed redundancy in the RF-window vacuum system.

5 STRUCTURAL SUPPORT

The cavity is a long, slender structure, sufficiently flexible that a statically-indeterminate support is required [22]. The cavity is suspended by five articulated links, one at the end of each resonant segment. This support meets the requirements that the gravitational deflection not exceed 0.0005 in and that the deflection due to predicted applied loads not exceed 0.005 in.

For assembly, the support structure was mounted in a vertical orientation on a pair of pyramidal towers (Fig. 3). The RFQ sections were stacked into the support structure. The entire assembly was then rotated to the horizontal and rolled into the linac tunnel. This concept was extrapolated from that used with the CWDD RFQ [10].

6 INSTALLATION STATUS

Fabrication of the cavity was completed in January of 1998, 28 months after commencement of the project. Preliminary RF tuning [23], vacuum testing, and assembly into the support structure was completed in the Spring of 1998. The unloaded Q of the cavity was measured at 8634, more than 80% of the value predicted by SUPERFISH. With the variable vane-skirt width, the Q calculated by SUPERFISH varies along the length of the RFQ so a length-weighted average value is quoted. Fig. 4 shows the complete 8-meter linac assembled for low power RF tuning.

The unit was installed in the linac tunnel in June of 1998. At the present time, the cavity vacuum system and cooling system are being installed. Fabrication of the ridged waveguide components [20] is underway at LANL and at AlliedSignal. Final testing of the RF-window vacuum systems is underway at LLNL [24]. High-power conditioning is scheduled to begin in the Fall of 1998.

7 SUMMARY

The detail design of the APT/LEDA RFQ cavity was scaled directly from the engineering-demonstration model [12]. The design, fabrication, and tuning tasks went smoothly were carried out at LANL and the original schedule was adhered to. The brazed-RFQ concept is robust and can be cost-effectively and predictably implemented at all duty factors up to CW and in the frequency range of about 200 to 800 MHz.

8 ACKNOWLEDGEMENTS

Other institutions participating in RFQ project include LLNL and TECH-SOURCE (vacuum system), AlliedSignal (resonance control cooling system), plus Northrop-Grumman (engineering support). Personnel from the Argonne National Laboratory (G. McMichael), the FERMILAB (M. May), General Atomics (C. Charman & L. Lommers), Northrop-Grumman (B. Abel & J. Rathke), TECH-SOURCE (P. Grande & N. Wilson), NOAO (E. Pearson), and LANL (T. Butler) served on the project's technical-review panels.

REAL-TIME TRANSVERSE EMITTANCE DIAGNOSTICS*

P. Piot, G.A. Krafft, R. Li, J. Song
Thomas Jefferson National Accelerator Facility, VA23606 Newport News, USA

Abstract

With the increasing interest in high-brightness beams and the recent advances in photoemission guns capable of producing such high-charge, low-emittance beams, measuring transverse emittance has become a primary concern, especially in driver accelerators for free-electrons lasers (FELs) where a degradation of this parameter could result in significant deterioration of the FEL gain. Hence frequent and fast measurement are needed, particularly when detailed parametric studies are required. Commonly used methods include optical transition radiation (OTR) based methods and trace space sampling methods. We will discuss these methods and provide motivation for our method of on-line emittance measurement in the Jefferson Lab FEL.

1 INTRODUCTION

The characterization and measurement of transverse phase space is a longstanding topic widely discussed in the literature [1]. In this paper we concentrate on methods that provide an on-line measurement of emittance and Twiss parameters. We quantify "on-line" as an update rate of the order of a second. Throughout this paper the JLab FEL driver-accelerator is taken as an example. In this paper we use the root mean square (rms) emittance. For the $x-x'$ trace space it is defined as:

$$\tilde{\varepsilon}_x = \kappa \left[\langle (x-x_0)^2\rangle\langle (x'-x'_0)^2\rangle - \langle (x-x_0)(x'-x'_0)\rangle^2\right]^{1/2} \quad (1)$$

where x and $x' = dp_x/dp_z = x/z$ are respectively the position and divergence coordinates. The $\langle . \rangle$ designates the average operator on the two-dimensional trace space distribution $\rho_2(x,x')$, the constants x_0 and x'_0 are the first order moments in position and divergence. κ is a scaling factor; henceforth we set its value to 1 to conform to the Sacherer [2] definition of rms emittance. Another commonly used definition of rms emittance was defined by Lapostolle [3] and now referred to as the effective rms emittance, defined by letting κ be 4. In this paper we will also use the normalized emittance defined as $\tilde{\varepsilon}^n_x = \beta\gamma\tilde{\varepsilon}_x$. The advantage of considering an rms-type emittance is that its definition is not as arbitrary as it is for the geometric emittance commonly used by experimentalists (which is defined as the trace space area of a contour encompassing a certain fraction of the beam particles). The rms emittance also allows comparison of beam quality from different facilities. Finally the concept of rms emittance is a figure of merit of the statistical properties of the beam since it is related to the beam entropy [4]. Along with the emittance, the trace space is also specified by the Twiss parmeters that are related to the moments: $\alpha_x = -\langle xx'\rangle/\tilde{\varepsilon}_x$, $\beta_x = \langle x^2\rangle/\tilde{\varepsilon}_x$, $\gamma_x = \langle x'^2\rangle/\tilde{\varepsilon}_x$. From Eqn.(1), the emittance measurement reduces to the measurement of the second order moments of the distribution.

We will use the JLab FEL photoinjector as a basis for numerical computations, it is worthwhile to recall in Tab. 1 the principal beam parameters at the two locations we wish to measure the transverse emittance. A more complete description of the injector is found in Ref. [5] and references therein. Our goal is to measure a normalized emittance ranging from 4 to 20 mm-mrad, with the nominal emittance being approximately 7 mm-mrad.

parameter	Location #1	Location #2
$\tilde{\varepsilon}^n_x$ (mm-mrad)	6.6	8.8
$\sigma_{x'}$ (mrad)	0.6	0.3
σ_x (mm)	2.3	1.9
$\tilde{\varepsilon}^n_y$ (mm-mrad)	6.0	6.2
$\sigma_{y'}$ (mrad)	0.5	0.2
σ_y (mm)	2.3	1.4

Table 1: Beam parameters predicted by PARMELA for the baseline design injector (Q=135 pC); the total energy is 10 MeV.

2 OTR-BASED TECHNIQUE

When a beam of charged particles has the electric permittivity of its environment changed, it emits transition radiation (TR). The use of this radiation for beam diagnostic purposes has become popular in recent years: in electron accelerators such radiation is generated by intercepting the beam with very thin metallic foils and observing the backward TR. For a single electron the TR angular distribution given by [6]:

$$\frac{d^2I}{d\omega d\Omega}(\theta,\gamma) = \frac{e^2\beta^3}{\pi^2 c} R \frac{\sin^2\theta}{(1-\beta^2\cos^2\theta)^2} \quad (2)$$

where $\beta^2 = 1 - 1/\gamma^2$ (γ being the usual Lorentz factor) and R is the reflection coefficient of the foil ($R \simeq 1$ for a metallic foil at optical wavelengths). The generated TR can be used to measure the rms beam spot size by computing the quantity:

$$\langle x^2\rangle = \frac{\int x^2 I(x,y)dxdy}{\int I(x,y)dxdy} \quad (3)$$

*Work supported by the US-DOE contract #DE-AC05-84ER40150, the Office of Naval Research, the Commonwealth of Virginia, and the Laser Processing Consortium.

where $I(x,y)$ is the two-dimensional density of the TR image on the foil. The beam divergence can be inferred from the observation of the TR angular distribution since it corresponds to the convolution of the TR intrinsic angular distribution with the beam angular density $P(x')$:

$$\frac{d^2I}{d\omega d\Omega}(\theta,\gamma) = \int \frac{d^2I(\theta-\alpha,\gamma)}{d\omega d\Omega} P(\alpha)d\alpha \qquad (4)$$

Hence if the upstream magnetic optics is properly tuned to achieve a waist at the location of the TR screen, the emittance can be estimated by computing the quantity:

$$\epsilon_x = \left[\langle x^2\rangle\langle x'^2\rangle\right]^{1/2} \qquad (5)$$

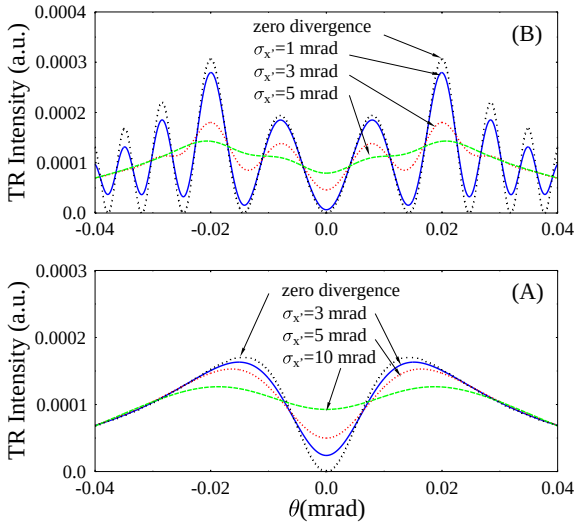

Figure 1: Dependence of the single foil TR angular distribution **(A)** and interferometric TR angular distribution **(B)** for different beam divergences. For case **(B)**, the wavelength of observation is λ =500 nm and the foil space is $L \simeq \lambda\gamma^2$.

Figure 1(A) shows the effect of beam divergence on the TR angular distribution for a beam of 38 MeV (at 10 MeV the effect is not very pronounced). The use of fitting to obtain the divergence (and subsequent emittance) measurement has been successfully implemented in several facilities [7, 8]: the experimental TR angular distribution is fitted with two parameters (energy and divergence). The minimum rms beam divergence that can be experimentally resolved is approximately $x' \simeq 0.15\gamma^{-1}$ [8]. Such a method was quickly replaced by a more precise method based on the Wartski [6] two-foil interferometer: instead of directly detecting the backward TR emitted from the foil, the interference pattern between the forward TR emitted as the beam crosses an upstream foil and the backward TR of a second foil is analyzed. The distance between the two foils must be larger than the far-field parameter $\Lambda = \lambda\gamma^2$ where λ is the wavelength at which the interference pattern is observed. In this case Eqn.(2) takes the form:

$$\frac{d^2I}{d\omega d\Omega} \propto \frac{\sin^2\theta}{(1-\beta^2\cos^2\theta)^2}\sin^2\left(\frac{\pi L}{\lambda}(1-\beta\cos\theta)\right) \qquad (6)$$

Simulations of the interference patterns for different beam divergences are presented in Fig. 1(B). In these numerical computations, we have simply convolved the Eqn.(6) with the beam angular distribution that is assumed to be gaussian, the beam energy being 38 MeV. The effect of increasing the divergence results in a blurring of the angular distribution. The previous remarks also pertains : for a 10 MeV beam we cannot resolve beam divergence comparable to the one expected in the JLab FEL injector (approximately 0.2 to 0.6 mrad). As in the single foil case, the experimentally obtained interference pattern is fitted using two parameters (divergence and energy) from which the divergence is computed, providing an emittance using Eqn.(5). The advantage of this method comes from the oscillations that occur at positions depending on energy, it generally gives more accurate fits compared to the single foil method. Also, because the distribution is dependent on the wavelength of observation and the distance between the two foils, it is possible, using these dependencies, to "tune" the interferometer in order to increase the accuracy of the measurement. TR-based methods are very attractive because of their simplicity, generally two CCD detectors and a beam splitter are needed. Unfortunately they have a number of drawbacks: Firstly, it is necessary to locate such devices at a beam envelope waist or to tune the upstream optics to achieve such waist. Secondly in the case of the two-foils scheme, the first foil used to emit forward OTR inevitably increases the beam divergence due to multiple scattering. This is especially important for low energy beams; typically this method is suitable only for a beam whose divergence $\sigma_{x'}$ and energy γ satisfy a relation of the type $\sigma_{x'} \gg f(Z,\Omega)/(mc^2\gamma)$ where f is a function of the foil atomic number Z and the mean number of collisions Ω, and can be estimated from results discussed in Ref.[9]. Also, both of these methods are difficult to apply to measure the emittance of a space-charge-dominated beam, e.g., as it is often the case for high-brightness injectors. Indeed, they can be used provided the beam sizes $\sigma_{x,y}$ at the horizontal waist satisfy the relation (the same equation obtains in the vertical plane replacing x subscript by y):

$$2K\sigma_x^2 / \left[\tilde{\varepsilon}_x^2\left(1+\frac{\sigma_y}{\sigma_x}\right)\right] \ll 1 \qquad (7)$$

where $K = 2I_p/((\beta\gamma)^3 I_A)$ is the normalized perveance (I_p and I_A are respectively the peak and Alfvèn current). Successful use of OTR interferometry has been reported by several groups, with an extensive study performed on the BOEING FEL facility [10]. A measurement of divergence of approximately 100 μrad for 650 MeV beam is planned on the APS undulator test line [11].

3 TRACE SPACE SAMPLING METHODS

Trace space sampling techniques are widely use to characterize the trace space density with high precision. The most popular example is the "slit and collector" method that has been used by several teams to characterize guns. Though it does not provide an on-line measurement, variants of this technique have been used to perform single shot measurements. In such methods a single slit is replaced by an interceptive mask where several apertures are bored. The different methods commonly in use differ in essentially two ways: in the shape of the sampling apertures but also in the type of "collector" device used to observe the beamlet profiles (fluorescent screens, optical transition radiation (OTR), wire scanner). The principle of the trace

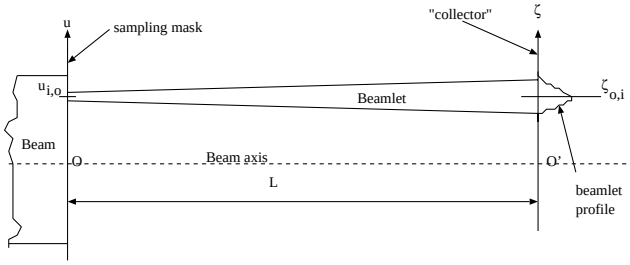

Figure 2: Basis of trace space sampling technique.

space sampling is sketched in Fig. 2, where we consider the one-dimensional case: the sampling aperture is assumed to have a zero-extension along the coordinate axis u. The generated beamlet strikes the collector device after propagating through a drift of length L. For the generated beamlet, the second order moments are $\langle u_{0,i}^2 \rangle$, $\langle ((\zeta - \zeta_{0,i})/L)^2 \rangle$ and $u_{0,i}\langle (\zeta - \zeta_{0,i})/L \rangle$. For a set of n beamlets, the second order moments are given by the relations:

$$\langle u^2 \rangle = \langle \sum_{i=1}^{n} u_{0,i}^2 \rangle, \langle u'^2 \rangle = \langle \sum_{i=1}^{n} \frac{(\zeta - \zeta_{0,i})^2}{L^2} \rangle \qquad (8)$$
$$\langle uu' \rangle = \langle \sum_{i=1}^{n} u_{0,i} \frac{(\zeta - \zeta_{0,i})^2}{L^2} \rangle$$

Using the set of Eqns.(8) and Eqn.(1), we can estimate the beam parameters of the incident beam.

In the case of on-line measurement, OTR screens or fluorescent screens are commonly used. The latter are generally preferred because they are very sensitive, but offer worse resolution, and care must be taken to use them in their linear response range. Also the persistence of such screens can be problematic for single-shot measurement. OTR screens, on the other hand, provide high resolution but the photon/electron conversion is very small (typically $1/\alpha$, α being the fine structure constant) and special attention must be directed toward maximizing the S/N ratio by reducing the background noise.

Another task common to all these method is the choice of mask material and thickness. If we restrict our discussion to uncooled systems, a high thermal conductivity material should be chosen to efficiently dissipate the beam deposited power. Also thermal bridges toward the exterior of the vacuum chamber should be used. Thermal analysis of the mask with the beam deposited power is necessary especially when OTR screens are used as collectors, since they require the highest possible average current to maximize the S/N ratio. Copper is a good choice because it offers a relatively good emissivity and therefore part of the deposited power is dissipated via black body type radiation. Other materials such as stainless steel are generally employed when the collector is a fluorescent screen. The deposited power may be reduced by choosing a proper beam temporal structure (micropulse frequency, and macropulse width and frequency) provided multi-bunch effects are not significant, a true assumption in the case of the JLab FEL where the bunches are separated by 8.03 m.

The thickness of the mask is a compromise between the S/N ratio on the collector and edge scattering of the electron on the aperture edge. Ideally, it is desirable to have a thickness that is of the order of the stopping thickness $\gamma mc^2/(dE/dx)$ where dE/dx is the energy loss per unit of pathlength in in the material. On the other hand, if the thickness is too large, particles can scatter on the aperture edges and thereby change their divergences [15]. The thickness can be determined by considering the rms scattering angle given by the Molière theory [12]:

$$\left[\langle \theta_{\text{scat}}^2 \rangle\right]^{1/2} = \frac{13.6}{\beta cp} z \sqrt{l/X_0}\,[1 + 0.038 \ln(l/X_0)] \qquad (9)$$

where p the momentum in MeV/c, z is the charge number, and l/X_0 is the mask thickness in units of radiation length X_0. Using the previous relation we can determine the thickness of the mask l so that the rms scattering angle is much larger than the angle subtended by the collector. In such cases, the scattered particles will contribute as a uniform background without biasing the beamlet pattern and one avoids erroneous values for the beam parameters. We have investigated the importance of edge scattering by using the PARMELA-generated phase space for the JLab FEL and numerically retracing each macroparticle through apertures. We found that in the case of the JLab FEL nominal emittance and divergence at the location where we perform the measurements, less than 5% of the particles were interacting with the edge even in the presence of a slight misalignment of the mask axis with respect to the beam axis of the order of 1 mrad. Therefore this latter effect is assumed to be insignificant, and no special care such as aperture tapering was considered for the case of the JLab FEL.

By a proper choice of aperture size, trace-space sampling allows the measurement of space-charge-dominated beams. The aperture size should be determined so that the space-charge contribution to the beamlets envelope equation is much smaller than the emittance contribution using

Eqn.(7). In such cases, the beam parameters can be inferred using Eqn.(8) since the beamlets are emittance dominated and their behaviour is governed by linear optics. If w_x and w_y are the characteristic sizes of the aperture, they should fulfill the relation:

$$\frac{K w_{x,y}^2}{6(\tilde{\varepsilon}_{x,y})^2 \left(1 + \frac{w_{y,x}}{w_{x,y}}\right)} \ll 1 \tag{10}$$

where the coefficients are as defined in Eqn.(7).
The separation between the apertures center d and the distance between the mask and the collector L depend on the beam size and beam divergence. By requiring the resolution to be the same in position and divergence a relation between the aperture spacing and distance can be derived:

$$\sigma_{x,y}/d \simeq L\frac{\sigma'_{x,y}}{r} \tag{11}$$

where r is the resolution of the detector. On the other hand, to ensure the beamlets do not overlap we must have:

$$4\sigma'_{x,y}L < d \tag{12}$$

Using the two latter equations we find for a given set of beam parameters all the geometric parameters of the mask.

The acquisition system requires a frame grabber to digitize the analog signal from the CCD detector. In the case of JLab FEL, we use a DATACUBE digitizer that operates under the EPICS environment. The digitized data are directly reduced on the same CPU as the one controlling the digitizer using the VxWorks language, and only results (values of beam parameters, trace-space plot) are broadcast on the network. These results can be accessed from any X-window stations using an EPICS-based screen [17].

3.1 The pepper pot method

In the pepper pot technique [13, 14], the mask consists of a matrix of generally circular apertures. The beamlets in the collector plane are given by:

$$I_{i,j}(x', y') \simeq \rho_4(x_i, x'; y_j, y')\delta S \tag{13}$$

where δS is the area of the apertures. The projection on the x-axis, i.e., summing on y_j and integrating on y' is:

$$P_i(x') \propto \rho_2(x_i, x')\delta S \tag{14}$$

From $P_i(x')$ we can compute the second order moments of the $x - x'$ trace space distribution $\rho_2(x, x')$ and deduce the beam parameters. In fact, the pepper pot method allows one to study coupling between the horizontal and vertical trace space; using Eqn.(13) the coupled second order moments $\langle xy\rangle$, $\langle x'y\rangle$, $\langle xy'\rangle$ and $\langle x'y'\rangle$ can be computed. Hence the rms hyper-transverse emittance can be estimated. Though this method can provide much information on the transverse trace space, it is difficult to get a decent signal by using an OTR screen as collector. In the JLab FEL case, the required aperture radius would be approximately 40 μm which implies that the average beamlet charge will be less than 6 pC, not a large enough number to produce enough OTR photons than can be detected with conventional CCD detectors.

3.2 The multislit method

In the case of the Jefferson Lab FEL, we have opted for this method which offers the same features of the pepper pot technique (without the possibility of measuring the hyper-emittance) with the advantage of providing much more signal. Its principal disadvantage is that the horizontal and vertical phase space measurements have to be performed separately and therefore the method requires two masks. Practically we have addressed this issue by mounting two sets of slits on the same mask, mounted on a two position air cylinder so that horizontal and vertical measurements can be performed one after the other. In the horizontal plane, the beamlets pattern generated by vertical slits centered at x_i is given by:

$$P_i(x') \propto w\rho_2(x_i, x') \tag{15}$$

where w is the slit width. When writing Eqn.(15) it is implicitly assumed that the slits are infinitely narrow. If such an approximation cannot be made; one should use formulae derived in Ref. [18]. For the JLab FEL we have carefully optimized the slits geometric parameters using PARMELA, taking as starting point numerical values computed from the previous discussion. For the baseline

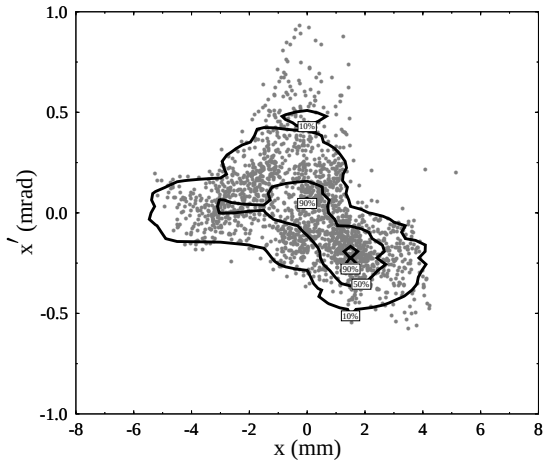

Figure 3: Simulation of emittance measurement with the multislit mask. The dots are macroparticles generated with PARMELA. The iso-contours are computed from the retrieved phase space after simulating the emittance measurement using the PARMELA distribution.

injector the optimized values for the multislit mask are: (1) a slit spacing of 1.5 mm, (2) a slit width of 0.75 μm, and (3) a mask thickness of 5 mm. In our case the distance between the mask and the OTR screen was set by mechanical constraints to 620 mm. With such parameters, a systematic error in the 10% range for the nominal emittance was found. In Tab. 2 we compare the PARMELA simulated emittance with the computed emittance simulating the emittance measurement, the initial and retrieved trace space are plotted in Fig. 3. Systematic errors are

numerically estimated using errors propagated with the anticipated distribution and include finite slit width effects. Other source of error such as remanent space-charge in the beamlets, space-charge field perturbation due to the slits have been considered and were found to be negligible. However, finite sampling error is a concern and should be reduced below 10% provided that 5 slits, at least, are illuminated by the incident beam. The first tests were performed

$\tilde{\varepsilon}^n_{\text{parmela}}$	$\tilde{\varepsilon}^n_{\text{retrieved}}$	$\Delta\tilde{\varepsilon}/\tilde{\varepsilon}$% **(a)**	$\Delta\tilde{\varepsilon}/\tilde{\varepsilon}$% **(b)**
8.094	8.077	0.2	9.9
3.947	4.014	1.7	19.9
24.282	23.016	5.2	2.7

Table 2: Simulation of emittance measurement for different emittance, after slit optimization. The quantity $\Delta\tilde{\varepsilon}/\tilde{\varepsilon}$ **(a)** is just a measure of the relative difference between the nominal and retrieved emittance while the quantity $\Delta\tilde{\varepsilon}/\tilde{\varepsilon}$ **(b)** represents the systematic error estimate.

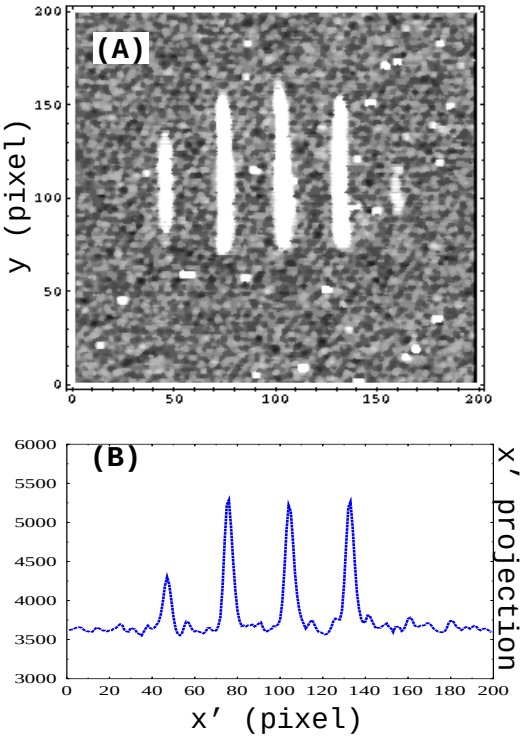

Figure 4: Typical beamlet pattern from a multislit mask. OTR image of the beamlets **(A)** and projection along the y-axis **(B)**.

in the JLab Injector Test Stand. Because of low energy, 350 keV, we were using, as collector, a fluorescent instead of an OTR screen. We compare the multislit method with the "slit and collector" apparatus [16, 17] and agreement at the 15% level was observed. Recent measurements performed in the JLab FEL operating at 60 pC (therefore with a lower beam emittance) are presented in Fig. 4. The emittance typically measured is approximately 6 mm-mrad which is somewhat larger than PARMELA prediction for this charge. Also because the beam divergence and size are different from those expected at 135 pC (the charge for which the mask has been optimized), the number of generated beamlets is only 4-5. This is a disadvantage of single shot phase space sampling method; they have to be designed for specific parameters and have a limited dynamic range. Multislit mask devices have been in use for several years in the UCLA group [19] to characterize a high brightness electron injector and in the CERN heavy ion injector to measure emittance of heavy ions beams [20].

The authors are indebted to the FEL commissioning team for support and operation of the machine.

PERIODIC PERMANENT MAGNET DEVELOPMENT FOR LINEAR COLLIDER X-BAND KLYSTRONS*

D. Sprehn, G. Caryotakis, E. Jongewaard and R. M. Phillips
Stanford Linear Accelerator Center
Stanford University, Stanford, CA 94309

Abstract

The Stanford Linear Accelerator Center (SLAC) klystron group is currently designing, fabricating and testing 11.424 GHz klystrons with peak output powers from 50 to 75 MW at 1 to 2 μs rf pulsewidths as part of an effort to realize components necessary for the construction of the Next Linear Collider (NLC). In order to eliminate the projected operational-year energy bill for klystron solenoids, Periodic Permanent Magnet (PPM) focusing has been employed on our latest X-band klystron designs. A PPM beam tester has operated at the same repetition rate, voltage and average beam power required for a 75 MW NLC klystron. Prototype 50 and 75 MW PPM klystrons were built and tested during 1996 and 1997 which operate from 50 to 70 MW at efficiencies greater than 55 %. Construction and testing of 75 MW research klystrons will continue while the design and reliability is perfected. This paper will discuss the design of these PPM klystrons and the results of testing to date along with future plans for the development of a low-cost Design for Manufacture (DFM) 75 MW klystron and invitation for industry participation.

1 AN INTRODUCTION TO PPM

Periodic Permanent Magnet (PPM) focusing is utilized in Traveling-Wave Tube (TWT) devices for commercial and military applications. Instead of a solenoidal magnet with its associated overhead of power supply, cooling, and controls, permanent magnets are used to reduce operational cost and weight. In PPM focusing the axial field changes polarity with every magnet. If the magnetic period is small enough when compared to the beam plasma wavelength, λp/L, then sufficient beam stiffness can maintain the beam profile in the presence of large space charge forces due to the rf bunching.

Due to the high energy-products required for the magnets combined with geometrical constraints, it is usually not possible to thread as much flux through the cathode as it is with solenoidal focusing so particular attention must be paid to the gun design and beam transport issues.

The ratio of the axial field to the Brillouin field, Bz/Br, is shown in Table 1 along with other important parameters for three SLAC solenoidal-focused klystrons and three PPM designs. The Brillouin field is that value of magnetic focusing at which all forces operating on the beam are balanced and it is possible to transport the beam with a constant radius. All of the klystrons have output power levels from 50 to 75 MW except the 150 MW DESY klystron. The cathode-to-beam area convergence, A_c, is approximately 100 for all the X-Band klystrons because of the smaller drift tube dimensions. As can be seen the B_z/B_r ratios for the PPM klystrons are not all that different than those found for the solenoidal-focused klystrons. The loss in axial beam velocity, Δu_z, is higher for the PPM klystrons due to the full reversal of the field as seen by the beam.

Table 1: Comparison of SLAC Klystrons (see above text)

Tube	5045	Desy	XL-4	50XP	75XP	DFM
Beam Focusing	Sol.	Sol.	Sol.	PPM	PPM	PPM
frequency, GHz	2.86	3.00	11.42	11.42	11.42	11.42
Beam kV	350	525	440	464	490	490
uK	1.90	1.85	1.20	0.60	0.80	0.75
A_c	18	40	129	144	98	126
Cathode A/cm^2	6.34	5.04	8.75	7.39	7.71	7.23
B_z confined, T	0.12	0.20	0.45	0.20	0.17	0.23
Flux cath/beam	0.85	0.94	0.92	0.50	0.55	0.75
B_z/B_r, axis	1.90	2.82	2.54	1.15	1.20	1.51
B_z/B_r, drift tube	1.90	2.82	2.54	2.03	2.11	2.66
Δu_z	0.1%	0.1%	0.1%	1.6%	2.5%	4.8%

The drawback with PPM focusing is that the construction complexity of the tube may be increased so construction costs and failure rates could rise. The magnetic circuit is fixed and so there may be no easily accessible "knob" for the operator to turn in case adjustment is required. If the beam voltage is reduced enough, λp/L becomes small and the beam will impact the drift tube. This is known as the "stop-band" voltage. Since the high voltage beam pulse has a finite rise and fall time, then a portion of the beam pulse is below the stop-band and interception occurs. There are also areas of beam instability in PPM focused tubes and the possibility of coupling to modes which grow from an undulating beam.

2 PPM DEVELOPMENT PROGRAM

PPM focusing had never been used successfully on very high-power klystrons and so there existed several unknowns with respect to the outcome of such an attempt. The large area beam convergence of 144:1, no axial field adjustability, possible interactions with an undulating beam, the presence of stop bands, and new materials and construction techniques presented several engineering challenges. It was decided to construct a beam-tester to test the gun optics followed by a 50 MW klystron, and lastly a 75 MW klystron. The 50 MW rf design was patterned closely after the successful solenoid X-band klystrons (XL series) at SLAC after allowances were made to drop the perveance to improve efficiency. The 75 MW klystron design requires a slightly higher perveance than the 50 MW design to keep the beam voltage below 500 kV to reduce modulator costs.

The beam-tester and 50 MW klystron were constructed with Samarium-Cobalt (SmCo) magnets and a gun coil. These magnets were die-pressed individually and a high level of quality control went into the manufacturing process. Inspection of the field on the axis agreed with simulation to within 1 %. To reduce cost, an experiment was performed on the 75 MW klystron by replacing the gun coil with permanent magnets and using Neodymium-Iron-Boron (NdFeB) magnets instead of SmCo. Replacing the gun coil forced large peak-to-peak variations in the field strength design on axis, and switching to bulk NdFeB resulted in a loss of control in material quality. These magnets were fabricated out of large blocks by slicing, core-drilling, and grinding to size. Magnetic, on-axis, field strengths of the individual magnets varied by as much as 20 % from simulation. The 75 MW design has more magnet periods in a plasma wavelength and a higher focusing field to Brillouin field ratio, both of which should allow for better focusing. Design parameters for both the klystrons are found in Table 2.

2.1 Beam-tester and 50 MW gun Design

In order to keep the cathode current density below an average value of 7.5 A/cm^2 for increased lifetime, a 2.25" diameter cathode was required which resulted in an area convergence ratio of 144:1. Since this value is higher than previous SLAC klystrons, a beam-tester was fabricated to prove gun and drift region optics for the PPM design. The design philosophy of the beam-tester was to eliminate all sources of trouble that could interfere with a study of the PPM beam formation and transmission. The issues of gun voltage breakdown, insufficient vacuum pumping, and collector power were addressed by using oversized components from previous klystron designs. This served to hasten the program and allowed for operation at higher voltages than the design required (in the interest of research into more powerful PPM designs). Furthermore, it was decided to control magnetic field in the gun with a standard bucking coil and the field in the region from the gun to the beam minimum with three compact coils closely wound around the drift tube. The gun and magnetic circuit were constructed so that operation with and without flux at the cathode was possible. The same general philosophy and beam focusing were used in the 50 MW klystron design.

Table 2: 11.424 GHz PPM klystron Specifications

rf power	50 MW	75 MW
Beam voltage	464 kV	490 kV
Beam current	190 A	257 A
rf pulsewidth	1.5μs @ 60Hz	1.5μs @ 60Hz
Cathode loading	7.4 A/cm^2	7.2 A/cm^2
A_c	144:1	98:1
RMS Gauss	1950	1680
Efficiency	55 %	55 %
Gain	55 dB	55 dB
Max gradients: Cavities	< 700 kV/cm	< 650 kV/cm
Anode	< 250 kV/cm	< 250 kV/cm
Focus electrode	< 220 kV/cm	< 210 kV/cm

The drift tube is constructed of alternating iron pole pieces and monel spacers that are brazed together in subassemblies and then welded together at specially split pole pieces. Each subassembly consists of eight permanent magnets where each magnet produces an axial field opposed in polarity to its immediate neighbor. EGUN[1] simulations were performed (Fig. 1) until the beam scalloping was less than 8 %. The testing began with the confined flow case because the beam is held in check by a larger magnetic field, and continued with the shielded flow case afterward.

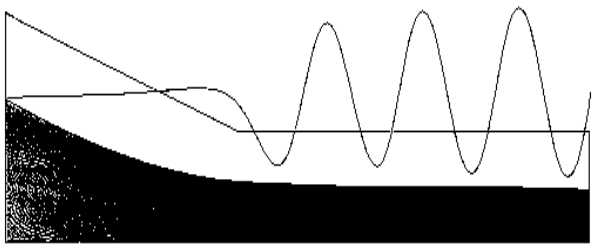

Figure 1: EGUN simulation of the beam as it enters the PPM stack as used for the beam-tester and 50 MW klystron.

When operated in the confined-flow condition the high-convergence gun design has 50 % of the beam flux threading the cathode (as measured at the axis). This is low for typical high-power klystrons. Ratios for other high-power klystron designs range from 80 to 95 %, which yield 1.7 to 3.2 times the Brillouin field condition. It is difficult to get large confinement ratios with PPM focusing because the pole pieces eventually saturate and

magnetic materials have finite strengths. There also exists a stability limit to the amount of field that may be applied because the axial velocity is reduced due to the large spin on the beam when the field is reversed from the direction of the field in the cathode. A value of 50 % yields 1.15 times the Brillouin field on the axis (Fig. 2) which increases to 2 times at the drift tube. This is an advantage because the further the beam strays from its radial position, the more focusing force it experiences. PPM focusing, as opposed to solenoidal focusing, increases as distance from the axis increases, which leads to a preference for focusing somewhat hollow beams. As such, hollow beams are a direct result of the gun design parameters in most high-power klystrons due to limitations in the possible emission current density of today's cathode materials for long-life.

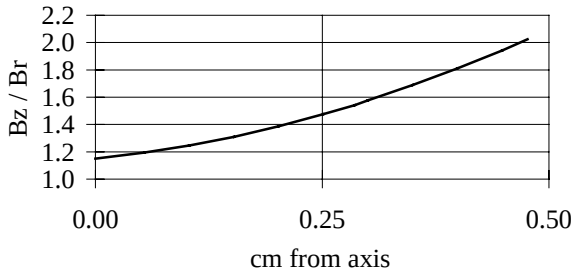

Figure 2: Variation of RMS magnetic field vs. radial distance from the axis for the PPM beam-tester and 50 MW PPM klystron.

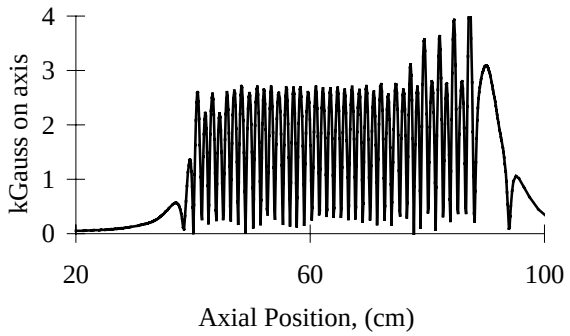

Figure 3: Axial field (Gauss) vs. axial distance (cm) for the 50 MW PPM klystron.

The 50 MW PPM klystron rf design was based on the highly successful XL-4 klystron development at SLAC. The PPM klystron, with its lower perveance, lossy materials, and higher operating voltage requires some modifications in the existing XL-4 rf circuit design. The rf circuit is adapted to the lower perveance beam by increasing the cavity spacings, altering tunings, and adding an extra cell in the traveling-wave output structure for a total of 5 cells. The number of cavities was kept constant and the bandwidth was reduced in order to maintain the required gain. This loss in gain between the two designs was primarily influenced by the lossy materials used in the PPM design. The PPM cavities have a lower Q_o than copper cavities and therefore suffer more rf heating. The lossy drift tube material may serve to dampen possible trapped oscillations and any coupling between the gun, cavities and collector. The magnetic field is very similar to the beam-tester until the last three cavities are reached where the field gradually tapers up to eventually peak (Fig. 3) in the output structure. Tapering serves to confine the beam as the space charge forces increase due to the growing rf current. The field in the output structure is unidirectional, unlike the rest of the klystron where it is periodic, and this forces the magnets to be larger.

2.2 Beam-tester and 50 MW Experimental Results

The beam-tester processing began with a 1 μs beam pulsewidth and proceeded up to 490 kV, 5 % above the design point, without incident. The beam microperveance was found to be 12 % higher than the design of 0.6 μK. The reason for this discrepancy is not fully known, although a full autopsy is scheduled to occur in October. To improve the reliability of beam transmission data, the pulse width was extended to 2.8 μs and the repetition rate increased to 120 Hz. At 490 kV, there was roughly 42 kW dissipated in the collector. The beam transmission at this point was found to be 99.9 %. This rather striking result is in direct contrast to experience with travelling-wave tubes (TWT) which traditionally are operated on a bench and iron shunts are placed along the magnet circuit to improve transmission. Such adjustments are not possible with this high-power device as most of the tube is covered in lead due to several kRads of radiation from the collector.

No instabilities or spurious oscillations arising from noise were detected at a 2.8 μs pulsewidth. No gas pressure rise other than that considered normal was seen and the collector vac-ion pump was running at about 10^{-8} Torr under full power and rep rate. With a design goal for the klystron of 1.5 μs and 465 kV, the operation of the beam-tester exceeded expectations and demonstrated the robustness of the design. The 490 kV level also happens to be that which is required for the 75 MW X-band klystron discussed later.

The three adjustment coils near the anode had negligible effect on the transmission data but one of the coils had a visible effect on the rising and falling edges of the collector current pulse. Most importantly of all, the shielded-gun operation and the confined-flow operation were essentially identical. Thus the formation and transport of the 144:1 area convergence beam into a shielded or an immersed PPM-focused drift tube for a high-power device has been proven feasible and robust.

Initial observations of the 50 MW klystron behavior revealed that the gun behaved identically to the beam-tester performance. An unusual gain curve

containing several jumps was believed to be due to multipactor in more than one location in the drift tube and/or cavities. The gain steps would decrease as beam voltage, drive frequency, or bucking coil setting was increased which means that the multipactor was not only a function of the rf drive but also of the rf current present on the beam and hence was located downstream of the input cavity. To eliminate these discontinuities, the tube was opened and the drift tube was coated with a titanium-nitride (TiN) layer roughly 100 Å thick to reduce the secondary emission coefficient of the surfaces subject to rf fields in the vacuum. After testing a second time, only one gain step remained.

Looking in the various coupling ports of the rf drive and rf output, and with a small antenna probe at the collector ceramic insulator, revealed no oscillations higher than 50 dB below the fundamental, which can easily be ignored. Small signal bandwidth was measured at 40 MHz, which closely agrees with the predicted value of 35 MHz. Measurements over a 70 dB range of rf drive power showed the small signal gain to be 65 dB at the design current, falling by 10 dB at the 50 MW power level.

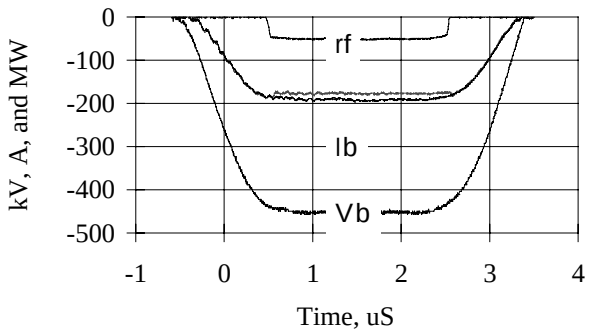

Figure 4: 50MW rf out, beam current (with and without rf present), and beam voltage vs. time for the 50 MW PPM klystron.

After removing the gun coils, replacing the first eight magnets, reducing the output magnet field, and applying prefabricated shunts along the whole magnet stack, the tube was tested in the shielded flow condition. The klystron reached 50 MW with essentially the same gain and efficiency with a 2 % increase in beam interception.

Despite the remaining step in the gain profile (believed to be in the input cavity due to an insensitivity to beam voltage) the PPM klystron reached the full operational specification (Fig. 4) of 50 MW at 2 μs. The efficiency at 50 MW was well over 55 %, and over 60 % at 60 MW, using calorimetric diagnostics. The intercepted beam power at 50 MW was about 1 % of the total beam power, but the beam current lost about 7 % while passing through the tube. This means that the energy of the electrons lost in the tube must be about 66 keV on average.

2.3 A 75 MW Experimental Design

In designing the 75 MW klystron, major changes made were enlarging the drift tube due to a higher beam current, a stainless steel drift tube, and the elimination of the gun focus coils. It was calculated that using a 5-cell travelling-wave output circuit would extract more than 75 MW. Opening the beam tunnel by 13 % to 0.425 inches reduced the efficiency of the beam-cavity interaction and thereby forced the inclusion of an extra gain cavity. This also allows more modes to propagate within the drift tube, including the second harmonic TM mode. The construction of the 75 MW PPM magnetic circuit differed in that the drift tube is a semi-continuous stainless steel structure interrupted by the cavities, with the iron pole pieces and non-magnetic spacers placed outside the vacuum envelope. This design change addresses three separate issues; avoiding the multipactor seen in the 50 MW klystron, taking a step toward the eventual low-cost design of a production klystron using a clamp-on magnetic circuit, and adding loss in the drift tube to increase the start-oscillation currents of the various parasitic modes which may arise.

The large drift tube opening resulted in a lower beam area convergence and lower current density in the beam, which in turn reduced the necessary magnet strength. On the other hand moving the pole pieces outside of the vacuum envelope increased the magnet strength required and the overall affect was a slightly higher energy-product required for the 75 MW design. Previously, SmCo magnets had been used that are highly resistant to radiation and temperature. The 75 MW design used NdFeB magnets which have higher energy-products, are easier to machine, are less brittle, but have a lower Curie temperature. However, at 500 keV photon levels, radiation effects do not seem to be an issue over the magnets projected lifetime. Furthermore, NdFeB magnets are less expensive in bulk quantities. Procurement of the NdFeB magnets presented many difficulties, as the vendor was unable to meet the required specifications. This material has been used in applications where the absolute value of the magnetic energy-product is not tightly held. This issue will be studied over the next few months and a decision will be made on the magnetic materials to be used in future designs.

Simulations of the klystron using CONDOR[2], a 2.5-D particle-in-cell code, show approximately 80 MW at the design beam power while maintaining low gradients in the output structure.

2.4 75 MW Experimental Results

Most of the completed magnets delivered to SLAC failed to meet the specification. Specifically the magnets at the beam convergence area near the gun, the gain cavity magnets, the penultimate cavity magnet, and the output magnets were all below specification. Due to time constraints it was decided to test the klystron and testing began with a 1 μs flattop beam pulse. Upon reaching 280

kV, an oscillation was noticed at the end of the beam pulse. The beam pulse was reduced to zero flattop, approximately 1 μs FWHM pulse, and the voltage was raised to 360 kV until the oscillation was again seen. A spectrum analyzer was used to carefully search for all frequencies between 11 GHz and 26.6 GHz and found only the fundamental, the second harmonic, and a signal at 20 GHz.

As the beam voltage was increased the oscillation could be damped by increases of the bucking coil, which tends to make the beam smaller, but the method has the limitation that too much of an increase and the beam impacts unpredictably on the vacuum envelope. Increasing the rf drive would also damp the oscillation but overdriving most klystrons will usually produce another set of instabilities. However, by combining the two methods it was possible to raise the voltage peak to 463 kV and attain 71 MW peak at a 200 ns pulsewidth. Despite the difficulties, gain was found to be between 55 and 60 dB and efficiency measured 60 % at the saturated rf output level of 70 MW.

The magnets have been removed from the klystron and are inserted on a full-scale model of the klystron circuit so that the field can be shunted on the bench to a desired profile. After simulation, theory, and measurement agree on the required field, the newly shunted stack will be installed on the klystron and testing will resume. It is expected that this will occur late in 1998.

2.5 A Low Cost Klystron

A low-cost design of a 75 MW klystron known as the Design For Manufacture klystron (DFM) has been under investigation for the past three years and seeks to minimize parts count, decrease complexity, reduce construction labor, and increase reliability of the klystron. A smaller gun and collector with reduced parts count, better output waveguide hardware such as mode converters and windows, and a simplified drift tube and magnet structure are the main areas of scrutiny. Industry participation will be solicited with several contracts awarded to build 50 MW klystrons. Close cooperation between industry and SLAC will be required for the successful construction and operation of several thousand 75 MW PPM klystrons. One key to the lower cost will be the development of a clamp-on magnet structure, which can be used repeatedly as klystrons reach the end of their useful lifetime. A clamp-on structure for evaluation purposes is currently under fabrication at SLAC and will be tested in the next few months.

Automated processing of the cathode activation, tube bake and rf processing must be implemented in order to keep up with the demand that will be an order of magnitude greater than any similar effort to date. It is currently planned that one or more factories on site will continuously build and repair klystrons while the accelerator is under construction and operation.

Eventually, the DFM klystron and the research prototypes along with industry efforts will merge in a single design using the best technologies from each.

3 CONCLUSIONS AND FUTURE WORK

The results of the 50 MW klystron testing exceeded the design goals in terms of output power, pulsewidth and efficiency, and provide a proof-of-principle for high-power PPM klystrons. The magnetic field difficulties with the 75 MW design can most likely be overcome by returning to a magnetic circuit similar to the 50 MW klystron. Further study is required to fully explore the failures and possible solutions concerning the 75 MW magnetic circuit. By early next year, a new design will be tested which relies on lessons learned from the previous 75 MW klystron. Furthermore, smaller gun and collector designs, elimination of some vacuum pumps, simpler output waveguide structures, and overall cost-reduction schemes will continue development.

Despite the requirement for further engineering work, this program has shown that a high-power PPM focused klystron is not only feasible, but has demonstrated to function in good agreement with simulation and engineering analysis. The elimination of the focusing solenoids for high-power accelerator sources is a major cost reduction in both the procurement and operational costs of such sources. It is likely that any future large-scale, linear electron accelerator constructed will be driven by PPM focused klystrons.

REVIEW OF FABRICATION OF SC CAVITY STRUCTURES

V. Palmieri

Laboratori Nazionali di Legnaro, ISTITUTO NAZIONALE DI FISICA NUCLEARE, Legnaro (Padova), I-35020 ITALY

Abstract

The search for higher and higher accelerating fields with low rf losses, plus the need of know-how transfer from scientific laboratories to firms for industrial cavity production, have contributed to the establishment of fabrication technology standards. Over years of research both on high beta and on low beta superconducting resonators, various criteria improving resonator rf performances has been codified as guide-lines or canons in the fabrication process. However, the simple transfer of the standard cavity fabrication technology developed so far, is no longer sufficient for the new generation machines. Not only the progressive achievement of higher accelerating fields, but also the drastic reduction in resonator production time and costs (K$ per MV/m) is compulsorily for the feasibility of more and more powerful accelerators. This is the motivation under the research toward simpler and cheaper fabrication techniques as for instance seamless cavities. The paper reviews the status of those new forming techniques under development in several laboratories, as hydroforming, spinning, backextrusion or superconductor/normal metal coated cavities suitable for prototype fabrication and at least in principle, considerable for mass scale production.

1 INTRODUCTION

About ten years ago, the Argonne National Laboratories under the chairmanship of K. Shepard hosted the third Workshop on RF Superconductivity [1]. In this occasion everybody involved in the superconducting cavity field was proud to show his last and best result. At that time the LEP design value consisted in a gradient of 5MV/m at a Q-value of 3e+09 and the three industries involved in the Nb/Cu sputtered resonator production did not yet even start to acquire know-how. D. Proch in a talk on SC cavities in Storage Ring Beam Tests, was reporting values of the accelerating field values ranging from 1.9 MV/m to 6.5 MV/m [2]. The maximum accelerating field reported for the TRISTAN 500 MHz 5-cells was lower did not overcome the 10 MV/m [3], while G. Mueller reported even fields up to 24 MV/m but on a Nb single cell and at 3 GHz [4].

About 10 years later again under the ANL organization, the 98 LINAC conference will see the presentation of results such as the 30 MV/m in the high 1e+9 - low 1e+10 range in horizontal test for some TTF 1.3 GHz 9-cell resonators coming from the industrial production [5] or such as the 40 MV/m at a Q of 1e+10 obtained by K. Saito on a 1.3 GHz Niobium single cell [6]. The superconducting resonator fabrication technology has made great strides, improving the manufacture standards, and importing the know-how of the ultra-clean from the neighbouring field of semiconductors. In parallel to the traditional technology of Electron Beam (EB) welded cavities, already three laboratories are able to form seamless Niobium cavities of the TESLA shape [7-9]. Besides to whom is depositing Niobium onto Copper, who reinforces Niobium with Copper is also coming to the fore [10]. Last, the traditional separation between "low beta people" and "high beta people" is becoming weaker and weaker, since middle beta cavities are becoming a subject more and more investigated.

2 THE MOST SAFE APPROACH: THE BULK NIOBIUM TECHNOLOGY

It is not by accident that TTF is installing bulk Niobium 9-cell cavities. The TESLA goal is 25 MV/m at a Q-value of 5e+09 and the bulk Niobium technology is the only one capable to satisfy this requirement at industrial level in the shortest possible time. This does not mean no room for the Nb/Cu sputtering approach, but only that an eventual R&D for sputtered nine-cells has compulsorily much longer R&D times. On the other side it must be own that the traditional approach to EB weld half cells, both for material and for manufacture, has been convenient for the TJNAF 1.5 GHz 5-cell production, but it is is definitely too expensive for a possible mass production of 20,000 cavities, as in the TESLA Project.

The traditional fabrication approach for beta 1 resonators consists in forming the cavity cups by spinning or preferably by deep-drawing. The cup edge are trimmed by machining. The possible variation in wall thickness due to the mechanical tolerances of the drawing tool can influence the geometry so the resonant frequency (df/dl_{9cell} = 300 KHz/mm). Pad rubber forming has been proven to show the best reproducibility [11]. Facing the cups is the most crucial operation and it is performed on a rotating machine: any misalignment will certainly result in cracks along the EB weld. The thickness of the lip to weld is much smaller than the equator diameter, moreover the heated zone will thermically expand respect the cold one. This can seldom result into a trivial problem especially occurring when going to weld cups drawn from textured slabs: it is not said that the ending point of the weld will necessarily coincide with the point from where the EB started. However, nowadays the Niobium EB weld technology for SC cavities is well-established and has been transferred with full success from research laboratories to industrial partners. Prior to the welding, cups and beampipes are chemically treated by a Buffered Chemical Polishing (BCP) $HF/HNO_3/H_3PO_4$ 1/1/2 in

volume, followed by ultraclean water rinsing and handling in clean environment. The Niobium is oxidized by the nitric acid, then the oxydes if transformed in fluoride thanks to the high electronic affinity of fluorine. The Niobium fluoride is a salt highly soluble in water. The phosphoric acid mainly works as moderator.

After welding the cavity undergoes two main steps: titanified at 1400 C in UHV and chemically etched in a virgin 1/1/2 bath, then Rinsed with ultrapure water under High Pressure (HPR) usually at 100 bar.

Besides this elementary recipe some other fabrication steps have been found necessary in order to achieve voltages in the 20-30 MV/m regime and are clearly reported by Matheisen in his paper about the "Improvements on standard Fabrication methods" [11]. They can be listed in the following:

1) Since the Niobium ingot is Electron Beam melted in the UHV oven, already it is necessary to exercise a strict control that ultra clean conditions are respected. The use of a furnace seldom used for melting other elements is risky.

2) Rolling of sheets from ingot is not a less crucial step, since microparticles produced during rolling are pressed and embedded into the bulk.

3) The defect diagnostics of Niobium slabs by eddy current scanning provides a more accurate selection of sheets. It has been seen that by this method, the quench limitations can be sorted out in a very early step of the production.

4) The control of the BCP temperature kept lower than 15 C, in order to avoid hydrogen charging of Niobium.

5) The adoption of a wiggled beam with 50% penetration on the first welding turn, followed by a wiggled full penetration beam, since this sequence is less sensitive to fabrication tolerances.

6) The vacuum in the welding furnace must be lower than 5e-5 mbar, depending the Residual Resistivity Ratio (RRR) value on the chamber residual pressure.

Besides to this DESY experience seems to advice that quenches below 30 MV/m in multicell structures can be avoided by a strict application of cleanroom techniques followed by postpurification of Niobium.

Recently K. Saito has perturbed the common beliefs about the Niobium chemical treatment, sustaining the superiority of electropolishing over chemical polishing on high gradients [6]. The problem must be encountered in deeper detail, however the fact remains that he has reached 40 MV/m at 1e+10 on a 100 micron electropolished cavity. Electrochemical-mechanical buffing has been also proposed in the framework of a KEK-Mitsubishi collaboration in order to get the smoothest Niobium surfaces. The combination of mechanical polishing and electrochemical polishing is a well-known technique adopted for silicon wafer polishing.

Following the above mentioned basic fabrication rules, bulk Niobium and the related EB welding is a paying technology also for low beta cavities. Facco at LNL [12] has produced and recently installed 80 MHz Quarter Wave Resonators in the low beta section of ALPI. An average accelerating field of 7 MV/m at 7 Watt has been reached after HPR. In place of an electronic fast tuner a mechanical dissipator is inserted into the resonator shaft, in order to damp vibrations caused by the environment. An accelerating field of 5 MV/m at 7 Watt has been achieved in the bulk Niobium QWR prototype developed at NSC in New Delhi [13].

A masterpiece of EB welding is however the bulk Niobium RFQ for the PIAVE Injector of LNL [14], that in its complexity is up to now the most difficult bulk Niobium SC resonator ever built. Machining of the electrodes, Extrusion of the Cylinder on the back of the Electrodes, deep drawing of the stems, stiffening of the external tank by titanium liners, EB welding, and BCP are all operations that must be done within a few hundreds of tolerance.

Last we wish to mention in this paragraph the experiments conducted at Wuppertal with Nb_3Sn, since Nb_3Sn was prepared by vapour diffusion onto a bulk Niobium cavity [15]. The purpose consists in operating at 4.2 K instead than at 1.8 K, due to the higher critical temperature of the compound. At 4.2 the cavity arrived up to 30 MV/m of peak field; moreover at low field the Q-value was a factor 2 higher that the value of the Niobium substrate at 2 K. A similar slope of Q versus field is found also for NbN thermally diffused Niobium cavities [16]. The investigation carried on this material however is some order of magnitude lower than the efforts paied on bulk Niobium cavities. However the problems related to such multicompositional material are much more complex than those of Niobium.

3 ALL NIOBIUM DEEPER THAN A FEW LONDON PENETRATION DEPTHS IS UNNEEDED

The rf loss mechanism in a SC cavity is confined within the first 5,000 Å, approximately ten times the London penetration depth. That means that all the Niobium deeper is there only for providing mechanical rigidity. Moreover Niobium is neither a good thermal conductor. The first Copper-superconductor resonators were done by electroplating a Lead film. Lead has a critical magnetic field of only 500 G at 4.2, moreover its porosity and its density is dramatically sensitive to the action of moderators mixed into the plating solution. Without the right moderator indeed Lead would grow according to a dentritic structure. The main problem of surface instability has been solved [17]. Under the electrodeposition of Lead there is no black magic. All the black or yellowish spots people found after deposition were caused from residuals of the fluoborate plating solution coming from an imperfect rinsing of the surface, or from the dehydratation of Lead hydroxyde.

A very nice material to play with is the Japanese Niobium clad Copper slabs, since in RF it behaves as Niobium, while mechanically is workable as Copper. Both the Argonne National Laboratory Split Loops [18] and interdigital QWRs [19-20], and the JAERI cavities have only the external enclosure in Nb-Cu, being the loop or the shaft instead in bulk niobium. Split Loops are

cavities that by now have been tested for a very long time since two machines have been built in ANL and Stony Brook respectively. With interdigital also "there are no surprises", since they are operational from '93. Considerably high performances were achieved by JAERI niobium clad copper QWRs. Maximum accelerating fields are normally higher than 7 MV/m, even up to 13 MV/m, that for such a resonator geometry means an electric peak field of 60 MV/m and a magnetic peak field of about 1000 G.

The sputtering of high quality Niobium films onto OFHC Copper cavities has been invented at CERN by C. Benvenuti and it has been successfully applied to LEP cavities. After the successful transfer to the European Industry, This technology has been recognized as a valid and in some cases superior alternative to bulk Niobium resonators. Almost concluded the 352 MHz production CERN is dedicating not little effort in order to understand the mechanism preventing the achievement of theoretical performances. Smaller size cavities such as the 1.5 GHz monocells are very suitable for this purpose. The coating method is based on a Cylindrical magnetron configuration: in a noble gas atmosphere, generally argon, at a pressure of the order of 1e-03 mbar, a potential difference is established between the central cathode and the grounded cavity. The electrical current of the glow discharge is stabilized by a permanent magnet internal to the cathode. The sputtering temperature takes place at 150 C and the coating thickness is 1.5 microns obtained in 15 minutes of treatment. The films have a RRR of 11, the average grain size is around 1000 Å [21]. It is worthwhile to report that the Copper substrate plays a crucial role for the film growth. All Nb films sputtered onto spun substrates have lower losses and Q-slope than those on hydroformed substrates. The role of sputtering parameters on RF performances are investigated as well as the relevance of physical mechanisms acting on BCS and Residual Losses.

Nb sputtering onto Copper has been applied also to low beta cavities as QWRs at Legnaro National Laboratories The first cryostat with sputtered cavities was already installed in 1995 on the ALPI beamline [22]. The average field was of 4 MV/m. Subsequently last year these four cavities were substituted with other four sustaining an average field of 6 MV/m at 7 Watt. In parallel it has started the operation of resputtering with Niobium the old Lead electroplated QWR in the ALPI middle beta section. The average field achieved with the first four resonators is of 4 MV/m. The sputtering configuration chosen at LNL was that of a DC Biased Diode, because it is the simplest to operate. A DC cylindrical magnetron sputtering instead is the configuration designed and built at the Australian National University [23]. All the needed investigation of correlation of the deposition parameters with the superconducting properties of the films has been carried out; the subsequent phase of sputtering onto the real Copper cavity is under investigation.

Sputtering opens new roads to superconducting cavities as the one of NbTiN films onto Copper. Some investigation has been carried on at CERN and at Saclay, but as for Nb_3Sn the problems to solve are hugely more complex than those under Niobium, but up to now they have been faced with hugely less people and investments.

A totally new solution in the Nb/Cu framework has been recently proposed by the Orsay group [10]. Thin Niobium cavities are Copper reinforced outside by Copper Plasma spray. A series of 3 GHz cavities has been fabricated by deep drawing and EB welding using 40 RRR Niobium sheets of 0.5 mm thickness. The cavities were heat treated at 1200°C with a titanium getter before Cu plasma spray. The first two tested cavities have a Q in the range 10^9 at 1.8 K and are limited by quench at field values around 15 MV/m. Taking benefit from the thermal conductivity and porosity of the sprayed copper layer (resulting in an increase of the heat transfer surface in superfluid helium), the quench fields measured before and after Cu plasma spraying are the same. Tests with high purity Niobium and at 1.3 GHz are in programme.

4 SEAMLESS CAVITIES: A WAY TO REDUCE FABRICATION TIME AND SAVE MONEY

Even not mentioning that the equatorial weld is the main source of defects, whenever 20,000 cavities will be done it is compulsory to conceive a fabrication method able to output at least one ninecell per hour. A few laboratories are mainly involved in this search.

1) At LNL the author has succeeded in cold forming both Copper and Niobium multicells by spinning a simple circular blank onto a collapsible mandrel [7]. The strong advantage of this method lays in the total absence of intermediate annealings. Moreover the method does not regard of the possible ununiformity and texture of the starting material, since during spinning all the material is mixed up again. Spun cavities have been sent to CERN, DESY, TJNAF and to KEK for characterization. CERN has proved that spun copper monocells are superior to hydroformed ones, because of lower losses and lower Q-slope. Accelerating fields up to 25 MV/m have been measured at DESY on 1.3 GHz Niobium monocells, while 28 MV/m has been achieved on a 1.5 GHz Niobium monocell by P. Kneisel. Niobium fivecells have been already successfully spun and are waiting for characterization. Clad Nb/Cu slabs were also spun in the framework of a LNL-KEK collaboration. Low RRR Niobium has been adopted for first test, however up to now no positive result has been found yet, since the cavity annealing after forming seems to open crack in Niobium. According the author, however this is a problem easily solvable when spinning a thicker slabs instead than a rolled blank.

2) At DESY a 1.3 GHz Niobium monocell has been successfully hydroformed from a seamless tube jacketed into a steel matrix [8]. The steel was removed chemically and after a preliminary chemistry, the cavity reached already 14 MV/m in range 1e+10.

3) At Saclay, C. Antoine succeeded too in hydroforming a Niobium single cell. Two intermediate annealings were applied, but what is surprising is that the Niobium was

very poor in RRR, nevertheless the cavity reached 18 MV/m [9].
4) Seamless Copper cavities were produced by explosive forming in the framework of a KEK-Toshiba collaboration, that however in recent times is evaluating the possibility to combine explosive forming with hydroforming [24].
5) Copper Electroforming is instead under investigation at CERN [25] and at Protvino [26].

5 THE NEW ARRIVALS: THE MIDDLE BETA CAVITIES

It is probable that middle beta cavities will play the leading role in the next future. In this framework Los Alamos National Laboratories already fabricated 0.48 and 0.64 beta cavities standing over 1e+09 up to 40 MV/m of peak field [27].

The spoke resonators [28] proposed by Shepard and Delayen are also structures over which already a certain amount of work has been done. New structures as reentrant cavities [29] or shorter QWRs are also suitable for being considered. However besides to new structures also new materials should be investigated. For high intensity machines Copper for instance is not the best material, because of the possible activation. The sputtering onto Alluminum or onto Graphite with buffer layers would be worthy of investigation.

6 ACKNOWLEDGMENTS

This is review paper, hence it reports mainly the work of other people. Among all already quoted, the Author has reported material mainly got from C. Antoine, C. Benvenuti, G. Bisoffi, S. Calatroni, A. Facco, M. Fouaidy, T. Junquera, P. Kneisel, L. Lilje, A. Lombardi, M. Pekeler, A. Pisent, A. Porcellato, D. Proch, K. Saito, K. Shepard, W. Singer, S. Stark.

Abstract

Particle accelerators are playing an increasingly important role in basic and applied science, and are enabling new accelerator-driven technologies. But the design of next-generation accelerators, such as linear colliders and high intensity linacs, will require a major advance in numerical modeling capability due to extremely stringent beam control and beam loss requirements, and the presence of highly complex three-dimensional accelerator components. To address this situation, the U.S. Department of Energy has approved a "Grand Challenge" in Computational Accelerator Physics, whose primary goal is to develop a parallel modeling capability that will enable high performance, large scale simulations for the design, optimization, and numerical validation of next-generation accelerators. In this paper we report on the status of the Grand Challenge.

1 INTRODUCTION

Several accelerator projects are planned or under consideration that will have major impacts in basic and applied scientific research. Examples include the Next Linear Collider (NLC),the Large Hadron Collider (LHC), the Spallation Neutron Source (SNS), and fourth-generation light sources. All of these projects will require high-resolution modeling far beyond that which has ever been performed by the accelerator community. Similar modeling will be needed for proposed accelerator-driven technologies, including Accelerator Production of Tritium (APT), Accelerator Transmutation of Waste (ATW), and Accelerator Driven Energy Production (ADEP).

For example, future high average power linear accelerators, such as the APT, will have to operate with extremely low beam loss (~ 0.1 nA/m) to prevent unacceptably high levels of radioactivity. To ensure that this requirement will be met, simulations with on the order of 100 million particles are needed. An equally challenging modeling problem exists in the NLC for which the linac design is dominated by the issue of beam emittance growth due to long-range transverse wakefields. To suppress this effect, a complex 3D accelerating structure, the Damped Detuned Structure (DDS), has been developed to control the wakefields and it is necessary to verify the effectiveness of the design by numerical simulation. This entails modeling a complete accelerator section that consists of 206 complex three-dimensional cavities requiring hundreds of GBytes of memory. It is evident that these simulations are beyond the desktop computer's capabilities, and can only be performed on the most advanced high performance computing (HPC) platforms using software and algorithms targeted to parallel and distributed environments.

In 1997 the U.S. Department of Energy initiated a Grand Challenge in Computational Accelerator Physics to support a collaborative effort involving LANL, SLAC, UCLA, and Stanford, together with two HPC centers, the National Energy Research Scientific Computing Center (NERSC) and the Advanced Computing Laboratory (ACL). The primary goal of this project is to develop a new generation of accelerator modeling tools for HPC platforms, and to apply them to large complex problems of importance in future accelerators, including those mentioned above. In this paper we will report the progress-to-date in two main thrust areas: electromagnetics and beam dynamics.

2 ELECTROMAGNETIC MODELING

The development of new electromagnetic tools for the Grand Challenge project originated from advanced accelerator structure research for the NLC. The main thrust of the effort is aimed towards large-scale simulations of realistic 3-D structures. Such a capability can be applied to system-scale analysis such as finding the wakefields in the entire DDS as described in Fig. 1, or to individual component design such as one cell in the DDS Fig. 2, by modeling with an accuracy approaching fabrication tolerance level. The new set of tools incorporates the following features to enable the high-resolution modeling required: (i) the use of unstructured grids to capture realistic geometries, (ii) the development of refinement algorithms to improve accuracy and optimize computing resources, and (iii) the implementation on parallel platforms to take advantage of the latest in HPC resources for large-scale simulations.

Presently, there are two types of solvers being developed for the tool set. The first type is formulated in the frequency domain using linear and quadratic finite elements on an ir-

regular grid, and includes eigenmode solvers in two and three dimensions, named $\Omega 2$ and $\Omega 3$ respectively. The parallel versions, $\Omega 2$P and $\Omega 3$P, use MPI and currently run on the SGI/Cray T3E at NERSC. In the case of $\Omega 3P$, the calculation proceeds in three steps: First, there is the mesh distribution step with a module called DistMesh that uses the parallel library ParMETIS for partitioning unstructured graphs. This is followed by the matrix assembly step which consists of the finite element formulation that provides the mass and stiffness matrices for the generalized eigenvalue problem. The final step is a solution step, with Lanczos or Jacobi-Davidson algorithms, that utilizes the parallel iterative library AZTEC to solve the sparse linear systems.

The other type of solver is a three-dimensional time-domain code, called $\tau 3$, that uses a generalized Yee algorithm on an unstructured grid [1][2], Fig. 3. A leapfrog time advancement scheme with filtering is implemented as well as a broadband termination at the waveguide ports. Therefore it is able to handle pulse transmission for S-parameter evaluations of RF components over a wide frequency range in a single run. Dipole excitation is also possible to calculate external Q's of waveguide-loaded cavities. A parallel version, $\tau 3$P, currently runs on a shared memory machine, like the 4-node Intel Xeon server, using threads while the distributed memory version for the T3E is presently under development. The inclusion of a transiting rigid beam to compute wakefields is planned.

2.1 *Examples*

We present here some recent results from $\Omega 3$P and $\tau 3$. First, we report the modeling of a single DDS cell using $\Omega 3$P on the T3E. Fig. 4 shows the cell geometry partition-

ing into 8 pieces using DistMesh/ParMETIS. Fig. 5 is the mass matrix distribution over 16 processors. Together they demonstrate the importance of domain decomposition to achieve load balancing. Currently, $\Omega 3$P is the tool we use to determine the new dimensions for improved versions of the DDS design. Another $\Omega 3$P result comes from the Spallation Neutron Source project for which we modeled the RFQ cavity as shown in Fig. 6. This cavity is difficult to simulate accurately due to the disparate lengthscales between the focusing vanes, the stabilizing rods, and the cavity proper. Fig. 7 shows the convergence of the calculated frequencies to measured data for the two modes of interest when the resolution is increased to require several million degrees of freedom in the simulation.

The $\tau 3$ capability is demonstrated by the matching and tuning of the input power coupler for the NLC accelerator section. Fig. 8 shows the mesh used in modeling a pair of couplers separated by two regular cells. $\tau 3$ finds the match by either single frequency or pulse excitation. The reflection is determined to be 0.005 at 11.424 GHz. The match is confirmed by the accelerating field amplitude and phase along the beam axis. Fig. 9 indicates the field that is due to a travelling wave with the correct phase advance of 120 degrees per cell from coupler to coupler. The advantage of $\tau 3$ over other commercial packages will be the ability to model much larger problems when the parallel version, $\tau 3$P, is completed.

3 BEAM DYNAMICS SIMULATIONS

Many systems involving intense charged-particle beams can be described by the Vlasov/Poisson equations. There are two main approaches to solving these equations: particle simulation techniques and direct methods.

In the particle simulation approach, the beam distribution function is represented by a number of macroparticles, typically 10's to 100's of millions in a large scale simulation. Often the single particle equations of motion are derived from a Hamiltonian which includes both externally applied fields and a mean field due to the beam's space charge: $H = H_{ext} + H_{sc}$. Such a form is ideally suited to the application of symplectic split-operator methods [3]. These methods provide a powerful framework capable of dealing with the complicated Hamiltonians often encountered in accelerator physics, where the Hamiltonian is usually approximated by a high-order polynomial in the phase space variables. Besides being able to treat Hamiltonians with many terms, the split-operator approach is easily generalized to high-order accuracy in time. A well-known fourth-order algorithm is due to Forest and Ruth [4], and an arbitrary-order scheme was derived by Yoshida [5]. There are also implicit symplectic methods that do not require the Hamiltonian to be split into a sum of exactly solvable pieces [3]. Finally, time-dependent systems are easily treated by "extending the phase space" [4].

Unlike some split-operator treatments that separate the Hamiltonian into terms involving only position and only momentum, our particle simulations separate the Hamiltonian into terms involving the external fields and terms involving the self fields. The external fields are treated using well-established techniques from magnetic optics. One advantage of this approach is that it enables one to take large time steps, since the dynamics due to external fields is usually dominated by a linear map which is easily obtained analytically or numerically. To treat the self fields, we use a 3D Particle-In-Cell (PIC) approach with area weighting. Open boundary conditions are treated using the convolution method of Hockney [6]. We are currently using and evaluating several methods of implementing our parallel particle simulation codes: High Performance Fortran (HPF), C++ with message passing via the POOMA framework [7], and Fortran 90 with message passing [8]. In our HPF codes, charge deposition and field interpolation are parallelized using the method of Ferrell and Bertschinger [9]. In our codes that use explicit message passing, a "particle manager" is used to make the data needed by processors local to the processors prior to charge deposition and field interpolation.

Stochastic corrections to Vlasov/Poisson evolution occur due to particle collisions and noise in external fields. To treat these effects we have modified our PIC codes to include Langevin forces and damping, which corresponds to solving the Fokker-Planck equation for the distribution function. An example is shown in the next section.

3.1 Examples

Fig. 10 shows the horizontal and vertical rms emittances from a 2D Langevin simulation of a beam in a potential that can produce chaotic dynamics. In the absence of damping and diffusion, the motion is governed by the Hamiltonian,

$$H = \frac{1}{2}(p_x^2 + p_y^2) + \alpha x^4 + \beta y^4 + \frac{1}{2}x^2y^2 + q\Psi, \quad (1)$$

where α and β are constants, and where Ψ is scalar potential associated with the beam space charge. Damping and diffusion were turned on at $t = 0$ in the simulation, and the beam approached thermal equilibrium quickly, as is evident from the emittance curves which reach their final values after about 20 units of time. As further evidence that that beam has reached equilibrium, we turned off the damping and diffusion at $t = 100$ and observed little or no change in the emittances.

Though early work in beam halo physics emphasized 1D and 2D models of the transverse beam halo, recent activity has turned to 3D models including longitudinal beam halo. We have developed a parallel PIC code called HALO3D specifically for studying beam halo formation in 3D bunches. Such a code is extremely useful for testing analytical models of halo formation, such as particle-core models. A unique feature of the code is that it has a capability to model a new 3D beam equilibrium distribution, developed by R. Gluckstern and A. Fedotov of the University of Maryland [10]. It also has the ability to include nonlinear rf focusing fields, a feature incorporated in collaboration with J. Barnard and S. Lund of Lawrence Livermore National Laboratory. Based on their CTP ("core test particle") code, Barnard and Lund had predicted that the period-2 parametric resonance widely known to be a major source of beam halo could be detuned by the presence of nonlinear rf fields. This was supported by HALO3D simulations, as shown in Figs. 11 and 12. These figures show a stroboscopic plot in longitudinal phase space of test particles moving in the field of a mismatched beam. The resonance is evident in Fig. 11, which has a linear model of the rf fields. In contrast, the resonance is absent in Fig. 12, which has a nonlinear model of the rf fields.

In addition to HALO3D, we are also developing a new 3D beam dynamics code called IMPACT (Integrated-Map and Particle Accelerator Tracking code). This code has an accurate and efficient treatment of RF accelerating gaps, obtained by numerical integration of the gap transfer map rather than integration of single particle trajectories. The code is especially useful for modeling superconducting proton linacs, where there are only a few types of accelerating cavities. An example input geometry that was used to test the code is shown in Fig. 13. The figure shows the quadrupole gradient in a FODO cell along with the electric field on-axis due to accelerating cavities between the quadrupoles. Finally, we have developed a parallel version of a code called LINAC, developed by K. Crandall, which is the primary code used by the APT project for halo simulations. In addition to parallelizing LINAC, we also added

a 3D space charge capability, as described in the preceding section.

HIGH-INTENSITY LINAC STUDIES IN FRANCE

J-M Lagniel

CEA-Saclay, DSM-DAPNIA-SEA, 91191 Gif-sur-Yvette Cedex, France

Abstract

Teams from different French research agencies are working on high-intensity high-duty factor proton, H^- and deuteron linear accelerators for several applications (waste transmutation, spallation neutron sources, tritium production, materials irradiation facilities...). The conceptual design of the TRISPAL project achieved by the CEA for tritium production is presented. A separate R&D program undertaken by a CEA-CNRS (IN2P3) collaboration is also discussed. This program includes both the construction of a high intensity (100 mA), cw (continuous wave), 10 MeV, prototype linac (IPHI) and the fabrication and test of $\beta < 1$ superconducting cavities.

1 OVERVIEW OF THE HIGH-INTENSITY LINAC ACTIVITIES IN FRANCE

Proton and deuteron accelerators with average beam power greater than 1 MW are being studied all over the world for numerous applications (see [1-2] for reviews), mainly because they are increasingly considered as ideal sources of neutrons (high flux, broad energy spectra, cw or pulsed mode, safety associated with fast shut-down...).

In France, the CEA (Commissariat à l'Energie Atomique) started the study of the TRISPAL project for tritium production in 1992. In this project, a high-intensity cw proton beam is used to produce a high neutron flux through spallation process in a heavy metal target. These neutrons are then used to transmute ^{6}Li into tritium. The TRISPAL conceptual design is now complete [3]. The 24 MW beam power linac (40 mA, 600 MeV, cw, protons) designed by a team from CEA-Bruyères-le-Châtel, CEA-Saclay and Thomson-CSF-Airsys is described in section 2.

The CEA-Saclay team is also involved for the last several years in the IFMIF project (International Fusion Material Irradiation Facility). The aim of this IEA (International Energy Agency) activity is the design of a high-flux neutron source with an energy spectrum peaked near 14 MeV for research and development of materials for the next generation of fusion reactors. The IFMIF team has the distinction to have a broad community of scientists from different fields (accelerator, Li-target, test facility, users, design integration) and from different countries e.g. the European Union (EU), Japan and the United States of America, along with the Russian Federation as an associate member. The EU contribution in the accelerator field is done by a Frankfurt University - CEA-Saclay collaboration thanks to a support of the European Commission. The confrontation of ideas with scientists from different labs is very fruitful and the work with our European, Japanese, American and Russian colleagues has been and is still highly appreciated. The IFMIF design is based on two 125 mA, 35-40 MeV, cw deuteron linacs. A full description of the work done during the IFMIF Conceptual Design Activity (CDA, 1995 and 1996) can be found in ref. [4]. The project is now in the Conceptual Design Evaluation (CDE) phase. The CEA-Saclay team is working on the ion source, high-power 175 MHz RF systems (in collaboration with Thomson-Tubes-Electronics) and beam loss.

The CEA is also involved in the 5 MW European Spallation Source (ESS) project [5]. CEA-Saclay will participate in the R&D program for the linac (1.33 GeV, 107 mA H^- peak current, 6% duty cycle). R&D studies are being contemplated in the development of H^- ion source, the beam diagnostics and the design of the accelerating structures including the evaluation of a superconducting cavity option for the high energy part of the linac.

Two French research agencies, CEA and CNRS-IN2P3 (Centre National de la Recherche Scientifique - Institut National de Physique Nucléaire et de Physique des Particules), have started an evaluation program for the accelerator driven transmutation of waste (ADTW) technology. In such a system, spallation neutrons are used to transmute long lived nuclei with high radio-toxicity into short lived or stable nuclei. The accelerator is coupled to a sub-critical target where minor actinides and/or fission products for transmutation are located [6-7]. A beam power of 20 - 40 MW or more is needed. For this, 20 - 60 mA cw proton beam will be accelerated by a linac up to an energy range 600 - 1200 MeV. The choice of beam intensity and energy must result from a complex optimization process of the whole system and the design must take into account the severe constraints on the accelerator availability and beam losses [7-8].

A significant R&D program has been undertaken by the CEA-CNRS (IN2P3) collaboration in order to optimize the design of such a high-power proton linac which could be also used for the next generation of radioactive ion beam facilities and for muon colliders. The program includes the construction of a high intensity (up to 100 mA), cw, 10 MeV prototype (IPHI, section 3) and the fabrication and test of $\beta < 1$ superconducting RF (SRF) cavities (section 4).

2 THE TRISPAL PROJECT

TRISPAL is the CEA project for tritium production using spallation neutrons. The accelerator parameters have been optimized to produce the requested quantity of tritium per year. Optimization process has taken into account the fluctuation in the cost of electricity during the year (electricity in France is ten times more expensive during the winter). The process has lead to the choice of a beam power of 24 MW delivered by a 600 MeV 40 mA cw proton linac [3].

The main directive to the TRISPAL design team was to be as conservative as possible for the choice of the technology and parameters. This accelerator based tritium production system compete directly with the process based on a conventional nuclear reactor. Thus, the linac must be built as part of an industrial facility. The major considerations that went into the design of the accelerator are :

- limit beam losses to an extremely low level ($\sim\Delta I/I < 10^{-9}$) in order to allow hands-on maintenance.
- achieve a high reliability/availability (greater than 90%) and minimize the number of abrupt beam interruptions to limit the stress in the target. It has been calculated that the TRISPAL target (including the window) can accept up to 10000 abrupt beam stops (longer than 100 ms) per year. This approximately corresponds to a mean value of one stop per hour which seems to be realistic.
- Minimize the total cost of the machine (construction and operation) without compromising the two previous items.

Figure 1 shows the layout of the TRISPAL linac. The 24 MW proton beam is produced using 4 types of RF cavities, all operating at the same frequency (352 MHz). This minimizes bunch compression which is always a source of mismatch and halo formation. The front end is composed of an 95 kV ECR source, a low energy beam transport line with two solenoids and a 5 MeV RFQ. The main parameters of the RFQ are listed in Table 1. The maximum electric field is limited to 1.5 Kilpatrick to reduce the sparking rate. The price for this choice is a relatively low transmission.

Table 1, TRISPAL RFQ main parameters

Length	8 m (578 cells)
Vane voltage	88.5 kV (1.5 Kp)
R_0 (mean aperture)	4.38 mm (min a = 2.8 mm)
ρ (vane radius)	3.72 mm ($\rho/R_0 = 0.85$)
Input trans. Emit.	0.25 π mm mrad (rms norm)
Output trans. Emit.	0.23 π mm mrad (rms norm)
Output long. Emit.	0.12 MeV deg (rms norm)
Transmission	93% (for 50 mA input current)

The high output energy of the RFQ is achieved in a 8 m long structure thanks to the segmented coupled RFQ concept developed at LANL [9]. This capability of pushing up the RFQ energy is very useful because as $\beta = v/c$ increases, the first cells of the DTL become long enough (~ 8 cm) to accommodate electromagnetic quadrupoles. The front end cavities can then operate at a relatively high RF frequency allowing the construction of a high energy machine without a frequency jump (352 MHz for the TRISPAL basic design), or only with a jump of a factor of two if 704 MHz SRF cavities are used in the high energy part. This is an important point to facilitate the beam matching in the accelerator, to avoid halo formation, and unacceptable beam losses.

The medium energy part of the TRISPAL linac is made up of an RFQ to DTL matching section, a 29 MeV DTL and SDTL cavities up to 85 MeV. The beam matching between the RFQ and the DTL is done in a ~ 80 cm section using four quadrupoles and two 352 MHz bunchers. The phase advances per unit length are kept constant from the last cells of the RFQ to the first cells of the DTL and the beam envelope modulations are minimized as much as possible in order to obtain an intensity independent matching and to minimize emittance growth. The transmission through the 29 MeV DTL is 100% ; a full beam dynamics study including errors on both the beam and accelerator parameters has been completed to determine tolerances [10]. The DTL has two tanks, each fed by an 1.3 MW RF system similar to those used in LEP or ESRF accelerators. A SDTL (Segmented DTL), mechanically simpler to build than a standard DTL, is chosen for acceleration from 29 to 85 MeV. The SDTL is composed of short DTL cavities (5-7 cells) with simple drift tubes, the transverse focusing being provided by the quadrupoles located outside the cavities.

LEP-type CCL copper cavities (see figure 2) take the beam to the final energy (600 MeV). The beam dynamics beyond the DTL has been studied using a simplified linear model ; more accurate simulations using multiparticle codes (including error analysis) may lead to an adjustment of the transition energies. In the present TRISPAL design, each SDTL and CCL cavity is fed by couplers capable of maximum power of 125 kW (a conservative value). The RF power is supplied by 49 1.3 MW RF systems. A quadrupole doublet focusing lattice is chosen. The SDTL uses seven β families in a total of 40 cavities with beam apertures ranging from Φ 50 to 30 mm and effective shunt impedance ranging from 44 to 34 MΩ/m (80% SUPERFISH). The CCL uses twelve β families in a total of 344 cavities with beam apertures ranging from Φ 30 to 60 mm and effective shunt impedance of ~30 MΩ/m. An option using superconducting RF cavities is also presented in addition to this basic conservative design.

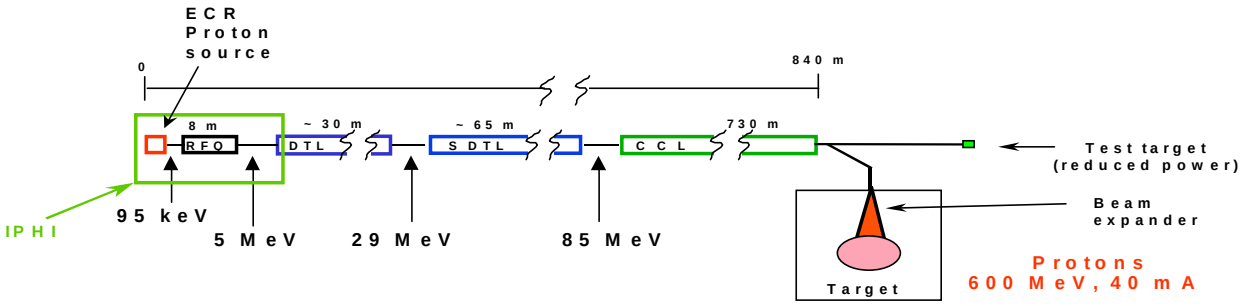

Figure 1 : TRISPAL layout

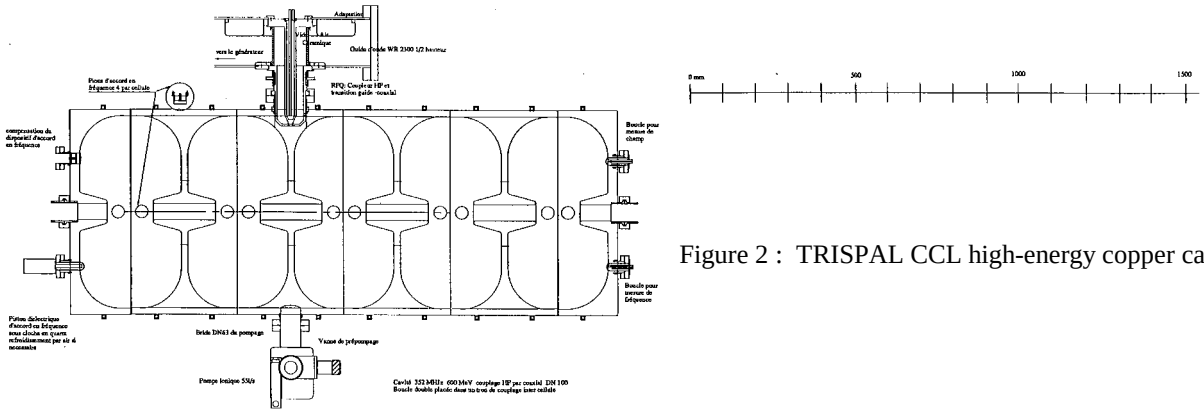

Figure 2 : TRISPAL CCL high-energy copper cavity

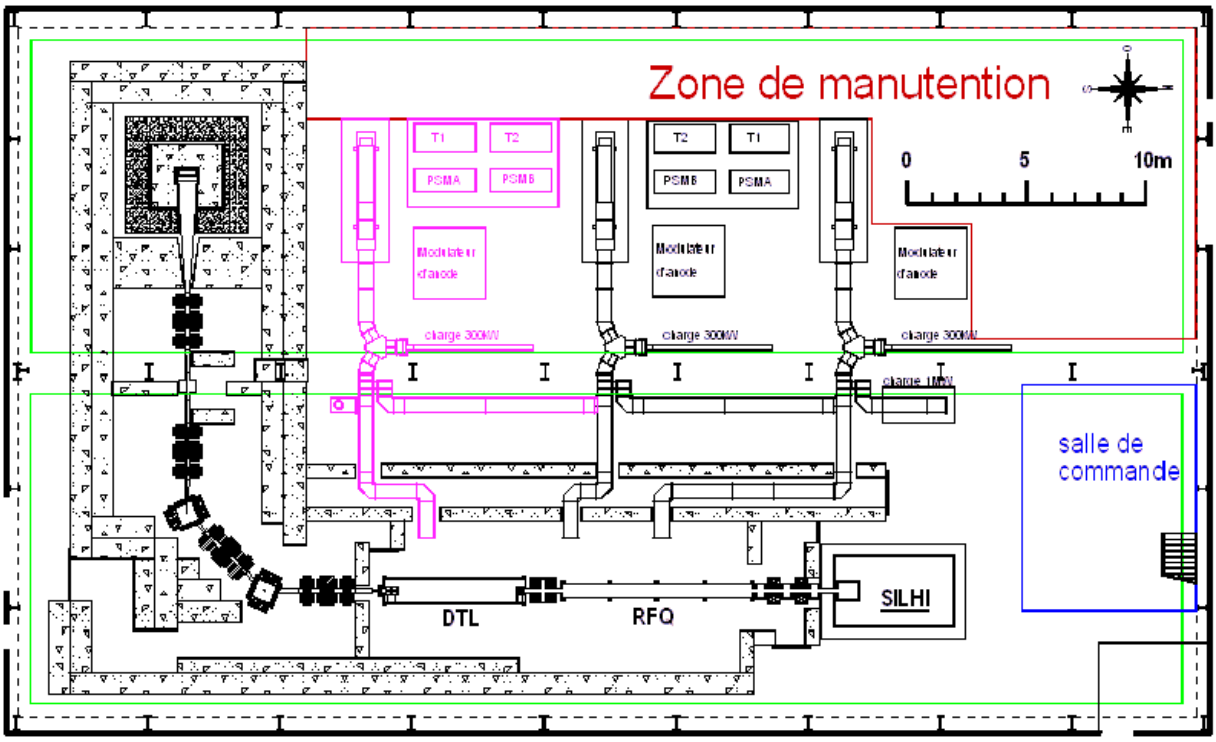

Figure 3 : General layout of the IPHI project

3 IPHI

IPHI (Injecteur de Protons Haute Intensité) is the name of the CEA-CNRS R&D program undertaken in 1997 for the front end of a typical high-power linac. The objective is to gain experience in this difficult part of the accelerator in order to optimize the whole machine in terms of performances, cost, reliability and availability. To summarize, the IPHI objectives are :

- validation of the beam dynamics codes in the low-energy sections where space-charge effects are dominant,
- knowledge of the beam distribution at an energy where halo considerations are crucial,
- demonstration of the merit of technological choices and adequacy of design codes,
- acquisition of data on reliability and availability, reality check on the cost of the components and ability of the manufacturers to build them.

The project goal is to build a 10 MeV "Injector for Protons with High Intensity" (up to 100 mA) and duty cycle up to 100%. The first stage is a High-Intensity Light-Ion Source, SILHI, designed to produce high-intensity proton or deuteron beams at 95 kV. This 2.45 GHz ECR source is now at a high performance level [11]. Table 2 shows the current performance data (consistent values except when specified) for two values of extraction diameter.

Table 2, status of the SILHI source

	Objective	Achieved	
Extraction Diameter (mm)	10	8	10
Proton current (mA)	100	91	98
Duty cycle (%)	100	100	100
Extraction voltage (kV)	95	95	92
Total current (mA)	~110	108	122.5
Proton fraction (%)	> 90	84	80
Plasma density (mA/cm^2)	140	215	156
RF power (W)	1200	1100	1200
Hydrogen mass flow (sccm)	< 10	2	3
Beam current noise (%)	± 1	± 2	NA
Norm. rms emittance (π.mm.mrad)	0.20	0.17 @ 80 mA	0.21 @ 97 mA

A first uninterrupted operation was done at the end of 1997 to measure the availability of the source. It was operated continuously for 100 hours (~5 days) at 100 mA cw. An availability of 96% was obtained with 1 h 45 mn for the Mean Time Between Failures and 4 mn 44 s for the Mean Time To Repair. Most of the beam interruptions occurred during the first day. When this conditioning period is not taken into account in the statistics, the source availability reach 99% (MTBF = 5 h 33 mn). EMC improvements made after this test and incorporation of an automatic restart controlled by computer is expected to improve these already high performance statistics.

No damage to the new HV extraction electrodes was observed after more than 300 hrs of cw operation at 100 mA. The stability and reproducibility of the beam are excellent. A non-interceptive emittance measurement system based on measurement of beam profiles with a CCD camera has been successfully tested recently [12].

The key parameters of the 5 MeV RFQ are now almost fixed. Table 3 shows that our objective to achieve a very high beam transmissions with a relatively low maximum electric field is at hand. The optimization of the beam dynamics has been done using a large set of codes developed at Saclay, LANL (PARMTEQM) and MRTI (LIDOS) [13]. An in-depth analysis of the different models used in these codes is underway [14].

Table 3 : IPHI RFQ main parameters

Length	8 m
Vane voltage	87.34 to 122.82 kV (1.7 Kp)
R_0 (mean aperture)	3.69 to 5.27 mm
ρ/R_0	0.85
A	3.56 to 4.41 mm
M	1.0 to 1.735
Input trans. Emit.	0.25 π mm mrad (rms norm)
Output trans. Emit.	0.25 π mm mrad (rms norm)
Output long. Emit.	0.18 MeV deg (rms norm)
Transmission (100 mA input current)	99.4% for 1.8 Kp 99.3% for 1.7 Kp 97.3% for 1.6 Kp

The thermo-mechanical analysis of the cavity and the study of the RFQ vacuum system has been successfully completed. Several prototypes will be built before the end of this year to validate the fabrication process. Financial commitment for the high-power RF system will be made in 1999 (klystrons, windows and circulators).

To optimize the geometry of the DTL, a full 3D magnetic analysis of the low energy quadrupoles (around 5 MeV) has been done. The field non-linearities have been calculated taking into account the effect of surrounding quadrupoles. The construction of a short tank (4 cells) for high-power tests will start at the end of this year. A affirmative decision for the construction of a 10 MeV tank is expected in 1999. Total investment for the IPHI prototype is ~8 M ECU (equipment only) and the CEA - CNRS-IN2P3 team consist of around 45 men-year/year. The key dates are :

Source / LEBT :
Test the matching conditions to the RFQ 1999

RFQ :
Tests of the 2 RF systems 01-06/2001
Tuning of the RFQ cavity 06-12/2001
Low beam current tests 01-06/2002
Nominal beam 06/2002

Diagnostic Line :
Beam measurements at nominal power 09-12/2002

DTL :

Short tank hot RF tests 04-08/2000

4 SRF CAVITY STUDIES

A strong R&D effort on $\beta < 1$ SRF cavities is justified by the fact that this technology brings important advantages, the most obvious one being economy. In fact, the high RF to beam power efficiency (almost 100%) significantly reduces the operation cost. In addition, the investment cost can also be slightly reduced through length reduction. Standard copper RF cavities typically provide ~1.5 MeV/m with a shunt impedance ~35 MΩ/m. A 1 GeV linac is then ~ 670 m long and ~43 MW of RF power is lost in the copper (~ 70 MW from the plug).

An important know-how for the SRF cavity has been obtained by the CEA - CNRS-IN2P3 collaboration (CEA-Saclay, IPN-Orsay and LAL) and by the French industry (CERCA...) thanks to several studies and constructions done for the TESLA-TTF electron linac. This expertise is obviously very useful in the high-power proton linac field for which $\beta < 1$ SRF cavities must be developed. The first studies done in 1996 by a LANL - CEA-Saclay team demonstrated that beam losses as high as 10^{16} protons/cm^2/s do not affect the superconducting properties of niobium cavities [15-16]. In 1997, four 700 MHz single-cell cavities (β = 0.48 and 0.64) were successfully built and tested at LANL with participation of CEA-Saclay [17-18-19]. Several single cell 704 MHz β = 0.6 Nb cavities have been made by CERCA for CEA-Saclay ; low power RF tests will start very soon. Studies are also underway for the development of high-power RF couplers. "CRYHOLAB", the horizontal cryostat being built by CEA and CNRS, will be available in 1999 to test multicell cavities.

In the near future, a full study for the best choice of the RF frequency (352 vs 704 MHz) in terms of cost, beam dynamics and reliability-availability will be done. A new R&D programme called "ASH" (Accélérateur Supraconducteur pour Hybrides) [20] has also been proposed for high-power RF tests. The aim is to design a cryomodule fully equipped with high field cavities, high-power couplers and cryogenic connections, to measure the real cryogenic losses of the system. The ultimate objective of this proposal (1999-2002) is to transfer technology to the industry.

Together with the SRF cavity technology development, beam dynamics studies including errors on both beam and accelerator parameters need to be done. This would answer several basic questions such as - Are the long focusing periods due to the use of room temperature quadrupoles lead to acceptable beam losses ? - Must we limit the accelerating field to avoid emittance growth due to a strong transverse-longitudinal coupling ? - Must we use superconducting quadrupoles to shorten the focusing periods ? - What is the best choice for the beam aperture ? - Is 100 MeV the right energy to start SRF cavities ? An answer to the last question is definitely needed before starting the R&D on $\beta \sim 0.5$ SRF cavities. Analysis and improvement of the codes to achieve high precision for these beam dynamics calculations are an important part of the current effort [21-22]. For this, as well as for the development of the SRF cavity technology, a strong and productive collaboration is in place with several laboratories around the world, particularly with LANL (USA) and INFN (Italy).

COMMISSIONING OF THE KEKB LINAC

Y. Ogawa, Linac Commissioning Group*
High Energy Accelerator Research Organization (KEK), Tsukuba, Ibaraki 305-0801 JAPAN

Abstract

The injector linac for the KEKB ring has been commissioned step by step since last autumn, while continuing the construction of the remaining parts as well as ordinary operation for beam injection into the Photon Factory. The commissioning has so far given quite satisfactory results: (1) A single-bunched beam with a charge of about 1.5 nC for direct injection into the ring was accelerated to the end of the linac (about 8 GeV). (2) A single-bunched beam with a charge of 6 nC for positron production was accelerated to a positron production target (3.3 GeV). Positron beams with a charge of about 0.5 nC have been successfully accelerated to the end of the linac (3.5 GeV) and transported to the beam line of the ring with a proper energy spread. (3) Various kinds of beam instrumentation have been employed and utilized for precise beam tuning and diagnosis.

1 INTRODUCTION

The construction of the KEKB linac [1] was completed on schedule at the beginning of May, 1998. The commissioning, which had been carried out step by step since October, 1997, has entered a full-commissioning phase at this moment so that two design beams for the KEKB ring could be realized: full acceleration of an electron beam (about 8.0 GeV) as well as the production of a large quantity of positrons and their acceleration (3.5 GeV).

The layout of the linac is shown in Fig. 1, comprising two parts: a newly constructed part (sectors A, B, C and J arc) and an upgraded part (sectors 1-5 and a beam switchyard). A beam starting from an electron gun passes two subharmonic bunchers (SHB1: 114.24 MHz and SHB2: 571.2 MHz) and an S-band bunching section (2856 MHz) to accomplish a single-bunched beam with a bunch width of about 10 ps (FWHM). After acceleration to the end of sector B (1.5 GeV), it enters into the J arc section, in which achromatic and isochronous conditions are fulfilled. It is then re-accelerated either to the end of the linac (8.0 GeV) or to the positron production target (3.3 GeV), depending on the operation mode. The 8-GeV electron beam is directly transported into the ring, while the produced positron beam is accelerated to the end of the linac (3.5 GeV) and passes into the ring injection line after an energy-compression system (ECS) located at the beam switchyard. In the case of positrons, the primary electrons also pass through a bunch-compression system (BCS) just before the target to decrease the bunch width so that a positron bunch-lengthening effect in the solenoids after the target can be partially compensated, realizing an appropriate bunch width for a positron energy spread.

Two operation modes (8-GeV, 1.2-nC electrons and 3.5-GeV, 0.64-nC positrons) have thus been almost established, realizing the designed beam characteristics.

For efficient commissioning, we have organized for the first time a linac-commissioning group comprising both members of the linac and the KEKB ring. We believe that it has made a great success in that linac beam parameters required for ring injection are being intensively pursued while sharing common commissioning experiences.

2 OUTLINE OF THE COMMISSIONING

Fig. 2 shows the results of commissioning concerning the beam positions and intensity in two operation modes of the KEKB linac: an 8-GeV electron beam and a 3.5-GeV positron beam. In the following sections, the beam-tuning process is discussed along with the beam flow of the linac.

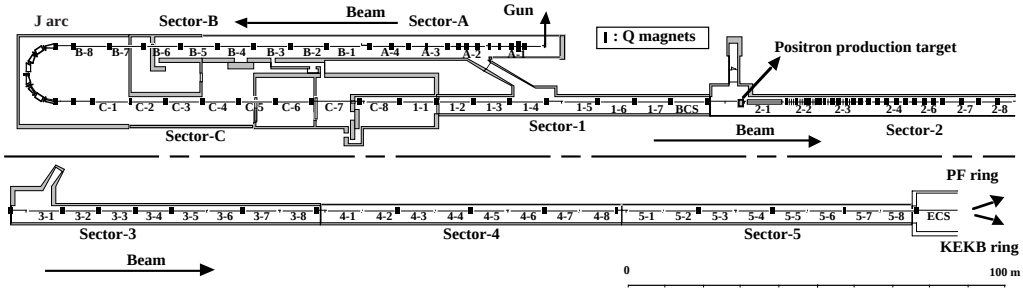

Figure 1: Layout of the KEKB linac. Sectors A, B, C and J-arc are newly constructed.

* N. Akasaka, A. Enomoto, J. Flanagan, H. Fukuma, Y. Funakoshi, K. Furukawa, T. Ieiri, N. Iida, T. Kamitani, T. Kawamoto, M. Kikuchi, H. Koiso, T. T. Nakamura, Y. Ogawa, S. Ohsawa, K. Oide, K. Satoh, M. Suetake, T. Suwada

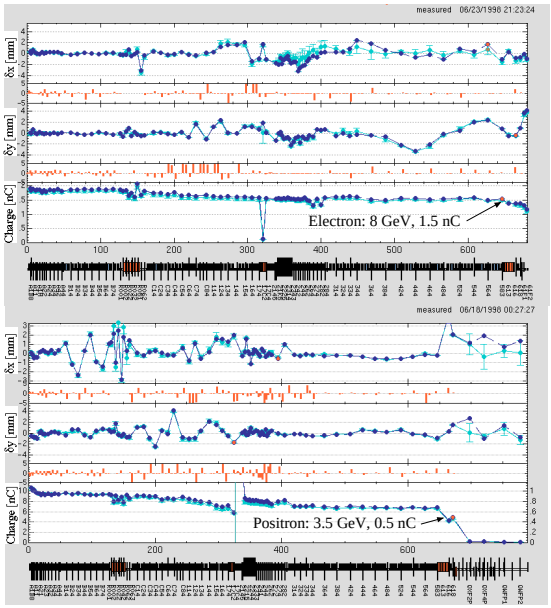

Figure 2: Two design beams have been achieved at the end of the linac: 8-GeV, 1.5-nC electron and 3.5 GeV, 0.5-nC positron beams.

2.1 Electron Gun and Its Orbit Measurement

The electron gun emits a beam with an energy of 200 keV and a pulse width of 2-3 ns (FW). The beam is immediately injected into the bunching section to form a single bunch in the S-band structure. Since the beam is still non-relativistic in this region, a solenoid-type focusing system is employed against strong space-charge forces among particles. It sometimes happens, however, that if a beam having even a slight inclination to the solenoid field axis is injected into this region, the central orbit may rotate in the magnetic field, causing an emittance growth. In order to prevent this kind of beam degradation, we not only checked the transverse components of the magnetic field, but also improved the alignment of the electron gun. As a result, the beam-orbit rotation is considerably minimized and the beam profile along the region becomes quite improved.

2.2 Tuning of Bunching Section

Tuning of the bunching section [2] has been carried out mainly by observing a bunch monitor with a streak camera (see Section 3.2) located at the end of the section. With proper powers fed into two SHB cavities, an S-band prebuncher and a buncher, as well as by precise tuning of the corresponding rf-phases, we succeeded to establish a single-bunched beam without any satellites. The bunch widths obtained in the 1.5-nC beam and the 10-nC primary beam for positron production are about 10 ps.

The energy spectrum is also measured at an energy-analyzing station at an energy of about 70 MeV, giving an energy spread of about 9% (FW).

2.3 Acceleration in Sectors A and B

In sectors A and B, the energy must reach the J-arc design energy of 1.5 GeV, which is realized by using 10 accelerator units with a margin of one unit. The last two units are used as a knob for adjusting the energy in a cross-phase configuration so as to compensate for any energy spread due to the slope of the sine function. In a high-current acceleration mode, the acceleration phase for the rest of units is set at an off-crest angle of about 15 degrees in order to minimize the energy spread, satisfying the J-arc energy acceptance of 2.8% (FW=4σ).

Beam transmission from the end of the bunching section to that of sector B is quite good, accomplishing almost 100% without any significant loss. It has been anticipated, however, that some problems related to wake-field effects might emerge for an intense primary electron beam with a charge of 10 nC. In fact, we sometimes observed some peculiar phenomena concerning beam profiles in high-current beam acceleration, while in beam acceleration with a small charge of 1.5 nC we found no such problems. Details concerning these items are discussed in Section 4.

2.4 Tuning of the J-arc Section

The J-arc section is designed to be achromatic and isochronous [3]. The achromaticity condition is fulfilled in the following manner:

- Measure the dispersion at all beam-position monitors (BPM: see Section 3.1) along the J-arc by changing the energy using the energy knob.
- Calculate the strengths of the quadrupole magnets so as to simulate the observed dispersion and obtain ratios to the set values.
- Set the strengths of the quadrupole magnets at the values calculated from the inverse ratios to the set values.
- Measure again the dispersion and iterate the process.

For the isochronicity condition, the same procedure is taken, except for the first step, which is replaced by:

- Measure the time delay with a streak camera system (see Section 3.2) at the end of the J-arc by changing the energy using the energy knob.

In achromaticity corrections, second-order effects are also cured by adjusting the strengths of the sextupole magnets.

The central energy in the J-arc is maintained at 1.5 GeV by introducing an energy feedback loop utilizing the energy knob. As mentioned in the previous section, we sometimes observed interesting phenomena related to a degradation of the beam quality, which made the beam transmission in the J-arc quite low. The cures obtained by using local bumps and adjusting the acceleration phases at sectors A and B were successfully tried, and are described in Section 4.

2.5 Acceleration in Sectors C and 1

In the midst of sectors C and 1, the newly constructed part and the upgraded part were joined together during the last week of March, 1998. In order to successfully make the prompt connection without causing any disturbances to the ordinary operation for the Photon Factory, we had prepared a temporary pre-injector comprising an electron gun and a bunching section at the first section of sector 1. Although two independent accelerators have been successfully connected without any obstacles, the short period for a connection has not allowed a satisfying alignment of the accelerator components. In fact, the beam losses in this region, which are suspected to be due to a misalignment, have so far not been avoided. A re-alignment of the linac is planned for this summer.

The largest amount of charge obtained for positron production was about 6 nC at the target, not reaching the design value of 10 nC. We expect a considerable improvement after a re-alignment.

2.6 Tuning of Primary Electrons at a e^+ Target

Primary electrons for positron production pass through BCS just before the target so as to partially compensate the bunch lengthening of positrons occurring in the following solenoids. The acceleration phases at sectors C and 1 are set at an off-crest angle of about 30 degrees, making the phase-space orientation for BCS. Although BCS worked quite well, fine-tuning will be carried out in the autumn.

Since the positron yield strongly depends upon the beam profile at the target, the beam waist was surveyed by changing the optics before the target. The minimum radius of the beam size was estimated to be around 1 mm, obtaining a maximum positron production.

2.7 Acceleration in Sectors 1-5

Acceleration in this region has proceeded without any problems for electron and positron beams. The beam characteristics have been measured for both beams at the end of sector 5, giving the quite satisfying results reported in Section 5.

2.8 ECS for e^+ beam

The energy acceptance required for the positron injection line to the KEKB ring is 0.5% (FW). In order to achieve this value, the positron beam is passed through ECS at the end of linac. An energy-compression ratio of about 0.5 was obtained: an energy spread of 1.7% (FW) became 0.8% (FW) after ECS. According to an analysis of the data (Fig. 3), it turns out that almost 90% of the positrons fall in the energy acceptance of the injection line. The remaining slight difference relative to the design value will be expected to be eliminated by fine tuning of the acceleration phases as well as that of BCS.

After passing through ECS, a positron beam with a charge of about 0.4 nC was successfully transported to the temporary beam dump in the midst of the injection line. Although the beam-loss monitors installed along the injection line showed an allowed level of radiation in this time of operation (5 pps), it turns out that for the full-injection mode (50 pps), the radiation level must be reduced by almost one half. This reduction will also be expected to be achieved with a proper tuning of the linac and the beam-transport line.

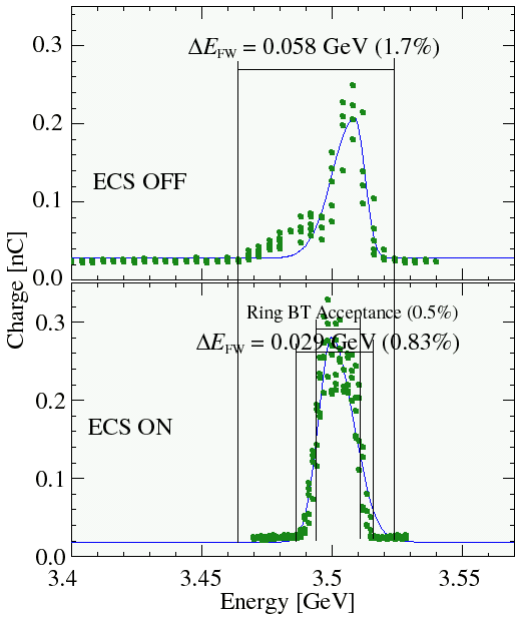

Figure 3: Energy spread of positron beams compressed into a half width by the ECS located at the end of linac, reaching almost the energy acceptance of the ring injection line.

3 BEAM INSTRUMENTATION

3.1 BPM Calibration

BPMs [4] installed in all quadrupole magnets have been quite efficient tools for beam diagnosis in the commissioning. We have performed several kinds of BPM calibrations using a beam: measurements of the position resolutions and offsets as well as estimations of the calibration factors by employing a recalibration method [5]. The obtained results are summarized in Table 1.

3.2 Bunch Monitor with a Streak-Camera System

Another important progress in beam diagnosis was the introduction of new streak-camera systems [6] for observing a bunch structure. Three systems (at the end of sector A and the J-arc, and just after the positron target) have been installed, while another one is being prepared at the end of the linac. One of the main features in the new

system is an integration of hardware and software; all of the necessary steps to observe streak-signals are integrated, and the handling becomes quite simplified. Detailed descriptions can be found in the reference.

3.3 Test of Wire Scanner

As non-destructive beam-profile monitors, wire scanners have been tested concerning several aspects: a detection scheme and its configuration as well as a radiation-shield method. The results indicate that with a suitable configuration of the detector, wire scanners give a sufficient signal-to-noise ratio against a strong radiation environment. We are planning to install three sets (each comprising three or four wire scanners positioned at proper distances) at the end of sector B, J-arc and the linac, respectively, so that the twiss parameters can be calculated in nearly real-time using signals from three or four wire scanners at the same time. Details are to be presented elsewhere [7].

3.4 Wall Current Monitor: Charge Calibration

Although the quantity of charge is one of the key parameters, the calibration is not a simple task, especially in the case of a very short pulse, like a single-bunch beam (10 ps) in the S-band linac. We employed two methods: a relative calibration utilizing a signal from the beam-induced field observed at the end of accelerator section as well as an absolute one using a Faraday cup installed in the straight branch line at the entrance of the J-arc. Details will be presented elsewhere.

4 FINE TUNING OF INTENSE BEAM

4.1 Acceleration-Phase Tuning

The acceleration phase for an intense beam has been set at an off-crest angle of about 15 degrees in sectors A and B for achieving an energy acceptance of the J-arc (Section 2.3). On the other hand, it has been about 30 degrees off-crest in sectors C and 1 for BCS (Section 2.6). The maximum beam transmission in these regions, however, was obtained by even a finer adjustment of the acceleration phases in sectors A and B, so that they were slightly shifted in the inverse direction relative to each other. In this way, the beam profiles in the J-arc were greatly improved, suggesting the existence of transverse wake-field effects, which are clearly shown in the next section. A detailed analysis will be carried out during the next commissioning period.

4.2 Orbit Tuning

Local bumps have been introduced somewhere in sectors A and B, depending upon the beam state to improve the beam transmission in the J-arc and sector C. In calculations of a bump, dipole transverse wake-field effects are taken into account so that the bump can be closed. The bump, however, sometimes failed to close the orbit, possibly because quadrupole wake-field effects emerged when the beam profile-deformation was large. Incorporating quadrupole wake-field effects in bump calculations might be necessary during the next opportunity.

4.3 Method of Downhill Simplex

Since the beam intensity at a certain point of the linac depends upon many parameters upstream, it may happen that searching the optimum combination of parameters would be practically difficult. We tried the method of downhill simplex [8] for obtaining the maximum positron yield by changing the strength of a few upstream steering coils together with some acceleration phases. The results suggest that this kind of method could be useful in some cases. A more elaborate application of the method will be introduced in the future.

5 BEAM CHARACTERISTICS

The beam characteristics obtained during the commissioning are listed in Table I, compared with the designed target values. As far as the beam intensity at the end of linac is concerned, the target values have been nearly realized for electron and positron beams, though a slight increase of positrons may be required. The single-bunch purity is practically 100%, while the bunch length is not in agreement with the design value, which does not seem to be a serious problem. The emittance growth observed in sectors A and B for an intense beam might be reduced by the effective use of local bumps or the method of downhill simplex. The energy margin for ring injection is rather poor at this time of commissioning, but can be considerably improved during the next commissioning period. The energy spread of both beams falls at almost the energy acceptance of the injection line.

6 CONCLUSIONS

The first commissioning of the KEKB linac was successfully completed, reaching two major goals: 8-GeV acceleration of electron beams and 3.5-GeV acceleration of positron beams with sufficient quantity and quality. High-quality hardware completion of the machine was also verified and confirmed through commissioning, satisfying the beam characteristics required for the KEKB ring.

7 ACKNOWLEDGEMENTS

The authors would like to thank to all of the staff members of linac for the high-quality completion of the construction. They also greatly appreciate various forms of support by the project leaders, Profs. K. Nakahara and S. Kurokawa.

A REVIEW OF ACCELERATOR CONCEPTS FOR THE ADVANCED HYDROTEST FACILITY

Alan J. Toepfer
Science Applications International Corporation, Albuquerque, NM, USA

Abstract

The Advanced Hydrotest Facility (AHF) is a facility under consideration by the Department of Energy (DOE) for conducting explosively-driven hydrodynamic experiments. The major diagnostic tool at AHF will be a radiography accelerator having radiation output capable of penetrating very dense dynamic objects on multiple viewing axes with multiple pulses on each axis, each pulse having a time resolution capable of freezing object motion (≈ 50-ns) and achieving a spatial resolution ≈ 1 mm at the object. Three accelerator technologies are being considered for AHF by the DOE national laboratories at Los Alamos (LANL), Livermore (LLNL), and Sandia (SNL). Two of these are electron accelerators that will produce intense x-ray pulses from a converter target yielding a dose ≈ 1,000 - 2,000 Rads @ 1 meter. LLNL has proposed a 20 - 40 MeV, 3 - 6 kA linear induction accelerator (LIA) driven by FET-switched modulators driving metglas loaded cavities. SNL has proposed a 12-MeV, 40-kA Inductive Voltage Adder (IVA) accelerator based on HERMES III pulsed power technology. The third option is a 25 - 50-GeV proton accelerator capable of ≈ 10^{13} protons/pulse proposed by LANL. This paper will review the current status of the three accelerator concepts for AHF.

1. INTRODUCTION

X-radiography is a well-known diagnostic for nondestructive test measurements, both of static and dynamic systems. Pulsed x-radiography is commonly used for the study of a number of physical problems involving the hydrodynamics of materials, for example, the stability of accelerated material interfaces and the response of targets to ballistic penetration. Intense, single-pulse x-ray sources have been used for the past 30 years to study hydrodynamic phenomena at the extreme energy densities produced in the hydrodynamic stage of a nuclear detonation (before criticality). Traditionally this data, obtained in non-nuclear tests, has supplemented that available from underground nuclear tests.

With the advent of the Comprehensive Test Ban Treaty (CTBT), assurance of the safety and reliability of the U.S. nuclear stockpile in the absence of underground testing requires the development of high resolution pulsed radiography systems capable of obtaining multi-axis, multi-pulse data in a single dynamic test. The ultimate goal of this Advanced Hydrotest Facility (AHF) is to produce a high-resolution radiographic movie of a dynamic test object. Achievement of this goal requires the development of a number of new technologies including accelerators, converters, beam steering/optics, and detectors which make up the AHF system, as well as the computational tools needed to interpret and visualize the data. This paper reviews accelerator technologies proposed for AHF which are currently under development by the DOE laboratories at LLNL, LANL, and SNL.

2. TECHNOLOGY APPROACHES

There are presently two conceptual approaches to AHF radiography, the traditional x-ray source produced by the interaction of a beam of (12 - 40 MeV) electrons with a high Z "converter" target, and a newer approach using a pulsed beam of (25 - 50-GeV) protons to directly irradiate the test object, which are then imaged by an innovative magnetic lens system. Both approaches must be capable of penetrating the high density test object and achieving the required spatial and temporal resolutions to resolve phenomena of interest. The resulting radiographic source requirements for each approach are given in Table 1.

Table 1: AHF Radiographic Source Requirements

Parameter	X-ray	Proton
Pulse length (ns)	≤ 50	≤ 50
Resolution at object (mm)	0.5 - 1.0	0.5 - 1.0
Equivalent flux - kRads @ 1m - protons/sec	 1 - 2 -	 - 10^{17}
Number of pulses	5 - 10	5 - 10
Number of views (axes)	4 - 12	4 - 12
Pulse separation (μs)	0.2 -15	0.2 - 15
Temporal coverage (μs)	1.5 - 75	1.5 - 75

2.1 X-Radiography Approaches

The U.S. hydrodynamic x-radiography program has traditionally used electron linacs such as the 20-MeV Phermex rf-linac at LANL, and the 18-MeV FXR single-pulse, linear induction accelerator (LIA) at LLNL. For AHF, LLNL has proposed a 20 - 40 MeV, 3 - 6 kA, high repetition rate, solid-state modulator driven LIA, with injector and cavity designs closely related to an advanced LIA being developed for the Dual Axis Radiography Hydrotest Facility (DARHT) now being built at LANL. [1]

* Work supported by Sandia National Laboratories under Subcontract No. AV-0973

An alternate x-ray source based on high current, inductive voltage adder (IVA) technology developed for weapon effects simulation has been proposed by SNL. Pulsed power-based x-ray sources were first developed and have been used extensively by the British Atomic Weapons Establishment (AWE) for hydrotest radiography. These machines have typically been < 10-MeV in energy, but the Sandia-developed IVA technology has extended the capabilities of these accelerators to 20 MeV in the HERMES III accelerator. The IVA AHF proposal is an extension of a pulsed power radiography concept developed as one of the options for DARHT. [2]. For AHF, SNL has proposed a 12-MeV, 60-kA, 50-ns pulse length IVA.

2.2 Proton Radiography

Proton radiography may be capable of measuring both mass density and the atomic number of materials in the radiographed object. For AHF, LANL has proposed a 25 - 50 GeV proton synchrotron fed by an 800-MeV linac injector similar to LANSCE. The required beam flux is 5 x 10^{12} protons/pulse. A unique magnetic lens system is used to discriminate between Coulomb multiple scattering and nuclear (strong interaction) scattering effects to extract target information.

3. ACCELERATOR TECHNOLOGIES

In the following paragraphs we discuss the LLNL, SNL, and LANL - proposed accelerators for AHF in more detail, covering the unique features of each, the technology status, and the issues to be resolved.

3.1 Linear Induction Accelerator (LIA)

The demonstrated utility of LIAs for pulsed radiography accompanied by advances in solid-state modulator technology have led LLNL to develop the AHF system concept shown in Fig. 1. A 20 - 40 MeV, 3 - 6 kA accelerator produces a MHz train of pulses ranging from 200 ns to 2 μs in length. Fast kickers are used to direct the individual pulses to various beam lines and converters arranged about the object to be radiographed.

The Advanced Radiography Machine (ARM) induction accelerator cells are driven by FET-switched modulators. Prototype ARM modulators have been built and tested at LLNL. The 2-MHz, three-stage ARM-II modulator has 4,032 FETs in a series-parallel array and produces a flat-topped 45-kV open circuit voltage pulse with a maximum source current of 4.8 kA. The 10-MHz ARM III modulator, currently under development, will take advantage of the FET's active amplification region to produce arbitrary waveform shapes with a 20-kV open circuit voltage and 7.2-kA output. In both ARM II and III, a separate reset circuit is connected in parallel with the induction cell load.

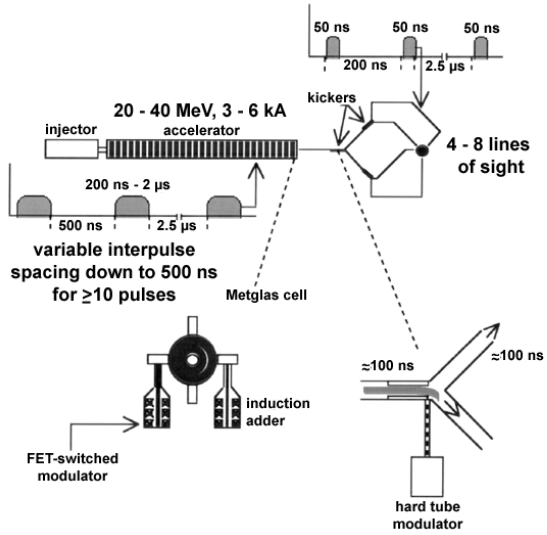

Fig. 1. Schematic of LIA AHF concept.

The LIA fast kicker system concept is shown in Fig. 2. It consists of four stripline electrodes and a fast pulser for driving the electrodes and deflecting the beam. A dc bias dipole wound over the kicker is used to steer the beam in the absence of a pulse to one of two or four desired output positions which are separated by several cm. The pulser drives the stripline electrodes to overcome the bias field and switch the beam to an output position. A drift space following the kicker amplifies the spatial separation, but not the angular separation. A DC septum magnet is used two steer the output beams apart and provide room for additional focusing magnets if necessary. A prototype kicker with two outputs has been installed on the ETA-II beamline at LLNL and preliminary tests give measured deflections consistent with theory.

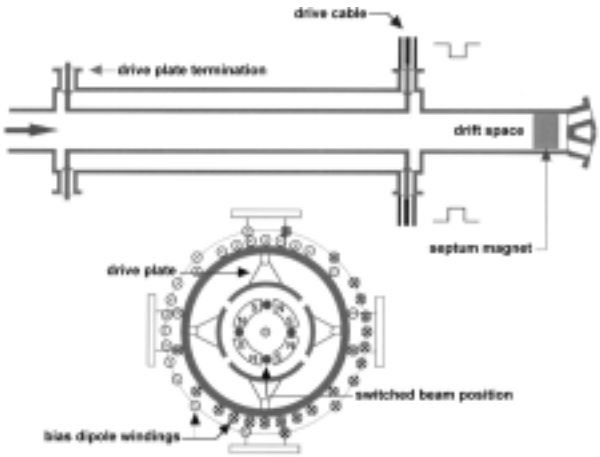

Fig. 2. LIA fast kicker system schematic.

Heating of the x-ray converter target by the incident electron beam will cause desorbtion of gas from the target, resulting in plasma formation and ion production which can defocus the incident beam and adversely impact the spot size. In addition shock waves induced in the target by the beam loading can alter the target for

succeeding pulses. LLNL is currently investigating several approaches towards alleviating these effects. In one, a retarding potential will be introduced at the target to reduce the accelerating fields produced by the beam and inhibit ion acceleration. An experiment using a modified ATA induction cell will test this concept. For multi-pulse systems, dynamic target concepts have been proposed, both linear (hypervelocity projectile or shaped charge jet) and rotating (flywheel). None of these concepts have been tested to date.

Two of the major technology issues raised regarding the LIA approach to AHF, namely the reliability of the solid-state electronics in the high voltage environment, and the feasibility of the kicker to maintain beam quality for suitable spot size have been addressed by LLNL in experiments and testing. Proof-of-principle tests have been encouraging. The remaining major issue to be addressed for the LIA accelerator concept is that of maintaining beam spot size at the target and developing a multi-pulse converter concept. The first of these will be addressed on DARHT. The second is the subject of ongoing research at LLNL, LANL, and SNL as part of the overall AHF program.

3. 2 Inductive Voltage Adder (IVA)

The SNL AHF concept is based on multiple modules incorporating the IVA pulse forming network shown in Fig. 3. The ≈ 1-μs, 3-MV output from a Marx generator is transformed through three successive pulse sharpening stages to a 1.5-MV, 60-ns pulse driving the cavities. Charging of eight metglas loaded cavities connected in series is synchronized with laser triggered gas switches to give a 12-MV voltage on the coaxial magnetically insulated transmission line (MITL). Electrons which are field emitted from the surface of the center charged conductor are trapped by the self-magnetic field of the current in the line. An ≈ 50-ns FWHM, 60-kA electron beam is produced at the cathode.

The engineering of IVA accelerators is well in hand, however the physics of the high current x-ray converter diode is complex. Electrons incident on the target are born at the cathode tip. Ions produced by beam interaction with the anode and ionization of neutral gas in the A-K gap stream counter to the electron flow. The diode geometry is designed to inhibit the flow of electrons born with large canonical angular momentum to the anode, and a 60-tesla, axial magnetic field is imposed on the cathode to inhibit the growth of ion hose instabilities in A-K region.

SNL has carried out proof-of-principle experiments at 9.2-MeV, 30-kA on the SABRE accelerator [3], achieving the anticipated 1.5-mm, FWHM x-ray spot. More recently, they have begun scaling experiments on HERMES III at 12 MeV, 150 kA; however, diode contamination on HERMES III caused premature shorting of the A-K gap. From this data summarized in Fig. 4, they have made substantial advances in understanding and modeling the physics of high current "immersed" diodes.

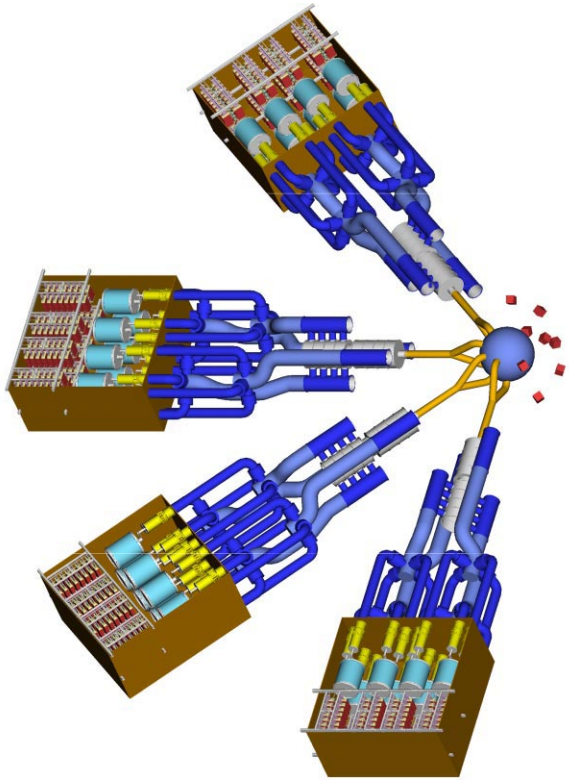

Fig. 3. IVA AHF concept.

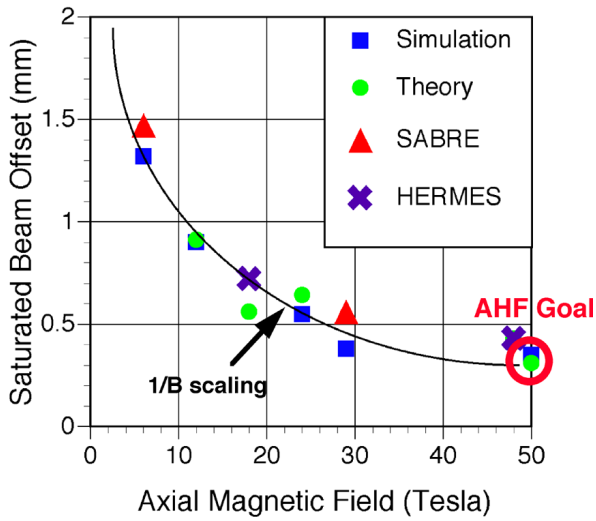

Fig. 4. IVA X-ray spot measurements and calculations.

The major issues confronting the IVA concept are the achievement of AHF parameters in the diode, the feasibility of multi-pulsing a single diode, and the feasibility of charging multiple transmission lines for a multi-axis system. To address the first issue, further experiments are planned on HERMES III. The second issue will be addressed by the construction of a Radiographic Integrated Test Stand (RITS). RITS can be configured to produce either a single 12-MeV pulse or two

6-MeV pulses along the same MITL with complete timing flexibility. The feasibility of splitting and combining pulses in multiple MITLs has been demonstrated in a number of pulsed power machines. Extension of this capability to an AHF accelerator should be straightforward, but is yet to be demonstrated.

3.3 Proton Radiography (PRAD)

The LANL concept for PRAD (Fig. 5) includes an 800-MeV H^- linac injector, a 20-GeV proton synchrotron low energy booster (LEB), and a 50-GeV high energy booster/ accumulator (main ring), and is based both on LAMPF technology and designs developed for the superconducting super collider (SSC). A fast kicker modulator extracts the beam from the LEB into the main ring, and a combination of ferrite kickers and electrostatic septum beam splitters transfers the beam bunches from the main ring into ultimately twelve separate beam lines at the test facility. The total number of 50-GeV protons stored in the main ring is $\approx 3 \times 10^{12}$. An earlier embodiment of this concept which assumed injection directly from the 800-MeV linac into a 50-GeV synchrotron was published in Ref. [4].

The rf technology assumed in the LANL PRAD concept is 45 MHz at injection (800 MeV), and is raised to 53.3 MHz at the entrance to the delivery system. Based on experience at Fermilab, the proton bunches should be less than 5 ns wide at extraction time, and if properly synchronized, the bunch pattern will be repeated once each 150 ns for as long as beam is delivered to the delivery system. At 800 MeV, a minimum 95% emittance of 4.7 π-mm-mrad is required.

From the requirements in Table I, he kicker modulator must be capable of pulsing up to 120 times on demand over a 1.5 - 75-μs interval. The ferrite kickers would be triode driven and operated with capacitors to make them resonant. Electrostatic septum splitters would be used to divide the beam transversely among two beam lines per stage.

The number of beam lines at the target is currently envisioned to be 8 - 12. Each beamline would transport up to 10 pulses to the target. In order to arrange that the beams all arrive at the target simultaneously, the lines must be equal in length. These long beam lines appear to be the dominant cost driver for the PRAD.

Interaction of the protons with the target occurs via three dominant processes:

- Multiple coulomb (elastic) scattering (MCS) from protons in the target nuclei. The MCS cross section increases with atomic number (A).
- Beam attenuation due to (inelastic) nuclear interactions with protons and neutrons in the target nuclei. The nuclear cross section decreases with increasing A.
- Energy loss due to collisions with target electrons. The cross section for this interaction increases very slowly with increasing A.

PRAD proposes to take advantage of the differing dependence of the elastic and inelastic cross sections on A to measure spatial and time resolved mass density and material composition of the target. To accomplish this, LANL has developed a two stage magnetic lens geometry (inset, Fig. 5) which differentiates between coulomb and nuclear scattered beam particles. [5] Since MCS scattered particles are deflected in the process, it is necessary to refocus them at the image plane following aperture 1. These particles are measured with the inelastic flux at the first detector. The MCS scattered protons are then stripped from the transmitted beam by aperture 2, so that the second detector measures only the beam component attenuated by nuclear scattering. Analysis of these two transmitted beam components should provide data on target mass distribution and A.

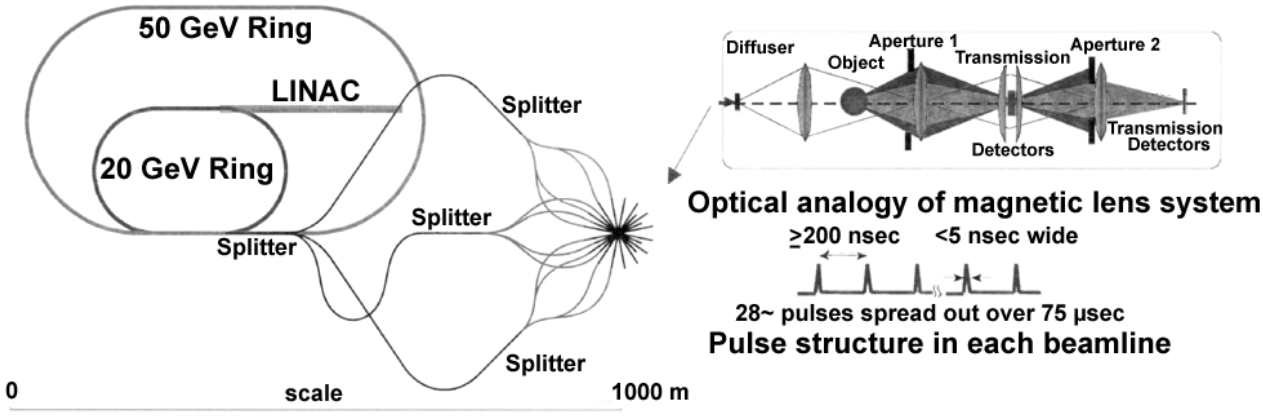

Fig. 5 Proton Radiography Concept

PRAD proof-of-concept experiments have been successfully carried out by LANL at 800-MeV on LANSCE and at 7 - 10 GeV on AGS at Brookhaven National Laboratory (BNL). Experiments at LANSCE (Fig. 6) have probed both static and dynamic targets, whereas only static target experiments have been carried out at AGS. A new beam line is currently under construction at AGS for 25-GeV, high intensity tests.

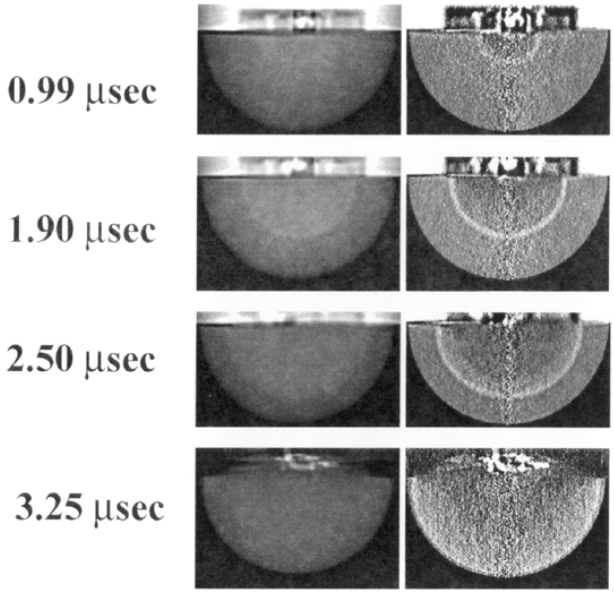

Fig. 6 Dynamic proton radiographs from LANSCE.

PRAD has the potential to significantly improve the utility of hydrodynamic radiography. The main technical issues associated with the accelerator and beam lines are the demonstration of the kicker modulator, resonant ferrite kicker, and electrostatic beam splitters required to extract and transport the beam bunches to the target. Proof-of-concept experiments must also be carried out at 30 - 50 GeV to demonstrate there are no "unknown unknowns" in the beam-target interaction that could give rise to inadequate resolution, loss of material discrimination capability, or unacceptable background.

The capability to discern material identity needs to be demonstrated. Experiments to date have shown excellent mass density resolution, but do not differentiate materials in the radiographed objects. This capability is a key feature of PRAD.

4. OUTLOOK

Achieving the AHF objective of a high-resolution radiographic movie of a dynamic test object extends the state of pulsed radiographic art well beyond present capabilities. The three approaches to developing a multi-pulse, multi-axis source each have their pluses and minuses. The LIA concept is an extension of existing systems to incorporate modern power electronics, and the IVA technology is an unproven, but potentially lower cost alternative. The major challenge facing these x-ray approaches is the development of multi-pulse converters having the radiation output and spot size necessary to do the job. PRAD is a potentially revolutionary approach which holds great promise for the long term, assuming no "unknown unknowns" are discovered, but may be too costly a system.

The DOE National Laboratories at Los Alamos, Livermore, and Sandia have embarked on a multi-year research and development effort to establish the capability of each approach and are making significant progress. The rate of progress is limited primarily by the availability of funds and facilities. DARHT, when it comes fully on line at the end of 2002, will help to address some of the multi-pulse issues in a real test environment that can only be approximated today.

5. ACKNOWLEDGMENTS

The author would like to thank George Caporaso of Lawrence Livermore National Laboratory, John McClelland of Los Alamos National Laboratory, and John Maenchen of Sandia National Laboratories for their cooperation in preparing this review paper.

REVIEW OF BEAM DIAGNOSTICS IN ION LINACS

P.N. Ostroumov
Institute for Nuclear Research of Russian Academy of Sciences, Moscow 117312, Russia

Abstract

High quality beam diagnostics have been found to be useful for rapid commissioning and good operation of ion linacs, especially for linacs containing many separate rf cavities. Our group, at the INR, has been working on the development and practical use of several beam diagnostic tools. As such, we have been engaged in beam measurements on operating ion linacs in close collaborations with several laboratories: CERN, DESY, Fermilab, GSI, KEK, SSC and TRIUMF. Experience with commissioning these new beam diagnostic devices, their use for beam measurements, and studies of the machine performance will be discussed. In particular, a description of the new tools for time-of-flight (TOF) and bunch shape measurements, and the results of beam studies using them will be reported.

The purpose of the paper is not to review all types of beam diagnostic devices to be used in ion linacs, but to familiarize the reader with several modern techniques for the measurement of ion beam parameters.

1 BUNCH SHAPE MONITORS

A device, allowing the measurement of the bunch shape (or phase spectrum) of the proton beam with high precision has been developed and built for the first time at INR [1]. The principle of operation (see fig. 1) is based on the analysis of secondary electrons produced by a primary beam hitting a 0.1 mm diameter tungsten wire (position 1 in fig. 1), to which a potential of -10 kV is applied. In a BSM the longitudinal distribution of charge of the analyzed beam is coherently transformed into a spatial distribution of low energy secondary electrons through transverse rf modulation. The temporal distribution of the secondary electrons follows the distribution of the beam being measured with a time delay <5 ps. The historical view of the BSM development is elsewhere [2].

A number of modified BSMs has been built recently with additional functional abilities. The Bunch Length and Velocity Detector (BLVD) provides a measurement of the average beam velocity as well as the bunch shape [3,4]. The traditional BSM can be modernized to measure longitudinal and transverse distributions of beam bunches including two component H^+ and H^- beams [5]. A further modification of the monitor is a 3D-BSM - a detector, which allows the measurement of the charge density distribution in a 3-dimensional space [6]. A fairly high level of mechanical design has been demonstrated during the development of BSM for the installation on the inter-tank space between the Alvarez tanks of the DESY 50 MeV Linac. The detector, called IT-BSM, fits onto the existing 2 ports on the cylindrical surface of the inter-tank space [7].

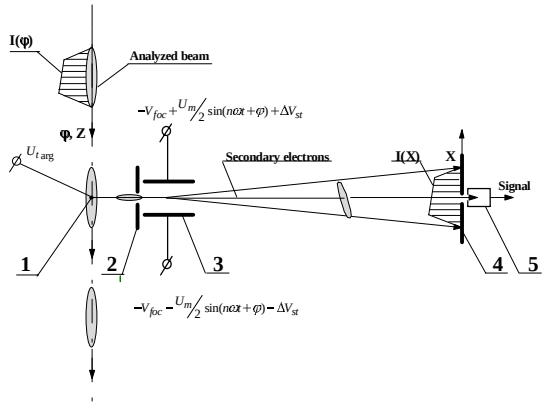

Figure 1: Principle of operation of the BSM. 1 – target, 2 – input collimator, 3 – rf deflector and electrostatic lens, 4 – output collimator, 5 – secondary electron multiplier (SEM).

BSMs have found applications in a number of accelerators [1-10]. Four BLVDs have been developed, designed and built at the INR for the meson factory linac (INR), CERN heavy ion linac [4], DESY H^- linac [7] and KEK H^- RFQ [9]. The 3D-BSM operates routinely in CERN proton linac [6]. IT-BSMs are installed at the DESY 50 MeV H^- linac. Similar IT-BSMs are being manufactured for the CERN proton linac.

1.1 Bunch Length and Velocity Detector

TOF methods have been used to measure the average velocity of beams with an rf bunch structure. Either two monitors installed a known distance apart [11] or a single movable one [12] can be used for this purpose. A BSM can be used as a movable detector [3]. When moving the BSM in a longitudinal direction one can observe a change in the bunch phase shape location by a value $\Delta\varphi_0=2\pi d/\beta\lambda$, where β is the relative velocity of the beam, λ is the wavelength of the deflector rf field and d is the distance of the monitor displacement. By measuring $\Delta\varphi_0$ and d one can find the beam velocity. For a high β it is expedient to use a higher harmonic for the deflecting field. The BLVD for the DESY Linac operates at the fourth harmonic f=810.24 MHz. For 50 MeV protons the value of the detector translation, $\beta\lambda/2$, is 60 mm. Fig. 2 shows the curves obtained during the

energy measurement output of the 50 MeV DESY linac. The phase positions of the centers of the bunches measured before and after the detector translation are practically the same and the energy found experimentally $W_{exp}=50.04$ MeV is practically equal to $W_{design}=50.00$ MeV.

The BLVDs provide energy measurements with an accuracy of about 0.15%.

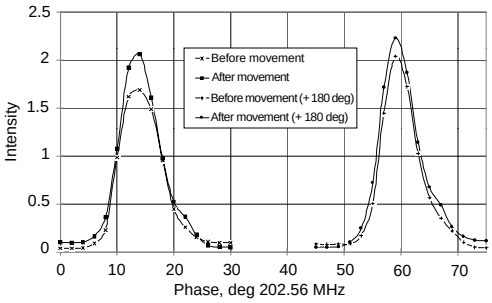

Figure 2: Bunch shapes during energy measurement.

1.2 Detectors to measure a three dimensional density distribution

In order to measure the 3-dimensional density distribution of a bunch, the following modifications of the BSM have been done: the target (pos. 1 in fig.1) is moved across the beam horizontally; the secondary electron beam is collimated by slit which is moved vertically and finally the electron beam is analyzed as in a standard BSM. Owing to the high strength of the electric field near the target, the electrons move practically horizontally and their vertical co-ordinates at the plane of the horizontal slit correspond to a short vertical section of the target wire determined by the position of the slit. Spatial distribution of the electrons after the passage through the rf deflector and drift space is measured with the 30 channel electron collector.

1.3 Phase resolution and sensitivity of BSM

The main parameter of the BSM is its phase resolution which depends upon a number of factors [1,2]. A resolution of 1° for frequencies up to 400 MHz can be achieved. The sensitivity of the BSM becomes important during the measurement of a low intensity beam or a longitudinal halo of a relatively high intensity beam. Normally electron multipliers are used in BSMs to detect secondary electrons. Typical values of the maximum gain of the multipliers for different types of the devices are ~10^5-10^8 and can be adjusted over three to four orders of magnitude by varying the HV. The multipliers can detect individual electrons so, as a matter of principle, by increasing the duration of the measurements it is possible to measure longitudinal parameters of extremely low intensity beams. Practically, the sensitivity is limited in any specific case. The minimum peak beam current we have made measurements by BSM was about 1 μA.

1.4 H^- beam measurements with a BSM

BSMs now operate with proton, H^- and lead ion beams. There are specific features of the BSM operation for each of these three types of ions. Particularly, for all type of ions there is a small fraction of high energy electrons (delta-electrons) but the number of such electrons compared to secondary ones is negligible and there is no real influence on operation of the bunch shape monitors. As for negative hydrogen ion beams, the electrons detached from the ions in a target can perturb the results of the measurements. An experimental study of the influence of detached electrons has been carried out during the commissioning of the DESY BSMs and KEK BLVD. In fig. 3 the bunch shape of the 30 MeV H^- beam is shown. The right bump in the figure is caused by the influence of the detached electrons. The secondary electrons can be separated from the detached electrons using a simple spectrometer located on the path of electrons to the electron beam detector [10].

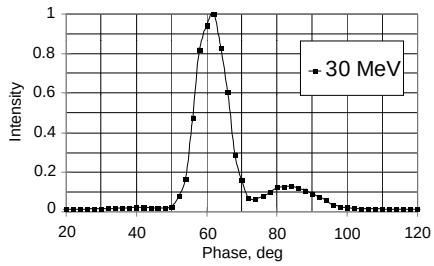

Figure 3: Bunch shape of 30 MeV H^- beam.

Further studies of the H^- beam have been made on the KEK 3 MeV RFQ with the help of a BLVD. In order to avoid the contribution of the detached electrons a 1 μm aluminum foil has been installed upstream of the BLVD wire target. The passage of the H^- beam through the foil produces a proton beam without any change of the longitudinal charge distribution. In order to measure the bunch shape in a wide dynamic range the measurements have been done with different gains of the SEM tube using the calibration curve. The longitudinal density distributions for H^- and proton beams are similar except for the halo region. Fig. 4 shows the particle fraction with respect to the phase extension for H^- and proton bunches. The proton beam contains much less particles in the halo, but still has a long tail. The

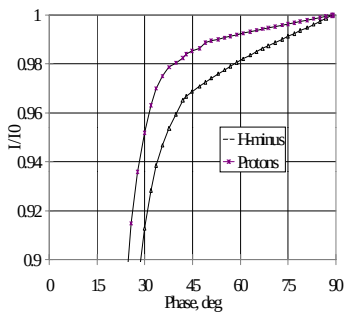

Figure 4: Particle fraction as a function of phase half-width for H– and proton

background for the proton beam is connected with a systematic error due to the electron beam interaction with the edge of collimator (pos. 2 in fig. 1) [9].

2 TRANSVERSE PARTICLE DENSITY MEASUREMENT

The use of high intensity beams for the irradiation of targets near the melting temperature requires control of the transverse beam density. The measurement of the profiles is not enough. As was mentioned the 3D-BSM could measure the density in three-dimensional space and the particle distribution on the transverse cross-section can be obtained by the integration along the longitudinal coordinate. However, the 3D-BSM has relatively small transverse aperture ~10x10 mm^2. For the measurement of the transverse particle density distribution a detector has been developed [13]. The electrons are produced due to the interaction of primary beam with the thin wire which is under negative potential. The electrons move on orbit in uniform magnetic field applied perpendicularly to the beam pipe axis. The secondary electrons are focused by electrostatic lenses in the vertical plane and by the magnetic field in the horizontal plane. The electron density distribution in the horizontal direction is transformed without distortion to the collector which is the multi-channel plate and located outside of beam pipe. The density distribution in the vertical direction is obtained with the help of wire movement along the vertical coordinate. The detector is installed in the 750 keV injection line of the MMF linac and an example of a beam density distribution is shown in fig. 5.

Another type of the particle transverse density measuring device is a residual gas monitor which is used on many accelerators. In Atomic Energy Institute, Moscow, this type of monitor has been modernized by adding an electrostatic analyzer which gives the possibility to observe on-line the density distribution of the particles [14]. The ions created in the residual gas are accelerated by the applied electric field and are collected by the multi-channel plate. The electrons at the exit of the multi-channel plate produce an image on the phosphor. After extraction from the beam pipe the trajectory of the residual ions is governed by the 45° electrostatic bend. Therefore the image on the phosphor directly corresponds to the density distribution of the primary beam. The use of ions, not electrons, allows one to deal with the signals with very low noise. The image from the phosphor is viewed by a CCD camera and is digitized. The residual ion beam current is directly proportional to the stopping power $d\varepsilon/dx$. The minimum collector current density which can be measured with good signal/noise ratio is ~10^{-16} A/mm^2. For example, for a 600 MeV proton beam with cross-section ~25 mm^2 the minimum peak current which can be observed by a residual gas detector at vacuum pressure of 10^{-6} torr is ~0.7 μA.

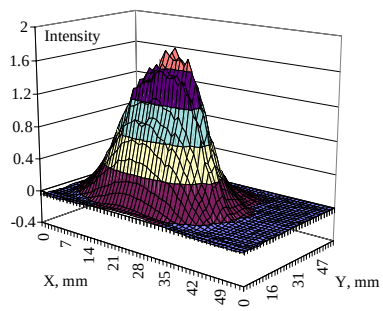

Figure 5: Transverse density distribution on 750 keV injection line of the MMF linac.

This type of monitor can be applied for all type of ions in wide energy range from several keV/n to hundreds of MeV/n. The range of beam current being studied is from nanoamps to hundreds of milliamps. The spatial resolution, whether one uses electrons or the ions, is limited, as space charge perturbs the trajectory of the collecting particles. This can be greatly improved upon applying high extraction voltages and a focusing magnetic field in the same direction.

3 WIRE-SCANNERS, HARPS

The wire scanners and harps are applied in all type of linacs. The use of wire-scanners is preferable for many reasons, but the harps are best for quick measurements in one beam shot. The spatial resolution of wire-scanners can reach a micrometer and with fast electronics, bunches can be observed individually. Their great sensitivity followed by the multi-gain amplifier allows the study of halos [15].

Carbon or SiC wires with a diameter > 0.002" are mostly used for high intensity beam diagnostics up to 1 mA average current for a 800 MeV beam. The wire scanners and harps must satisfy the following main specifications: 1) Multiple scattering of the primary must be small; 2) High vacuum; 3) Must not be destroyed by thermal expansion; 4) Must not melt; 5) Must be strong enough to withstand shock waves due to sudden vacuum failures; 6) Cooling is by radiation – the emissivity should be high; 7) The thermionic emission must be a small fraction of the secondary emission current. There are additional features in the design of scanners and harps for heavy ion [16].

4 TIME-OF-FLIGHT MEASUREMENTS

In a multi-cavity rf linac the measurements of relative as well as absolute energy is required. For this purpose TOF measurements are widely used [11]. The beam energy is calculated through the beam velocity. The TOF device includes a phase monitor and signal processing circuit. As a phase monitor coupling loop, capacitative pickup [16], wall current monitor [17], directional coupler [18] and rf resonators [19-21] have been used. The latter provides most sensitive measurements, a phase monitor capable to measure 1nA beam current has been reported [20,21].

In rf linacs the TOF is calculated through the measurements of phase difference. For relative

measurements it is enough to observe the phase difference between the induced signals. However to obtain the absolute beam energy the calibration is required. For calibration purposes two detectors must be excited by an external rf in phase. The relative velocity of bunched beam is calculated as $\beta = \frac{L}{\lambda}\frac{1}{n+\Delta\varphi/2\pi}$, where L is the distance between the monitors, $\Delta\varphi$ is the phase difference of the induced signals with wavelength λ, n is determined as a integer of $L/\beta_0\lambda$. The latter means that the beam velocity β_0 must be known roughly. The rough value of the absolute velocity β_0 can be found, for example, using one more phase probe [16] located closer to the other in order to have $n=0$. If a chopper exists in the linac one can produce single bunch mode for the measurement goals [17].

The precision of the velocity measurements is found as $\frac{\delta\beta}{\beta} = \frac{\delta L}{L} + \frac{\delta(\Delta\varphi)}{2\pi n + \Delta\varphi}$. By the selection of long enough distance the first term can be made negligibly small. An accuracy of phase measurement depends on processing circuit. Careful design of phase detectors can provide a precision of ~1° at a frequency of ~1 GHz. TOF measurements can be applied for beams with kinetic energy close to the rest energy of the particle. Relative energy measurements can be performed with resolution as low as $6\cdot10^{-5}$ [21], for absolute measurements the precision is $\sim10^{-3}$.

5 EMITTANCE MEASUREMENT

Conventional slit-collector measurements give detailed information about the emittance which may be neither elliptical nor symmetrical. They may be extended up to perhaps 200 MeV before multiple scattering in the slit ruins the profile resolution. Several methods have been reported in which the emittance is assumed to be elliptical (see references in [16]). For low energy beams <10 MeV/n the conventional method of the emittance measurement has been modified by using a phosphor screen instead of the particle collector. The beam image after the slit or pepper-pot is directly digitized by a CCD camera connected to a personal computer. This technique produces emittance during single shot and is successfully used for proton [22] or heavy ion beams [23,24].

New opportunities are being discovered for H^- beam diagnostics because of the simplicity of H^- beam neutralization by the laser beam [25]. H^0 transverse emittances are measured downstream of an H^- beam bending. To measure the longitudinal emittance the detached electron beam is analyzed.

5.1 Emittance measurement of 50 MeV H^- Beam

As an example, we describe a technique to measure the emittance in all 3 planes at the output of the DESY 50 MeV H^- linac. At the output of the linac the ellipse in the longitudinal phase space is assumed as a canonical shape. Then the longitudinal emittance is determined as a multiplication of the momentum spread and phase width. The longitudinal phase distribution has been measured with the help of a BLVD located close to the exit of the last tank. The momentum spread is measured by magnet spectrometer which operates on-line owing to a target converting H^- to protons. Owing to a narrow target (28 μm wire) and unit transformation of the transverse emittance from the target to the "momentum" harp location, the effect of the transverse emittance on the momentum measurement resolution is negligible. The horizontal profile determined by the harp well corresponds to the beam momentum distribution with a conversion ratio $\Delta p/p$ = 0.0526·x, where $\Delta p/p$ is in [%] and x is in [mm]. The spatial resolution of the "momentum" harp has been improved by sweeping the beam center at the harp position by the setting of several values of the bending magnetic field. Energy spread and phase spectrum measured at the signal level of 98% result in an emittance value of 2104 π·keV·deg, which is 5.05 times larger than the rms value.

For fast measurement of the transverse emittance on there is a procedure of the emittance restoration based on three profiles measured by the harps [26]. To improve the spatial resolution of the harps we have measured the beam profiles by sweeping the beam position on the harps. To produce a beam center deviation the steering magnets located upstream of the harps have been calibrated. The rms value of the density distribution has been calculated from 20-30 measurements on each harp. Emittance calculation has been done by using the least squares method. Table 1 shows rms emittance in all 3 planes.

5.2 Emittance measurement of 50 MeV Proton Beam

The proton Linac at CERN serves as an injector to the booster and operates with a peak current up to 170 mA in routine operation. For the emittance measurement during one shot in all 3 planes special equipment has been developed [27]. The transverse emittances are measured by the help of two kicker magnets for the sweeping of the beam position on the slit. Downstream of the slit a quadrupole doublet allows the adjustment of the resolution on the collector. Longitudinal measurement equipment contains two 54.3° bending magnets to provide the spectrometer function, rf cavity located downstream of the first spectrometer and slit. The rf cavity tuned to the linac frequency works as a rotating lens in the longitudinal phase space transforming the phase dispersion into an energy dispersion which is analyzed by the second spectrometer magnet. After the installation of the 3D-BSM 90 cm behind the last Alvarez tank, the measurements of both transverse and longitudinal rms emittances became available. The measurement of the transverse rms

emittance with the help of the 3D-BSM is performed by several (more than 3) settings of the quadrupole gradients and taking measurements for the calculation of rms radius. In table 2 the rms emittance data for a 170 mA proton beam is listed. The measurements performed by direct measurement of the emittance area in the phase space and by the help of 3D-BSM are consistent. The longitudinal rms emittance is determined as a multiplication of rms phase width by the rms energy spread from the spectrometer measurement.

HALO FORMATION IN INTENSE LINACS

Chiping Chen

Abstract

Halo formation is an important issue in the development of high-power accelerators. In this paper, we discuss from the point of view of beam transport the mechanisms of halo formation in root-mean-square (rms) matched, high-brightness, space-charge-dominated beams in periodic focusing transport systems. In particular, it is shown theoretically that an important mechanism of halo formation in rms matched beams is due to chaotic particle motion induced by charge-density fluctuations about the ideal uniform density profile transverse to the direction of beam propagation. Experimental evidence is presented in support of the theoretical predication of halo formation in rms matched beams. Finally, to gain a better understanding of the equilibrium and stability properties of periodic focused intense charged particles, a rigid-rotor Vlasov equilibrium is discussed, and the effect of beam rotation on the phase space structure is studied.

1 INTRODUCTION

The problem of halo formation in intense charged-particle beams has been the subject of recent vigorous theoretical, computational and experimental investigations [1]-[19]. It is of fundamental importance in the development of next generation high-power accelerators for basic scientific research in high-energy and nuclear physics as well as for a wide variety of applications ranging from heavy ion fusion, accelerator production of tritium, accelerator transmutation of nuclear waste, spallation neutron sources, high-power microwave sources, to high-power free-electron lasers. In such high-power accelerators, beam halos must be controlled in order to keep beam losses at minimum.

It is well-known that a space-charge-dominated beam can develop a sizable halo if there is a root-mean-square (rms) mismatch between the beam and the focusing field [2]-[4],[6],[9]-[11]. The mechanism for halo formation in rms mismatched beams has been well described in the particle-core model [3, 6]. When there is a sizable mismatch, the halo can contain a substantial fraction (up to 15%) of the entire beam.

Recently, it has been shown theoretically [5, 8, 14, 15] that in periodic focusing transport systems, charge density fluctuations in rms-matched space-charged-dominated beams can also cause halo formation. An important mechanism of halo formation in rms matched beams has been identified with chaotic particle motion and nonlinear resonances occurring in the vicinity of the boundary of phase space occupied by the particles in the beam core. Invariant (Kolmogorov-Arnold-Moser) surfaces [20] play an important role in confining halo particles transverse to the direction of beam propagation. Because halos in rms matched beams are relatively tenuous compared with those in rms mismatched beams, experimental observations of halos in rms matched beams require detectors with a wide dynamic range. A recent observation of a halo in an rms matched potassium K^+ ion beam at the 2-MV Heavy Ion Beam Injector Experiment at Lawrence Berkeley National Laboratory (LBNL) [13] provides the first experimental evidence in support of the theoretical prediction [5, 8, 14, 15] of halo formation in rms-matched beams in periodic focusing transport systems.

For beam propagation through a *periodic* focusing transport system with the periodicity length S and the vacuum phase advance σ_0, a *space-charge-dominated* beam satisfies the condition [15]

$$\frac{SK}{4\sigma_0\varepsilon} > 1, \tag{1}$$

whereas an *emittance-dominated* beam satisfies the condition

$$\frac{SK}{4\sigma_0\varepsilon} \ll 1. \tag{2}$$

In Eqs. (1) and (2), $K = 2q^2N_b/\gamma_b^3\beta_b^2mc^2$ is the normalized beam perveance, ε is the unnormalized rms emittance of the beam, q and m are the particle charge and rest mass, respectively, N_b is the number of particles per unit length, $\beta_b c$ and γ_b are the characteristic velocity and relativistic mass factor of the particles, respectively, and c is the speed of light *in vacuo*. For an electron beam,

$$\frac{SK}{4\sigma_0\varepsilon} = 2.9\times10^{-5}\frac{1}{\sigma_0}\left(\frac{S}{\varepsilon_n}\right)\frac{I_b}{\gamma_b^2\beta_b^2}, \tag{3}$$

where I_b is the electron beam current in amperes, $\varepsilon_n = \gamma_b\beta_b\varepsilon$ is the normalized rms emittance in meter-radians, and S is in meters. For an ion beam,

$$\frac{SK}{4\sigma_0\varepsilon} = 1.6\times10^{-8}\frac{1}{\sigma_0 A}\left(\frac{q}{e}\right)\left(\frac{S}{\varepsilon_n}\right)\frac{I_b}{\gamma_b^2\beta_b^2}, \tag{4}$$

where A and q/e are the atomic mass and magnitude of the charge state of the ion, respectively, I_b is the ion beam

current in amperes, $\varepsilon_n = \gamma_b\beta_b\varepsilon$ is the normalized rms emittance in meter-radians, and S is in meters.

In this paper, we review recent theoretical, computational and experimental investigations of halo formation in high-brightness, space-charge-dominated beams that are rms matched but not fully matched (in terms of phase-space distributions) in periodic focusing transport systems. In particular, it is shown theoretically that the mechanism of halo formation in rms matched beams is due to chaotic particle motion induced by charge-density fluctuations about the ideal uniform density profile transverse to the direction of beam propagation. Experimental evidence is presented in support of the theoretical predication of halo formation in rms matched beams. Finally, to gain a better understanding of the equilibrium and stability properties of periodic focused intense charged particles, a rigid-rotor Vlasov equilibrium is discussed, and the effect of beam rotation on the phase space structure is studied.

2 MECHANISM OF HALO FORMATION IN RMS MATCHED BEAMS

It has been shown theoretically [5, 8, 14, 15] that in periodic focusing transport systems, charge density fluctuations in rms-matched space-charged-dominated beams can also cause halo formation. The mechanism of halo formation in rms matched beams has been identified with chaotic particle motion [20] and nonlinear resonances occurring in the vicinity of the boundary of phase space occupied by the particles in the beam core.

To illustrate the mechanism of halo formation in rms matched beams, we consider test-particle motion in the field configuration consisting of the self-electric and self-magnetic fields of a thin, continuous, intense charge-particle beam and the periodic solenoidal focusing field

$$\mathbf{B}_0(\mathbf{x}) = B_z(s)\mathbf{e}_z - \frac{1}{2}B_z'(s)(x\mathbf{e}_x + y\mathbf{e}_y). \qquad (5)$$

Here, $\mathbf{e}_x$ and $\mathbf{e}_y$ are unit Cartesian vectors perpendicular to the beam propagation direction, $s = z$ is the axial coordinate, $x\mathbf{e}_x + y\mathbf{e}_y$ is the transverse displacement from the beam axis at $(x, y) = (0, 0)$, the superscript 'prime' denotes d/ds with $B_z'(s) = dB_z(s)/ds$, and the axial component of magnetic field satisfies

$$B_z(s + S) = B_z(s), \qquad (6)$$

where S is the axial period of the focusing field.

The self-electric and self-magnetic fields [21] are readily determined from the steady-state Maxwell equations, assuming the following transverse density profile (Fig. 1)

$$n_b(r, s) = \begin{cases} \hat{n}_b + \delta\hat{n}_b[1 - 2r^2/r_b^2], & r < r_b(s), \\ 0, & r > r_b(s), \end{cases} \qquad (7)$$

where $r_b(s) = r_b(s + S)$ is the outermost radius for the rms-matched beam core, $\hat{n}_b(s) = N_b/\pi r_b^2(s)$ (with N_b being the number of particles per unit axial length), and $\delta\hat{n}_b(s) = \delta N_b/\pi r_b^2(s)$ is a measure of beam density fluctuations. The outermost beam radius $r_b(s)$ can be determined from the rms envelope equation. Note that the Kapchinskij-Vladimirskij (KV) beam equilibrium [22] corresponds to $\delta\hat{n}_b = 0$.

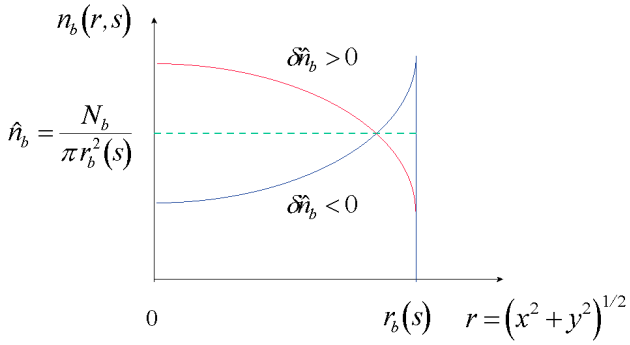

Figure 1: Transverse density profile described by Eq. (7).

It can be shown that in the Larmor frame of reference [23], the transverse equations of motion for a test particle in the combined periodic solenoidal and self fields are expressed as [15]

$$\frac{d^2x}{ds^2} + \kappa_z(s)x + \frac{q}{\gamma_b^3\beta_b^2mc^2}\frac{\partial}{\partial x}\phi^s(x, y, s) = 0, \qquad (8)$$

$$\frac{d^2y}{ds^2} + \kappa_z(s)y + \frac{q}{\gamma_b^3\beta_b^2mc^2}\frac{\partial}{\partial y}\phi^s(x, y, s) = 0, \qquad (9)$$

where $\kappa_z(s) = [qB_z(s)/2\gamma_b\beta_bmc^2]^2$, and the self-field potential ϕ^s is defined by

$$\phi^s = \begin{cases} -q(N_b + \delta N_b)r^2/r_b^2 + q\delta N_b r^4/2r_b^4, & r < r_b(s), \\ -q(N_b + \delta N_b/2) - 2qN_b\ln[r/r_b], & r > r_b(s). \end{cases} \qquad (10)$$

Figure 2 shows a Poincare surface-of-section plot in the phase space (x, x') for 2000 test-particle trajectories moving through 20 periods of a step-function lattice with filling factor η for a beam with a hollow density profile. The test particles are loaded initially on a circle defined by

$$W(x, y = 0, x', y' = 0, s = 0) = 1, \qquad (11)$$

where W is defined in [15]. The Poincare surface-of-section plot is generated by plotting the positions and momenta of the test particles as they pass through the lattice points $s/S = 0, 1, 2, \cdots, 20$. In Fig. 2, x and x' are scaled by the multiplication factors $r_b^{-1}(0)$ and $r_b(0)x'/4\varepsilon_m$, respectively, where $\varepsilon_m = (1 + 2\delta\hat{n}_b/3\hat{n}_b - \delta\hat{n}_b^2/3\hat{n}_b^2)^{-1}\varepsilon$. There is a pair of stable and unstable fixed points at the edge of the beam, i.e., at $x/r_b = \pm 1$ in the phase space. The unstable fixed point is located inside the beam,

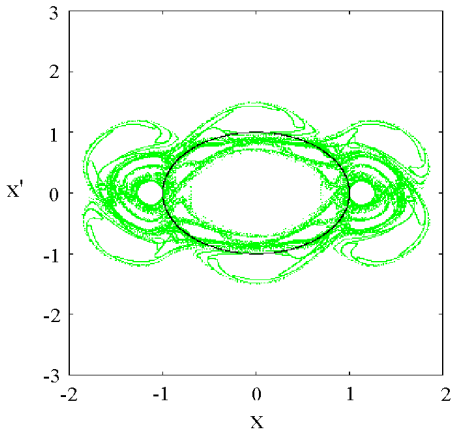

Figure 2: Poincare surface-of-section plot in the phase space (x, x') for 2000 test particles moving through 20 lattice periods. Here, the choice of system parameters corresponds to $\eta = 0.2$, $\sigma_0 = 88.8°$, $SK/4\sigma_0\varepsilon = 6.45$, and $\delta\hat{n}_b/\hat{n}_b = -0.95$.

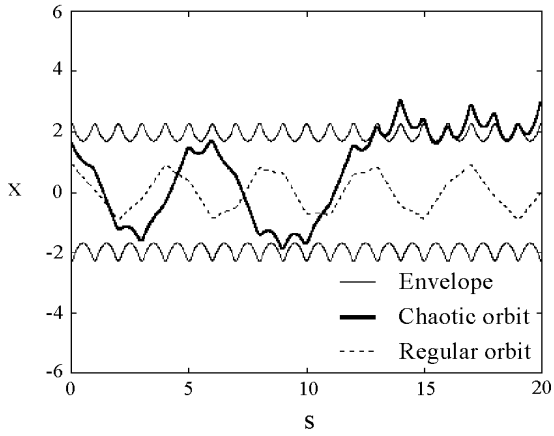

Figure 3: Shown as the dashed and bolded solid curves are, respectively, regular and chaotic trajectories for the same choice of system parameters shown in Fig. 2. Also shown as the two solid curves are the outermost periodic boundaries of the rms-matched beam core. The chaotic trajectory intersects the beam core envelope approximately at the thirteenth period of the focusing channel.

whereas the stable fixed point and associated island are located outside of the beam. Because of the symmetry in the underlying equations of motion (8) and (9), there is another pair of stable and unstable fixed points at $(x, x') \cong (-1, 0)$. These fixed points, which correspond to periodic solutions of the equations of motion (8) and (9), are induced by excessive space-charge at the edge of the hollow beam. Associated with the two unstable fixed points is a thin chaotic layer (separatrix) which occupies both the region with $W < 1$ and the region with $W > 1$ in the phase space. Particles in this thin chaotic layer can cross the beam envelope, forming a halo around a dense core of beam determined by $W \leq 1$ in the phase space. Although the chaotic layer has a sizable excursion along the x'-axis, it extends to $x/r_b \cong 1.8$ along the x-axis. Therefore, the halo size in this case is about 1.8 times the beam core radius. Because the chaotic layer is thin, the particle density in the halo region is expected to be very tenuous compared with that in the core region.

Shown in Fig. 3 as the dashed and bolded solid curves are, respectively, examples of regular and chaotic trajectories for the same choice of system parameters shown in Fig. 2. In Fig. 3, s is scaled by the multiplication factor S^{-1}, and both x and r_b are scaled by the multiplication factor $(4g\varepsilon S)^{-1}$, where $g = (1 - \delta\hat{n}_b/\hat{n}_b)^{-1}$. The regular trajectory is initialized well inside the beam envelope with $x' = 0$, whereas the chaotic trajectory is initialized near the unstable fixed point with $x' = 0$. Also shown in Fig. 3 as the two solid curves are the outermost periodic boundaries $\pm r_b(s)$ of the rms-matched beam core. The chaotic trajectory intersects the beam core envelope approximately at the thirteenth period of the focusing channel.

3 COMPARISON BETWEEN THEORY AND EXPERIMENT

Experimental evidence of halo formation has been observed in a space-charge-dominated potassium (K^+) ion beam in the 2-MV Heavy Ion Beam Injector Experiment at the Lawrence Berkeley National Laboratory (LBNL) [13]. In this experiment, a potassium ion beam was extracted from a 1-MV diode. The beam was then accelerated and transversely focused by four electrostatic quadrupoles (which correspond to two periods in a periodic focusing transport system). The four electrostatic quadrupoles add a total of 1 MeV to the ions at the end of the injector. Table 1 gives the basic system parameters measured at the end of the injector. The measured density profile at the end of the injector shows a density depression on the beam axis, and a halo extending 1.47 times the core envelope. The halo was tenuous, containing about 2% of the ions in the beam. A detailed description of the experimental setup and measurements can be found in [13].

A comparison between theory and experiment has been made. In the theoretical analysis, the electrostatic quadrupoles are treated as an alternating-gradient focusing system but the effect of acceleration is ignored. The elliptical cross section of the beam is incorporated. The transverse beam density profile is assumed to be

$$n_b(x, y, s) = \begin{cases} \hat{n}_b + \delta\hat{n}_b(1 - 2T), & T < 1, \\ 0, & T > 1, \end{cases} \tag{12}$$

where $T(x, y, s) = x^2/a^2(s) + y^2/b^2(s)$, and $a(s) = b(s + S)$ and $b(s) = b(s + S)$ are the outermost core envelopes in the x- and y-directions, respectively. For an rms matched

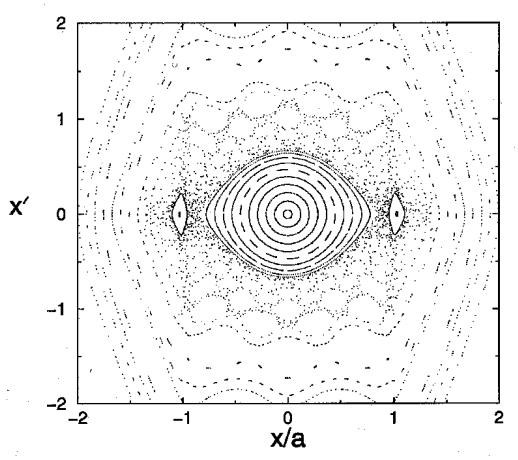

Figure 4: Poincaré surface-of-section plot in (x, x') phase space for 41 test particles in a nonuniform density beam. Here, the choice of system parameters corresponds to $\sigma_0 = 70°$, $\eta = 0.5$, $SK/4\varepsilon_x = 16$, $\varepsilon_x = \varepsilon_y$, and $\delta\hat{n}_b/\hat{n}_b = -0.2$.

beam, $a(s)$ and $b(s)$ are determined from the rms envelope equations.

Figure 4 shows the overall phase space structure for test-particle motion in a Poincaré surface-of-section plot for the nonuniform density beam. The choice of system parameters used to generate Fig. 4 is listed in Table 2, corresponding to the basic system parameters listed in Table 1. Shown in Fig. 4 are the trajectories

Table 1. Basic Parameters of the LBNL Experiment

$SK/4\sigma_0\varepsilon_x$ $(\varepsilon_x = \varepsilon_y)$	13.1
$\delta\hat{n}_b/\hat{n}_b$	-0.2

of 41 particles as they pass through the lattice points at $s = 0,\ S,\ 2S, \cdots, 400S$. The initial conditions for these particles are: $x(0)/a(0) = 0.1n$, $y(0) = 0$, and $x'(0) = y'(0) = 0$, where $n = 0, \pm 1, \cdots, \pm 20$. Note that for $y(0) = 0 = y'(0)$, the motion in (x, x') phase space is decoupled completely from that in (y, y') phase space. In Fig. 4, the vertical axis is scaled by the dimensionless quantity $(S/4g\varepsilon_x)^{1/2}$. There are two stable period-one orbits near the edge of the beam at $(x, x') \cong (\pm a, 0)$. These stable period-one orbits are accompanied by two *unstable* period-one orbits located approximately at $(x, x') \cong (\pm 0.9a, 0)$. It is the chaotic separatrix associated with the unstable period-one orbits that is responsible for particle escape from the beam interior to form a halo.

For beam propagation through several lattice periods, the Kolmogorov-Arnold-Moser (KAM) surface [20] at $(x, 0) = (\pm 1.42a, 0)$ is expected to determine the halo size. Therefore, the halo size in the x-direction is estimated to be $x_{\text{halo}} = 1.42a$, which is in good agreement with the measured halo size $x_{\text{halo}} = 1.47a$ [13]. Detailed numerical studies of the beam dynamics with a properly chosen initial distribution function show that a relatively small fraction (4%) of the particles in the beam become halo particles after five lattice periods, and the experimental measurements indicate that about 2% of the particles become halo particles in one lattice period.

4 RIGID-ROTOR VLASOV EQUILIBRIUM

The results presented in Secs. 2 and 3 show that charge-density fluctuations about the ideal uniform density profile induce chaotic particle motion and halo formation in rms matched space-charge-dominated beams in periodic focusing transport systems. Therefore, it is important to gain a better understanding of the equilibrium and stability properties of periodically focused beams. In this regard, we discuss a rigid-rotor Vlasov equilibrium [24, 25] discovered recently for intense beam propagation through a periodic solenoidal magnetic field.

The rigid-rotor Vlasov equilibrium distribution function can be expressed as [24, 25]

$$f_b^0(R, P_R, P_\Theta)$$

$$= \frac{N_b}{\pi^2 \varepsilon_T}\delta\left[P_R^2 + \frac{P_\Theta^2}{R^2} + R^2 + 2\omega_b P_\Theta - (1-\omega_b^2)\varepsilon_T\right]. \tag{13}$$

In Eq. (13), $\omega_b = \text{const.}$ $(-1 < \omega_b < 1)$ is a parameter measuring beam rotation relative to the Larmor frame. The normalized canonical phase-space variables $(R, \Theta, P_R, P_\Theta)$ are related to the Larmor-frame phase-space variables $(r, \theta, P_r, P_\theta)$ by

$$R = \frac{\sqrt{\varepsilon_T}}{r_b(s)}r, \quad \Theta = \theta, \tag{14}$$

$$P_R = \frac{1}{\sqrt{\varepsilon_T}}\left[r_b(s)\frac{d}{ds}r - r\frac{d}{ds}r_b(s)\right], \quad P_\Theta = P_\theta. \tag{15}$$

It can be shown that $n_b(r, s) = \int dx'dy' f_b^0$ is indeed identical to the step-function density profile defined in Eq. (7) with $\delta\hat{n}_b = 0$. It can also be shown that the well-known KV equilibrium corresponds to the special case with $\omega_b = 0$. Finally, a recent analysis [26] shows that beam rotation with $\omega_b \neq 0$ reduces the degree of chaotic behavior in phase space.

5 CONCLUSIONS

We have discussed several important mechanisms of halo formation in high-brightness, space-charge-dominated beams from the point of view of beam transport. In particular, it has been shown theoretically that the mechanism of halo formation in root-mean-square (rms) matched beams is due to chaotic particle motion induced by charge-density fluctuations about the ideal uniform density profile transverse to the direction of beam propagation. Experimental evidence is presented in support of the theoretical predication of halo formation in rms matched beams. Finally, to gain a better understanding of the equilibrium and stability properties of periodic focused intense charged particles, a rigid-rotor Vlasov equilibrium is discussed, and the effect of beam rotation on the phase space structure is studied.

RF PULSE COMPRESSION FOR LINEAR COLLIDERS

H. Mizuno
KEK, High Energy Accelerator Research Organization
Oho, Tsukuba-shi, Ibaraki-ken 305, JAPAN

Abstract

In the high gradient electron linacs at X or S band, a conventional klystropn driver cannnot supply short pulses that a linear collider operation requires. Therefore, some RF pulse compression system that can compress the RF pulse length and at the same time heighten the peak RF power become necessary. Such an RF pulse compression system has been already utelized successfully in the S-band electron linacs of several laboratories. In the studies of the X-band linear accelerators, such RF pulse compression systems, SLED (SLAC Linac Energy Doubler) [1] or its direct successors SLED2 [2] and VPM (VLEPP Pulse Multiplier) [3][4] were studied and developed as the RF pulse compression system for the future machines. These system are all based on the same principle that the RF pulse energy is once stored in some storage circuit (a resonance cavity or a delay line) and thereafter emitted within short time to create the shorter RF pulse. Instead of these schemes, BPC (Binary Pulse Conpression) [5] and DLDS (Delay Line Distribution System) [6] use the delay lines as the tool to make the RF pulse shorter (BPC), or to adapt the longer RF pulse into the shorter linac driving pulse (in case of DLDS). A DLDS was recently introduced as an RF pulse compression equivalent system based on the different operation principle from an ordinary pulse compression system. DLDS is expected as the RF pulse compression equivalent system for the future RF system of X-band linear colliders.

1 INTRODUCTION

As the typical example of the modern X-band linear collider, general parameters of JLC (Japan Linear Collider) are summarized in the Table 1 [7].

To achieve an accelerating gradient of ~70MeV/m or greater in an accelerating strcture with shunt impedencec of ~80Mohm/m, the RF power fed per unit length of the linear collider should be around 100MW/m or higher. Duration of the RF pulse should be 250nsec, which is the sum of the filling time of and to time length of the multi-bunch train that consist of 90 bunches each separated by 1.4 nsec.

In the JLC design, to provide a peak power up to 130MW/mto the accelerating structure, klystrons are distributed every 4-5m to feed 3-accelerating units with the RF power totaling 390MW. Clearly, such a high peak power is out of reach for a single klystron, even with the most advanced modern klystrion technologies. In addition, the required RF pulse duration of 250ns is too short to drive klystrons efficiently. Present high voltage modulators with a step-up pulse transformer can never drive a klystron with the rise time much shorter than 100ns.[7][8] Thus the klystron modulator systems will suffer from poor efficiency if it were to drive klystrons with output pulses of 250ns.

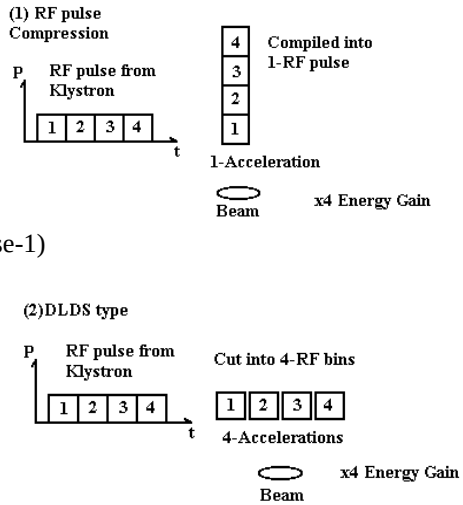
Table 1. General parameters for the next generation linear colliders

RF frequency(GHz)	11.4
Accelerating gradient(MeV/m)	
Unloaded/Loaded	76/57
Active linac length(km)	9.2
Total linac length(km)	10
Peak power /meter(MW/m)	100
Structures/power unit	6
Structure length per power unit(m)	7.8
Total number of power unit	1180
Total number of klystrons	4720
Total number of modulators	2360
Repetition rate(pps)	150
RF pulse length at str.(nsec)	250
Peak beam current(mA)	0.79
Total average RF power at Str.(MW)	34.5

Consequently, the RF power system of the X-band linear collider must supply the RF power that is shorter in pulse length and at the same time higher in peak power, than the present technology could achieve. This requirement imposes a notable change in the RF power system of the X-band linear colliders. As shown above, the energy consumption of the future collider is considered to reach to several hundred megawatts, it is quite important to supply these RF power with high conversion efficiency. Thus the major change was introduced to the X-band RF power system. It is, the introduction of the RF pulse compression stage to compress the klystron RF output pulse shorter about factor 4. This difference are due to the fact that the X-band RF power system has to deliver about factor 4 shorter RF pulse than S-band system. The most important difference between the S and X-band Rf power echnogy is that an RF pulse which dirves an X-band linac is about 4-times shorter than that of S-band case. Therefore, 4-times longer RF pulse that is created by the present klystron modulator technology limit must somehow adapted to this 4-times shorter linac driving pulse length. On this point, there is the absolute necessity of the RF pulse compression measure.[7][8]

2 RF PULSE COMPRESSION SYSTEMS

The RF pulse compression system is generally considered as the measure that can make an RF pulse shorter and higher while preserving its total RF pulse energy as much as possible. As an linac RF power sources, this condition is can be re-considered as follows. If an RF pulse that is several times longer than the linac driving pulse can drive a linac utilizing all its RF energy i.e. its longer pulse, this system has the same effct as the ordinary type pulse compression system driving a linac. Thus, the present Rf pulse compression methods can be divided into two categories. Firstly, the conventional RF pulse compression schemes such as SLED, SLED2 and VPM etc. [9] These methods are based on the same operational principle that the RF pulse are once stored in some energy storage system such as a resonnant cavity or cavity equivalent system, and later extracted as the shorter and higher RF pulse. In other words, the RF pulse is re-shaped into the shorter



case-1)

case-2)

Fig. 1. Two types of RF shortening scheme

but higher RF pulse. On the other hand DLDS and its application are based on the fact that the RF pulse are applied on the beam in the different linac position to achieve the multiple acceleration by each RF bis that are cut from the longer original RF pulse. The main important feature of this DLDS like methods are that the RF pulse is divided into several shorter RF pulses (bins) and each pulse accelerates the same beam in the different position of the linac to adjust the time delay. Fig. 1 illustrates these operation principles in case of factor 4 compression ratio for each case. The ordinary RF pulse compression is illustarted in case-1) in this Figure. Longer RF pulse from the klystron is re-shaped into the shorter and higher RF pulse using the energy store system mostly resonnant cavities. On the other hand, as illustrated in case 2), RF pulse is divided into 4 RF bins in time domain and each shorter RF bin accelerates the same beam independently instead being piled up to the higher pulse like SLED type pulse compression system. In this DLDS system the longer RF pulse from the klystron are only divided into shorter pulses and steered into the different parts of the linac to meet the identical beam. These two systems can be considered as essentially the same, because both utilizes the longer Rf pulse to drive the linac that has 4-times shorter driving pulse. And the beam also gain the energy that is 4-times more than expected from the klystron output peakpower. Thus, this second type can be also called as the RF pulse compression system of the factor 4 compression ratio.

3 SLED SLED2 & VPM (SLED-FAMILY)

The operational principle of this SLED group is illustrated in Fig. 1.[1] All of this family has the same operational principle as the original SLED operation. As shown in the figure, RF energy is once stored in the resonnant cavities and later extracted through 3-dB hybrid which steers the RF pulse into the output port direction within short period.

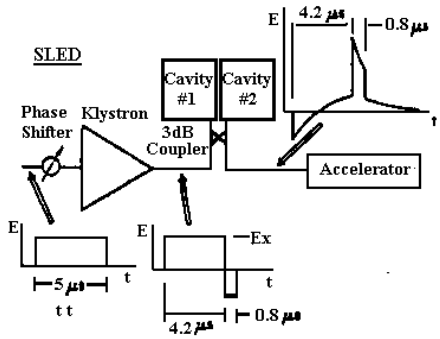


Fig. 2. Principle of operation of SLED

This kind of system necessarily has the two main causes of the energy loss in their operation process, firstly the reflection of the incoming RF pulse while the build up period especially at the early part of this stage and this reflection can never be avoided as long as the RF output pulse from the klystron are flat shape.[9] This device and the necessity of the time to build up RF energy in these storage cavity or cavities, mainly determines it's energy efficiency. The energy losses in this system are consist of following two categories, (1) The wall loss on the inner surface of the energy storage cavity, (2) the RF reflection while the storage period. and the RF energy left after extraction of the energy from the storage devices. The main part of loss in this stage, is the reflection of the input RF pulse while the build up period of the SLED operation. Thus the energy efficiency of this system is about 80% even neglecting the possible wall loss.

As illustrated above, this original SLED can only re-shape the RF pulse into the exponentially decaying pulse

waveform. However, several methods that can shape the RF pulse into a flat pulse are proposed. One is SLED2 that uses a pair of delay lines instead of the resonant cavities. Others uses the chain of the RF cavities for energy strage. One more possibility is to control the phase, amplitude or both to make a flat pulse. Detail of these sre omitted but the essential character of the system remains almost the same.[3][4]

4 BINARY PULSE COMPRESSION (BPC)

One more RF pulse compression system based on the different operational principle from these energy storage type pulse compression of the SLED family is the BPC (Binary Pulse Compression). This pulse compression system was proposed by D.Farkas and the first high power test was successfully achieved in SLAC.[10]

The operational principle of this BPC system is graphically illustrated in Fig. 3 in case of the compression factor of 4. This system is driven by two independently phased klystrons and their output pulses are divided into 4-short pulses respectively. The phase of each part of the RF pulse are coded as shown in Fig. 3. Through the 3-dB hybrid and delay lines, RF pulse trains from each klystron are combined and at the same time sterred to the two output port of the hybrid.

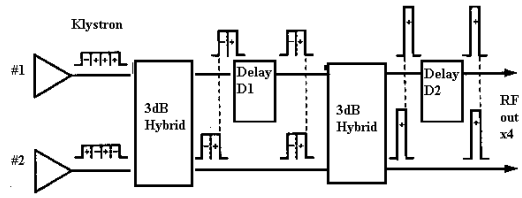

Fig. 3. Principle of ooperation of BPC

One port of the hybrid is connected to the delay lines which gives the necessary delay time to the first half of the RF pulse to meet with the following half of the RF pulse just in time at the input of the next 3dB hybrid. Through next hybrid, first and the second part of RF pulse are combined to give the twice peak power with one half of the original pulse duration. And as illustrated in the figure, this RF pulse again guided to the next stage as the figure illustrates. Repeating this process as shown in Fig. 3, 2^n pulse compression could be achieved. If the wall loss of the delay lines are neglected, it is quite easy to find that an n-stage of the BPC system can give the factor 2^n times higher pulse with 2n-th of a original pulse duration. It is also easy to recognize that in this BPC system the intrinsic energy efficiency could reach to 100% in case of the loss-less delay lines.

Due to this rather cumbersome configuration of the system, this BPC has been considered as of secondary importance even it can achieve better energy efficiency of close to or more than 90% in case of compression factor 4.[5]

5 DELAY LINE DISTRIBUTION SYSTEM (DLDS): A NEW RF POWER DISTRIBUTION METHOD EQUIVALENT TO A PULSE COMPRESSION SYSTEMS

Recently, the new RF power distribution system named DLDS(Delay Line Distribution System) which works as the replacement of an ordinary RF pulse compression system and has the better energy efficiency was proposed by the authors [6][7]. This system is based on the new operational principle different from the existing any other RF pulse compression systems. Like BPC, in this new DLDS, the short pulse trains that are divided into from the long klystron output pulse are led to the different parts of the linac respectively. The most specific point of this new system is that the divided RF pulses are never compiled again like SLED family or BPC. In this new system, the flight pass of the beam itself works as the delay line in the BPC, thus the half of the delay time necessary for the divided short RF pulse trains is given by the beam flight itself. In this new system, the length of the delay lines and consequently their losses can be decreased by about factor 2 compared to that of BPC. The operation principle of this new system DLDS is described in some detail below.

5.1 Basic factor 2 DLDS

In this new scheme, as shown in Fig. 4, the RF power from two klystrons that are independently phase controlled are combined together through the 3-dB coupler. One output port of the 3dB hybrid is connected to the upstream of the linac about one half of the linac operating time apart from the klystron location through the low-loss waveguide, and another port is connected to the structure located close to the klystron position. The first half of the RF pulse which is equal to the sum of the filling time and the bunch train is sent to the upstream of the linac through the delay line shown in the figure. The second part of the RF pulse is fed to the structure close to the klystron without delay. Delay line gives the delay time of Tdelay=L/Vg and the beam flight time between two structures is Tbeam=L/c. If these time delay satisfies next relation neglecting the delay time in the other RF transport system such as 3dB hybrid etc.,

$$T_{delay} + T_{beam} = L/V_g + L/c = t_a$$

where t_a is the pulse length of the linac operation, just the sum of the structure filling time and the duration of the bunch train. It is easily recognized that the timing of the bunch train and the RF pulse is adjusted to accelerate the beam and the beam is accelerated just as the ordinary linac pulses. Thus, The factor 2 DLDS (Delay Line Distribution System) which works equivalently as the factor 2 RF compression system can be constructed. The timing relation of this delay line scheme is illustrated in the “train diagram” shown in Fig. 5 in case of the RF

pulse from the klystrons are divide into two consecutive RF bins.

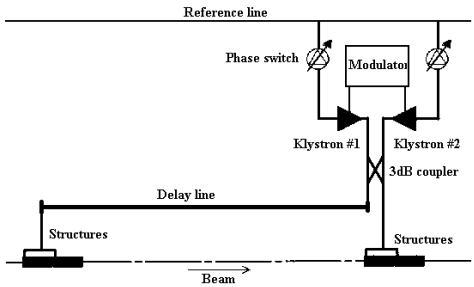

Fig. 4. A schematic diagram of the simplest factor-2 delay line distribution system

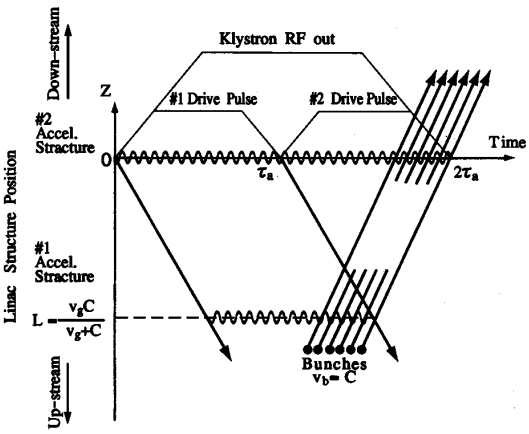

Fig. 5. A train diagram of factor 2 DLDS

In general , this scheme can be extended to the factor 2^n combined pulse height as follows. Each of the 2-klystrons in the factor-2 scheme mentioned in the previous section, can be replaced by the pair of 2-klystrons combined through a 3-dB hybrid coupler, thus this new system also works as factor-2 system, and remaining 2-output ports of the 2-hybrid couplers can be connected to the one more 3-dB hybrid coupler which serves as the additional factor 2 DLDS same as Fig. 4.

This process can lead to the construction of the factor-2^2 DLDS system. It may be easy to understand this procedure illustrated in the Fig. 6. Apparently, the train diagram of this factor factor-2^2 DLDS is easily understood as the extension from the factor 2DLDS case.

It should be noted that in this scheme the time domain compression equivalent factor i.e. klystron pulse length can be chosen from 1 to 2^n times longer than the linac operational RF pulse length. This system is generally noted as factor 2^n/m Delay Line Distribution System(2^n/m DLDS), 2^n represents the number of independent RF sources, and m represents the time domain compression equivalent factor. In this case, the (2^n - m) ports left unconnected to any structure.

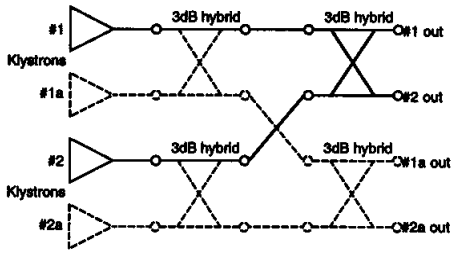

Fig. 6. A factor-4 DLDS built from factor-2 DLDS blocks.

Recently, an interesting application of this DLDS operation principle was proposed for a driving beam system for TBA (Two Beam Accelerator)[12]. Each RF bins in DLDS is replaced by the bunched beams that carries the RF power, and these bunch trains are transported to the counter direction to the accelerated beam like the RF bins in DLDS. The ssame operation principle as DLDS can be applied to the driving beam of TWA. Thus, even in TBA, an RF pulse compression equivalent system can be constructed and this scheme can replace the intense drive beam to the less intense but longer drive beam. It is expected that this new configuration could relax the technological problems on the drive beam compared to an ordinary co-direct drive beam cionfiguration.[12]

5.2 Design of a 4/3 DLDS for the JLC X-band main linacs

As an example of DLDS at X-band linear collider, 4/3 DLDS was designed as the RF pulse compression equivalent system for JLC. Fig. 7 schematically illustrates the 4/3 DLDS. Note that the 4-set of the klystrons and 3 groups of accelerating atructures that are seperated to adjust the time delay. The train diagram and the operational principle of this 4/3 DLDS are the essentially the same as factor 2DLDS, therefore further detailed explanation is unnecessary.

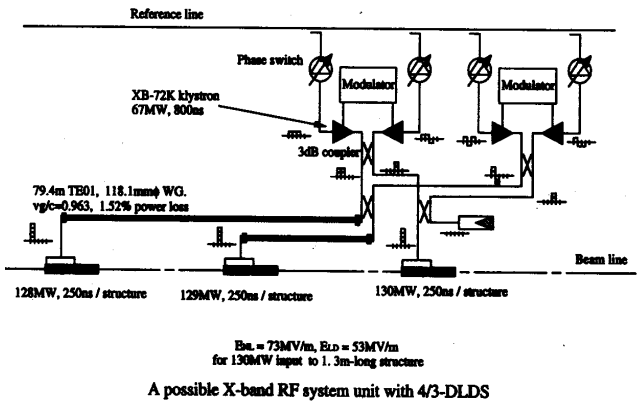

Fig. 7. 4/3 DLDS for JLC

6 MULTI-MODE DLDS

Recently, SLAC group proposed a clever configuration of DLDS which could save the delay line length by the use of multi-mode loading of the lines. This Multi-mode DLDS scheme works as follows. instead of the several delay lines, one delay line is set to have several mode extractor that are inserted on the one delay line to give the delay time as required by the DLDS operation.[11] Each mode extractor is designed as to extract only a specific mode and at the same time to transport the other modes completely. The one end of the delay line where RF sources are located, the mode launcher is attached. Primary RF pulse from the klystron is divided into the short RF bins and each RF bin is converted into the different mode through the mode launcher and lead into the delay line. Thus, each RF bin is extracted, in other words, distributed to the necessary location just as an ordinary DLDS. This new version of DLDS is currently considered as the best candidate for the next linear collider that is under study by joint effort of SLAC/KEK.

This multi-mode DLDS requires several new RF device such as a mode launcher, Intensive R&D plan is now going on at SLAC and KEK aiming the design of 4/4 multi-mode DLDS for their next linear collider.

7 CONCLUSION

The most important advantage of this new DLDS pulse compression equivalent system is firstly the high energy efficiency, as considered in the previous section its intrinsic efficiency could reach 100%. To compare this system efficiency with that of the ordinary SLED2 pulse compression system, , the efficiency of the DLDS is better than that of the SLED2 by about 20%. In comparison between an original DLDS and a muti-mode DLDS, if 4/4 DLDS is intended, a multi-mode DLDS is expected to be less cost due to the saving of delay length by its multi-mode loading of the delay lines. Considering the present status of R&D on the RF pulse compression schemes for an application to X-band linear colliders, following points can be pointed as a brief summary on this subject.

1) At X-band, DLDS especially muti-mode type is considered as the top ranked candidate as an RF pulse compression scheme for linear colliders.
2) DLDS has several advatage to other conventional RF pulse compression systems, howeveer DLDS can be applied only to a long linac such as a linear colilider.
3) traditional RF pulse compression schemes, such as SLED family, will remain as the useful measure for most of electorn linacs especially at S-band.
4) For the realization of the application of DLDS to linear colliders at X-band, technological R&D's such as high power tests, developments of several RF parts and beam operation oriented studies are still needed.
5) The operation principle of DLDS can alsobe applied to TBA drive beam system.

THE DESIGN OF AN ACCELERATOR FOR ADVANCED PULSE RADIOLYSIS EXPERIMENTS*

C. D. Jonah and R. A. Crowell
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

New accelerator techniques have made it possible to make shorter and shorter electron pulses. If appropriate detection techniques are available, these pulses make it possible to measure many important sub-picosecond chemical processes. We are proposing an accelerator system that can be used to measure important sub-picosecond chemical processes, such as solvation, vibrational relaxation, excited state relaxations and molecular fragmentation.

1 INTRODUCTION

It has long been known that radiation can induce highly complex reaction chemistry. At Argonne National Laboratory, one of the first pulse radiolysis experiments was done.[1] In pulse radiolysis a short pulse of ionizing radiation is used to create radicals and ions and the evolution of this chemistry is then observed.

In the more than 35 years since the first pulse radiolysis experiments, the time resolution of pulse radiolysis has increased from microseconds to under 5 ps.[2] With the advances in accelerator technology, it is now possible to push the time resolution to below a picosecond.

Pulse radiolysis and flash photolysis experiments are complementary. Pulse radiolysis excels in creating ions and in mimicking the chemistry that can occur in real-world systems such as waste storage tanks and biological systems after the impingement of ionizing radiation. In such systems, the concentration of reactants is very high and so the chemistry can occur at times less than a few picoseconds.

The important chemistry that needs study has prompted the Argonne Chemistry Division to propose a new pulse radiolysis facility. We envision a facility that will be used by the entire radiation chemical community to probe important chemical processes. In this paper we shall discuss

- The Chemical and Physical Processes that can occur.
- The design criteria for the facility.
- Some of the specific experiments that we plan to do

2 PHYSICAL AND CHEMICAL PROCESSES

Figure 1 displays a simplified picture of the chemical and physical processes that can occur after radiolysis. If there are high concentrations of reactants, they can easily compete with relaxation fragmentation and solvation.

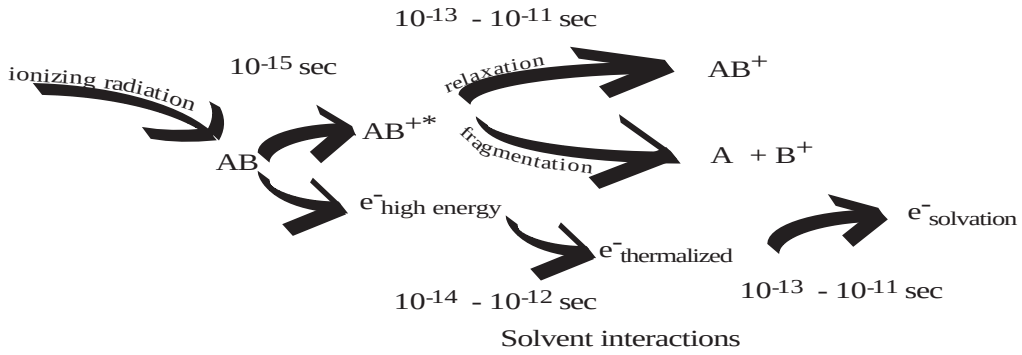

Figure 1: Schematic of the physical and processes occurring after radiolysis.

As one can see from looking at the figure, there are many processes that will occur at times where time resolution better than the 5-30 ps that are presently available in radiolysis experiments.

* Work performed under the auspices of the Office of Basic Energy Sciences, Division of Chemical Science, US-DOE under contract number W-31-109-ENG-38.

3 THE DESIGN CRITERIA FOR THE FACILITY

Recently there have been several reports of sub-picosecond pulses from linear accelerators.[3] However the goal of our project is to develop a sub-picosecond pulse radiolysis facility. This means that 1) there must be a sufficiently large concentration of species created and 2) there must be a detection technique that can make use of the short pulse and that will be of sufficient generality to

make meaningful measurements for a large variety of chemical systems. In addition, we had the desire to make a facility that would be usable for more general experiments and would not be limited to sub-picosecond experiments.

The initial design criterion was to create a system that could be used for optical absorption measurements. Optical absorption is applicable to a large variety of chemical systems. While single shot kinetics would be ideal, such measurements at short time scales are very difficult. Streak cameras are unsuited to such measurements. A typical experimental layout is shown in Figure 2.

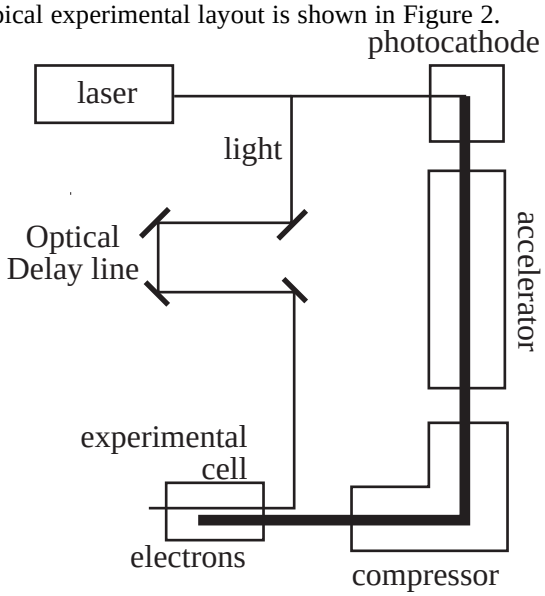

Figure 2: Pump probe measurement technique.

This figure shows a simple pump-probe detection technique. The time that the light strikes the cell can be altered by changing the length of the optical delay line. Thus time resolution depends only on the width of the electron pulse, the light pulse and the synchronism between them. Time resolution can then be reduced to a distance. For 1 ps, a distance of 0.3 mm is needed, easily measured and controlled. A similar technique could be used for fluorescence detection using upconversion or for 4-wave mixing techniques such as CARS (Coherent Antistokes Raman Scattering). These techniques make use of the availability of a synchronized laser.

3.1 General Requirements

To make use of the resolution available from the width of the accelerator pulse, it is necessary to

- Have the pulse width of the probe laser pulse to be less than the width of the electron pulse.
- Have the electron pulse and the accelerator pulse be synchronized as they pass through the sample cell
- Keep synchronization between the linac pulse and the laser pulse

The width of the laser will be narrower than the electron pulse. In fact, one of the problems will be stretching the laser pulse to a width that is appropriate for injecting electrons into the accelerator. Modern lasers will have a pulse width of a few hundred femtoseconds, too short for injecting electrons into an accelerator.

The synchronization between the light and the electrons can be assured by keeping the length of the cell sufficiently short. If we assume a refractive index of 1.5 for the sample, then the difference in transit times for the electrons and the light will be less than 0.5 ps if the sample length is less than 0.3 mm long. There is no difficulty in creating a cell of that depth; the primary difficulty is that such a short cell will limit the amount of optical absorption.

The most difficult problem will be the synchronization between the light and the electrons. While the electrons and the light should be synchronized when the electrons are formed, they may not be synchronized at the exit of the accelerator. Because the compressor works by changing the transit time through the magnets as a function of electron energy, anything that changes the energy of the electron pulse will change the time at which the electrons strike the cell relative to the light pulse. These can include different amounts of energy in the accelerating waveguides and the synchronization of the laser pulse relative to the RF of the accelerator. For example calculations suggest that a shift of 1 ps in the timing between the RF and the laser can yield a shift of 0.5 ps in the transit time.

Table 1 shows the proposed pulse widths. The larger pulses will be very useful for experiments when second order reactions are studied or when weakly absorbing species are formed.

Table 1 – Pulse characteristics.

Pulse Width	Charge
0.6 ps	2 nC
1.0 ps	5 nC
3 ps	10 nC
8 ps	50 nC
45 ps	90 nC
30 ps	25 nC (present linac)

3.2 Detection Options

A large variety of optical detection techniques are available that will make use of the synchronized probe light source. Figure 2 shows the experimental layout for optical absorption. The diagram suggests that the laser that ejects the electron will be used as the detection light source. This is clearly an over simplification because techniques such as optical parametric oscillators can produce a wide variety of wavelengths that can be used as probe sources. With the high powers available, continuum generation can be used, which will provide a white light source that can be used as a probe light source.

Present picosecond experiments have used Cerenkov light as the probe light. Experiments using this probe source have been limited in signal-to-noise because of the shot-noise limit. With a laser available as a probe light source, the signal-to-noise should be much larger.

Fluorescence can be detected either using a streak camera or fluorescence upconversion. With fluorescence upconversion, one can impinge the fluorescence signal and the probe light on a crystal. The probe light source can act as an optical gate that will sample the fluorescence when the probe light is there.

With the availability of intense, synchronized probe laser pulses, all the sophisticated techniques available in laser spectroscopy may be used when appropriate. One well-known technique is CARS spectroscopy where the vibrational state of a molecule can be measured using visible spectroscopy.

4 SCIENTIFIC GOALS FOR A SUB-PICOSECOND PULSE RADIOLYSIS FACILITY

As stated in the introduction, pulse radiolysis and flash photolysis are complementary techniques. While the time resolution of flash photolysis has always been greater than pulse radiolysis, there are experiments that are best done using pulse radiolytic techniques. These include:

Studies of the primary processes in radiation chemistry can only be studied using these techniques. The kinetics of the geminate recombination reactions of the electron in water has been studied using lasers. It has been shown that the rates of these reactions depend on the photon energy producing the hydrated electron.[4] This means that the spatial distribution of the electron depends on the photon energy. Thus there will be no straight-forward correlation between the laser experiments and the radiation experiments. These recombination reactions depend on the distance distribution that is created in the ionization event and the distribution depends on the source of ionization.

Laser studies have been very effective in studying the solvation of excited states (dipole solvation). However until radiation chemical techniques were used to study solvation, ionic solvation was not measured. The unexpected differences between ion solvation and dipole (excited state) solvation were only discovered with pulse radiolytic techniques.

Ionization by lasers depends on the optical cross sections while ionization by ionizing particles depends on the number of electrons present. These differences will allow one to probe a wide variety of chemical processes.

4.1 Nonhomogeneous processes

Radiation deposits energy nonhomogeneously, which leads to many of the important characteristics of radiation-induced chemistry. These high local concentrations of radicals and ions will recombine very quickly. The competition between the fast recombination and reaction with other species in the system will determine the efficacy of the radiation-induced reactions. With the new radiolysis facility, we will probe these reactions on faster time scales.

4.2 Chemistry before Relaxation

Radiation will produce radicals, ions and highly excited states in fluids. In traditional chemical experiments, the concentration of additives is low so that the reactions with the additives will occur much more slowly than the relaxation of the excited states and highly excited vibrational states of the solvent. However, when the concentration of reactants is high, one will have reaction competing with the relaxation process. Without an explicit understanding of the relaxation processes, it then is not possible to predict the final chemistry.

We have tried to summarize a few of the experiments that will require the very fast time resolution of a new facility. In such a short space and in this forum further details are not appropriate.

5 SUMMARY

In this short discussion we have tried to summarize our design goals for a subpicosecond pulse radiolysis facility. We have tried to show that such a facility is more than a short pulse – detection techniques must be taken into account when designing the facility because the goal is to make chemically significant measurements. We have tried to highlight a few fields of study for the future.

Details on the machine design have been ignored in the present discussion. Information about the design process can be found in the paper by Hans Bluem and coworkers in this conference. Details about the laser design can be found in the paper by Robert Crowell and his coworkers.

6 ACKNOWLEDGMENTS

We gratefully acknowledge the scientific discussions of the Radiation and Photochemistry Group, Alexander D. Trifunac, David M. Bartels, Ilya A. Shkrob and David W. Werst and discussions of the Electron Transfer and Energy Conversion Group, John R. Miller and Dani Meisel. Nothing could have been done without the simulations of Hans Bluem, Alan Todd and their collaborators at Northrop Grumman.

Abstract

In the 1997-98 run, the luminosity of the SLAC Linear Collider (SLC) increased by about a factor of four compared to previous runs. A significant contribution to this improvement came from revised emittance tuning techniques throughout the accelerator. A new strategy was used to cancel wakefields and dispersion in the LINAC. Careful monitoring and control of the ARCs optic reduced the emittance growth due to coupling, wakefields and synchrotron radiation. New Final Focus optics and upgraded diagnostics improved the emittance measurement resolution and otpimization. These and other new procedures resulted in an average 25residual emittance growth in both planes from the damping rings to the interaction point.

1 LUMINOSITY OVERVIEW

During the 1997-98 run, a total of 350,000 Z^0s were recorded with an average electron beam polarization of 74%. This was nearly double the total sample of events from all previous SLD runs and reflected a substantial increase in luminosity of about a factor of four. The peak luminosity delivered was 300 Z^0s per hour or 3 10^{30} $cm^{-2}s^{-1}$ with a record of more than 5300 Z^0 events recorded in 24 hours. The luminosity steadily increased throughout the run bringing the SLC to within a factor of two of design [1]. The improvement was due almost entirely to changes in tuning procedures and reconfiguration of existing hardware with no major upgrade projects.

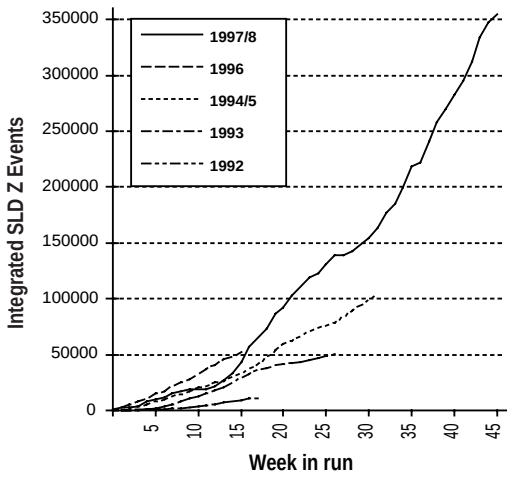

Figure 1: History of integrated SLD Z^0 events from 1992 through 1998, showing the steep increase in 1997-98.

† present address: CERN, SL division, Geneva, Switzerland

The luminosity of a linear collider L is given by

$$L = \frac{N^+ N^- f}{4\pi\sigma_x\sigma_y} H_d, \quad (1)$$

where $N^\pm$ are the number of electrons and positrons at the interaction point (IP), f is the repetition frequency, $\sigma_{x,y}$ are the average horizontal (x) and vertical (y) beam sizes, and H_d is the disruption enhancement factor which depends on the beam intensities and on the transverse and longitudinal beam sizes. At the SLC, the repetition frequency is 120 Hz and the beam intensity is limited by wakefield effects and instabilities to about $4\ 10^{10}$ particles per bunch. The only route to significantly higher luminosity is by reducing the effective beam size. Using the definition of emittance as the product of the beam size and angular divergence ($\theta_{x,y}$), $\epsilon_{x,y} = \sigma_{x,y}\theta_{x,y}$, one may reexpress the luminosity as

$$L \propto \frac{\theta_x}{\epsilon_x}\frac{\theta_y}{\epsilon_y} H_d. \quad (2)$$

For higher luminosity, the basic strategy was to decrease the emittance and increase the angular divergence. Any reduction in beam size strengthens the disruption, or mutual focusing of the beams, and further increases the luminosity.

2 EMITTANCE TRANSPORT

A variety of new techniques were used to minimize the emittance growth from the damping rings to the final focus. In the ring-to-linac transfer lines where the bunch length is compressed, the horizontal beam size is large and fills the available aperture, causing emittance dilution and beam loss. Ballistic beam-based alignment minimized dispersion generated in the strong matching quadrupoles. A new optics with a larger momentum compaction factor better matched the beam size to the apertures and reduced losses [2]. Shielding sleeves were also added to reduce wakefields generated by the bellows in the beamline.

In the linac, a new implementation of two-beam dispersion free steering [3] constrained the electron and positron beams to follow the same trajectory, minimizing dispersion and wakefields. Once established, the trajectories were stable over several months, with only occasional resteering required. A stronger focusing lattice [4] improved the damping of incoming oscillations while ensuring compatibility with PEP-II (the SLAC B-factory) operation. This also allowed a reduction in the beam energy spread introduced for BNS damping which helped minimize chromatic emittance growth. Known sources of jitter from vibrations in the mechanical systems near 10 Hz and in the water cooling systems near 59 Hz were reduced by stiffened supports, upgraded water pumps [5], and special high-speed feedbacks.

Another important improvement was the development of a fast, accurate procedure for phasing the rf accelerating voltages. All of the 30 linac subboosters, each of which drives 8 klystrons, could be phased in about 2 minutes to an accuracy of 1-2 degrees. This provided a stable, well understood energy profile throughout the run [6].

In the collider arcs, emittance growth is inevitable due to the emission of synchrotron radiation in the bending dipoles. In addition, the non-planar geometry of these beamlines can cause transverse coupling. In this run, the optical properties of the arcs were more precisely optimized and maintained. First the beam trajectory was carefully centered through the magnets to reduce wakefields. Then the emittance growth was constantly monitored and minimized using refinements of the techniques first developed in 1990 [7]. The realization that the final focus dispersion matching quadrupoles strongly coupled the beam led to the development of new methods for matching dispersion in the arcs themselves.

Most importantly, the strategy for global optimization of the linac emittances was changed significantly. Since 1991, the SLC has used closed betatron oscillations early in the linac to cancel wakefield tails caused by residual structure misalignments [8]. Studies showed that where the energy spread is large, dispersion dominates the emittance growth. Oscillations used to cancel dispersion may generate additional wakefield tails. At low energy, the optics is also extremely sensitive to small errors in the energy profile. Tuning further downstream in the linac where the energy spread is small, produced more stable, reproducible results.

In previous runs, emittances were optimized using wire scanners located near the end of the linac at about the 90% point. Measurements in 1997 indicated that significant emittance growth can occur in the last 200 meters, as predicted by simulations [9]. The solution was to use wire scanners early in the final focus for the global optimization. To provide high precision measurements during luminosity running, several upgrades were required. Thin carbon wires were installed to allow measurements while the SLD detector was logging data. New optics improved the phase space coverage and high resolution (≈ 2 μm) beam position monitor electronics allowed precision correction for pulse-to-pulse orbit fluctuations. The revised optimization strategy produced not only a smaller emittance, but also much less variability without anomalous sources of emittance growth. Most significantly, for the first time, the emittance transport was qualitatively and quantitatively understood and controlled.

3 FINAL FOCUS IMPROVEMENTS

The key to improving the performance of the SLC final focus (FF) was the understanding that for non-Gaussian beam distributions, the beam sizes, $\sigma_{x,y}$, in Eq. 1 must be calculated from the integral over the beam overlap distributions and not from the root mean square (RMS) distribution. The upper curve in Fig. 2 shows the RMS beam size as a function of angular divergence for the 1996 FF optics. Because the RMS is dominated by tails containing only a small fraction of the beam, it increases after an optimum divergence value. The second curve shows the effective beam size when the integrals are properly evaluated and predicts higher luminosity for increased angular divergence. The third curve demonstrates the gains from a different FF optics used for this run where the final demagnification was moved closer to the interaction point (IP). With these optics, the divergence, beam size, and predicted disruption enhancement (assuming a 1 mm bunch length) were changed from $\theta_x = 350$ μrad, $\sigma_x = 2.0$ μm, $H_d = 1.3$ to $\theta_x = 470$ μrad, $\sigma_x = 1.5$ μm, $H_d = 2.0$. This was still less than the optimal values of $\theta_x = 530$ μrad, $\sigma_x = 1.3$ μm, and $H_d = 2.2$.

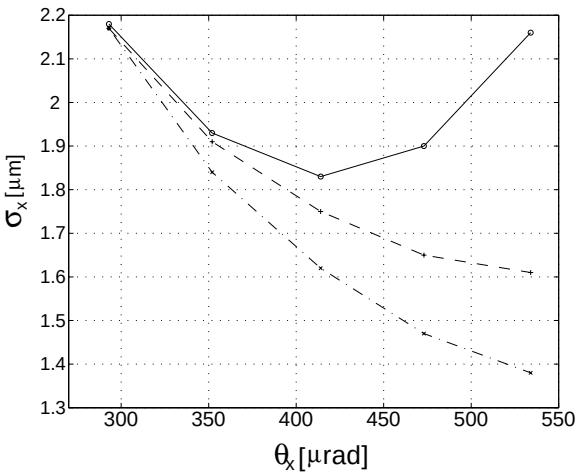

Figure 2: Horizontal beam size σ_y at the SLC IP as a function of angular divergence θ_y. Curves (solid), RMS, and (dashed), with proper integration, are for the 1996 optics. The dot-dashed is for 1997 optics.

At the SLC, the maximum achievable angular divergence is limited primarily by backgrounds in the SLD detector. In preparation for the 1997 run, changes were made to the FF collimation and to the masking near the IP. Collimators from the FF were moved to the arcs and rotated by 45° to allow for 'round' collimation. In addition, for most collimators ($\approx$60 jaws in total), a new technique ensured that they were properly centered on the beam to minimize wakefield kicks. Later, offline studies using upgraded tracking codes revealed that part of the detector backgrounds were generated by higher order chromatic terms ($\sim \delta^2$), specifically T_{266} and T_{226} in transport notation. Based on these results, permanent magnet sextupoles were installed just after the end of the linac and additional sextupoles were energized in the FF to cancel these contributions.

In addition to the new optics mentioned above, several other upgrades to the FF were implemented during the run to reduce the emittance growth due to synchrotron radiation and to cancel residual higher order aberrations. The additional FF sextupoles not only reduced backgrounds, but also reduced the contribution to the vertical beam size from two third-order aberrations, U_{3246} and U_{3244}, generated by the interleaved sextupoles. At the end of 1997, the average bend radius in the FF was increased by using offset quadrupoles and steering dipoles. This reduced synchrotron radiation emittance growth in both planes. In

February, permanent magnet octupoles were installed to further cancel the U_{3246} and U_{3244} vertical aberrations. The observed decrease in the vertical beam size was about 15%. Finally, in May the strength of the final quadrupole nearest the IP was increased to further raise the horizontal angular divergence. The horizontal and vertical beam sizes achieved were $\sigma_x = 1.5$ μm and $\sigma_y = 0.65$ μm, which together yield a beam area which is a factor of 3 smaller than the SLC design value.

4 LUMINOSITY OPTIMIZATION

To achieve and maintain the minimum beam size at the SLC IP, 5 final corrections are routinely optimized for each beam. These include centering of the x and y beam waist positions, zeroing of the dispersion η_x and η_y, and minimization of an $x-y$ coupling term. Since the first SLC collisions, an automated procedure has been used to scan the beam size as a function of each parameter and set the optimal value. The beam size was measured with a beam-beam deflection scan but this technique lacked the resolution required to measure micron-size, disrupted beams. It was estimated [10] that poor optimization caused a $20-30\%$ reduction in luminosity during the 1996 run. For 1997, a novel 'dithering' feedback was implemented which optimizes a direct measure of the luminosity (i.e. the beamstrahlung signal) as a function of small changes in each parameter [11]. By averaging over thousands of beam pulses, it was possible to improve the resolution by a factor of 10.

The feedback was configured to cycle through each of the 10 parameters automatically, typically every hour or two. In contrast, the old, slower, more invasive procedure was typically implemented only a few times per day. Because of the improved resolution, it was possible to align the FF sextupoles and new octupoles much more accurately and to develop new methods for cancelling all of the second order chromatic and geometric aberrations. An added benefit of the feedback optimization was that it was highly reproducible and no longer required operator intervention. Lastly, with the improved optimization and increased stability in the upstream systems, high luminosity was more quickly reestablished after any interruption.

5 DISRUPTION

In the 1997-98 SLC run, a significant luminosity enhancement from disruption was demonstrated for the first time. As the beams collide, each beam is focused by the field of the other beam, causing the transverse size to shrink. If the resultant focal length is shorter than the bunch length, the average beam size seen by the other beam decreases, which increases the luminosity. The magnitude of the disruption, or pinch effect, depends on the transverse beam size, the bunch length and the beam intensities. For this run, along with the significant reduction in beam size, the bunch length was carefully monitored and set to the optimum value [12]. In addition, the beam currents were maintained at record levels partly due to bunch precompression in the damping ring [13]. Fig. 3 shows the ratio of luminosity as recorded by SLD to that calculated from the measured beam parameters assuming rigid (i.e. undisrupted) beams. The data are in agreement with the theoretically calculated disruption enhancement. At the highest luminosity, the enhancement was more than 100%.

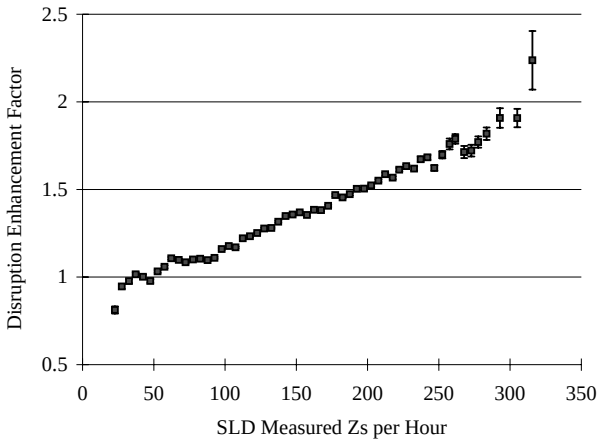

Figure 3: Ratio of luminosity measured by SLD to that calculated for rigid beams without disruption.

6 SUMMARY

The remarkable increase in luminosity after nearly a decade of operation demonstrates that the SLC remains on a steep learning curve and has far from exhausted its potential for further improvements and for a deeper understanding of linear colliders. The success of the 1997-98 SLD run was due to the hard work and dedication of many groups and individuals. In particular, we acknowledge the outstanding efforts of the operations crews and the engineering and maintenance staff as well as the physicists from SLD and the Accelerator Research departments.

TOWARDS THE ZERO BEAM DIAGNOSTICS

A. Rovelli
INFN Laboratori Nazionali del Sud, via S. Sofia 44/a, 95123 Catania, Italy

1 INTRODUCTION

Low intensity beam diagnostics is a challenge that has involved the accelerator community in the last years. The interest in this activity is due to the fact that a number of applications are based on the use of low intensity beams. The produced effort is mainly oriented to improve the performances of the conventional beam diagnostics in order to work properly also when the beam intensity goes down to $10^8 \div 10^6$ pps. A very important incentive for this activity came few years ago with the development of a new type of beam facility for the production of radioactive ion beams (RIB) [1]. The new challenge was very hard because the required sensitivity for the beam diagnostics was in the range $10^{10} \div 10^5$ pps, or even lower. The necessity to measure the beam characteristics all over such a wide range and the variety of ions and energies involved forced the development of a complete set of beam instrumentation able to satisfy all the requirements.

2 THE PROBLEM EVALUATION

A facility for the production of radioactive ion beams is the best reference to evaluate all the problems related to the low intensity beam diagnostics; the typical variety of ions, energies and intensities involved, offers the meaningful scenery inside which the new apparatus have to be developed [2]. The first items to be considered are the expected intensity and energy range. From an overview all around the projects it is possible to individuate two ranges:

- beam intensity: $10^5 \div 10^{11}$ pps
- beam energy: $10^4 \div 10^7$ eV

Once fixed the operative ranges, it is necessary to fix also few general requirements related to the specific use of these devices. In addition to the typical parameters to characterize an ion beam in the longitudinal and in the transverse plane, a new request, typical for a RIB facility, is the unambiguous isotope identification. To perform all these measurements these devices have to guarantee:

- the highest sensitivity to the lower current;
- the highest sensitivity to the lower energy;
- the highest reliability;
- the highest strength;
- the highest simplicity to use and to maintain it.

Furthermore, all these requirements have to be added to the typical ones for standard beam diagnostics.

3 THE GUIDELINES

Two main guidelines are followed approaching the low intensity beam diagnostics problem. The first one, based on the performances improvement of conventional techniques, consists of a deep investigation about the typical sensitivity limitations of the beam diagnostics. The second one is based on the evaluation of using particle detection techniques very reliable for sensitivity and precision in nuclear as well as high energy physics research. It is evident that a realistic solution is represented by two different sets of devices with an overlapped operative range to perform relative calibrations for absolute measurements.

3.1 Conventional techniques

Conventional beam diagnostics is a very wide set of instrumentation: secondary electrons emission (wire, grids, etc.), light emission (screen, fiber, etc.), gas ionization (residual, chamber, etc.) and charge induction (pick-up, transformer, etc.) are the most diffused techniques. The typical advantages are the simplicity in their structure, use and maintenance. This is a very important consideration that has to be always taken in account also developing low intensity beam diagnostics. The reason of this simplicity is that they were developed mainly looking the operative procedures performed by the people (the console operators), which are not necessarily expert of particles detection techniques, that have to accelerate and transport the beam from the source to the experimental point. The low signal-to-noise ratio of a lot of these devices is the main limitation to their use for low intensity beam diagnostic. With the exception of the ionization chambers, extensively used also as particles detector, all the others techniques have to be subjected to a deep revision in order to increase the general performances toward the lower limits. This revision has to be performed following two directions: the research for new materials (as sensor) and the electronics improvement. The new materials have to guarantee:

- higher conversion efficiency;
- higher collection efficiency;
- lower background noise;
- higher radiation hardness;

The electronics improvement has to guarantee:

- lower electronic noise (connectors, contacts, cables, components, etc.);

- lower electromagnetic noise (grounding, shielding, etc.);
- higher signal first amplification;
- improving the read-out electronics;
- higher radiation hardness;

The goal is to reach the minimum sensitivity of $10^7 \div 10^5$ pps. In this way it will be possible to overlap the typical highest limit of the nuclear detectors and to perform absolute calibrations with respect reference devices.

3.2 Particles detection techniques

The typical instrumentation and techniques used in nuclear as well as high energy physics research can be used for low intensity beam diagnostics if they are modified looking the peculiarity of this application. Semiconductors, gas chambers and scintillators based detectors offer, together with other ones, a wide choice in terms of performances and versatility.

The advantages are the sensitivity, the precision and the absolute measurements that can be performed after a suited calibration. The main limitation is the setup complexity from the point of view of its structure and use. Beam diagnostic measurements require a fast read-out of the information, on-line if possible, and at the same time well understandable by the operators. In this sense the main effort has to be devoted to:

- reduce the setup complexity;
- reduce the measuring time;
- increase the general hardness;
- increase the automated procedures;

3.3 The ideal solution

All the arguments up to now mentioned allow the identification of the ideal solution. A list of the recommendations for such a device is the following:

- measure different beam characteristics;
- cover a wide intensity range;
- cover a wide energy range;
- allow self calibration;
- minimize the interferences with the beam;
- minimize maintenance operations and price;
- maximize reliability and versatility;
- allow different measurement modes:
  - charge/current collection;
  - continuous/pulsed acquisition;
  - integration time settable;

Very important is the integration of this instrumentation in the main control system of the facility. This feature means that the operator in the console must operate the beam management with no regard to the beam intensity. Furthermore, the choice of the right device has to be done considering that the setup structure has to be strong enough to resist to quick intensity changes. If necessary, a suited interlock system has to be provided in order to protect the device in case of mistakes or faults.

4 SEMICONDUCTORS

The semiconductors probably are one of the most popular materials category used to develop nuclear detectors. Their versatility allows the realization of different configurations very useful also for beam diagnostics. In the end of this chapter it will be reported also some applications based on a particular material, the diamond. It is an insulator but it can be considered, from the applications point of view, the most important alternative to the use of semiconductors.

4.1 Silicon based detectors

To state the reason for the wide use of the silicon as particles detector the best and the easiest way is to list its main characteristics:

- the mean energy to produce a pair is 3.62 eV;
- well suited for different configurations;
- good timing performances;
- medium price.

Unfortunately its radiation hardness is very low. This aspect limits its use for beam diagnostics; in particular, it can be used only in single particle counting mode and, in any case, great care has to be devoted to protect it.

Silicon based detectors can find useful applications for very low intensity beam diagnostics. Silicon micro-strips, for example, can be used as beam profile and position monitor. The sensitivity and the spatial resolution (higher than 100 μm over a 10×10 cm^2 area) are very good, but the electronics and the price are very expansive. Much more suited is the application for isotope identification [3]. A thin Au target is used and a silicon telescope is positioned at a suited angle in order to match a suited scattering counting rate. The ΔE-E information allows the isotope identification. The operative energy range depends by the silicon and dead layers thickness.

4.2 Germanium based detectors

This very sophisticated kind of detector is mainly used for high resolution gamma ray spectroscopy. Its main characteristics are.

- the mean energy for a pair production is 2.96 eV;
- operating at 77 °K;
- very low radiation hardness;
- very complex experimental setup;
- very high price.

It is obvious that such a detector has several limits for beam diagnostics application but, for a specific use, can be very useful. For example, it is a powerful tool for very rare radioisotope identification [4]. The main advantage of this setup is that implanting the radio-isotope at very low energy it is possible its identification just after its production, allowing an efficient tune of the transport line avoiding any beam contamination.

4.3 Diamond based detectors

The operating principle of this isolating material is the same of the semiconductors one. Its main features are:

- the mean energy to produce a pair is ~ 13 eV;
- the collection length is 50 ÷ 100 μm;
- very good radiation and power hardness;
- very good timing performances;
- versatility for different configurations;
- high price.

Nevertheless the higher energy to produce a pair, an important advantage with respect the semiconductors is the high energy gap that strongly reduces the noise. The strength of this material allows its use with high intensity as well as low intensity beams. The very short collection length, depending by the nature and density traps, determines very high performances in terms of spatial and time resolution. Can be used in pulses counting mode, for very low beam intensities, as well in current mode looking the continuous component of the signal produced by high intensity beams. An interesting application is the use of diamond film with 100 μm pitch micro-strips [5]; this setup allows the beam profile and position measurement. The increasing interest on such a material is due to the advanced techniques nowadays available for the production of synthetic diamonds at realistic prices. The CVD (Chemical Vapor Deposition) technique allows the production of very thin diamond films of some centimeter size; the possibility to realize wide homogeneous layers with controlled impurity characteristics, justifies the big effort that is devoted to test new devices for beam diagnostics.

5 GAS BASED DETECTORS

Many detectors are based on the ionization produced by a charged particle crossing a gas volume. The gas can be used to fill a chamber with thin entrance and exit windows, or can be the residual gas itself contained along the beam pipes used to transport the beam.

The most famous gas detector is the gas chamber; it founds many applications also for beam diagnostics. Its versatility in terms of dimensions and shapes allows to develope a variety of setups well suited for beam diagnostics applications. The signal is produced by the energy loss into the gas and its amplitude depends by the gas pressure and by the collecting electric field. The mean energy to produce a pair is about 30 eV, depending by the gas. Very important features are:

- very good radiation hardness;
- energy loss and charge multiplication effect;
- very good sensitivity;
- versatility for different configurations;
- medium price.

The most interesting configurations for beam diagnostics purposes are the wire chambers and the micro-strips chambers [6]. Their main are the sensitivity and the spatial resolution. Particular interest is devoted to the micro-strips chambers because the lithographic procedure to realize the strips on a suited substrate (typically glass) allows to obtain 100 ÷ 200 μm (the pitch) of spatial resolution. Also the chamber size can be reduced as well as the setup complexity.

Two very interesting devices were developed at the LNS to measure the beam profile [7] and for particles identification [8]. Both are based on the use of a 5×5 cm^2 glass plate with 200 μm pitch of Au strip. To measure the beam profile the strips are parallel with respect the beam direction, while for particles identification are perpendicular. The whole structure, very simple and light, can be inserted or removed, through a suited actuator.

5.1 Residual gas detectors

The ionization produced by the beam interaction with the residual gas contained along the beam pipes can be used to measure several beam properties without any interference with the beam itself. Generally and especially with low intensity beams, the ionization events are very rare then it is necessary some signal amplification. The typical setup foresees a charge collecting field and an electron amplifier, generally a micro-channel-plate (MCP), to collect the charges. This setup has no problems for the radiation damage, on condition that it is prevented from the direct beam interaction. The MCP choice depends by the application; several model with different characteristics and performances are available. Here is reported a brief description of two different techniques.

The MCP with electric readout is a detector where the signal coming from the collecting electrode is directly acquired and analyzed. This system, in different configurations, is very useful for both transversal and longitudinal beam profiles. To measure the transverse beam profile, as well as the position, the collecting electrode is coupled with a silicon micro-strips plate; the spatial resolution is very good (0.3 ÷ 1 mm). A similar setup [9], but coupled with a 50 Ω anode is used to measure the longitudinal beam profile with a very good time resolution (100 ÷ 200 ps).

The MCP with light readout is similar to the previous one; the only difference is that the electrons coming out from the amplification stage are sent onto a scintillating screen. The light produced by the electrons hitting the scintillator can be acquired through a common CCD camera [10] or directly through silicon strips. The signal is acquired by a frame-grabber PC board. A simple program allows displaying the on-line acquired images together with the beam profile and position information; is better to use a camera with gain and shutter control to match the setup sensitivity.

6 SEM BASED DETECTORS

Secondary electrons emission based devices probably are the most diffused ones for beam diagnostics. The ions hitting the outer layer of several materials produce an

electron emission that is proportional to the released energy. Because only the electrons contained in the first microns can exit from the material, the emission is a typical surface effect and it is proportional to the surface exposed to the beam. Moving wires, grids and thin foils are commonly used to measure several beam properties. The limitation of their use for low intensity beam diagnostics is mainly due to the bad signal-to-noise ratio. To improve their performances it is possible to devote particular care to the material selection and to the electronic noise reduction; in any case it is very difficult to increase their sensitivity more than 10^7 pps. To do that, it is necessary to develop most sophisticated apparatus based on such an amplification (MCP, channeltron, etc.) of the detected signal [11].

7 SCINTILLATORS BASED DETECTORS

As the previous category, also the scintillating materials are very well known and used for beam diagnostics applications. The main advantage with respect the SEM based devices is that the wide choice of materials and light detectors allows to develop several apparatus well suited also for low intensity beams. Very briefly, the main items for the scintillating materials are:

- fluorescent light due to the particles energy loss;
- mean energy to produce a photon is $10 \div 100$ eV;
- good radiation hardness for the inorganic ones;
- poor radiation hardness for the plastic ones;
- versatility for different configurations;
- medium price.

The first important question concerns the material choice. It is not so easy to have a global view on the scintillating materials because of their very big number, continuously in progress with the fast improvement of the technology to produce them. A significant contribute comes out also from other sectors of the scientific research where scintillating materials are employed for completely different applications. A simple way for a choice is to select them in terms of:

- the mean energy to produce a photon;
- the decaying time constant;
- the photon wave length;
- the refraction index of the material;
- the efficiency of photon collection;
- the radiation hardness.

Many other properties have to be taken in account: for examples, the mechanical features as well as the hygroscope one. In literature [12] are reported the most important features of the common organic and inorganic scintillators; also some amorphous materials like glasses, usually doped with rare earths elements (Tb, Gd, Ce, etc.), represent an alternative choice for radiation hardness and light emission efficiency. However, a scintillator based detector also consists of a suited photo-sensor and, sometime, a suited light-guide. Once fixed the scintillating material to be used, it is necessary to match its characteristics with the proper light-guide and photo-sensor. Also for the light detector there is a wide choice of devices. Rather than a long list of the available devices (photomultipliers tubes, photodiodes, avalanche photodiodes, hybrid photodiodes, etc.) it is better to do a brief overview of the most significant applications for low intensity beam diagnostics. Profile, total current and time measurements can be easily done using scintillating optical fibers and screens.

7.1 Beam profile and position monitor

The simplest setup is based on the use of a scintillating screen that intercepts the beam; the emitted light is collected through a quartz window by a CCD camera. The main limitation is the bad light collection efficiency that limits the use with low intensity beams. To improve its performances it is possible to use more efficient scintillating screens (Cr doped alumina, rare earths plastic sheets, etc.) or collecting with the same camera the light emitted at different solid angles.

A more sensitive setup was developed for very low intensity ($10^4 \div 10^6$ pps) and energy (higher than 10^4 eV) [13]. It is based on the use of the CsI(Tl). A small brick of this material is positioned behind a moving slit and it is coupled with a compact photo-tube by means of a PMMA prism. The photo-tube is completely shielded by the slit itself with respect to the beam. The use of faster scintillators (CsI, BaF_2, etc.) increases the upper limit of the count rate allowing absolute calibrations with normal intensities.

The scintillating fibers offer an interesting alternative. The advantage with respects the previous systems is that the efficiency in the light transmission is strongly improved. Plastics as well as glass fibers can be successful used depending by the application. A very simple setup was developed to measure the beam profile and position [14]. It is based on the same idea of the moving wires monitor. Sensitivity and spatial resolution depend by the fiber choice. Using glass fibers the radiation hardness is higher but the mechanical strength is lower. The light collection is performed through a compact photo-tube able to work also inside the beam pipe. A special I/V converter [15] was developed to get the continuous signal component as well as the impulsive one coming from the tube. This configuration allows to do measurements over the widest intensity range. The only limitations are the damage produced by the power released by the beam and the outer dead layer of the fiber (only the core is scintillating); this last problem limits its functionality at the lower energies.

7.2 Time structure and total current monitor

For this applications the best choice is the use of very fast organic scintillators. The high counting rate obtainable allows, if coupled with a suited photo-sensor, to get high time resolution and absolute current measurements over a wide intensities range.

To measure the phase of pulsed beams a useful setup is based on the use of a fast plastic scintillator [16]. The PILOT-U sensor is coupled with a photo-tube through a long optical fiber; the whole setup is mounted on a radial probe to measure the beam time characteristics inside the cyclotron. The operating range is $10^4 \div 10^6$ pps. The same setup can be also coupled with a silicon detector to perform ΔE-E measurements but at lower rates (10^3 pps).

Total current measurements can be performed using very fast scintillators after a suited calibration [17]. The short decay time of the polymeric plastic scintillators allows very high acquisition rates; they can be easily shaped in different geometry and are very cheap. The main drawback is their poor radiation hardness if used at low energies and high intensities.

8 SUMMARY AND PROSPECTS

It is not so easy to report a complete overview of the activities that are coming out developing low intensity beam diagnostics. The wide choice of materials, detectors and techniques involved produces an increasing quantity of experimental apparatus very different in terms of performances and operating ranges. In any case, this is an encouraging situation meaning that the interest is very high as well as the number of the possible applications.

At the end of this very general overview it is possible to draw some conclusions regarding the state of art and the prospects of this activity. To satisfy all the requirements for the low intensity beam diagnostics the investigation on the use of particles detecting techniques has produced the most promising results. Gas chambers as well as scintillators based detectors represent the preferred solutions for their versatility, reliability and cost. For the next future, also the diamond based detectors will represent a good alternative.

NONLINEAR SPACE CHARGE EFFECTS AND EMITTANCE GROWTH IN LINAC*

Yinbao Chen and Zhibin Huang
China Institute of Atomic Energy, P.O. Box 275(17), Beijing 102413

Abstract

The nonlinear space charge effect of bunched beam in linac is one of the important reasons that induce the emittance growth. The general formulas for calculating the potential of space charge with nonuniform distribution in surrounding structure are presented. For a bunched beam with different distribution in waveguide of linac, the expresses of the nonlinear field energy of a cylinder model of space charge are derived, and the numerical results of the nonlinear field energy for different density distributions are given. The emittance growth caused by these nonuniformities are discussed.

1 INTRODUCTION

In high-current beam for Free Electron Laser (FEL) and linear accelerator for high energy physics, induction linac for heave ion fusion, microwave devices and other applications, the space charge force is no longer small compared with the externally applied focusing forces. And the space charge effect is assumed to be one of the fundamental factors governing the beam dynamics.

Since the theoretical study and numerical simulation show that the nonuniform particle distributions have more electrostatic field energy per unit length than that of the equivalent uniform beam with the same current I, rms radius, and rms emittance. Therefore, it is suggested that this additional field energy is converted into particle kinetic energy and caused emittance growth as the distribution tends to become more homogeneous. This concept has been already accepted by many studies. Historically, the relationship between rms emittance and space charge field energy term for a continuous beam in a continuous focusing channel was firstly derived by Lapostolle [1]. The rms envelope equation with space charge was obtained by Sacherer [2]. An equation for emittance growth in space-charge-dominated beam having nonuniform density was derived by Struckmeier, Klabunde, and Reiser [3]. For a round continuous beam with an arbitrary distribution in a linear focusing channel, a differential equation for emittance change was derived by Wangler [4]. And, a generalized differential equation for a bunched beam was derived by Hofmann and Struckmeier [5]. Also, there are many further study results on the subject (see for examples Ref. [6] and [7]).

We should point it out that the above results concerning the calculation of the space charge field energy are based on the assumption of a continuous beam in a tube or a bunched beam in free space though involved with different density distributions. There is an obvious difference between these results and the reality of the electron (or ion) bunched beam in a linear accelerator or some microwave devices.

With regard to a bunched beam in surrounding structures, the space charge effects of nonuniform density distributions in waveguide of linac have been studied in our early work [8]. In this paper, first we review the main point of Ref. [8] to give the general formulas for potential induced by a cylinder of space charge with nonuniform density distribution in a surrounding cylinder (Section 2); in Section 3, for a bunched beam with nonuniform distributions in waveguide of linac, we present the expresses of the nonlinear field energy of a cylinder model of space charge; in Section 4, we show the numerical results of the nonlinear field energy for different density distributions; and finally, in Section 5, we discuss the emittance growth for a bunched beam in linac.

2 GENERAL FORMULAS FOR POTENTIAL OF NONUNIFORM CHARGE DISTRIBUTION

For the convenience of understanding and application, here we review the main point of Ref.[8] in which the general formulas for calculating the potential of space charge with nonuniform distributions in waveguide have been obtained.

A cylinder model of space charge is used to present a space charge bunch in linac as shown in Fig.1.

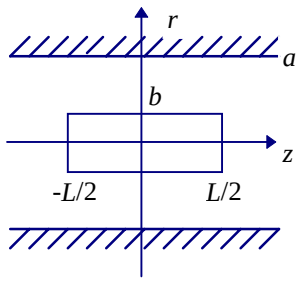

Figure 1. Cylinder model of space charge.

Letting a as the accelerator waveguide radius, b and $\pm L/2$ as the boundaries of the cylinder model in r and z directions,

* Supported by National Natural Science of China.

respectively. The potential induced by the space charge bunch with uniform distribution ρ in a cylindrical coordinate system can be written as follows [9]:

$$\varphi_0 = \rho\, f_0(r,z;b,L/2), \tag{1}$$

where f_0 is the potential induced by a unit space charge density.

According to the general formulas in Ref.[8], for the space charge bunch model with nonuniform charge density distribution $\rho(r,z)=\rho(r)\rho(z)$, we have the induced potential as follows:

$$\varphi = \int_0^{\frac{L}{2}}\int_0^b \rho(\xi,\zeta)\frac{\partial^2 f_0(r,z;\xi,\zeta)}{\partial\xi\partial\zeta}d\xi d\zeta\,. \tag{2}$$

Therefore, so long as the potential φ_0 (in the form of Eq.(1)) induced by a space charge bunch model with uniform distribution is known, the potential φ induced by the space charge with the same model but nonuniform distribution can be obtained from Eq.(2).

The potentials of a cylinder of space charge with uniform density distribution inside a conducting cylinder have been obtained : [9]

$$\varphi_{1,2} = \frac{2\rho ab}{\varepsilon_0}\sum_{l=1}^{\infty}\frac{J_1(k_l b)J_0(k_l r)}{(k_l a)^3 J_1^2(k_l a)}sh\frac{k_l L}{2}e^{-k_l|z|},\ \left(|z|>\frac{L}{2}\right), \tag{3}$$

$$\varphi_3 = \frac{2\rho ab}{\varepsilon_0}\sum_{l=1}^{\infty}\frac{J_1(k_l b)J_0(k_l r)}{(k_l a)^3 J_1^2(k_l a)}\left[1-ch(k_l z)e^{-\frac{k_l L}{2}}\right],\ \left(|z|<\frac{L}{2}\right), \tag{4}$$

where $J_i(k_l x)$ is the Bessel function of the ith order, and k_l is chosen so that $J_0(k_l a)=0$. Substituting Eqs. (3) and (4) into Eq. (2), we can rewrite the general formulas for calculating the potential induced by the same cylinder of space charge with nonuniform distribution as follows:

$$\varphi_{1,2} = \frac{2}{\varepsilon_0 a}\int_0^{\frac{L}{2}}\int_0^b \rho(\xi,\zeta)\sum_{l=1}^{\infty}\frac{\xi J_0(k_l\xi)J_0(k_l r)}{(k_l a)J_1^2(k_l a)}ch(k_l\zeta)e^{-k_l|z|}d\xi d\zeta,\ \left(|z|>\frac{L}{2}\right), \tag{5}$$

$$\varphi_3 = \frac{2}{\varepsilon_0 a}\int_0^{|z|}\int_0^b \rho(\xi,\zeta)\sum_{l=1}^{\infty}\frac{\xi J_0(k_l\xi)J_0(k_l r)}{(k_l a)J_1^2(k_l a)}ch(k_l\zeta)e^{-k_l|z|}d\xi d\zeta + \\ + \frac{2}{\varepsilon_0 a}\int_{|z|}^{\frac{L}{2}}\int_0^b \rho(\xi,\zeta)\sum_{l=1}^{\infty}\frac{\xi J_0(k_l\xi)J_0(k_l r)}{(k_l a)J_1^2(k_l a)}ch(k_l z)e^{-k_l\zeta}d\xi d\zeta,\ \left(|z|<\frac{L}{2}\right). \tag{6}$$

Suppose that the density is given by

$$\rho(r,z) = N_{t,l}\rho_{t,l}\,, \tag{7}$$

where the normalization constants $N_{t,l}$ are chosen to satisfy $2\pi\int_0^b\int_{-\frac{L}{2}}^{\frac{L}{2}}\rho(r,z)rdrdz = Nq$, where N is the total number of particles, the subscription t presents the distribution in transverse direction and l represents that in longitudinal direction. Therefore, t and l can be u (for uniform), w (for waterbag), p (for parabolic) and g (for Gaussian). We list all possible combinations of the four distributions in Table 1, where

$$\rho_{u,u}(r,z)=\frac{Nq}{\pi b^2 L}, \qquad \rho_{w,u}(r,z)=\frac{2Nq}{\pi b^2 L}\left(1-\frac{r^2}{b^2}\right),$$

$$\rho_{p,u}(r,z)=\frac{3Nq}{\pi b^2 L}\left(1-\frac{r^2}{b^2}\right)^2, \qquad \rho_{g,u}(r,z)=\frac{Nq}{2\pi\alpha^2 L}e^{-\frac{r^2}{2\alpha^2}},$$

$$\rho_{u,w}(r,z)=\frac{3Nq}{2\pi b^2 L}\left[1-\frac{z^2}{(L/2)^2}\right], \qquad \rho_{w,w}(r,z)=\frac{3Nq}{\pi b^2 L}\left(1-\frac{r^2}{b^2}\right)\left[1-\frac{z^2}{(L/2)^2}\right],$$

$$\rho_{p,w}(r,z)=\frac{9Nq}{2\pi b^2 L}\left(1-\frac{r^2}{b^2}\right)^2\left[1-\frac{z^2}{(L/2)^2}\right], \qquad \rho_{g,w}(r,z)=\frac{3Nq}{4\pi\alpha^2 L}e^{-\frac{r^2}{2\alpha^2}}\left[1-\frac{z^2}{(L/2)^2}\right],$$

$$\rho_{u,p}(r,z)=\frac{15Nq}{8\pi b^2 L}\left[1-\frac{z^2}{(L/2)^2}\right]^2, \qquad \rho_{w,p}(r,z)=\frac{15Nq}{4\pi b^2 L}\left(1-\frac{r^2}{b^2}\right)\left[1-\frac{z^2}{(L/2)^2}\right]^2,$$

$$\rho_{p,p}(r,z)=\frac{45Nq}{8\pi b^2 L}\left(1-\frac{r^2}{b^2}\right)^2\left[1-\frac{z^2}{(L/2)^2}\right]^2, \qquad \rho_{g,p}(r,z)=\frac{15Nq}{16\pi\alpha^2 L}e^{-\frac{r^2}{2\alpha^2}}\left[1-\frac{z^2}{(L/2)^2}\right]^2,$$

$$\rho_{u,g}(r,z)=\frac{Nq}{\pi b^2 LD}e^{-\frac{z^2}{2\beta^2}}, \qquad \rho_{w,g}(r,z)=\frac{2Nq}{\pi b^2 LD}\left(1-\frac{r^2}{b^2}\right)e^{-\frac{z^2}{2\beta^2}},$$

$$\rho_{p,g}(r,z)=\frac{3Nq}{\pi b^2 LD}\left(1-\frac{r^2}{b^2}\right)^2 e^{-\frac{z^2}{2\beta^2}}, \qquad \rho_{g,g}(r,z)=\frac{Nq}{2\pi\alpha^2 LD}e^{-\frac{r^2}{2\alpha^2}}e^{-\frac{z^2}{2\beta^2}}, \tag{8}$$

and

$$\alpha^2=\langle r^2\rangle,\ \beta^2=\langle z^2\rangle,\ D=\frac{1}{2}\int_{-1}^{1}e^{-\frac{L^2}{8\beta^2}t^2}dt\,. \tag{9}$$

Table 1. Density Distributions

Distribution in transverse direction	Distribution in longitudinal direction			
	uniform	waterbag	parabolic	Gaussian
uniform	$\rho_{u,u}$	$\rho_{u,w}$	$\rho_{u,p}$	$\rho_{u,g}$
waterbag	$\rho_{w,u}$	$\rho_{w,w}$	$\rho_{w,p}$	$\rho_{w,g}$
parabolic	$\rho_{p,u}$	$\rho_{p,w}$	$\rho_{p,p}$	$\rho_{p,g}$
Gaussian	$\rho_{g,u}$	$\rho_{g,w}$	$\rho_{g,p}$	$\rho_{g,g}$

Substituting the density distributions of Eq. (8) into Eqs. (3) to (6), we can get the potentials induced by the cylinder of space charge with different density distributions. (For details of the derivation see Refs. [10] to [12]).

3 NONLINEAR FIELD ENERGY OF A CYLINDER OF SPACE CHARGE IN LINAC

The nonlinear field energy of the cylinder model of space charge in a waveguide of linac can be found by integrating φdq over the entire volume occupied by the space charge: [9]

$$W = 2\pi\int_{r=0}^{r=b}\int_{z=-\frac{L}{2}}^{z=\frac{L}{2}}\rho\varphi rdrdz\,. \tag{10}$$

Substituting the different density distributions of Eq.(8) and the potentials φ induced by these space charge in the regime ($|z|<L/2$) from Eq.(6) into Eq.(10), we get the self-field energy of the cylinder of space charge in waveguide as the following.

For a bunched beam with longitudinal uniform distribution and different distributions in transverse direction, we get:

$$W_{u,u}=\frac{2N^2q^2a^2}{\pi\varepsilon_0 Lb^2}\sum_{l=1}^{\infty}\frac{J_1^2(k_lb)}{(k_la)^4J_1^2(k_la)}A_{kv}\ , \tag{11}$$

$$W_{w,u}=\frac{32N^2q^2a^4}{\pi\varepsilon_0 Lb^4}\sum_{l=1}^{\infty}\frac{J_2^2(k_lb)}{(k_la)^6J_1^2(k_la)}A_{kv}\ , \tag{12}$$

$$W_{p,u}=\frac{1152N^2q^2a^6}{\pi\varepsilon_0 Lb^6}\sum_{l=1}^{\infty}\frac{J_3^2(k_lb)}{(k_la)^8J_1^2(k_la)}A_{kv}\ , \tag{13}$$

$$W_{g,u}=\frac{N^2q^2}{2\pi\varepsilon_0 L}\sum_{l=1}^{\infty}\frac{e^{-k_l^2\alpha^2}}{(k_la)^2J_1^2(k_la)}A_{kv}\ , \tag{14}$$

where

$$A_{kv}=1-\frac{2}{k_lL}sh\frac{k_lL}{2}e^{-\frac{k_lL}{2}}\ . \tag{15}$$

For a bunched beam with longitudinal waterbag distribution and different distributions in transverse direction, we get:

$$W_{u,w}=\frac{18N^2q^2a^2}{\pi\varepsilon_0 Lb^2}\sum_{l=1}^{\infty}\frac{J_1^2(k_lb)}{(k_la)^4J_1^2(k_la)}A_{wb}\ , \tag{16}$$

$$W_{w,w}=\frac{288N^2q^2a^4}{\pi\varepsilon_0 Lb^4}\sum_{l=1}^{\infty}\frac{J_2^2(k_lb)}{(k_la)^6J_1^2(k_la)}A_{wb}\ , \tag{17}$$

$$W_{p,w}=\frac{10368N^2q^2a^6}{\pi\varepsilon_0 Lb^6}\sum_{l=1}^{\infty}\frac{J_3^2(k_lb)}{(k_la)^8J_1^2(k_la)}A_{wb}\ , \tag{18}$$

$$W_{g,w}=\frac{9N^2q^2}{2\pi\varepsilon_0 L}\sum_{l=1}^{\infty}\frac{e^{-k_l^2\alpha^2}}{(k_la)^2J_1^2(k_la)}A_{wb}\ , \tag{19}$$

where

$$A_{wb}=\frac{2}{15}-\frac{1}{3(k_lL/2)^2}+\frac{1}{(k_lL/2)^3}\left[1+\frac{1}{(k_lL/2)}\right]-$$
$$-\frac{1}{(k_lL/2)^3}\left[1+\frac{1}{(k_lL/2)}\right]^2e^{-\frac{k_lL}{2}}sh\frac{k_lL}{2}\ . \tag{20}$$

For a bunched beam with longitudinal parabolic distribution and different distributions in transverse direction, we get:

$$W_{u,p}=\frac{20N^2q^2a^2}{7\pi\varepsilon_0 Lb^2}\sum_{l=1}^{\infty}\frac{J_1^2(k_lb)}{(k_la)^4J_1^2(k_la)}A_{pa}\ , \tag{21}$$

$$W_{w,p}=\frac{320N^2q^2a^4}{7\pi\varepsilon_0 Lb^4}\sum_{l=1}^{\infty}\frac{J_2^2(k_lb)}{(k_la)^6J_1^2(k_la)}A_{pa}\ , \tag{22}$$

$$W_{p,p}=\frac{11520N^2q^2a^6}{7\pi\varepsilon_0 Lb^6}\sum_{l=1}^{\infty}\frac{J_3^2(k_lb)}{(k_la)^8J_1^2(k_la)}A_{pa}\ , \tag{23}$$

$$W_{g,p}=\frac{5N^2q^2}{7\pi\varepsilon_0 L}\sum_{l=1}^{\infty}\frac{e^{-k_l^2\alpha^2}}{(k_la)^2J_1^2(k_la)}A_{pa}\ , \tag{24}$$

where

$$A_{pa}=1-\frac{3}{(k_lL/2)^2}+\frac{63}{2(k_lL/2)^4}+\frac{945}{2(k_lL/2)^6}+\frac{2835}{2(k_lL/2)^7}+\frac{2835}{2(k_lL/2)^8}$$
$$-\frac{315}{2(k_lL/2)^5}\left[1+\frac{3}{(k_lL/2)}+\frac{3}{(k_lL/2)^2}\right]^2e^{-\frac{k_lL}{2}}sh\frac{k_lL}{2}\ . \tag{25}$$

For a bunched beam with longitudinal Gaussian distribution and different distributions in transverse direction, we get:

$$W_{u,g}=\frac{2N^2q^2a^2}{\pi\varepsilon_0 Lb^2}\sum_{l=1}^{\infty}\frac{J_1^2(k_lb)}{(k_la)^4J_1^2(k_la)}A_{ga}\ , \tag{26}$$

$$W_{w,g}=\frac{32N^2q^2a^4}{\pi\varepsilon_0 Lb^4}\sum_{l=1}^{\infty}\frac{J_2^2(k_lb)}{(k_la)^6J_1^2(k_la)}A_{ga}\ , \tag{27}$$

$$W_{p,g}=\frac{1152N^2q^2a^6}{\pi\varepsilon_0 Lb^6}\sum_{l=1}^{\infty}\frac{J_3^2(k_lb)}{(k_la)^8J_1^2(k_la)}A_{ga}\ , \tag{28}$$

$$W_{g,g}=\frac{N^2q^2}{2\pi\varepsilon_0 L}\sum_{l=1}^{\infty}\frac{e^{-k_l^2\alpha^2}}{(k_la)^2J_1^2(k_la)}A_{ga}\ , \tag{29}$$

where

$$A_{ga}=\frac{k_lL}{8D^2}\int_{-1}^{1}\left[\left(1-|t|\right)\int_{-1}^{1}e^{-\frac{L^2}{8\beta^2}\left(\frac{1-|t|}{2}v+\frac{1+|t|}{2}\right)^2-\frac{k_lL}{2}\left(\frac{1-|t|}{2}v+\frac{1+|t|}{2}\right)}dv\right]\times$$
$$\times e^{-\frac{L^2}{8\beta^2}t^2}ch\frac{k_lL}{2}tdt+\frac{k_lL}{8D^2}\int_{-1}^{1}e^{-\frac{L^2}{8\beta^2}t^2-\frac{k_lL}{2}|t|}\times$$
$$\times\left[|t|\int_{-1}^{1}e^{-\frac{L^2}{8\beta^2}\left(\frac{|t|}{2}v+\frac{|t|}{2}\right)^2}ch\frac{k_lL}{2}\left(\frac{|t|}{2}v+\frac{|t|}{2}\right)dv\right]dt\ . \tag{30}$$

4 NUMERICAL RESULTS OF NONLINEAR FILED ENERGY

As an example, take a cylinder model of space charge with total charge $Nq=6\times10^{-9}$ Coulomb in a surrounding cylinder with radius $a=0.015$m. The calculations of nonlinear field energy W versus b/a of the bunch and wall radius and b/L of the bunch radius and length are carried out. The related plots for different transverse distributions combining different longitudinal distributions are shown in Figures 2 and 3. As can be seen, first, the all nonuniform particle distributions have more nonlinear field energy than that of the equivalent uniform beam. Second, the nonlinear field energies increase as b/L increases and decrease as b/a increases for all distributions. Thirdly, from Fig.2, it can be seen that the smaller the b/a, the bigger the nonlinear field energy W. Therefore, it can be predicted, the nonlinear field energy tends its maximum in free space for a space charge bunch with any distribution.

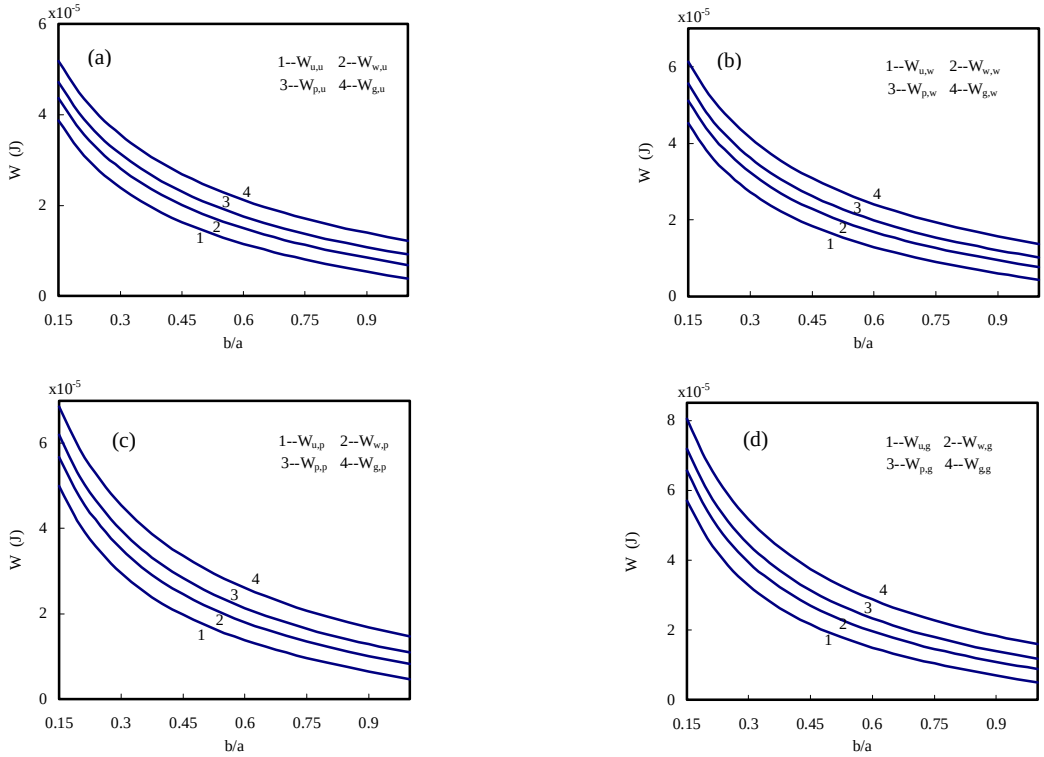

Figure 2. Field energy W versus b/a of the bunch and wall radius for different transverse distributions and (a) longitudinal uniform distribution; (b) longitudinal waterbag distribution; (c) longitudinal parabolic distribution; (d) longitudinal Gaussian distribution.

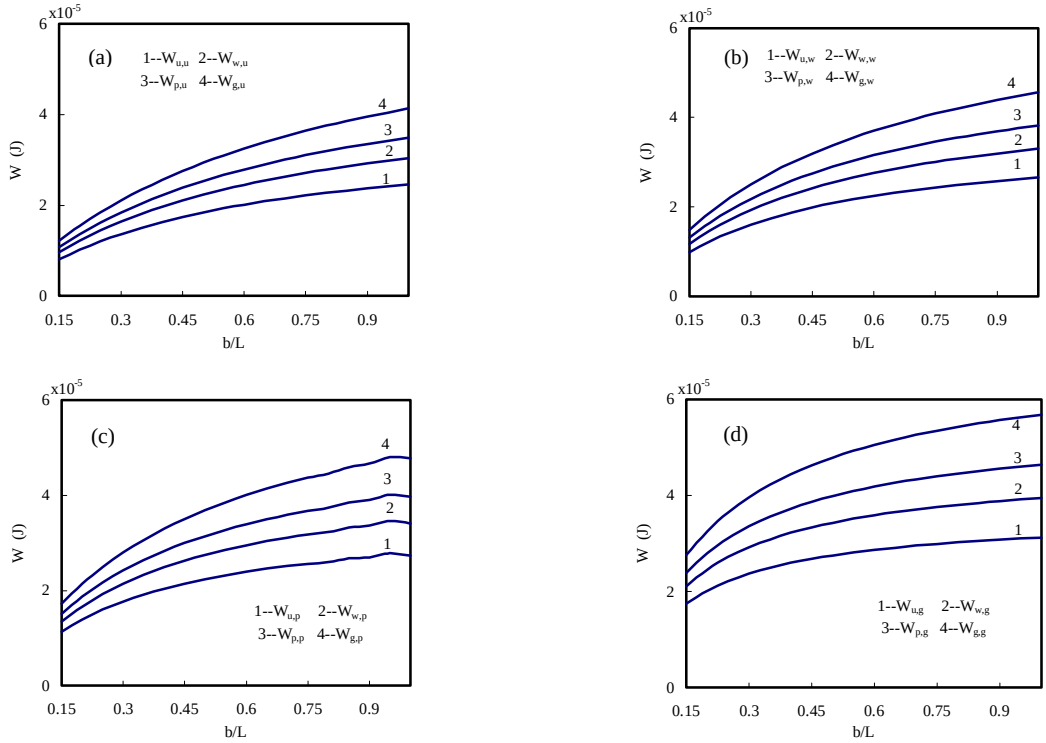

Figure 3. Field energy W versus b/L of the bunch radius and length for different transverse distributions and (a) longitudinal uniform distribution; (b) longitudinal waterbag distribution; (c) longitudinal parabolic distribution; (d) longitudinal Gaussian distribution.

5 EMITTANCE GROWTH FOR A BUNCHED BEAM IN LINAC

The generalized three-dimensional equation for the emittance and field energy of high-current beams in periodic focusing structure was derived by Hofmann and Struckmeier [5], and can be written for three degrees of freedom *x*, *y* and *z (*with linear focusing in each plane) as:

$$\frac{1}{x^2}\frac{d}{ds}\varepsilon_x^2+\frac{1}{y^2}\frac{d}{ds}\varepsilon_y^2+\frac{1}{z^2}\frac{d}{ds}\varepsilon_z^2=-\frac{32}{m\gamma^3v^2N}\frac{d}{ds}(W-W_u), \qquad (31)$$

where $s=v\cdot t$, ε_x , ε_y and ε_z present rms emittance in *x*, *y* and *z* directions, respectively, W and W_u are the space charge field energies of the real beam and equivalent uniform beam. The equation allows one to estimate the total emittance growth if the change of nonlinear field energy can be predicted.

In linear accelerator, the real beams have to be considered in some channels. And hence, the nonlinear field energy of the beam should be calculated in a surrounding structure. It can be seen clearly, from the Fig.2 and Fig.3, the nonlinear field energies are not only dependent of the ratio b/L of the bunch radius and length, but also dependent of the ratio b/a of the bunch and wall radius. It is also true for the free energy. Letting the quantity U_n:

$$U_n=(W-W_u)/W_u \ . \qquad (32)$$

U_n is a measure of the nonuniformity of the charge density and represents the field energy which can be converted into particle kinetic energy as the distribution tends to become more homogeneous. And hence it leads the emittance growth. As some examples, taking $W_u=W_{u,u}$, and W equals to $W_{w,w}$, $W_{p,w}$, $W_{g,w}$, $W_{w,p}$, $W_{p,p}$, and $W_{g,p}$ respectively, we obtain U_n versus b/a for these distributions as shown in Fig.4.

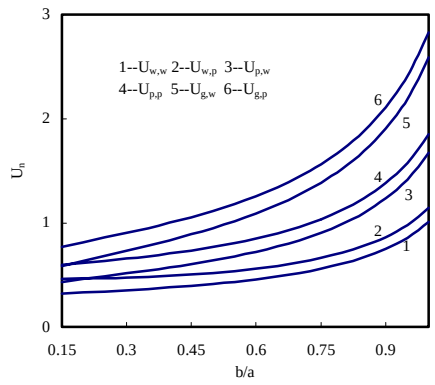

Figure 4. Free energy U_n versus b/a for some distributions.

Obviously, the emittance growth caused by the free energy U_n will be also dependent of the ratio of the bunch and wall radius, and may tend its minimum in free space. Therefore, it may be not enough to form a true estimation of the emittance growth if the change of nonlinear field energy is predicted with the value in free space in stead of that in a channel of linac.

A HIGH CHARGE, HIGH DUTY FACTOR RF PHOTOINJECTOR FOR THE NEXT GENERATION LINEAR COLLIDER

E. Colby
Stanford Linear Accelerator Center, MS07, Stanford, CA, 94309 USA

Abstract

Testing of the prototype TESLA Test Facility (TTF) RF photoinjector has been completed, and fabrication of the high duty factor TTF injector is underway. Experimental results from the prototype tests conducted at Argonne National Laboratory will be presented. Engineering design work for the high power TTF gun will be discussed together with initial operating experience with a Cesium telluride photocathode in short (50 microbunch) pulse trains, and long RF pulses (1000 millisecond), conducted at Fermilab[1]. An outline of future advanced accelerator R&D activities at Fermilab will also be presented.

1 INTRODUCTION

The TeV Superconducting Linear Accelerator (TESLA) is unique among the world's linear electron accelerator proposals as the only scheme using superconducting radiofrequency (scrf) cavities for acceleration. The TESLA Test Facility (TTF) is being constructed at the Deutsches Elektronen-Synchrotron (DESY) to address engineering and economic questions about the viability of constructing superconducting electron accelerators at energies reaching to 0.5 TeV and beyond. Table 1, reproduced from the design report [1], outlines the parameters of both TESLA-500, a 0.5 TeV collider proposed as the first step towards a 5 TeV machine, and the parameters for the TTF.

Fermilab's participation in the planning and construction of the TTF has been extensive, including key contributions to the cryogen handling systems, cryomodule design, rf input power couplers, and the rf photocathode electron source for the second phase of the TTF testing program.

Initially, a conventional thermionic source was used to supply low bunch charge (37 pC) bunches to the TTF linac at a 216 MHz micropulse repetition rate to provide the correct beam loading current (8 mA) for rf and transport studies. The thermionic injector will be replaced by an rf photocathode gun capable of delivering the TESLA-500 bunch charge (8 nC) at the required repetition rate (1 MHz). Higher order mode power deposited by the bunch wakefields will be studied with the nearly 1 kA beams produced.

[1]Operated by the Universities Research Association for the U. S. Department of Energy. Work also supported in part by grants DE-FG03-ER40796 and W-31-109-ENG-38.

Table 1: TESLA-500 and TTF Parameters

Parameter	TESLA 500	TTF
Linac Energy	250 GeV	500 MeV
RF Frequency	1300 MHz	1300 MHz
Gradient	25 MeV/m	15 MeV/m
No. Cryomodules	~2500	4
Bunch population	5×10^9	5×10^9
Energy Spread[1]	0.15 %	0.1%
Energy Spread[2]	0.1 %	0.2%
Bunch Length[3]	1 mm	1 mm
Beam Current	8 mA	8 mA
Macropulse length	0.8 ms	0.8 ms
Injection Energy	20 MeV	20 MeV
Emittances[4]	20 x 1 μm	20 x 20 μm
Beam Size[5]	260 x 60 μm	3.5 mm
Beam Size	50 x 12 μm	0.5 mm
Micropulse spacing	1 μs	1 μs
Macropulse spacing	100 ms	100 ms

[1]RMS, single bunch
[2]RMS, bunch-to-bunch
[3]RMS, one-sigma
[4]RMS, one-sigma, normalized
[5]RMS, one-sigma

Once the wakefield and transport studies have been completed, plans call for replacement of the high charge gun with a low-charge low-emittance photocathode gun for the FEL experiments. A Self-Amplified Spontaneous Emission Free Electron Laser (SASE-FEL) will be installed, initially operating in the 100-25 nm range. Ultimately, plans call for a doubling of the linac energy, and modification of the undulator to produce radiation in the 20-6nm range [2]. Operation of the high-charge gun, with suitably altered laser parameters, may provide an effective interim alternative [3] for the first phase of the SASE-FEL studies while the new gun is being constructed.

2 INJECTOR DESIGN

Two rf photocathode guns have been built, and a third is currently in fabrication: a low duty cycle($<10^{-3}$) gun for single bunch testing, and two high duty factor guns incorporating differing methods of water channel fabrication.

The design has been described in detail elsewhere [4,5], with only a brief summary provided here. Electrons are produced from a cesium telluride photocathode (plain copper in the low duty cycle prototype) which is on the

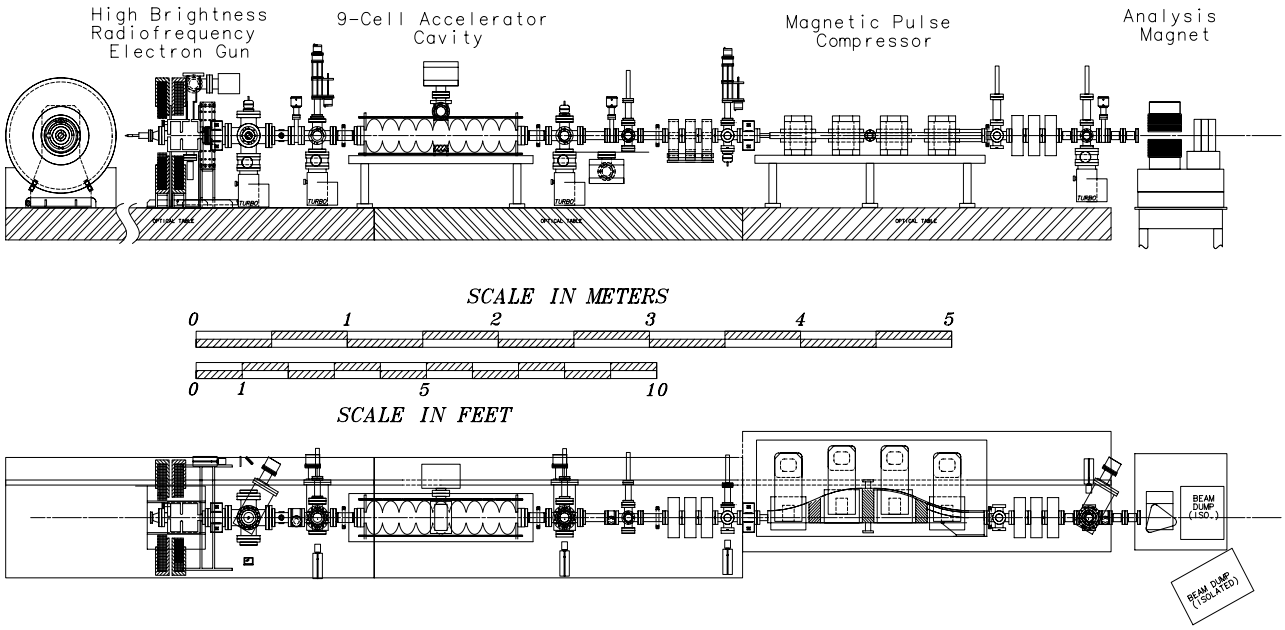

Figure 1: Layout of photoinjector components

rear conducting wall of a 25% elongated half cell. A system of four external solenoids (two focussing and two bucking) provide adjustment of both the strength and longitudinal profile of the magnetic field used to simultaneously focus and space charge correlation compensate ("emittance compensate" [7]) the electron bunch, permitting correlation compensation to be attained over a wide range of accelerating gradients. The bunch is accelerated in the low gradient (18 MeV/m) gun structure of 1.625 cells. The 3.9 MeV electron bunch exits the gun and drifts approximately half a plasma wavelength to the entrance of a superconducting 9-cell booster linac (normal conducting for the prototype).

In the booster it receives moderate acceleration (15 MeV/m) to approximately 18 MeV, and a modest phase-energy correlation. To preserve the transverse emittances, the initial bunch length is 2.2 mm, which is compressed to 1 mm in a dipole chicane (temporal dispersion: $(\phi|dp/p)=2.50$ rad) using the phase-energy correlation developed in the booster linac, which is run off-crest by some 15-20°.

An entrance quadrupole doublet and exit triplet permit beta function matching to the pulse compressor. At the TTF, several quadrupole doublets and triplets relay the beam from the exit of the pulse compressor to the first cryomodule. At Fermilab's A0 Photoinjector installation, quadrupole triplets will provide an interaction region for a variety of advanced accelerator experiments.

Experimental testing of the injector has been taking place in three separate phases:

- With single electron bunches and the low duty factor gun to establish the basic design;
- With short bunch trains (<50 microbunches) and the cesium telluride photocathode to study cathode lifetime effects [6], and with long rf pulses (1 ms), but low duty factor to test for rf breakdown problems;
- With the high duty cycle gun operated with long rf pulses (1 ms) and acceleration provided by a superconducting cavity to study long pulse train operation of the injector.

3 PROTOTYPE TEST PHASE

The prototype injector was installed in two steps at the Argonne Wakefield Accelerator Facility at Argonne National Laboratory. The gun was assembled with a short test beamline, to permit direct diagnosis of the beam produced by the gun, then the test beamline was removed and the booster linac and pulse compressor installed to permit testing of the completed injector.

Shown in figure 2 below is a slit mask emittance measurement of the horizontal emittance as a function of the gun solenoid field strength, made at 16.5 MeV. The emittance compensation minimum is clearly visible.

The energy spectrum of the uncompressed 8 nC bunch is shown in figure 3 below.

Measurement of the bunch length was done with a Hamamatsu streak camera (C1587 streak tube, 1 ps quoted resolution) examining the Cerenkov radiation from an aerojel target. Measured pulse lengths generally showed poor pulse compression, which from subsequent simulations of wakefield effects [8] is believed to have arisen from interactions with the irises in the gun and booster linac. Electron bunches as short as 12 ps FWHM were observed, corresponding to a peak current of more than 850 amperes. Table 2 below outlines the desired, predicted and measured parameters for the injector.

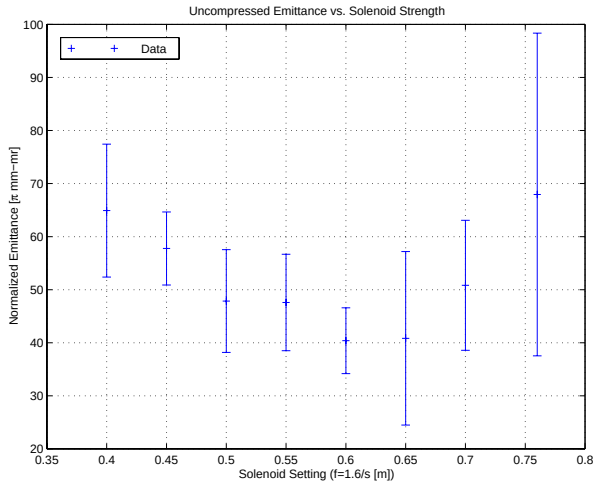

Figure 2: Horizontal emittance measurement versus gun solenoid strength. Error bars are sample variances from ten trials per point.

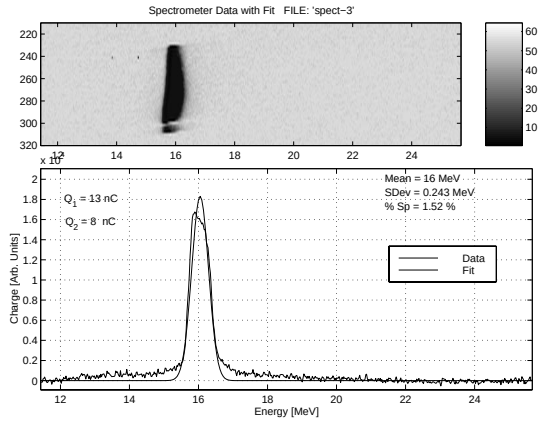

Figure 3: Energy spectrum of uncompressed 16 MeV beam at exit of injector.

Although design values for the injector meet or exceed the requirements for the TTF installation, the conditions under which the injector was tested were different from the idealization in the design. Simulation of the injector using a modified version of PARMELA and the measured values for the rf structure field balances and the measured spatio-temporal distribution of the laser pulse, but excluding wakefield effects shows reasonable correspondence to the measurements, as listed in table 2 below.

As before, quantities are RMS, one-sigma, and the emittances are normalized. It is worth noting that the dominant contributions to the emittance over the design values arise primarily from strong transverse filamentation and Gaussian temporal profile of the laser pulse, and from the unbalanced field strengths in the half and full cell of the gun. Incomplete pulse compression is seen in simulations [8] to be most likely from wakefield effects in the rf structures, which can be compensated effectively by further advancing the phase of the linac.

Table 2: Desired (D), predicted (P), and measured (M) Injector II parameters. 'NM'=not measured.

Parameter	D	P	M	Unit
Charge	8	8	8	nC
Energy	>10	18.3	17 ± 0.2	MeV
Energy Spread	<500	234	260 ± 200	keV
H. Emittance	20	37	40 ± 7	μm
V. Emittance	20	37	N.M.	μm
Bunch Length	1.0	1.6	1.4 ± 0.3	mm
Current, Peak	960	600	<850	A

4 HIGH DUTY CYCLE INJECTOR

With experimental evidence accumulating that the basic injector design was sound, work began to design a gun capable of sustaining the 1% duty factor (50 kW average power deposited in approximately a cubic foot) photocathode gun.

Detailed thermo-mechanical simulations were carried out [9] using Swanson's Ansys analysis system to establish that surface temperature rise due to rf pulse heating, peak surface stress levels, average temperature and average stress levels did not exceed the yield strength of OFE copper.

Given the long rf pulse length (Δt=1 ms) the expected thermal diffusion depth in copper is approximately:

$$\delta = \sqrt{4\alpha\Delta t} \approx 0.67 mm$$

where α is the linear coefficient of thermal expansion for copper. This implies that the deposited power does not reach the water channels during the rf pulse. Hence, the problem breaks into two parts: the pulsed-heating problem, which influences only the material choice and peak power, and the average power problem, which controls the water channel placement.

Peak surface temperature rise determines the peak surface stress and the vacuum outgassing, and is approximately:

$$\Delta T = 2\frac{dP}{dA}\frac{1}{\rho C}\sqrt{\frac{\Delta t}{\pi\alpha_{\varepsilon}}} \approx 29\,^{o}C$$

where dP/dA is the power flux (30 MW/m^2), ρ and c_ε the density and specific heat of copper, respectively.

Figure 4 below shows the predicted thermal cycling at depths of 0.0mm to 4.0mm in 0.5 mm steps, showing the peak surface temperature rise is $\approx 28^{o}$C, as predicted.

Simulation of the volumetric stress induced by the surface temperature rise shows that the peak stress of 79.7 MPa occurs on the iris, where the power density is a maximum. This value is comparable to the yield strength for pure copper, 76 Mpa, but as the surface is constrained by the underlying bulk material, it is not expected that surface spalling will occur at an appreciable rate.

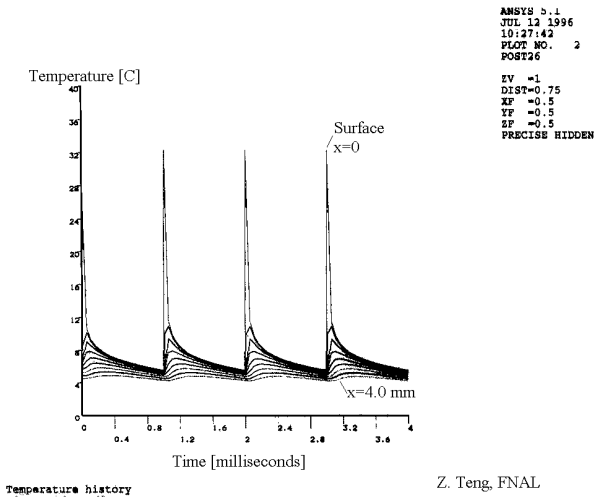

Figure 4: RF Pulse heating in the gun as a function of time.

Computation of the outer wall deflection was also carried out to determine the net cavity detuning that would take place during the RF pulse. The radial displacement before (lower trace) and after (upper trace) the 1 ms rf pulse are shown in figure 5 below. The initial net deflection corresponds to the "steady state" thermal distribution of the gun. The vertical scale is units of 10 microns, the horizontal is units of cm. An outward deflection (by ≈100 microns) of the outer wall close to the iris separating the half and full cell indicates the iris reaches a temperature slightly above the body at steady state.

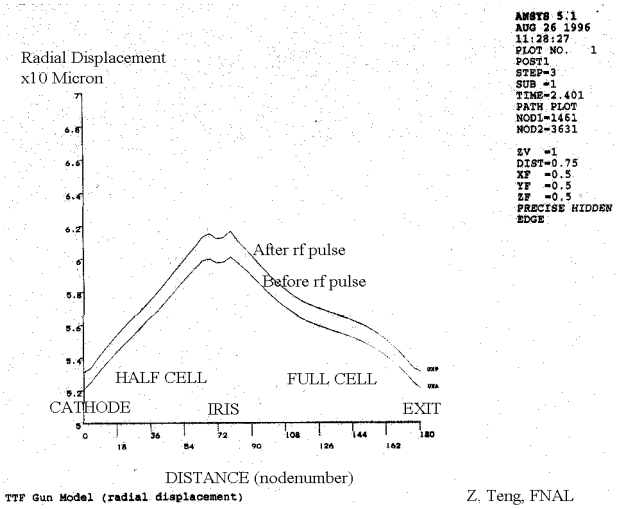

Figure 5: Outer wall radius change before and after rf pulse.

Owing to the high heat load in the thin iris separating the half and full cells of the gun, a cooling channel was machined into the iris to extract the heat. The low duty cycle gun and first high duty cycle gun had the iris cooling channel machined as an open channel (machined in from the full cell side) that was sealed shut by an electron beam welded annular cover. The iris face was machined after the electron beam weld some 0.080" to remove the weld fillet and produce a smooth surface for the high rf fields. This technique succeeded in the low duty cycle gun, but failed in two subsequent trials, fracturing open along and across the weld joint, and succeeded on the third trial with the high duty cycle gun. The reason for the failures is believed to be higher than acceptable impurity content in the copper, a problem worsened by annealing, which concentrates the impurities at the grain boundaries, giving sites of material weakness from which cracks can propagate. XDS analysis of the copper showed elevated levels of oxygen (but below the ASTM-F68-82 specification) and chlorine.

Consequently, another copper billet was purchased from Hitachi, and a fourth gun body produced, but with the iris cooling channel machined in from the gun exterior (not through the face of the full cell), and the channels brazed shut with copper water barriers.

5 HIGH DUTY CYCLE TESTS

Upon completion of the single bunch test at Argonne, the low duty factor injector was disassembled, transported to Fermilab's A-Zero experimental hall, and reassembled with a short diagnostic beamline. After brief rf testing to establish that the gun would successfully hold off much longer rf pulses (50 μs), the gun was dismounted and modified to accept the cesium telluride photocathode. RF conditioning, cathode lifetime and low energy beam experiments took place over the ensuing 6 months while the high duty cycle gun was being fabricated.

As the low and high duty cycle guns were in many respects equivalent for pulsed heating purposes (but not in average power dissipation) extensive rf conditioning of the low duty cycle gun was undertaken to discover limitations of the design. The low duty cycle gun conditioned unexpectedly well, holding off full klystron power (3.4 MW) for more than a millisecond with only occasional breakdown. Conditioning was halted by damage to the rf window incurred during the study. Vacuum was observed to rise from a base value in the 10^{-10} Torr range to the mid-10^{-8} Torr range during the long rf pulses, indicating that substantial rf conditioning will be necessary to obtain good vacuum at the full 1% duty cycle.

Photocathode lifetime was also investigated with the low duty cycle gun, and is described in detail elsewhere in these proceedings [4]. Once vacuum conditions had stabilized in the gun and beamline, we obtained 1.0% or better quantum efficiency from a cesium telluride cathode for more than four months, beginning from an initial QE value in excess of 10%.

Dark current was observed to be substantial (≈4 mA) from the low duty factor gun, and when imaged with the gun solenoid to a screen was seen to be composed of a ring with four or five bright spots on the periphery, implicating either (1) the cathode rf choke-joint spring,

(2) a sharp but recessed ridge in the cathode hole, (3) multipactoring brought on in the cathode-gun gap, perhaps exacerbated by the choke spring's silver plating, or (4) plasma formation, fed with gas by a nearby suspected virtual leak. The geometric features giving rise to (2) and (4) have been eliminated in the high duty cycle gun, and a plain beryllium copper spring has been used to reduce or eliminate the cause of (3).

Beam studies with short (10 microbunch) and longer (50 microbunch) pulse trains were undertaken, with the results being reported elsewhere in these proceedings[9]. Limitations of laser pulse energy limited the bunch charges to a nanocoulomb or less for long pulse trains, but short pulse trains of high charge bunches were also produced.

The first of the two high duty cycle guns was completed at the end of April, and has been successfully conditioned to accept full power, 1 ms rf pulses, with results reported in these proceedings [10]. The second high duty cycle gun should be completed by mid-September.

6 OPEN QUESTIONS

A number of physics issues remain to be resolved. The effect of variation of the solenoid "position" by adjusting the two gun focussing solenoid strengths has not been experimentally observed, and remains an interesting exploration of one facet of the space charge correlation compensation process. Pulse compression (to 1 mm and below) remains to be thoroughly investigated, both in itself, and for its potentially serious effects on the transverse phase space. Finally, finding the source and cure for the large dark current observed from the low duty cycle gun will be important.

7 FUTURE RESEARCH AT A-ZERO

A somewhat modified version of the photoinjector commissioned at DESY will be commissioned at Fermilab for use in an advanced accelerator R&D program. R&D projects which have real resources currently committed are:

- Electro-optically detected wakefield bunch profile measurement (Ph.D. research of M. Fitch, University of Rochester);
- Plasma wakefield acceleration experiments in the under-dense regime (J. Rosenzweig, UCLA, and P. Colestock, FNAL);
- High-efficiency photocathode material preparation and lifetime testing in RF cavity environment (Led by C. Pagani, Istituto Nazionale Di Fisica Nucleare, Milano)
- Fabrication and testing of superconducting rf cavities (H. Edwards, FNAL).

In addition, many more applications of the A0 facilities have been discussed:

- Polarized photocathode source development for RF injectors;
- Testing of next generation photoinjector structures;
- Bunched beam stochastic cooling;
- Impedance probing of stochastic cooling pickup/kicker antennae;
- Beam-beam tune shift neutralization in the Tevatron.

8 ACKNOWLEDGEMENTS

I gratefully acknowledge the support of the Fermilab Beams Division, under whose direction this work has been accomplished. Thanks also to the staff of the Argonne Wakefield Accelerator for their help in conducting the prototype experiments.

STATUS OF THE ISAC ACCELERATOR FOR RADIOACTIVE BEAMS

R. Laxdal, R. Baartman, P. Bricault, G. Dutto, R. Poirier, P. Schmor
TRIUMF, Vancouver, Canada

Abstract

The ISAC radioactive beam facility under construction at TRIUMF includes a 500 MeV proton beam ($I \leq 100\ \mu$A) impinging on a thick target, an on-line source, a mass-separator, an accelerator complex, and experimental areas. The accelerator chain includes a 35 MHz RF Quadrupole (RFQ) to accelerate beams of $A/q \leq 30$ from 2 keV/u to 150 keV/u and a post-stripper, 105 MHz variable energy drift tube linac (DTL) to accelerate ions of $3 \leq A/q \leq 6$ to a final energy from 0.15 to 1.5 MeV/u. The present status of the accelerator complex will be summarized. In particular, first rf and beam tests with the RFQ and the fabrication status of the DTL will be reported.

1 INTRODUCTION

A radioactive ion beam facility with on-line source and linear post-accelerator is being built at TRIUMF[1]. [1] In brief, the facility includes a proton beam (I$\leq$100 μA) from the TRIUMF cyclotron impinging on a thick target, an on-line source to ionize the radioactive products, a mass-separator for mass selection, an accelerator complex and experimental areas. Beams of $E \leq 60$ keV and $A \leq 238$ will be delivered to the low energy experimental area. The accelerator chain includes a 35 MHz RFQ to accelerate beams of $A/q \leq 30$ from 2 keV/u to 150 keV/u and a post stripper, 105 MHz variable energy drift tube linac (DTL) to accelerate ions of $3 \leq A/q \leq 6$ to a final energy between 0.15 MeV/u to 1.5 MeV/u. The accelerators have several noteworthy features. Both linacs are required to operate cw to preserve beam intensity. The RFQ, a four vane split-ring structure, has no bunching section; instead the beam is pre-bunched at 11.7 MHz with a single-gap, pseudo sawtooth buncher. The variable energy DTL is based on a unique separated function approach with five independent interdigital H-mode (IH) structures providing the acceleration and quadrupole triplets and three-gap bunching cavities between tanks providing transverse and longitudinal focussing respectively. A layout of the ISAC accelerator chain is shown in Fig. 1.

During 1998 TRIUMF management shifted the priority in ISAC to the target hall and mass-separator areas. Consequently progress on the accelerator has slowed somewhat. Nonetheless the building is complete and occupancy of the accelerator floor began in July 1997. In less than a year a source and injection line have been commissioned and initial rf and beam tests with the RFQ in an intermediate configuration have been successfully completed. In addition the first DTL buncher has been delivered in preparation for rf tests and the first DTL IH tank is ready for copper plating.

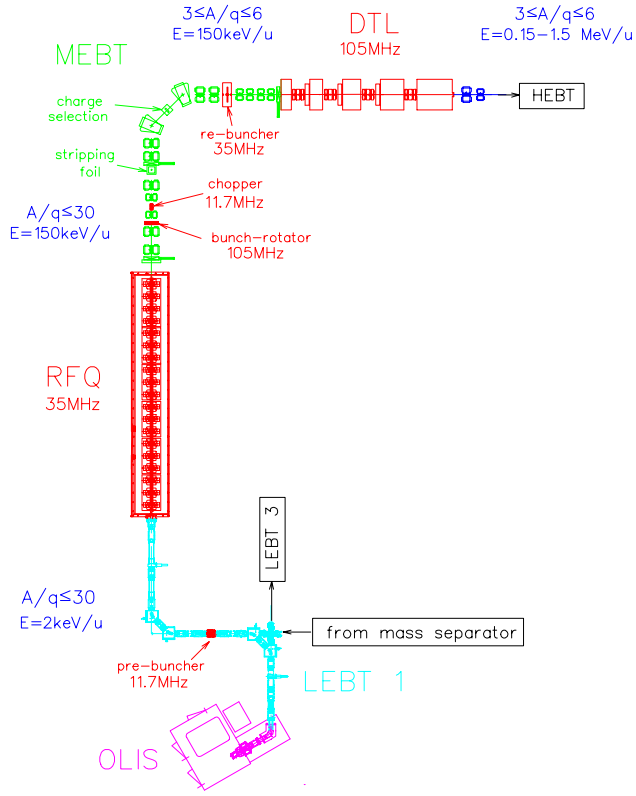

Figure 1: The ISAC linear accelerator.

2 LEBT

The low energy beam transport (LEBT) consists of electrostatic elements; quadrupoles, steering plates and spherical bends, that transport the exotic beams from the mass-separator and stable beams from an off-line ion source (OLIS) located on the accelerator floor[2]. An electrostatic switchyard allows selection of either the stable or unstable beam for acceleration while the other beam can be sent to the low energy experimental area.

The beam to be accelerated is pre-bunched at 11.7 MHz, the third sub-harmonic of the RFQ frequency, in a single gap, multi-harmonic pseudo-sawtooth pre-buncher. The pre-buncher frequency was selected at the request of experimenters to give a longer bunch spacing (86 ns), a useful feature for certain TOF and coincidence rejection techniques.

The pre-buncher is positioned ∼5 m upstream of the RFQ. The last four quadrupoles upstream of the RFQ match the beam to the RFQ acceptance.

Installation of the off-line ion source (OLIS) began in July 97 with first beam extracted in November 97. Commissioning of the LEBT from OLIS to the RFQ followed soon after. The saw-tooth prebuncher was installed and commissioned with three harmonics in February 98. The fourth harmonic will be added following an upgrade to the wide band amplifier. During commissioning the bunched beam structure was measured with a cone type fast Faraday cup. Tuning proved relatively straight forward, the phase of each harmonic was determined with the beam and the amplitudes were set to pre-determined values followed by empirical optimization.

3 RFQ

The 8 m long, 1m×1m ISAC RFQ tank (Fig. 2) houses 19 split ring structures each feeding 40 cm lengths of modulated electrode. Both rings and electrodes are water cooled to dissipate the expected 100 kW of rf power[3]. The design peak voltage between electrodes is 74 kV, with a bore radius of r_0=7.4 mm.

The buncher and shaper sections of the RFQ have been completely eliminated from the design in favour of a four-harmonic sawtooth pre-buncher[4]. This not only has the benefit of shortening the structure but also reduces the output longitudinal emittance. These gains are made at the expense of a slightly lower beam capture. We expect 81% of the beam will be accelerated in the 11.7 MHz buckets while ∼3.5% will be accelerated in the two 35 MHz side-buckets with ∼15% of the beam unaccelerated and lost in the MEBT.

The initial seven ring segment of the RFQ (2.8 m) has been installed for an interim rf and beam test[5]. A copper wall is located just downstream of the seven ring section to isolate the rf fields. The beam is accelerated to 55 keV/u and

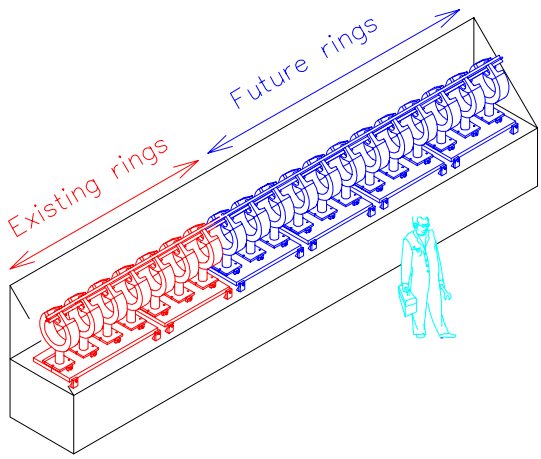

Figure 2: The ISAC 35 MHz RFQ.

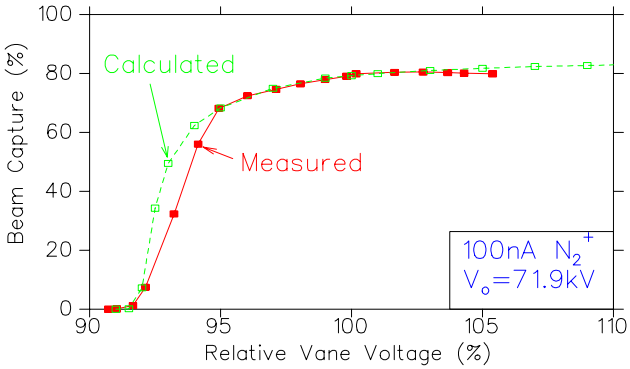

Figure 3: Beam test results from the RFQ. Shown is the capture efficiency of a N_2^+ beam as a function of relative vane voltage (solid line). The calculated capture efficiency is plotted (dashed line) for comparison.

then eight electrostatic quadrupoles, located inside the RFQ tank, transport the beam to a diagnostic station located at the exit of the RFQ. Signal level measurements of the rf have determined a frequency of 35.7 MHz, a shunt impedance of 292 kΩ·m and $Q = 8700$. Power level tests have confirmed stable operation in cw mode at peak voltage[3]. First beam was accelerated June 6/98. Since then both N^+ ($A = 14$) and N_2^+ ($A = 28$) have been accelerated testing performance at both low and high power with excellent results. In particular, in the case of N_2^+, 80% of the beam was accelerated with three harmonics on the pre-buncher in perfect agreement with PARMTEQ predictions (Fig.3). The beam quality also is as expected. The tests will continue through October 98. The remainder of the rings will then be installed with the commissioning of the full RFQ in the fall of 1999.

4 MEBT

The beam is stripped in the medium energy beam transport (MEBT) with a thin carbon foil (3 μgm/cm^2) to boost the charge state before acceleration in the DTL. The beam from the RFQ is focussed in three dimensions onto the stripping foil with quadrupoles and a 105 MHz double gap bunch rotator to minimize emittance growth due to multiple scattering and energy straggling. A chopper eliminates the small quantity of beam (∼3%) accelerated in the two 35 MHz buckets neighbouring the main pulse. After charge selection the beam is matched into the DTL with quadrupoles and a 35 MHz re-buncher.

All quadrupoles have been received. A two-gap spiral re-buncher is presently in development. A model has been completed to study the mechanical rigidity. The MEBT will be installed in the summer of 1999 in time to commission the full energy RFQ.

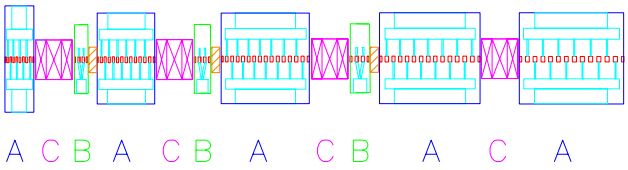

Figure 4: Schematic drawing of the ISAC variable energy separated function DTL. Five IH tanks (A) provide acceleration at 0° synchronous phase, three triple gap spiral resonators (B) provide longitudinal focus ($\phi_s \sim -60°$) and quadrupole triplets (C) provide transverse focus.

5 DRIFT TUBE LINAC

A schematic drawing of the DTL is shown in Fig. 4. The separated function design [6] offers the flexibility and beam quality of a super-conducting linac but at a reduced cost and complexity. To achieve a reduced final energy the higher energy IH tanks are turned off and the voltage and phase in the last operating tank are varied. The three-gap split ring cavities are adjusted to maintain longitudinal bunching. In this way the whole energy range can be covered with 100% transmission and no longitudinal emittance growth.

Fabrication of the first IH tank and the first split-ring buncher are proceeding in advance of the bulk of the DTL in order to get experience with the fabrication techniques. The stems and ridges of the first tank have been received. They are both fabricated from solid copper. The completed tank is being copper plated prior to final assembly. Power tests are scheduled for the fall.

The first DTL buncher[7], a split-ring three gap structure operating at 105 MHz, has been designed and fabricated at INR-RAS Troitsk and has been delivered to TRIUMF for power level tests. The fabrication of the remainder of the cavities will proceed after the acceptance tests are complete. The quadrupole triplets have been specified and are presently in design. Commissioning of the DTL is expected in the middle of 2000.

6 BEAM QUALITY

The beam from the source is expected to have a transverse emittance no larger than $\epsilon_{x,y} = 50\pi\mu$m corresponding at 2 keV/u to a normalized emittance of $\epsilon_n = \beta\gamma\epsilon = 0.1\pi\mu$m. The expected transverse and longitudinal emittances at various locations in the accelerator chain are shown in Table 6. The values quoted enclose 98% of the particles. Note the effect of multiple scattering and energy straggling in the stripping foil and the small emittance growth in the MEBT rebuncher. The transverse acceptance of the RFQ and DTL are large enough that no emittance increase is expected during acceleration. The technique of pre-bunching the beam entering the RFQ and eliminating the bunching and shaping section in the RFQ gives a very compact beam in longitudinal phase space. The longitudinal acceptance of the DTL and flexibility of the design are such that not more than 10% emittance growth is expected over the whole energy range.

Table 1: Simulation results showing the beam emittance at various locations in the ISAC accelerator chain. The values quoted enclose 98% of the particles.

Position	Transverse		Longitudinal	
	$\epsilon_{x,y}$	$\beta\epsilon_{x,y}$	ϵ_z	ϵ_z
	($\pi\mu$m)	($\pi\mu$m)	(π% ns)	(πkeV/u ns)
LEBT	50	0.1	DC	DC
After RFQ	5	0.1	0.33	0.5
After Foil	10	0.2	0.45	0.67
Before DTL	11	0.22	0.50	0.74
After DTL	$11\cdot(\frac{0.018}{\beta_{fin}})$	0.22	$0.5\cdot(\frac{0.15}{E_{fin}})$	0.74

7 FUTURE PLANS - ISAC2

TRIUMF is currently preparing a new five year plan requesting additional funding from the Canadian Government for the period beginning in April 2000. A major element of this plan includes an upgrade of the ISAC facility, ISAC2, to permit acceleration of radio-active ion beams up to energies of at least 6.5 MeV/u for masses up to 150[8]. In brief the proposed acceleration scheme would use the existing RFQ with the addition of an ECR charge state booster to achieve the required charge to mass ratio ($q/A \geq 1/30$) for masses up to 150. A new room temperature drift tube linac would accelerate the beam from the RFQ to 400 keV/u where the beam could be more efficiently stripped to give a charge to mass ratio greater than 1/7 for the full mass range. This beam would then be accelerated by a linac consisting of many short superconducting cavities. The design is compatible with staging scenarios that achieve beams up to ~5 MeV/u and A up to 60 as early as 2003 albeit with reduced ion intensity compared to the completed facility.

Abstract

The SCHERM space charge routine reported in the 1996 linac conference is based on a representation of the charge density distribution in a bunch with an Hermite series expansion. Approximate values of the field components are deduced from the properties of the Hermite functions. First applications of the method for the 180 mA CERN proton linac showed promising results, however the method has shown its limitations when it was tested in a periodic accelerating channel (6 MeV to 100 MeV) with highly tune-depressed beams. Problems underlying the approach are discussed, and solutions are proposed.

1 INTRODUCTION

A new type of approach for the space charge computation, without the need of a strict symmetry has been reported in [1]. It is based on the 3-dimensional representation of the charge density distribution with a Hermite-series expansion. Approximated values of the field components were deduced in order to be good in the bunch core where most of the particles lie. The method had been successfully applied at the 180 mA CERN proton linac beam. Results compared very well with those computed with SCHEFF for this beam. Emboldened by the initial success, we applied this approach to a periodic channel with highly tune-depressed beam. This exercise has revealed underlying limitation of the method. These limits are found to be purely mathematical in origin and lie with the limitations of Hermite-series expansion of the charge density distribution and the field components. Solutions for circumventing these difficulties are proposed in this article.

2 PROBLEMS WITH SERIES REPRESENTATION

The difficulties with series representation had been reported at the end of the eighteenth century. Dirichlet had shown (~1870) that the Fourier-series expansion of some class of functions does not always converge uniformly (e.g. Gibbs phenomena). Moreover, when they converge uniformly, they oscillate around the function in a random manner. Using the studies of Cesaro on the divergent series, Fejer (~1890) presented solutions to such problems. Here, one represents, for simplification, the process in one dimension, which can be extended in 3 dimensions. Among the two representations of the m-order Hermite series expansion $S_m(x)$ of the function f(x), only the expression proposed in [1,3], converges to zero, when x goes to infinity, and as such can be used for the charge density distribution representation as:

$$S_m(x) = \sum_{n=0}^{m} A_n \cdot H_n(x) \cdot \exp\left(-\frac{x^2}{2}\right). \qquad (1)$$

For functions f without Gaussian appearance (meaning continuous functions decreasing to zero at the infinity more rapidly that any power of 1/|x|), S_m usually does not converge uniformly to f when m increases. However S_m always minimises the quadratic means square I_m :

$$I_m = \int_{-\infty}^{+\infty} \left(f(x) - S_m(x)\right)^2 \cdot dx\,. \qquad (2)$$

Due to eq. (2), the Hermite series in eq. (1) oscillates around the function f(x) (Weisstrass Minimax theorem). If S_m converges uniformly to f, these oscillations disappear when m increases to infinity. As the value of m is always limited, S_m can have a random behaviour with unexpected effects when the function f(x) changes during the computation. Moreover, if S_m does not converge uniformly to f, these oscillations are amplified with increasing m. This problem can be circumvented with the Cesaro-Fejer transformation. Here, one replaces the Hermite series $S_m(x)$ by the Cesaro-Fejer series $\sigma_m(x)$:

$$\sigma_m(x) = \frac{1}{m+1} \sum_{n=0}^{m} S_n(x)\,. \qquad (3)$$

According to the Theorem of Cesaro, if the limit f(x) exists, the Cesaro-Fejer series in eq. (3), converges uniformly to f(x), when m increases. The unexpected oscillations are attenuated. An example can be seen in figure 1.

As presented in ref.[1], the local charge density expressed in terms of Hermite-series polynomial is given by:

$$\rho(x,y,z) = \exp\left(-\frac{u+v+w}{2}\right)\cdot \sum_i\sum_j\sum_k A_{ijk}\cdot H_i(u)\cdot H_j(v)\cdot H_k(w) \quad (4)$$

with :

$$A_{ijk} = \frac{q}{(2\pi)^{3/}\, i!\,j!\,k!\,abc}\cdot\sum_{n=1}^{N} H_i(u_n)\cdot H_j(v_n)\cdot H_k(w_n) \quad (5)$$

where u=x/a, v=y/b, w=z/c, a, b and c are the rms size of the bunch in the x, y and z directions respectively and N is the number of particles.

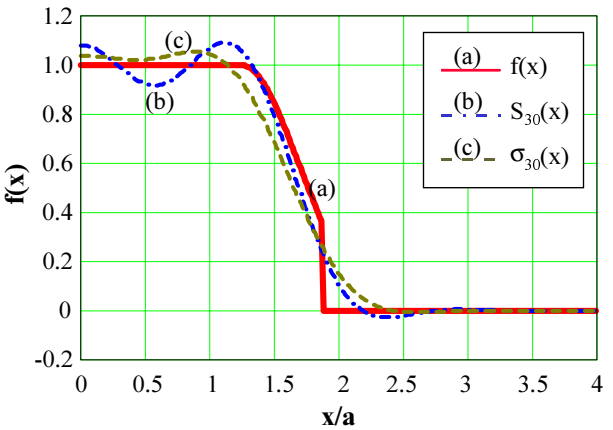

Figure 1: A function f(x) (in a) is represented by a 30-order Hermite series (in b). The oscillations practically disappears using a Cesaro-Fejer transformation (c).

The Cesaro-Fejer transformation of the one dimensional function in eq. (1) leads to :

$$\sigma_m(x) = \sum_{n=0}^{m} A_n\cdot\left(1-\frac{n}{m+1}\right)\cdot H_n(u)\cdot\exp\left(-\frac{u^2}{2}\right), \quad (6)$$

this can be extended to 3 dimensions.

From eq. (6), we see that Cesaro-Fejer transformation is an Hermite-expansion with attenuated high order coefficients. This plays the role of a low-pass filter in the Hermite base suppressing oscillations, but having a slope smaller than that of the Hermite-series.

The effect of the Cesaro-Fejer transformation can be seen in fig 2, where are presented the transverse emittance growth in a periodic accelerating channel with highly tune depressed beam (APT linac from 6.7 MeV up to 100 MeV). The computations are made for identical conditions with and without the Cesaro-Fejer transformation. It should be noted that the improvements in the field computation, explained below, have not yet been introduced. The difference in emittance growth, is due to the unexpected oscillations resulting from the Hermite series expansion of the charge density distribution. This oscillation of the charge density representation seems to introduce a diffusion like effect (or more precisely a stochastic coupling effect between directions) adding to the transverse emittance growth.

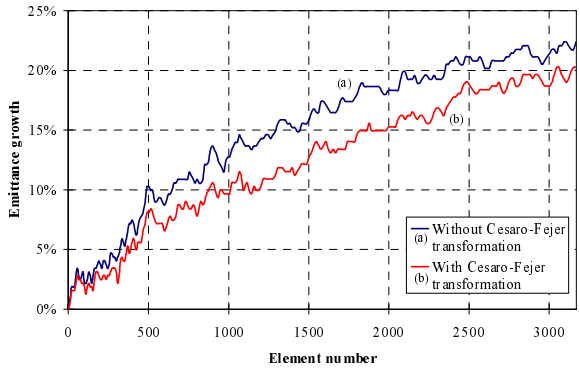

Figure 2 : Transverse emittance growth in a periodic accelerating channel (6.7 MeV to 100 MeV) with a highly tune-depressed beam. The results are obtained from the simple Hermite series expansion (a), and from the Cesaro-Fejer transformation (b).

3 SELECTION OF THE NUMBER OF TERMS IN THE HERMITE SERIES EXPANSION

It has been shown in [1], that the charge density distribution can be considered to be a Gaussian:

$$\rho_0(x,y,z) = A_{000}\exp\left(-\frac{u^2+v^2+w^2}{2}\right), \quad (7)$$

corrected by various terms (coefficients A_{ijk} in eq. (4)), each of them of total charge zero. In practice most of these coefficients can be neglected. It is essential to define a criterion, allowing the selection of the most significant terms. The Hermite polynomials $H_i(u)$ are obtained from the recurrence relation :

$$H_{i+1}(u) = u\cdot H_i(u) - i\cdot H_{i-1}(u). \quad (8)$$

Even and odd Hermite functions are represented in fig.3:

$$\mathcal{H}_i(u) = H_i(u)\cdot e^{-\frac{u^2}{2}}. \quad (9)$$

With even functions, the extremum is obtained when u=0. Near this point, from the Hermite recurrence relation, one obtains :

$$\left|H_{2l}(u)\right| \le (2l-1)\cdot(2l-3)\ldots 1. \quad (10)$$

For odd Hermite functions, the extremum lies between $0.5 < u < 0.75$, and one can write :

$$\left|H_{2l-1}(u)\right| \le (2l-2)\cdot(2l-4)\ldots 0.75. \quad (11)$$

Introducing the following numbers:

$$g(0) = 1$$
$$g(1) = 0.75 \quad (12)$$
$$g(n+2) = (n+1)\cdot g(n),$$

one obtains from eq. (10) and eq. (11) :

$$\left|A_{ijk}\cdot H_i(u)\cdot H_j(v)\cdot H_k(w)\right| \le \left|A_{ijk}\right|\cdot g(i)\cdot g(j)\cdot g(k). \quad (13)$$

Comparing the magnitude of the right term in eq. (13), relative to the Gaussian in eq. (7) allows us to select the more significant terms. They are chosen such that:

$$\left|A_{ijk}\right|\cdot g(i)\cdot g(j)\cdot g(k) \ge \delta\cdot A_{000}\,, \quad (14)$$

with δ = 0.1, 0.01, ..., depending on the accuracy desired. An estimation of the relative importance of the terms neglected can be obtained from eq. (14). The field contributions from only relatively more significant terms are considered.

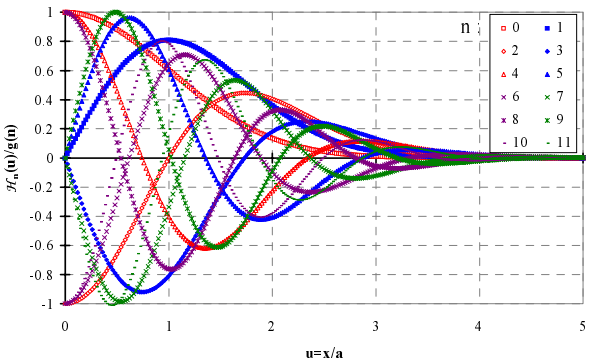

Figure 3 : The functions $H_n(u)/g(n)$ for n=0 to 11. They decrease rapidly to zero and might be considered null when u>5 (corresponding to 5 standard-deviation). The definition of g(n) is given in the text.

4 COMPUTATION OF THE FIELD COMPONENTS

Computation of the field components due to the dominant term A_{000} in eq. (7) is based on one quadrature calculation as explained in [2,3]. The field components due the other terms A_{ijk} are exactly calculated from the Poisson equation, instead of the approximated approach given in [1].

The corresponding potential from each term is given by the Poisson law :

$$\Delta U_{ijk}(u,v,w) = \frac{-A_{ijk}}{\varepsilon_0}\cdot \mathcal{H}_i(u)\cdot \mathcal{H}_j(v)\cdot \mathcal{H}_k(w) \quad (15)$$

Fourier transforms applied to eq. (15) leads to analytical expressions of the field components with a 3 dimensional (3D) integral in a 3D complex plane. Extensive effort was devoted to reduce the computation time of the field components.

The calculus of residues allows to reduce the 3D quadrature to a 2D one. This 2D quadrature is solved using numerical methods, which required several steps. Moreover, most of the values involved in these quadratures are independant of the particle co-ordinates and can be pre-calculated only once at the beginning of a simulation.

The analytical formulation of the method is quite extensive and beyond the scope of this paper.

5 CONCLUSION

Solutions to overcome the limits of the method presented in [1] are formulated. In particular:

- Cesaro-Fejer transformation would avoid the unexpected effects arising from the oscillations in the Hermite-series expansion, reducing the observed emittance growth.

- Criterion has been set (eq. (14)) to select the most significant terms of the series expansion. Computation have shown that only some tens of terms are sufficient for a suitable fit of the charge density distribution.

- Precision of field calculation has been improved and efforts have been done to reduce the computation time. Transformations applied to Poisson equation are being studied. Possibilities to reduce the 2D quadrature to a 1D one are also being looked out.

All the components of the above formualtion must be fully implemented in the space-charge code SCHERM before a fair beam-dynamics comparison could be done with DYNAC [4] and PARMILA [5] codes.

Abstract

The Advanced Photon Source (APS) has a thermionic-cathode rf gun system capable of providing beam to the APS linac. The gun system consists of a 1.6-cell thermionic-cathode rf gun, a fast kicker for beam current control, and an alpha magnet for bunch compression and injection into the APS linac line. This system is intended for use both as an injector for positron creation, and as a first beam source for the Low-Energy Undulator Test Line (LEUTL) project [1]. The first measured performance characteristics of the gun are presented.

1 INTRODUCTION

The APS injection system currently uses a 100-kV DC thermionic-cathode gun as its main electron beam source, followed by five 3-meter sections of S-band linac structures, as a means for providing beam to a positron conversion target. The principal measures of electron beam quality have been beam current at the positron target and positron generation efficiency. The transverse beam quality provided by the DC gun, however, is insufficient for many planned experiments utilizing the APS linac system.

The APS linac now includes a thermionic-cathode rf gun system. An alpha magnet bunch compressor is used to inject beam into the linac line between the first and second 3-meter linac sections. Although the rf gun system cannot provide as much current as the original DC gun system, the beam brightness is higher, and it is suitable as a source for some of the experiments slated to use the APS linac line. Because of the gun's placement in the APS electron linac line, beam energy at the positron target is limited to approximately 175 MeV instead of the nominal 220 MeV the full line can provide.

We have begun to characterize the performance of the thermionic-cathode gun in light of its potential as a hot spare for the DC gun. The performance measurements completed to date are presented, along with additional measurements relating to the suitability of this gun for other experiments using the APS linac line.

2 OVERVIEW OF THE RF GUN SYSTEM

The rf gun system includes the gun itself, the transport line from the gun to the entrance of the linac section, a fast crossed-field kicker used to limit injected charge, and various diagnostics. A schematic of the system is shown in Figure 1.

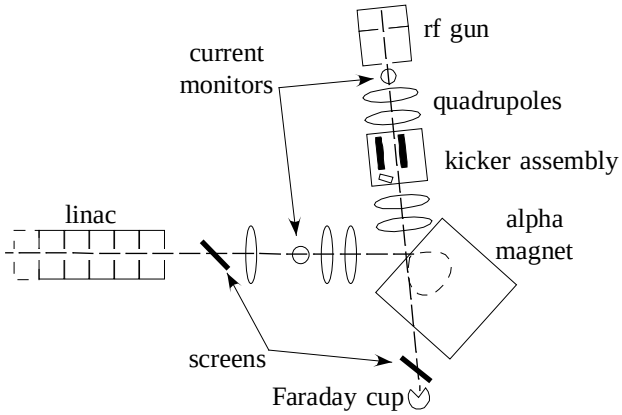

Figure 1. Schematic layout of the rf gun beam transport optics and diagnostics. Steering correctors are not shown.

2.1 Rf Gun Properties

The rf gun itself is a 1.6-cell π-mode structure. Up to 7 MW of rf power can be supplied to the full cell via an end-coupled waveguide, with a side-coupled cavity providing power transfer from the full cell to the cathode cell. The cathode used is a tungsten dispenser cathode with a diameter of 6 mm. The gun can produce peak beam energies of up to 4.5 MeV (kinetic) and peak macropulse currents of up to 1.3 A. Expected beam emittances and peak currents vary considerably with beam energy and current, but are expected to be as low as 5 π mm mrad (normalized rms) and as high as 150 A, respectively. More details of calculated gun performance may be found in [2].

2.2 Diagnostics

Several diagnostics are located along the rf gun beamline. A current transformer is located immediately after the exit of the gun and provides measures of beam current and total charge emitted. A combination Faraday cup and viewscreen is located on the far side of the alpha magnet from the gun, so kicker system tuning can be performed with the alpha magnet off.

Other diagnostics, such as fluorescent and transition radiation screens, beam position monitors (BPMs), spectrometers, and bunch length monitor cavities, are

* Work supported by US Department of Energy, Office of Basic Energy Sciences, under Contract No. W-31-109-ENG-38

present at various locations along the linac line for further characterization of the rf gun beam properties.

2.3 Gun-to-Linac Transport Line

The beam from the rf gun is injected into the second 3-meter linac structure via an alpha magnet. This alpha magnet also serves as a bunch compressor. An asymmetric transport lattice of four quadrupoles before the alpha magnet and three following the alpha magnet is used. The calculated beam size for a typical set of gun parameters is shown in Figure 2, from the exit of the rf gun to the entrance of the linac. The simulation code **elegant** [3] was used for all transport simulations external to the rf gun.

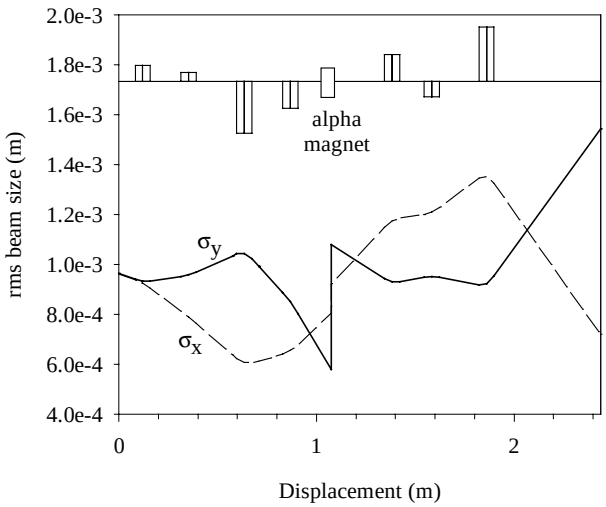

Figure 2. calculated beam spot size for a typical set of rf gun operating conditions. The discontinuity of the beam size at the alpha magnet is due to the use of transport matrix modeling formalism through the magnet.

2.4 Kicker System

The rf gun system includes an electric/magnetic crossed-field kicker system to limit the total current injected into the linac line. [4] A permanent magnet is used to deflect the beam from the gun into a beam dump; when the kicker fires, a delay line is used to provide a bucking E-field for 40 ns.

Proper kicker operation was verified by operating the rf gun and kicker with the alpha magnet off, and observing the current transmitted to the combination fluorescent screen and Faraday cup located straight-through the alpha magnet. A plot of the full current macropulse from the rf gun, and transmitted beam current detected on the Faraday cup, is shown in Figure 3. The noise on the current monitor signal trace is due to the kicker firing. Simulations indicate that a maximum of 75% of the total beam current can be transmitted to the Faraday cup if the beamline is optimized for such transport. For Figure 3, the beamline was optimized for injection into the linac so the transmitted current is slightly lower.

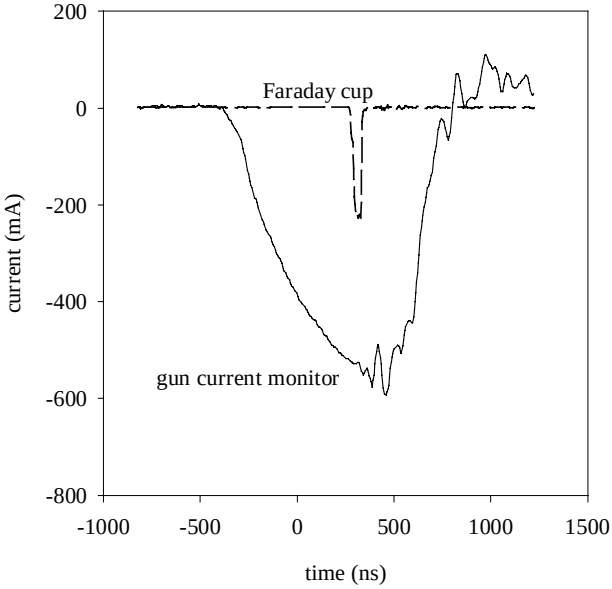

Figure 3. Gun current monitor and Faraday cup signals.

3 SYSTEM PERFORMANCE

3.1 Transport Efficiency and Energy Gain to the Positron Target

Electron beam transport efficiency measurements were made using the current monitors located in the rf gun beamline and the BPM sum signals from the APS linac diagnostics. Approximately 70% of the total charge emitted from the gun can be injected into the linac. The majority of the loss occurs over the length of the gun-to-linac transport line in the low-energy tail of the beam, which would be lost in any event during linac capture. Losses along the linac line are measured using the linac BPM sum signals. From after injection into the linac, about 85% of the beam can be transported to the positron target at high rf gun currents (~600 mA), and essentially all of the beam can be transported to the positron target at low rf gun currents (~200 mA).

An energy spectrometer immediately upstream of the positron target was used to measure the electron beam energy and energy spread at the end of the electron linac. The peak beam energy was found to be approximately 175 MeV. The beam energy was measured as a function of the phase between the linac sections and the rf gun, for a constant alpha magnet current (see Figure 4). The minimum rms energy spread found was 0.5% and was achieved by varying the linac-to-gun rf phasing and minimizing the spot size on the spectrometer screen.

Positron conversion efficiency was also measured at rf gun beam currents of 200 mA and 600 mA. In both cases, measured conversion efficiency was on the order

of 0.3% - 0.5%, depending more upon final focusing and positron linac setup than beam current. These efficiencies are in the expected range, given the target design and beam energy.

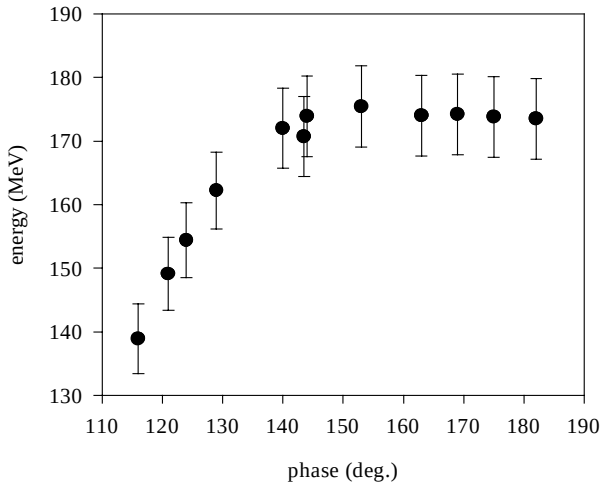

Figure 4. Peak electron beam energy vs. phase between the rf gun and linac. The error bars represent uncertainty in centroid location and spectrometer calibration.

3.2 Bunch Length Measurements

The APS linac includes a fifth-harmonic (of the linac frequency) rf cavity intended for real-time bunch length diagnostic measurements. The cavity is located upstream of the positron target and downstream of the energy spectrometer magnet [5].

No direct calibration of the cavity signal to actual bunch length has been made using the rf gun. We can vary the cavity output signal considerably simply by varying the linac-to-gun phase relationship while maintaining constant delivered current. Thus, the cavity appears to be functional and, once the cavity signal can be calibrated to beam current and correlated with streak-camera measurements, should provide real-time bunch length measurements.

Using a fast diode and scope, we can observe the buildup of rf power in the fifth-harmonic cavity. The signal builds up over a period of approximately 40 ns, then begins to decay. This is consistent with the duration of the electron beam passed by the kicker system.

A plot of observed signal strength vs. alpha magnet current is shown in Figure 5. For this measurement, the beam current from the gun was stabilized at 200 mA, with an input rf power of 3.5 MW. The relative rf phase between the gun and linac was varied to obtain the minimum energy spread on the spectrometer magnet, which should correspond to the minimum bunch length. In Figure 5, the fifth-harmonic cavity signal strengths have been normalized to the square of the beam current at the positron target.

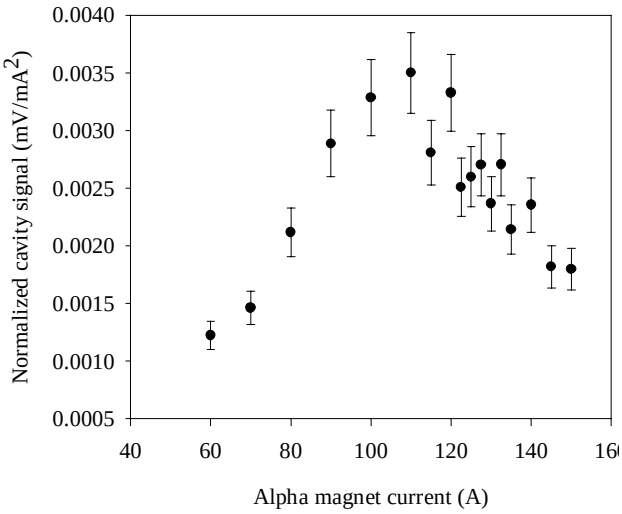

Figure 5. Fifth-harmonic cavity signal as a function of alpha magnet current, normalized to electron beam current. The signal strength is inversely proportional to the bunch length divided by the beam current squared.

We have also measured bunch lengths on the order of 3 – 6 ps using a streak camera and are in the process of calibrating the fifth-harmonic cavity with the streak camera measurements.

4 CONCLUSIONS

The commissioning process for the thermionic-cathode rf gun is proceeding well. Reasonable beam transport along the APS linac line has been achieved. Positron conversion efficiency has been measured and indicates that the rf gun could be used to fill the APS storage ring if required, albeit at a reduced rate. Bunch length measurements are in progress, and a fifth-harmonic cavity is being correlated to streak camera measurements for use as a real-time bunch length monitor. Beam emittance measurements are also planned.

Abstract

The Thomson parabola spectrograph (TPS) is an excellent device to give a general overview of the charge states and the velocity (energy) distribution of all the types of ions produced by a single laser shot focused onto a target. Using the TPS and other diagnostics based on the time-of-flight method - ion collectors (IC) and a cylindrical electrostatic ion energy analyzer (IEA) – the laser produced plasma of different heavy elements was analyzed in a far expansion zone. As target material Ta, W, Pt, Au, Pb and Bi were chosen. The photodissociation iodine laser system PERUN was used for this purpose and results are compared with experiments obtained with the CO_2 laser ion source.

1 INTRODUCTION

The results of experiments on laser ion sources (LIS) performed up to now proved the feasibility of laser-production of highly-charged ions of heavy elements [1-4]. Current densities of multiply charged ions are about two orders of magnitude higher than those from the ECR ion source. This fact has lead to the construction of a LIS which may become a source for LHC. Nevertheless, the LIS still faces major technological problems as for applications of that kind.

TPS measurements [5,6] made it possible to analyze very effectively ions emitted from the target of different elements and also of ions in extracted ion beam [7]. A more detailed analysis of expanded ions was performed using a time-of-flight method.

In the presented contribution results obtained up to date with the photodissociation iodine laser at Prague are summarized and compared with those obtained with the CO_2 laser ion sources [1,3]. In addition, both the mentioned lasers are discussed with respect to their use for a considered LIS.

*This work was partially supported by a grant A1010819 from the Grant Agency of the ASCR

2 EXPERIMENT

The photodissociation iodine laser PERUN at Prague is operating at $\lambda = 1.315$ μm, with the energy up to 40 J and with the pulse-length of 300-500 ps. Focusing the laser beam with either lens optics or with a parabolic mirror to a spot size of about 100 μm means attainable power density on the target up to about 1×10^{15} W/cm^2 (reduced intensity $I\lambda^2 = 1.7\times10^{15}$ Wμm^2/cm^2).

The operation principle of the TPS is based on the passage of ions through parallel magnetic and electric fields, $\boldsymbol{B}$ and $\boldsymbol{E}$. From the solution of equations of motion for a charged particle we obtain the coordinates x and y of the point in the recording plane of a plane detector (a MCP in our case), onto which an ion of given parameters impacts. After eliminating the kinetic energy of ions E_i we obtain an equation, which describes the Thomson parabolas [5,6]. Points of intersection of parabolas with a straight line passing through the origin of coordinates, Oxy, correspond to ions of a fixed velocity v_i. To overcome difficulties with the identification of highly charged ions, to make the evaluation of parabolas easier and to help further data processing, the computer program THOMSON was developed [6,8].

Two types of ion collectors (IC) - a flat one and a ring (coaxial) one, which allows to measure the ion current close to the TPS or IEA axis - were used for a registration of the time-resolved ion current signal, from which the ion current densities can be derived. The humps on a collector signal usually indicate several ion groups which may be ascribed to different mechanisms of their production [2]. We also used a cylindrical electrostatic ion energy analyzer (IEA) for a separation of ions with different ratio of mass to charge state M_i/z to determine the relative abundance of ions produced. Experimental arrangement as well as the ion diagnostic tools are described, in a more detail, elsewhere [9,10].

The results obtained with the iodine laser used are summarized in the Table 1 (with exception of Ta for not fully optimized conditions). Paths of flight of ions ranged from 84 cm to 187 cm. The average total current densities

j_{th} and j_f are the peak values of the fast and thermal ion signals, recalculated to the distance of 100 cm according to a L^{-3} law, the widths (FWHM) of corresponding signals Δt_{th} and Δt_f are usually about 2 μs and 0.7 μs, respectively, or lower. Results for Ta and Pb ions produced by CO_2 laser [1,3] are included in this Table, too, for a comparison (Δt_{th} is about 5 μs in this case).

From the values of j_f, j_{th}, Δt_f and Δt_{th} the number (fluency) of considered ions can be estimated, if the relative abundance of ions in the group is known. Such estimations give for iodine laser produced Ta^{40+}ions the value of about $1x10^8$ ions/cm^2, for Ta^{20+} values about 6 times higher.

3 DISCUSSION

Table 1 shows that the short-wavelength and short-pulse iodine laser achieves much higher charge-states than the CO_2 laser and that the group of fast ions is missing in the second case. The ions are generated by an intense collisional ionization in the hot core of plasma, formed by a short intense laser pulse. Owing to a long wavelength of a CO_2 laser the critical density is low (about 65 times in comparison to that for iodine laser) and the ionization is slow. In the case of iodine laser the estimated electron temperature of plasma exceeded 1.5 keV, while in the case of CO_2 laser it is only about 400 eV [11].

The higher power density, the higher plasma temperature is and the higher charge states are produced [9,12]. Losses of the charge suffered by ions emitted from a laser plasma were studied recently for Ag, Cu, Ta and Pb using the iodine laser. Two ion collectors (a ring one and a flat one) were used to measure simultaneously ion current in the same direction and at two distances from the target (from 84 cm to 187 cm). It was confirmed that the decrease in the total charge carried by ions obeys nearly a L^{-2} law, as it is generally accepted, independently of the amount of transferred charge [13]. It means that recombination of ions does not proceeds at these distances and high charge states are really "frozen". Different situation is valid for the CO_2 laser. According to calculations of Roudskoy [11] the critical distance L_{cr} from the irradiated target, where the sharp rise of the recombination losses changes to a slow descend, may reach a few meters. The TPS, when installed at CERN, gave evidence for ion recombination not only in freely expanding plasma, but pictures of recombined ions were registered also after an extraction of Ta ion beam from the plasma [7].

4 CONCLUSIONS

From the experiments performed up to now it is possible to conclude:

a) Lasers with a shorter wave-length and shorter pulse-lengths can produce ions with higher charge-states much more easily than CO_2 laser.
b) Ions of heavy elements with charge states up to about 50+, and current densities above 10 mA/cm^2 at the distance of 1 m may be achieved with iodine laser at power densities of $1x10^{15}$ W/cm^2.
c) The occurrence of the highest charge states in the far expansion zone is ascribed to the presence of a fast ion group (fast electrons) [2].
d) Practical reasons (high energy at 1Hz repetition rate with 10^6 shots now achievable for an acceptable amount of money) dictated the use of the CO_2 laser as the first choice for a driver at CERN, considered as an alternative ion source for LHC [14]. Iodine, but more probably Nd lasers are predestined for a LIS of the next generation (smaller size, more progressive solution - one level of stripping might become superfluous, at least).
e) TPS seems to be a very good device for checking the LIS operation.

Table 1: Main parameters of laser produced ions of heavy elements.

	iodine laser						CO_2 laser	
	Ta	W	Pt	Au	Pb	Bi	Ta	Pb
z_{max}	55	49	50	51	51	51	25	35
$\langle z_f \rangle$	42	45	40	38	40	40		
$\langle z_{th} \rangle$	35						20	30
$E_{i,max}$, MeV	8.8	4.9	8.5	4.8	5.1	5.1	0.5	0.5

NON-INTERCEPTIVE EMITTANCE MEASUREMENT OF A HIGH INTENSITY BEAM AT LOW ENERGY

R. Ferdinand, P.-Y. Beauvais, D. Bogard, R. Gobin, B. Pottin, CEA/Saclay,
DSM/DAPNIA/SEA, Bat 706, 91191 GIF-sur-Yvette FRANCE

Abstract

A CW Electron Cyclotron Resonance source has been constructed at CEA-Saclay and is now under test. The aim is to reach a 100-mA proton current at 95 keV with an rms normalized emittance smaller than 0.2 π.mm.mrad and a very high reliability. In order to match this beam into the Radio Frequency Quadrupole linac (RFQ), its characteristics have to be monitored on-line. An emittance measurement unit (EMU) located close to the RFQ entrance is a very powerful diagnostic tool. We developed a non-interceptive EMU based on the video analysis of the residual gas illumination. Methods and results are presented and discussed.

1 INTRODUCTION

This work is a part of a wide range of activities presently being undertaken at the CEA in the field of high power proton or deuteron linear accelerators. We are studying the CW IPHI demonstration project [1]. This accelerator will consist of a high intensity light ion source (SILHI) [2], an RFQ [3] and a DTL up to 10 or 11 MeV. The main application of this kind of accelerators is the production of high flux neutrons by spallation reactions, for use in the IFMIF and nuclear waste treatment projects.

The SILHI requirements are: 100 mA proton or 140 mA deuteron in more than 90% of the total extracted beam, at 95 keV and with a rms normalized emittance of 0.2 π.mm.mrad. The ECR ion source operates at 2.45 GHz with an approximately 875 G axial magnetic field. The first proton beam was produced in July 1996.

In order to match the beam into the RFQ accurately, a precise knowledge of its characteristics measured close to the cavity entrance is required. Presently, beam position and size along the low energy test line are obtained from the CCD video cameras. The emittance is measured by means of a classical "hole-slit" type Emittance Measurement Unit (EMU). This kind of EMU is esteemed for its precision but presents several disadvantages (slow mechanism, interceptive system, r-r' emittance…). Moreover, the power density allowed by the sampler, (limited to 1 kW/cm^2), prohibits us from tuning the beam around the cross-over. So it was felt necessary to develop a fast and non interceptive EMU. We decided to study a CCD video camera based system and calibrate this EMU with the classical one.

Here, we present the method and the first results obtained.

2 METHOD

For the beam monitoring, four CCD video cameras - (MICAM VHR 2000 Model) - are in operation on the Low Energy Beam Transport (LEBT) line. Two cameras are located between the extraction system and the first solenoid and another set of two 1.5 meter behind this solenoid. In both the locations, H and V planes can be observed. The MICAM camera is equipped with a 752×582 pixel matrix, its sensitivity is 0.25 lux for a 1.2 F/D ratio. The beam area observed is about 120×90 mm. Remote controls, data acquisition and analysis are performed by using LABVIEW™.

The CCD cameras give directly a signal proportional to the light emitted by the residual gas integrated over the observed plane. It means that we can acquire only transverse (x-x') emittance. The light is considered proportional to the current density and to the residual gas pressure. The logical way to obtain the beam emittance is to employ the well-known 3 gradients method. We want to obtain the emittance value ε and the Twiss parameters of the beam (α, β, γ). Due to the relation $\alpha^2 = \beta\gamma - 1$, we have in fact only 3 unknown parameters. The beam radius x is related to β, and the beam angle x' is related to γ. The principle consists in measuring the beam profile for at least three different solenoid currents. We then adjust the unknown parameters and transport the beam from upstream of the solenoid to the measurement position. The difference between the measured values and the calculated ones is the number we minimize. The beam transport has to be done with space charge. From the experience of previous measurements we take a beam neutralization of 97% [4]. Space charge and solenoid focusing (transfer from one plane to the other) imply that we cannot use a matrix formalism. The beam transport is calculated with the well known envelope equation :

$$\begin{cases} \tilde{x}'' + k^2(z)\cdot\tilde{x} - \dfrac{K}{2\cdot(\tilde{x}+\tilde{y})} - \dfrac{\tilde{\varepsilon}_x^{\,2}}{\tilde{x}^3} = 0 \\ \tilde{y}'' + k^2(z)\cdot\tilde{y} - \dfrac{K}{2\cdot(\tilde{x}+\tilde{y})} - \dfrac{\tilde{\varepsilon}_y^{\,2}}{\tilde{y}^3} = 0 \end{cases}$$

where $\tilde{x}$ and $\tilde{y}$ are the rms transverse dimensions, $K = \dfrac{qI}{2\pi\varepsilon_0 m(\gamma\beta c)^3}$ is the defocusing factor due to space charge forces, $k^2(z) = \dfrac{q^2B^2}{4\gamma^2m^2\beta^2c^2}$ is the confinement term due to the magnetic field and

$\tilde{\varepsilon} = \sqrt{\langle r^2 \rangle \langle r'^2 \rangle - \langle r \cdot r' \rangle^2}$ is the rms emittances to be calculated

At present time, we use only the camera that looks at the horizontal plane behind the solenoid. With the assumption of a cylindrical beam, the space charge forces can still be calculated. We do not expect a big difference in that case.

It is more reliable to optimize the values with about 10 measurements. Moreover, we improve the S/N ratio by averaging about 20 video columns.

The measurement code has been developed using Labview 4.0. It automatically acquires the beam and line parameters (energy, current, solenoid currents...), proposes some solenoid current values and acquires the data. It then launches the optimization code developed in C^{++}, and displays the result.

3 RESULTS

3.1 Qualitative approach.

By changing the solenoid current we can obtain a convergent beam, a divergent beam or a cross over in front of the video diagnostics. We call the “cross-over curve” as the curve of the beam size as a function of the focusing:

A complete analysis as a function of the position of the measured points on this “cross-over curve” has been done. We considered the localization of the acquisition points on this curve as shown in Figure 1 :

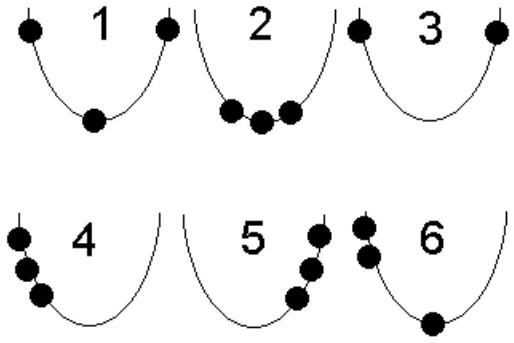

Figure 1 : Different locations of acquisition points on the "cross-over curve".

Cases 4 trough 6 generate the worst solutions: the minimization algorithm converges rarely and the results are never reproducible. Case 3 produces uncertain results. Case 1 with points equally spaced, represents the best compromise for fitting a curve that describes the dots. It produces the most reliable results and is also the "closest" to the reference EMU ones.

Preliminary exploration of the system shows that it is better to limit the beam size at the acquisition point to 2 to 3 times the cross over size. This is probably due to some optics limitation in the acquisition system.

This emittance measurement is fast. It takes about 1 minute to acquire and obtain the twiss parameters. Under the conditions defined earlier, it is a reproducible measurement, which is one of our main criteria.

3.2 Quantitative comparisons.

In order to validate this EMU, a complete comparison has to be made with a reference system. We have developed several years ago a precise "hole-slit" measurement unit. The smallest step size of the sampler is 0.6 µm, but we normally never work below 0.2 mm. Under such conditions, the acquisition takes about 10 min to be completed. A typical example is given in Figure 2.

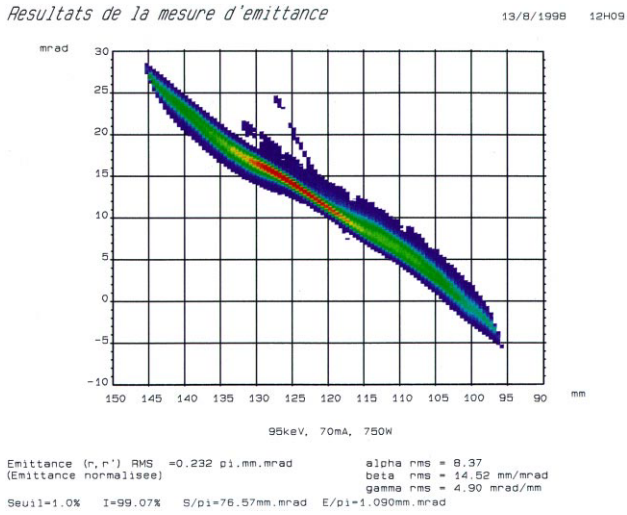

Figure 2 : Typical measurement with the reference EMU.

Typical values obtained with this reference unit are in the range of $0.23\,\pi$.mm.mrad (rms, r-r’). It depends mostly on the extracted current, pressure and the potential on the intermediate electrode. With the assumption of a cylindrical beam and a cylindrical velocity distribution inside the beam, the r-r’ value equals to $\sqrt{2}$ times the x-x’ emittance value. This gives us an rms x-x’ emittance of $0.16\,\pi$.mm.mrad. Under the same conditions, we measured the emittance with the video EMU. The result is around $0.3\,\pi$.mm.mrad, with a standard deviation of 0.0028.

We are able to produce an emittance increase of about 20% by changing the source parameters. In that case, both EMU measurements show an increase of 20%.

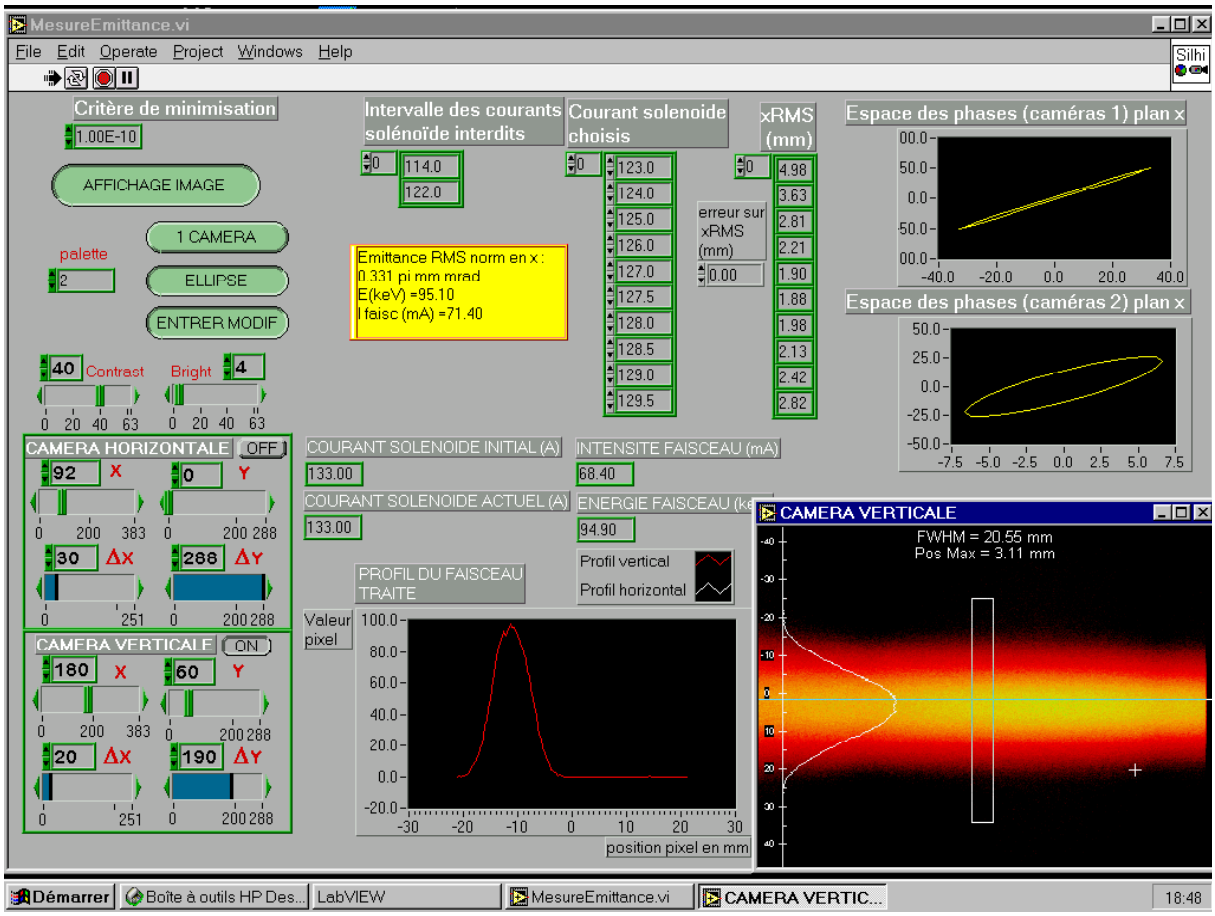

Figure 3: Front image of the video EMU.

3.3 Interpretation.

To explain this discrepancy between the two measurements, we have to carefully consider the nature of the information given by the video EMU. The light emitted originates from the background gas de-excitation. The profile measured on the video camera suffers from an enlargement due to the diffusion of the excited particles before they emit. In that case the profile increase should have a fixed error, independent of the beam size but will depend on the background pressure. Based on this assumption, we have subtracted 0.4 mm from all the measured rms beam size. It then produces a nice reproducible value of about 0.18 π.mm.mrad for the video rms emittance measurement.

Other acquisition errors are certainly present. For example, we can list the possible errors due to the optics and possible non-linearity of the CCD with light intensity.

4 CONCLUSION

So far, the EMU provided reproducible measurements with the use of some hypotheses. The measurements are fast and easy to perform. Extensive set of measurements will be needed to validate the method. A complete analysis of the collected light has also to be performed, in order to confirm the systematic observed rms error. Studies are underway for different source/LEBT tunings conditions (pressure, current…).

5 ACKNOWLEDGMENTS

The authors would like to thank the other team members for their contribution to this work and especially Nicolas Pichoff for discussions on some of the results. We would also like to thank S. Nath from LANL for is fruitful help during the writing of this document.

PERFORMANCE OF AN S-BAND KLYSTRON AT AN OUTPUT POWER OF 200MW

S. Choroba, J. Hameister, S. Jarylkapov*
DESY, 22603 Hamburg, Germany, * on leave from INR, 117312 Moscow, Russia

Abstract

In order to provide RF power to the accelerating sections of a future S-Band linear collider, klystrons producing 150MW of output power at a frequency of 2.998GHz are required. Two S-Band klystrons with a nominal output power of 150MW at a pulse duration of 3μs and a repetition rate of 50Hz were developed in a collaboration between SLAC, Philips, TH Darmstadt and DESY [1]. They were built and successfully tested at SLAC in 1994 and 1995 and then shipped to DESY to feed the accelerating sections of the S-Band test facility linac. In order to explore their power potential one of the klystrons was operated at an even higher output power of more than 200MW at the test facility. HV pulses up to 610kV at a current of 780A were applied to the klystron cathode. This paper reports the results of the measurements of the various parameters of the klystron at this power level (e.g. output power, efficiency, perveance). It describes the performance and the limitations of the klystron in this power range.

1 INTRODUCTION

A possible future S-Band linear collider would require more than 5000 klystrons, capable of an output power of 150MW at a pulse duration of 2.8μs and repetition rate of 50Hz. Until 1992 klystrons meeting these demands were not available. The well known SLAC 5045 klystron achieved 65MW at a pulse duration of 3.5μs [2]. A klystron with an output power of 150MW at 1μs pulse width was developed at SLAC in 1985 [3]. In 1992 a collaboration between SLAC, TH Darmstadt, Philips and DESY was settled to develop a klystron meeting the demands of an S-Band linear collider. Two klystrons were built and successfully tested at SLAC. The results are reported in [1]. Table 1 shows the design and the parameters of the two klystrons, which were measured during the tests at SLAC.

Later C. Bearzatto and G. Faillon of Thomson in France reported, that they had developed and tested an S-Band high power klystron with an output power of 150MW at a pulse width of 1μs [4].

Both klystrons, built at SLAC, are now in operation at the S-Band test facility at DESY. The second tube was used to investigate whether an even higher peak output power than 150MW is possible. The output waveguides of the klystron were connected to RF water loads. The klystron cathode voltage was carefully raised from 550kV to a higher voltage. In the following we describe the klystron operation at the higher power level. The results of the measurements are presented.

Table 1: Parameters of the klystrons for the S-Band test facility (design and measured during tests at SLAC)

	Design	Tube#1	Tube#2
Power Out	150 MW	153 MW	150 MW
Pulse Duration	3 μs	3 μs	3 μs
Repetition Rate	60Hz	60Hz	60Hz
Beam Voltage	535 kV	527 kV	508 kV
Beam Current	700 A	680 A	652 A
Microperveance	1.79	1.78	1.80
Efficiency	40 %	43 %	45 %
Gain	> 50 dB	56 dB	57 dB

2 THE KLYSTRON

Figure 1 shows klystron #1. The total height is 2.6m, the diameter of the anode housing is 40cm and the weight is about 300kg. The cathode has a diameter of 13.3cm and a cathode loading of 6.12A/cm^2. The beam area convergence is 40:1. The maximum electric fields on the focus electrode and anode are 180kV/cm and 210kV/cm, respectively. Seven cavities including the input and output cavities are in the 3.2cm wide drift tube.

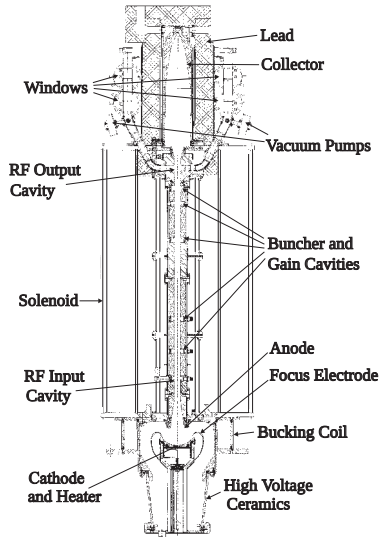

Figure 1: Layout of klystron #1

The klystron has two output waveguides, which are splitted and recombined again, so that there are two RF windows in each output waveguide. The waveguide assembly on each side is the well proven design of the SLAC 5045 klystron.

The klystron requires a solenoid with a magnetic field of 1800G and a power consumption of 14kW. A bucking coil is needed to achieve zero magnetic field on the cathode surface.

Although the two tested tubes are very similar in general, there are three major differences between tube #1 and #2. Already at the design state it was decided to use different output cavities for the two tubes. Tube #1 has one single cavity, whereas tube #2 has two coupled cavities at the output. The expectation was, that the second tube would have a slightly better efficiency than the first tube. During the tests of tube #1 an oscillation at 8.1GHz was observed depending on the beam voltage and solenoid field settings. Therefore it was decided to fabricate tube #2 with a stainless steel drift tube between the cavities 3 and 4, and 4 and 5 instead of using only copper for the drift tube as for klystron #1. This added additional losses to the disturbing oscillation. No oscillations were observed during testing of tube #2. The cathode of tube #2 was changed to a scandate cathode for tube #2, whereas tube #1 uses an osmium coated M-type cathode. More details can be found in [1].

3 OPERATION OF KLYSTRON #2

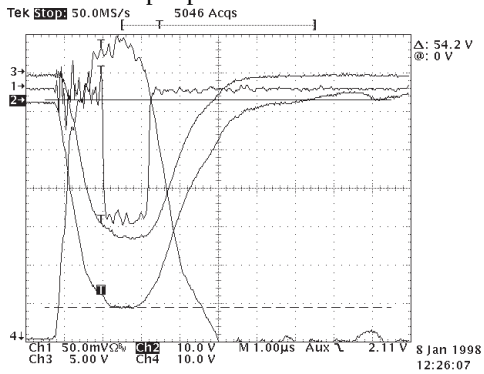
Since klystron #2 did not show disturbing oscillations up to an output power of 150MW and in addition has a slightly better efficiency than klyston #1, it was chosen to investigate the power potential of this type of klystron. Whereas klystron #1 has to provide RF power to the accelerating sections of the test facility, two sets of high power water loads, made by Nihon Koshuha, Yokohama, Japan, were installed at the two output waveguides of klystron #2. Each of the loads consists of a splitting T which devides the output power of each output waveguides. At the end of each waveguides the power is absorbed by water flowing behind a thin ceramic window. The VSWR of the loads is less than 1.10 at 2.998GHz.

Two 75dB hole coupler were installed at each output waveguide to measure the forward and reflected output power. A 2.998GHz band pass filter (30MHz bandwidth) was used to eliminate other frequency components in the measurements. In addition the output power could be determined by calorimetric measurements by measuring the water flow rate through the loads and by taking the loads water in and outlet temperatures. By taking into account these numbers, the repetition rate and the output pulse shape it was possible to calculate the klystrons peak output power. Since we were also able to measure the temperatures and flow rates in the klystron coolant circuits, e.g. the collector and body cooling circuit, we were also able to determine the power absorbed in the klystron itself. The difference between the power absorbed in the klystron at operation with and without RF power generation gives the klystron output power, too.

The high voltage pulse duration could be changed by adding or removing capacitors of the line type modulators pulse forming network. A detailed description of the modulator can be found in [5].

4 MEASUREMENTS

The measurements were performed at a high voltage flat top pulse duration of 1μs and a repetition rate of 12.5Hz, because both, klystron and modulator, were operated beyond their peak power specification during the tests. The cathode voltage was slowly raised from 550kV up to the maximum possible voltage of 610KV at a current of 780A. At a voltage level of 600kV it was necessary to increase the magnetic field in the solenoid by about 6%. Otherwise the RF output power would break down at the end of the 1μs long RF pulse. Later it turned out, that by adjusting the independent coils of the solenoid, operation at a beam voltage up to 610kV could be achieved even with a lower setting of the solenoid currents. Figure 2 shows the waveforms at a voltage of 610kV and total output power of 213MW.



Ch1 RF output power out of waveguide 2 107MW
Ch2 Klystron cathode voltage 610kV
Ch3 Klystron collector current 781A
Ch4 Klystron gun current 778A
Time 1 s/div

Figure 2: Waveforms at a voltage of 610kV

The measurement of the perveance of klystron #2 gives numbers lower than in the SLAC measurements. Although klystron #1 is operated at a different modulator with different devices for voltage and current measurement as klystron #2, we measure also a lower perveance than in the SLAC tests. The reason for the difference is not clear up to now. Figure 3 shows perveance and efficieny as a function of the beam voltage. The klystron efficiency increases with increasing beam voltage and reaches 47%. Figure 4 shows the output power as function of the beam voltage. At a voltage of 610kV a power of 213MW in a 1μs long pulse can be extracted from the klystron. Figure 5 shows the dependence of the output power from the drive power for different beam voltages. Four data points are included, which were taken at four different beam voltages but at fixed drive power.

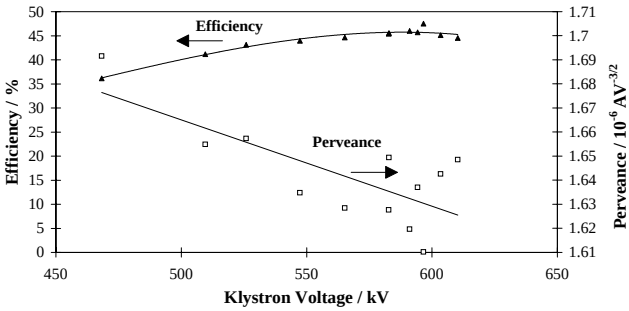


Figure 3: Efficiency and perveance as function of beam voltage

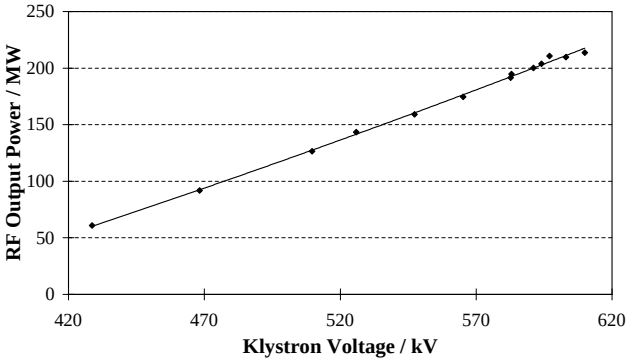

Figure 4: Output power versus beam voltage

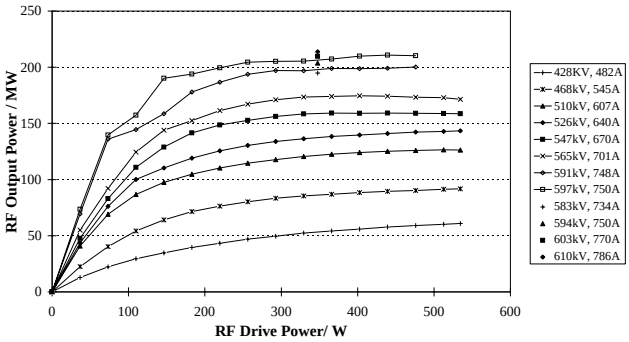

Figure 5: RF output power versus RF drive power for different klystron voltages and currents at an RF pulse duration of 1μs

At a drive power of 300W the output power is saturated. The saturated gain at this point is 58dB for an output power of more than 200MW. For beam voltages above 550kV the curves start to show a strange behavior on the rising part of the curve, where bumps appear. This can be seen more easily in figure 6, which shows the gain at a beam voltage of 583kV. The gain, which usually decreases with increasing drive power, shows a bump at 95W of forward drive power. Since the reflected drive power increases almost linearly as function of the forward drive power and shows no distinct bump, the drive power absorbed by the klystron should show a similar behavior. The vacuum pressure in the tube was not conspicuous in any way. A variation of the solenoid filed affected the bumps. The bumps could be shifted to other points or could be made more or less distinct. It is even possible to find curves which show two or three of these bumps on the gain curve. The reason for this behavior is not clear up to now. It might be, that it indicates multipacting in the tube.

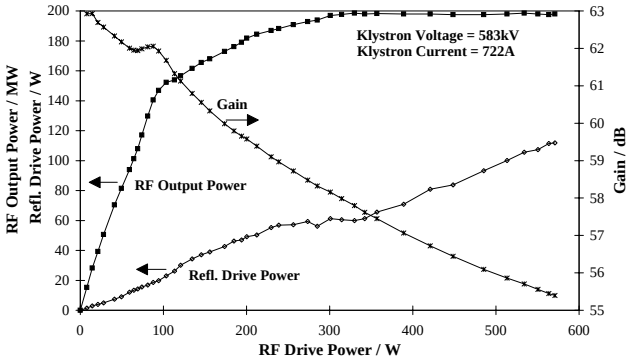

Figure 6: RF output power, gain and reflected drive power at 583kV and 722A

5 CONCLUSION

It is possible to operate an S-Band klystron at a pulse duration of 1μs at more than 200MW of output power. Even longer RF pulses at this power level might be achievable. Since we wanted to use the klystron to provide RF power for the test facility, we refrained from trying to reach more than 200MW at longer pulse duration. Both, the klystron and the modulator, were operated beyond their original specification. The e-beam needs careful focussing when the beam voltage is in the 600kV range. The reason for the bumps on the gain curves is not clear. Since these can be affected by varying the magnetic field, this might indicate multipacting in the tube.

Abstract

A line type modulator with a Blumlein pulse-forming network (PFN) to drive a 75 MW pulsed klystron for the main linac of an X-band Linear Collider is under development at KEK. This Blumlein modulator yields a reasonably fast rise time and hence, an improved efficiency. A high power test of the modulator showed that an output pulse with a rise time(10%-90%) of less than 350ns can be generated for the klystron. This paper describes the design, specifications and results of the performance tests of the Blumlein modulators.

1 INTRODUCTION

The klystron pulse modulator for an X-band Linear Collider requires to produce a 454kV, 367A, 1.5μs flat-top pulse to drive a 75MW klystron[1]. The present configuration of the 0.5TeV linear collider requires more than 3200 modulators. The large number of klystrons and modulators dictate the need for a reliable and efficient system.

The power efficiency of the modulator are extremely important. The effective output power of the modulator is the power of the flat-top portion of the high voltage output pulse and hence, the pulse with a fast rise time and fall time is required. The main contributor to the pulse waveform is a pulse transformer(PT) as well as a pulse-forming network(PFN). For these designs, the transformer turns ratio plays a very important role. Using a Blumlein method allows a lower transformer turns ratio, which yields a reasonably fast rise time and hence, an improved efficiency. The efficiency target for the modulator system (wall plug to usable pulse flat-top) is 75%.

The R&D's of the Blumlein type modulator, which is based upon conventional technology and components that exist at present, are being performed at KEK.[2] Two kinds of modulators have been developed. First modulator, which is called Modulator #1 after this, has been built to study the practical application of Blumlein type modulator. The second modulator, which is called Modulator #2 after this, has been built to study a compact and high performance Blumlein modulator.

2 KLYSTRON

The X-band klystron development program at KEK had been originally designed for 80 MW peak power at 400ns pulse length. The rf parameters of the main linac were recently changed after reconsidering the rf system. The main parameters of the klystron developing at present are given in Table 1.[3]

Table 1. Specifications of X-band klystron

Operating frequency	11.424 GHz
RF pulse length	1.5μs
Peak output power	75MW
Repetition rate	120pps
RF efficiency	45%
Beam voltage	454kV
Beam current	367A
Perveance	1.2μ
Gain	53-56dB

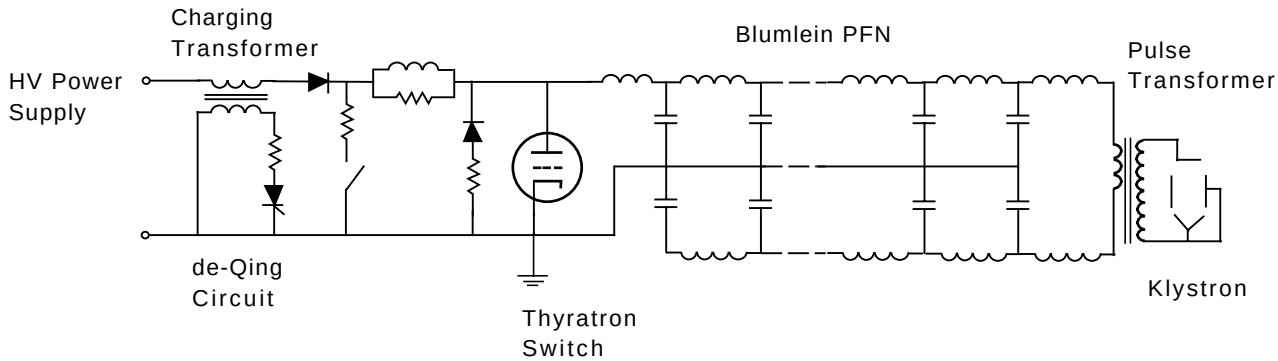

Figure 1. Circuit of the Blumlein type modulator.

3 BLUMLEIN CIRCUIT

The basic circuit of the Blumlein type modulator is shown in Figure 1. It consists of a conventional PT, a Blumlein PFN, a single-thyratron switch tube and a resonant charging circuit with a de-Qing circuit.

4 MODULATOR #1

4.1 Hardware

The modulator components shown in Figure 1 are all housed in air. The main parameters of the modulator #1 are given in Table 2. Maxwell mini double-ended capacitors were used as a PFN capacitor. The internal inductance of the PFN capacitor itself should be lower for faster discharge and it limits the shortness of the rise time. The internal inductance of this capacitor is approximately 20nH. Each section capacitor consists of two these capacitors which are placed in series to get 100kV. These capacitors have a standard value of 7nF and a rated voltage of 50kV. The thyratron EEV CX1937A with a rated voltage of 80kV was used as a switch tube which discharges the Blumlein PFN.

Table 2. Main parameters of the modulator #1

	unit	Design	Upgrade
Output pulse			
Secondary voltage(Max.)	kV	560	560
Secondary current(Max.)	A	503	503
Pulse width	μs	0.8	2.4
Flat-top	ns	400	1500

4.2 Output pulse waveform and circuit analysis

The solid line in Figure 2 shows an example of the klystron voltage waveform. An output pulse with a peak voltage of 470kV, a rise time(10%-90%) of 350ns, a flat-top width(flatness ±1%) of 400ns and a fall time(10%-90%) of 350ns was successfully generated. The rise time is a sufficiently short because the rise time of the requirement is less than 400ns.

We have analyzed the modulator circuit by a simulation method. The broken curve in this figure shows result simulated by a computer code Micro-Cap IV. The simulation gives a good fit to the measured data. From this analysis, it was found that total distributed capacitance in the pulse transformer, the tank and the klystron is about 180pF. This large value mainly limits the rise time of output pulse. The calculated values of distributed capacitances for the klystron and the PT are about 80pF and 40pF, respectively.

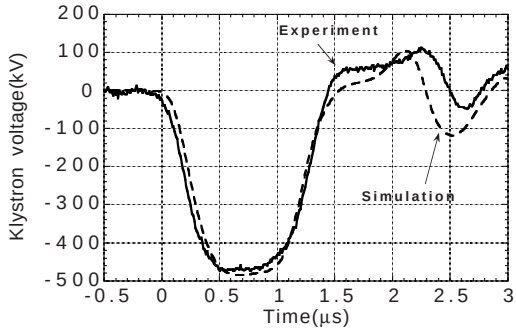

Figure 2. Output pulse waveform at the klystron.

4.3 Upgrade

We upgrade the modulator #1 to produce a pulse with a flat-top of 1.5μs. To increase the pulse width, the number of the PFN section is increased up to 20. Each line is made in two parallel lines to increase the value of the section inductance in order to improve the PFN characteristic. The charging transformer and the PT are also remade. The parameters of the upgrade modulator are given in Table 2. We simulated the output pulse waveform by using circuit parameters obtained by the circuit analysis above subsection. Figure 3 shows the result for a charging voltage of 70kV. The simulation shows that an output pulse with a rise time(10%-90%) of 350ns and a flat-top width of more than 1.5μs can be achieved.

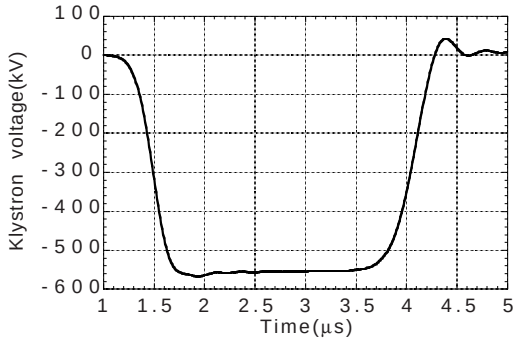

Figure 3. Output pulse waveform simulated by a computer code Micro-Cap IV.

5 MODULATOR #2

5.1 Hardware

The modulator components shown in Figure 1 are all housed in a cylindrical stainless oil tank which also mounts the klystron. This allows to make all circuits

significantly compact, and also to make circuit wiring short. The slow rise time caused by stray inductance of wiring is therefore improved and it makes modulator efficiency better. Figure 4 is a photograph of the modulator #2. The size of the oil tank is 1.8m in diameter and 1.6m in height. The thyratron EEV CX2199 with a rated voltage of 100kV was used as a switch tube. For the Blumlein PFN, a compact double-ended capacitor with a capacitance of 1.9nF, a rated voltage of 80kV, a voltage reversal of 65%, an internal inductance of 40nH and a design life of $2x10^8$ shots was developed by Maxwell Energy Products, Inc.. The size of the capacitor is 4''wide x 6''deep x 10.25''high. The main parameters of the modulator are given in Table 3.

5.2 High-voltage test

A preliminary test has been performed to confirm the performance of the modulator. The secondary side of the PT was connected to a 1120Ω ceramic resistor. The modulator was operated up to a charging voltage of 80kV without any faults. Figure 5 shows the output waveforms obtained for a charging voltage of 40kV. An output pulse with a peak voltage of 280kV, a rise time(10%-90%) of 210ns, a flat-top width(flatness ±4.5%) of 400ns and a fall time(10%-90%) of 280ns was successfully generated.

6 FUTURE PLANS

The upgrade work of the modulator #1 is now in progress and will be completed on October, 1998. We plan to test the modulator #2 connecting to a XB72K klystron to confirm its performance in this winter. In order to reduce both production costs and spaces of the modulators, we make a design study of the modulator operating two or four klystrons.

Abstract

We have initiated a program to develop superconducting (SC) RF technology for high-power proton linacs. These linacs are useful in accelerator-driven transmutation applications and the Accelerator Production of Tritium (APT) Project. We are developing 5-cell niobium cavities with elliptical-cell shapes at 700 MHz. These cavities, unlike most elliptical cavities for electron accelerators, are designed to accelerate protons at $\beta<1$. Coaxial power couplers are being developed to transmit high (250 kW) CW RF power to the cavities. The couplers will be tested both at ambient temperature and at 2-K temperature, and power-handling and thermal properties measured. The cavities and power couplers will be integrated into a prototype cryomodule, which will be tested and characterized with RF under cryogenic conditions as required for a high-power proton linac.

1 INTRODUCTION

We have a program to develop SCRF technology for proton linacs in Los Alamos. Although this program has been initiated to support the APT SCRF linac [1], the technology development will be useful for all SC proton linacs with high CW power and current. The merit of using SCRF linacs for high-power applications, like accelerator-driven transmutation technology, has been described in Ref. 2. In this paper, we describe the issues encountered in the development of cavities, power couplers, and cryomodules. Design features of these components are given in Ref. 3 and will be repeated here only to the extents of explaining the issues.

2 CAVITY SHAPES

Figure 1 shows the cell-shape used for the APT 5-cell cavities, usually known as the elliptical cell shape which has been widely adopted in SCRF cavities that accelerate relativistic electrons. For proton linacs, the lengths of the cells are reduced to maintain synchronism with the slower proton beams (β=0.64 and 0.82). The shorter cell lengths lead to cell walls that have smaller slopes that could easily collapse under vacuum pressure and prone to multipacting. We have designed the APT cavities with a 10-degree slope for the cell wall. This is the optimum slope to minimize peak electric and magnetic peak fields and to maximize mechanical stability. With a slight increase in wall thickness (from 3 to 4 mm), we can eliminate the need of costly stiffeners that are otherwise needed to withstand the vacuum load. We have tested single-cell cavities [4]. Results (Fig. 2) show the APT cavity field can be achieved with more than a factor of two margin, and with no limitations due to multipacting, even in the case of β=0.48.

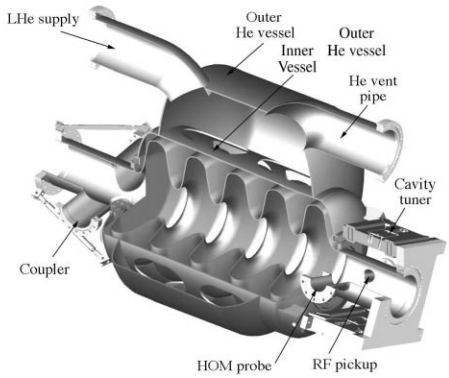

Figure 1: Illustration of β=0.64 cavity design.

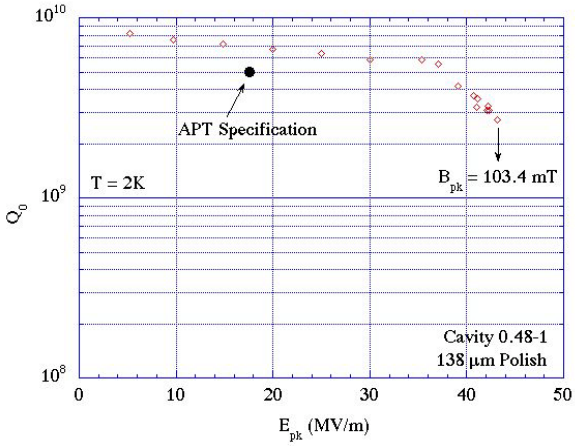

Figure 2: Typical test results of a β=0.48 cavity

3 POWER COUPLER ENGINEERING DESIGN

Figure 3 shows an illustration of the APT power coupler. Because of the high beam power, each coupler needs to deliver 210 kW of CW power to the beam. This

*Work supported by US Department of Energy
**On sabbatical leave from CEA Saclay, 91191 Gif-sur-Yvette, France

power level was achieved only recently by a waveguide-type coupler; and it has not been achieved by coaxial-type couplers [5]. Additionally, since the APT-linac is required to produce tritium with high availability over 40 years, it is important that APT coupler operate reliably at high power.

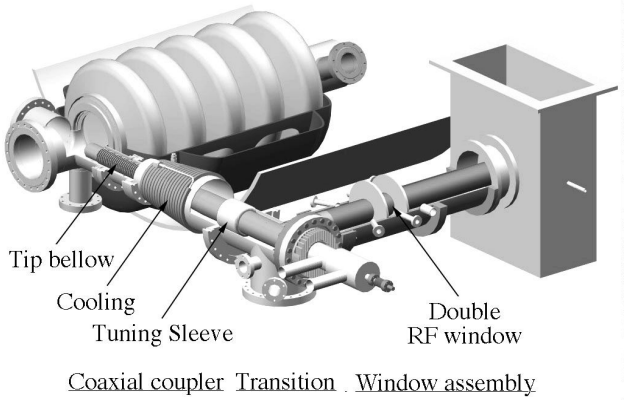

Figure 3: Illustration of the APT power coupler.

Based on experience from other laboratories, we have chosen a coupler design [3] with features that enhance reliability. Usually, RF windows are the primary source of coupler failure. In our design, we use warm RF windows with two ceramic pieces for redundancy, no direct line of sight to the beam, and window diagnostics to detect signs of the onset of failures. These windows, fabricated as complete assemblies by the klystron industry, have been designed, and will be tested to 1 MW.

The APT coupler consists of three sections: the RF-window assembly, the transition, and the coaxial coupler. To minimize reflected power during operation, extensive 3D electromagnetic modeling has been done to attain a good match between sections. The modeling procedure started with the design of separate components and benchmarking the simulations by building and measuring some of these components. Finally, a fully integrated study was performed. As a result, a coupler has been designed that has an excellent power transmission at and around the 700-MHz operation frequency. We have also minimized the electromagnetic interactions between the RF-window assembly with the transition and coaxial-coupler sections. The transmission of the coaxial-coupler section is maximized by adjusting the length of a quarter-wave stub and the shape of a tuning sleeve. The RF window as a complete assembly has also been simulated extensively with respect to thermal performance to minimize thermal stress.

There are two features in the coupler that can potentially reduce the reliability of the coupler: bellows and copper plating. First, two bellows will be used in a coupler, one to allow the joining between the RF-windows and the transition sections, and one (close to the tip of the inner conductor) for changing the length of the inner conductor and consequently the coupling to the cavities. These bellows could become work-hardened and yield after repeated elongation, compression and thermal cycling. Bellows made of BeCu are ideal for our application, but their availability is expected to be limited because of the toxicity of machining Be. We are studying options including copper alloys, electroformed copper bellows, and copper-plated or sputtered stainless-steel bellows. Second, copper plating will be used on the inside surface of the stainless-steel outer conductor. Stainless steel is chosen as structural material for the outer conductor because of its low thermal conductivity. Unfortunately, it also has high RF resistivity and RF heat loss. Copper has low electrical resistivity and RF heating. Copper-plated stainless steel will offer both low RF loss and low heat transfer at 2-K temperature. To maintain reliable performance, it is important that plating have a low outgassing rate and good adhesiveness to stainless steel. The plating process must produce these performance and thickness uniformity consistently. There are three ways to achieve copper plating: plating with UBEC (Ultra Bright Electroplated Copper), plating with OFE (oxygen-free electrolytic) copper, and plating with vacuum sputtering. We plan to perform outgassing and adhesive tests on plating samples produced using these three methods. We will also construct couplers with these plating methods and tests them at high RF power.

4 COUPLING COEFFICIENTS OF POWER COUPLER

For the amount of power needed to accelerate the beam, we need to obtain an external-Q (Q_L) of 2.5×10^5. This Q_L will be provided by two couplers, each having a Q_L of 5×10^5. We have investigated different coupler geometries to provide this Q_L. Results [6] show that we need to expand the beamtubes for the β=0.64 cavities from 6.5 cm to 8 cm. Lower coupling can further be achieved by slightly expanding the tip of the coupler center conductor. We have also extended the standard beam-loading theory for beam loading with multiple couplers [7]. Reflected powers resulting in failure scenarios and when the two couplers are not exactly identical were calculated.

5 OPERATING TEMPERATURE

The cavity operating temperature has been set at 2.15 K [8]. This temperature was chosen for two reasons. First, we evaluated the total cryoplant cost, including the capital cost and operating cost, as a function of the operating temperature. The total cost has a minimum around 2.4 K caused by a tradeoff between higher cryogenic efficiency at higher temperature and lower surface resistance at lower temperature. The minimum is broad, with the total cost increased by 3% by operating at 2.15 K. Second, we decided to operate in the temperature regime of superfluid for better helium heat-transfer properties and better margins against quench. An operating temperature of 2.15-K is the highest temperature for which that we presently feel confident to control the LHe temperature so

that LHe remains superfluid. It may be lowered in the future.

6 HEAT LOADS AND POWER COUPLER COOLING

We are designing our components and cryomodules to maximize cryogenic efficiency and to minimize the required cryogenic power. Table 1 shows a summary of the baseline heat loads for a $\beta = 0.82$ cryomodule. Such a cryomodule will have 4 cavities and 8 power couplers. For this case, heat is removed by LHe boiloff and at an intermediate temperature of 45 K.

Table 1: Typical heat loads of a β=0.82 cryomodule

	2.15-K (W)	45-K (W)
Cavities	96.4	0
Power Couplers	40.0	176
HOM	6.8	0
Others	8.0	90.9

The major heat loads are from the RF losses in the cavities. The Qo used to calculate this load is $5x10^9$. The second major heat load is the power coupler. The power couplers are the primary thermal connections between room temperature and the 2.15-K temperature. They are also major heat sources because the RF losses in the couplers. Typically, the RF losses are 230 and 50 W, respectively, for inner and outer conductor. It is important to prevent these losses from reaching the 2.15-K temperature. We have developed a thermal model to explore a wide range of cooling schemes and operating conditions. This model includes heat-transfer mechanisms like conduction, radiation, RF heating, and cooling by forced convection. We considered cooling of the outer conductor with single- and two-temperature thermal intercepts and with a counter-flow heat exchanger. Results [9] showed that the power-coupler heat loads could be reduced to 16W at 2.15 K using counter-flow heat exchangers. Results from the model also showed that the inner conductor could be cooled using room-temperature gaseous helium.

7 CRYOMODULE ASSEMBLY

For high-performance of SC cavities and power couplers, it is important to maintain clean assembly of the cryomodule. For our power coupler design [10], with the absence of a cold RF window to seal off the cavity, we are required to assemble the power couplers with the cavities in a cleanroom (Class-100) environment. Figure 4 shows the assembly that will be assembled in the cleanroom. After cleanroom operation, we will rotate the assembly through the axis by 90-degrees to facilitate the installation of superinsulations, magnetic shields, LHe tubings, and instrumentation. After that, we will install all the LHe and vacuum connections and the two endcaps and test for vacuum.

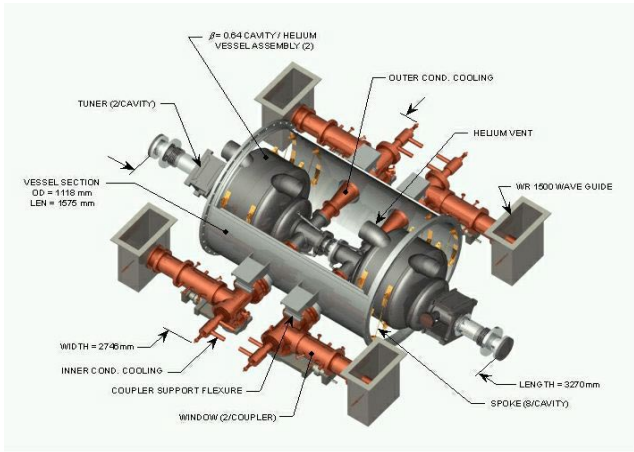

Figure 4: Part of cryomodule assembled in a Class-100 cleanroom

8 SUMMARY

We are developing SC RF cavities, couplers, and cryomodules to accelerate high-intensity proton beams. Issues identified during this development have been described in this paper.

DEVELOPMENT OF A FAST TRAVELING-WAVE BEAM CHOPPER FOR THE SNS PROJECT*

S.S. Kurennoy and J.F. Power
Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Abstract

High current and stringent restrictions on beam losses, below 1 nA/m, in the designed linac for the Spallation Neutron Source (SNS) require clean and fast – with the rise time from 2% to 98% less than 2.5 ns – beam chopping in its front end, at the beam energy 2.5 MeV. The development of new traveling-wave deflecting current structures based on meander lines is discussed. Three-dimensional time-domain computer simulations with MAFIA are used to study transient effects in the chopper and to optimize current structure design. Two options for the fast pulsed voltage generator – based on FETs and vacuum tubes – are considered, and their advantages and shortcomings for the SNS chopper are discussed.

1 MEBT CHOPPER SYSTEM

The SNS is a next-generation pulsed spallation neutron source designed to deliver 1 MW of beam power on the target at 60 Hz in its initial stage [1,2]. It will consist of a 1-GeV linear H^- accelerator and an accumulator ring. The SNS storage ring accumulates the linac beam during a few hundred turns (a macropulse, about 1 ms) using H^--injection through a carbon foil. The beam injected into the ring is stacked into a single long bunch, and the linac macropulse must be chopped at near the ring revolution frequency 1.188 MHz to provide a gap required for the kicker rise time during a single-turn ring extraction. The final clean beam chopping in the linac is to be done in the Medium Energy Beam Transport (MEBT) line.

The MEBT transports 28 mA of peak beam current from a 2.5-MeV 402.5-MHz RFQ to a drift-tube linac. A 0.5-m space is allocated for the chopper that deflects the beam into a beam stop during the 35% beam-off time. The chopper parameters are summarized in Table 1.

Table 1: MEBT Chopper Specifications

Parameter	Value	Comment
Beam energy	2.5 MeV	β=0.073
Length	≤0.5 m	Shorter is better
Gap	1 cm	adjustable
Pulser voltage	±900 V	Currently achievable with FETs
Deflection angle	18 mrad	
Chopping period	841 ns	
Duty factor	35 %	65 % beam on
Rise / fall time	< 2.5 ns	2–98 % (final goal)

To mitigate the effects of a partial chopping or small errors in the timing system, an identical "anti-chopper" is placed in the MEBT line at an optically symmetric point from the chopper to return uncollimated beam to the axis. Two preliminary chopping stages (at the ion source and in the LEBT line, at 100 keV, see [2]) are introduced to reduce the beam power deposited at the MEBT beam stop.

At any given moment of beam passing through, there are about ten bunches along the chopper length. Even having an ideal pulse generator, the only way to avoid partially chopped bunches is to apply a traveling-wave current structure. The deflecting electric-field pulse fills the chopper with the phase velocity along the beam path matching the beam velocity and propagates together with the beam. The bunches following the pulse front are fully deflected while those ahead of the front are not disturbed. Providing the field-pulse front (and its end) shorter than the bunch-to-bunch spacing (2.5 ns, or about 5 cm) is the most challenging requirement to the chopper system. As an initial goal, the rise/fall time below 5 ns is acceptable; it will lead to one partially chopped bunch at the front and the end of each chopper pulse.

2 CHOPPER CURRENT STRUCTURE

A traveling-wave chopper for $H^{\pm}$ beams at 750 keV [3] has been working successfully for many years at LAMPF. It provides the rise time of about 7 ns, mostly due to the pulse modulator. Its coax-plate current structure itself is capable of providing a pulse front about 2-3 ns with an overshoot on the 10% level ringing for a few ns. The 1-m long structure consists of two parallel plates, each interfaced with many small strip segments connected with coaxial cables on the reverse side of each plate to form a continuous circuit along the structure. The voltages on the upper and lower plates are synchronized and have opposite signs so that the resulting vertical electric field deflects the beam. The structure rise and fall time limitations are caused by stray capacitance between the segments and by multiple coax-to-segment transitions.

A new current structure based on a meander line with separators (Fig.1) has been proposed in [4]. A strip line forming the meander can be either straight or notched (as the one shown in Fig. 1). The line parameters are adjusted to provide the line characteristic impedance 50 Ω. The meander bends are chamfered to avoid pulse reflections.

* Work supported by the US Department of Energy.

The separators (or guard barriers) rising from and electrically connected to the ground plane are used to reduce the coupling between the adjacent sections of the meander line, see in Fig.2. The new design has no multiple coax-to-plate transitions and is easier for manufacturing.

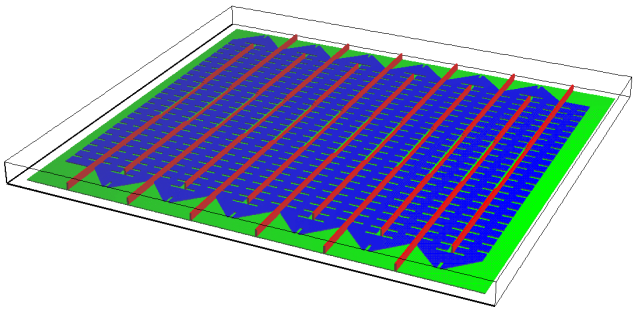

Figure 1: 1/4-length model of meander current structure: notched meander strip line (blue) above the ground plate (green) with separators (red), cf. Fig.2. Only the lower plate is shown.

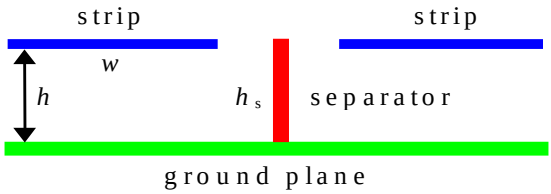

Figure 2: A partial vertical cut in the beam path plane of the meander current structure: the separator is inserted between two adjacent pieces of the transmission line.

3-D time-domain simulations with the electromagnetic simulator MAFIA [5] have been used to study transient effects in the current structure. It was shown [4] that even without separators, the meander structure has a rise time 2–2.5 ns; with separators it can be reduced down to 1–1.25 ns, depending on the separator height. The structure fall time was found to be about the same as the rise time. High separators, however, reduce the effective field on the beam path by 10–20% depending on their height h_s.

Our previous work [4] dealt mostly with straight-strip meander structures. Using a notched strip line in the meander instead of a straight one has some advantages. First, the notches provide an additional inductive load that slows down the wave along the strip. It increases the field efficiency due to a larger ratio of the strip width w to the strip-to-strip gap width g: the notched-strip width w is 8 mm compared to 5 mm for a straight line. The meander width transverse to the beam is about 11 cm, h=1 mm and g=2 mm in both cases. In addition, the notches also reduce the magnetic coupling between adjacent strips since the wave magnetic field is concentrated closer to the strip center. As a result, our recent efforts have been directed toward optimizing the notched-strip design.

For earlier simulations [4] we needed to load a TEM wave into the structure. The latest version of MAFIA [5] allows simply to feed the strip with a voltage having any time profile. We have used voltages shaped as either step-functions (often smoothed by a squared *sin* to filter out very high frequencies) or as finite-length pulses. As the voltage pulse propagates along the structure, the electric field on the beam path is recorded. As an example, Fig.3 shows the deflecting field created by a voltage pulse with 1-ns sin^2 front, flat top at 1 kV for 3 ns, and 1-ns sin^2 end, in the full-length 50-cm model of the type shown in Fig.1. Such a pulse would kick out exactly two linac bunches. As the pulse propagates, its shape is slightly distorted by developing an overshoot, but its front and end remain well within 2-ns range, see also Fig.4.

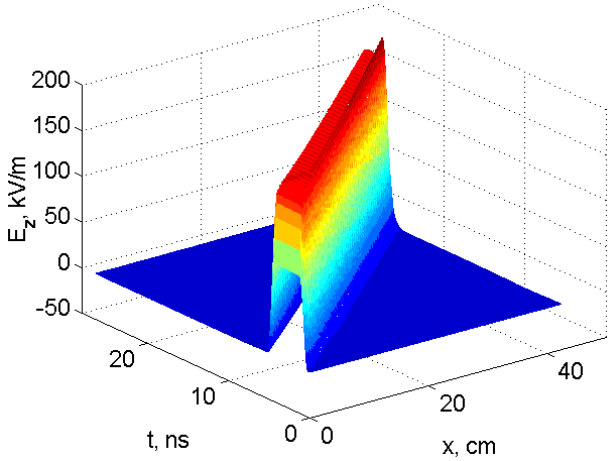

Figure 3: Deflecting field on the beam path versus time and position in the notched-strip meander structure for a 1-3-1-ns 1-kV driving pulse.

Cross-sections of the surface plot in Fig.3 for a given position x along the structure show time dependence of the field at this location, cf. Fig.4. Straight-strip meanders produce slightly larger pulse distortions, see in [6].

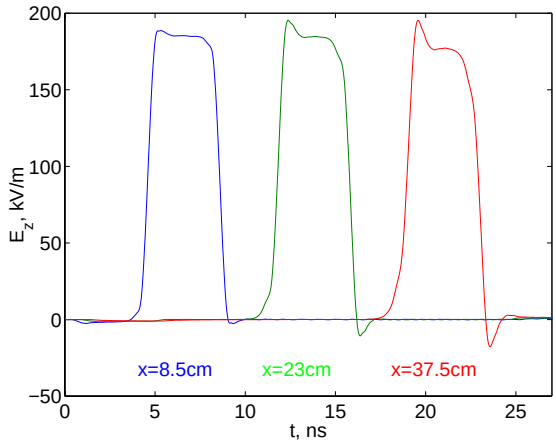

Figure 4: Deflecting field versus time in 3 different points on the beam path in the notched-strip meander structure.

Cross-sections of Fig.3 taken at given time t produce snapshots of the deflecting field as shown in Fig.5. Small wiggles on the pulse tops are due to differences of the field in points above the middle of the strip and above the separators. In fact, these field variations will even help to spread the deflected beam slightly on the beam stop.

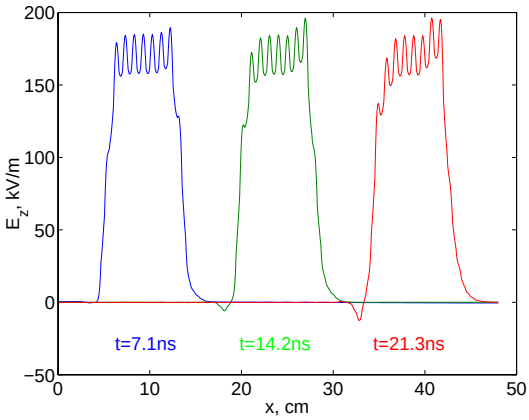

Figure 5: Snapshots of the deflecting field on the beam path in the notched-strip meander structure (cf. Fig.3).

As a result of our design optimization, the notched-meander structure looks as shown in Fig.1. Extra notches on the bends have been added to eliminate reflections. To increase the effective field on the beam path without increasing the rise time, the profiled separators have been introduced: they are low (flash with the strip line) near the beam and higher near the edges, see Figs.1-2.

3 CHOPPER PULSE GENERATOR

There are two technologies applicable to generating the required chopping voltage. These are the planar triode vacuum tubes and power FET devices.

Planar triodes, such as the Eimac 8940, could be used as switches to generate the required pulses. A number of difficulties would be challenging to overcome. The duty factor rating of these small triodes is a factor of ten lower than needed, so multiple tubes must be connected in parallel. Increasing the number of tubes increases the stray capacitance and the current rise time. These tubes are designed for operation at several kilovolts, which results in high grid currents at low voltage operation (such as 2 kV). Excessive grid power dissipation is a concern [7]. Generating the grid-drive will be as difficult as producing the output pulse. On the positive side, sub-nanosecond rise time has been demonstrated with these tubes at low duty factors [7,8] and a previous LANSCE chopper using six tubes produced 3-ns rise times and 4.5-ns fall times at 500 volts with similar duty factors [9].

Power FETs, such as the DEI 102N02, are capable of switching high currents at the <1-kV level at high repetition rates. A FET-switched pulser should be able to meet all of the specifications fairly easily, except for the rise time. The available FETs from current manufacturers are inherently limited to rise times on the order of 3-4 ns, with 5 ns being a demonstrated number [10]. We feel that the power FET devices are the best choice for the switching technology for the chopper application.

Starting next year we will build and test a proof-of-principle chopper pulser using FET devices that are currently available. This will be a low-average-power system whose purpose is to verify what level of performance can be expected using existing technology. We will build both a positive-output and negative-output polarity pulsers that are capable of generating 900-V pulses across 50-Ω loads. Each pulser consists of two high-voltage FETs, their gate-drive circuits, optical trigger links, an impedance-matched chassis assembly, power supplies and instrumentation. Output rise times and fall times are expected to be on the order of 5 ns.

In parallel with the proof-of-principle chopper pulser work we will attempt to develop FET devices which are faster than presently available. This entails fabricating new FETs whose bulk-silicon and doping characteristics will be specifically optimized for fast switching. Directed Energy Inc. (DEI) feels [10] that they can produce a significantly faster device, but the development cost will be significant. We will contract out this work to a suitable company with experience in the production of similar devices. If this effort is successful, we will incorporate these new FETs into our proof-of-principle pulser design.

4 CONCLUSIONS

A new current structure based on a meander line has been developed. The 3-D time-domain modeling shows that the structure is capable to provide the rise and fall times on the order of 1 ns. Further simulations will include more engineering details like supports, as well as beam dynamics and PIC-simulations. Manufacturing of the prototypes and their measurements are also planned.

The voltage generator development remains the most important and challenging issue. We will proceed with the proof-of-principle pulser design using currently available technology, while continuing to work with manufacturers on development of faster powerful FETs.

Useful discussions with Andy Jason and Frank Krawczyk are gratefully acknowledged.

Abstract

A variable energy radio-frequency quadrupole (RFQ) linac system, the LANSAR™ Model DL-5, has been developed at AccSys Technology, Inc. as a fast neutron source. The energy variation is accomplished by coupling two RFQ cavities with an adjustable rf power phase shift between them to provide two modes of operation, beam acceleration or beam transport. The beam dynamics code PARMTEQ was used to model this system and calculate the output beam parameters as a function of phase shift between the two RFQs. Output beam measurements were performed using a Rutherford back-scattering (RBS) technique and beam scanner developed for this system. The results are compared to the calculations.

1 INTRODUCTION

A compact variable energy RFQ linac, the LANSAR™ Model DL-5, has been developed by AccSys Technology, Inc. for the production of fast neutrons for resonance neutron radiography. The system was designed to accelerate deuterium ions to two discrete energies for injection into a high pressure windowless deuterium gas target that employs a rotating shutter. Precise deuteron beam energies are required for the neutron radiographic imaging technique being employed. The beam size at the gas target must also be small as this determines the spatial resolution of the imaging system.

This system produces a deuteron beam in the selected energy range of 3.60–4.90 MeV by directly coupling two RFQ cavities with an rf power phase shift between them to provide two modes of operation, beam acceleration or beam transport. Depending on the relative rf phase shift between RFQ1 and RFQ2, RFQ2 can either add or subtract energy from the 3.94 MeV deuteron beam from RFQ1. However, the large bore and strong transverse focusing permits most of the particles to be transmitted through RFQ2, regardless of phase.

2 SYSTEM DESCRIPTION

The Model DL-5 linac system consists of a deuterium ion injector and two close-coupled RFQ resonators. Each RFQ is powered by an rf amplifier supplying up to 300 kW of peak rf power via a semi-rigid coaxial cable. The high energy beam transport system (HEBT), consists of a beamline, a toroid for monitoring the pulsed output beam current, two orthogonal steering magnets and a quadrupole triplet for beam focusing. The performance specifications of the LANSAR™ Model DL-5 system are presented below in Table 1.

Table 1. Model DL-5 Performance Specifications

Operating frequency	425	MHz
Injector output energy	25	keV
RFQ1 output energy	3.94	MeV
RFQ2 output energy via transport mode via acceleration mode	 3.90 4.86	 MeV MeV
Injector output current (pulsed)	12	mA
RFQ2 output current (pulsed)	6-8	mA
Maximum average current	0.1	mA
Linac total length	4.4	m
Maximum beam pulse width	90	μs
Repetition rate (variable)	20-200	Hz
RF power (RFQ1/RFQ 2)	280/160	kW
Maximum rf duty factor	1.5	%
Nominal beam transmission (RFQ1/RFQ2)	84/95	%
Nominal HEBT beam transmission	> 95	%

3 VARIABLE BEAM ENERGY

The beam dynamics code PARMTEQ was used to model the linac design. As shown in figure 1, the calculated beam dynamics indicates a strong periodic variation of the accelerator output energy as a function of the relative phase shift between the two RFQ structures.

The Rutherford back-scattering (RBS) technique was used to measure the output deuteron energy as a function of the relative rf phase shift between RFQ1 and RFQ2. A water-cooled, thick tantalum target was mounted at 45° to the beam direction. The scattered particles were counted with a silicon surface barrier detector which was calibrated using an ^{241}Am α-source and positioned at 90º to the beam direction.

Significant pile-up and detector dead-time were initially observed in the RBS measurements due to the linac's low duty cycle (1.5%), high peak current (6–8 mA), and low repetition rate (100–200 Hz). Significant beam de-focussing and collimation had to be employed in order to avoid the pile-up effects, resulting in an average acquisition time of ~15 min per RBS spectrum.

The measurements were performed with the linac operating at two duty cycles: 0.32% (repetition rate of 80 Hz, beam pulse width of 40 μs) and 0.6% (repetition rate of 125 Hz, beam pulse width of 40 μs). The results of the RBS measurements are presented in figure 2. These measurements correlate very well with the calculations presented in figure 1 and display the calculated periodicity. The variations of the beam energy for the two selected duty cycles are within the measurement errors.

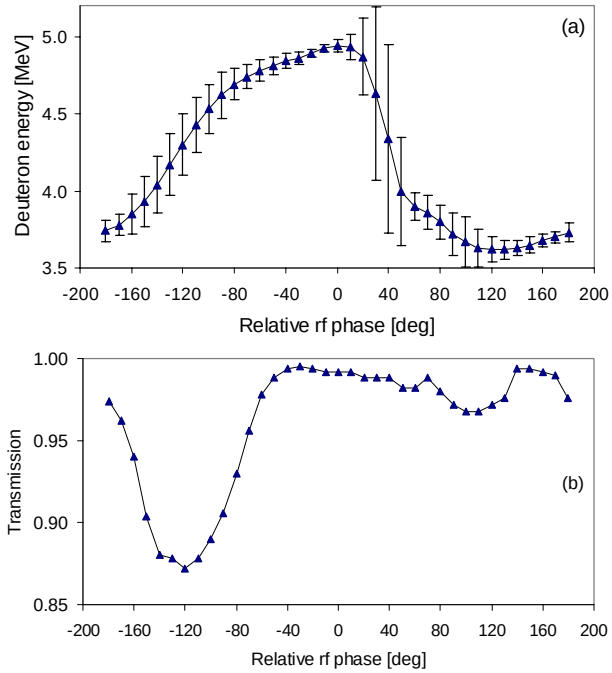

Figure 1. Calculated beam energy (a) and transmission (b) as a function of relative phase shift.

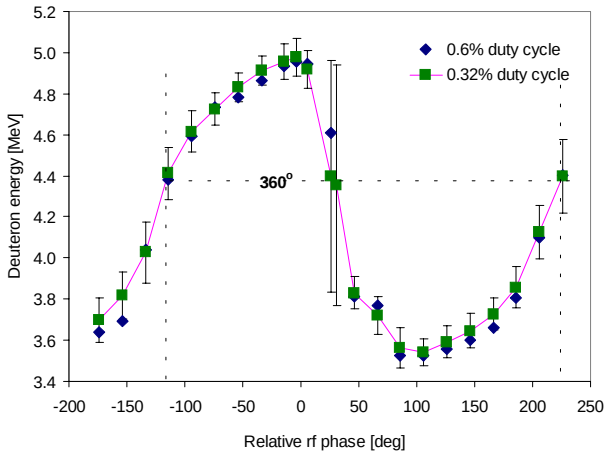

Figure 2. RBS measured beam energy as a function of relative rf phase shift at two beam duty factors.

The output deuteron energy is stable in the 4.7-4.9 MeV energy region over the relative phase range from 0° to -60° about the design synchronous phase of –28°. It is also stable over the 3.5 – 3.7 MeV energy range for relative input phases from 80° to 180°. The mean value of the output energy varies from 3.62 MeV to 4.93 MeV over the full 360° phase range. The exact amplitude and phase settings for operation in the dual energy mode depend on the operating duty factor, since the operating frequency and hence the phase relationship change slightly with the duty factor. However, for the two duty factors used for the RBS measurements, these changes were within the experimental measurement error.

The deuteron beam energy was also measured with RFQ2 switched-off, i.e. in the condition where the ions are only accelerated in RFQ1 but subsequently drift through RFQ2. The measured beam energy was 3.90±0.05 MeV.

4 BEAM CURRENT PROFILES

A standard National Electrostatic Corporation beam profile monitor (Model BPM-45) was used to measure the output deuteron beam profile. In this BPM, a single wire formed into a 45° helix is rotated about the axis of the helix at a frequency of about 16 Hz. It sweeps across the beam in two independent directions in every cycle. The secondary electron current released from the wire as it intercepts the beam is a measure of the beam intensity.

The normal use of this BPM is not effective with the linac operating at a beam repetition rate of 100 Hz and beam pulse width of 100 μs. Primarily due to the frequency mismatch, the BPM's wire misses most of the beam pulses. In order to use the BPM more effectively the trigger signal generated by the BPM during every revolution (traditionally used as a trigger signal for the oscilloscope) was used to trigger the accelerator. By varying the delay of the trigger signal, the deuteron beam pulses were probed at different spatial positions, and the intensity of the beam was measured on a digital oscilloscope. Knowing the trajectory of the wire, its dimensions and rotation frequency, the trigger delay time was scaled into the linear extent of the beam.

The toroid, steering magnets and quadrupole magnets were removed from the HEBT to provide access to the beamline for the BPM. The beam spot dimensions were measured at several positions downstream from the exit aperture of RFQ2 at different settings of the relative rf phase, i.e. energy. A gaussian function was fit to all measured beam profiles and the FWHM was calculated. An example of the beam profiles obtained at 284 mm from the RFQ2 aperture, for the relative rf phases of -80° (E_d~4.65 MeV), 0° (E_d~4.90 MeV) and 160° (E_d~3.70 MeV), is presented in figure 3.

The results of measurements of the deuteron beam profiles as a function of the relative rf phase shift are presented in figure 4 for a distance of 284 mm and 404 mm from RFQ2 exit. The beam diverges in both planes as it travels down the beamline because the focusing elements have been removed. There are two regions of relative rf phase (deuteron energies) where the beam

dispersion is small and varies little with small changes in the relative rf phase.

These regions are separated by a region of high beam dispersion, which corresponds to a transition region between high and low deuteron energy, as seen in figure 4. The large beam dispersion in this region is caused by the large deuteron energy spread within the bunch, which results in spatial de-focusing.

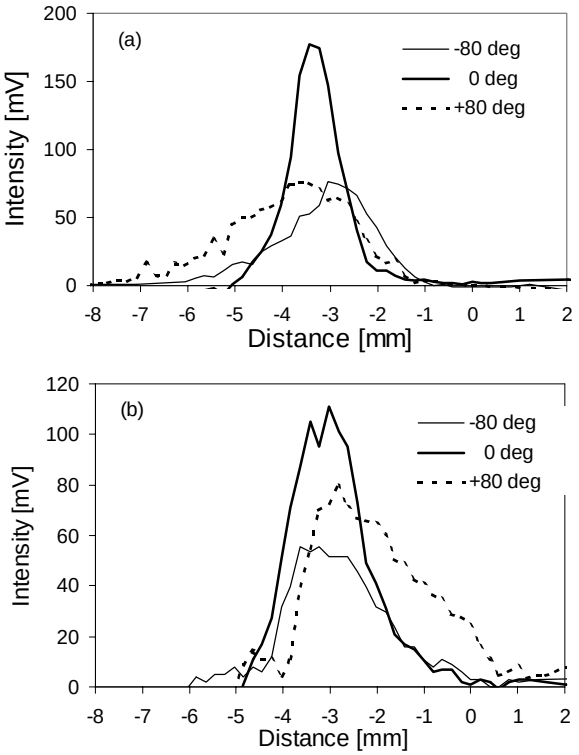

Figure 3. Measured x (top) and y (bottom) beam profiles at a distance of 284 mm from RFQ2 exit. The *x*-axis is the distance from the center of BPM's helix axis.

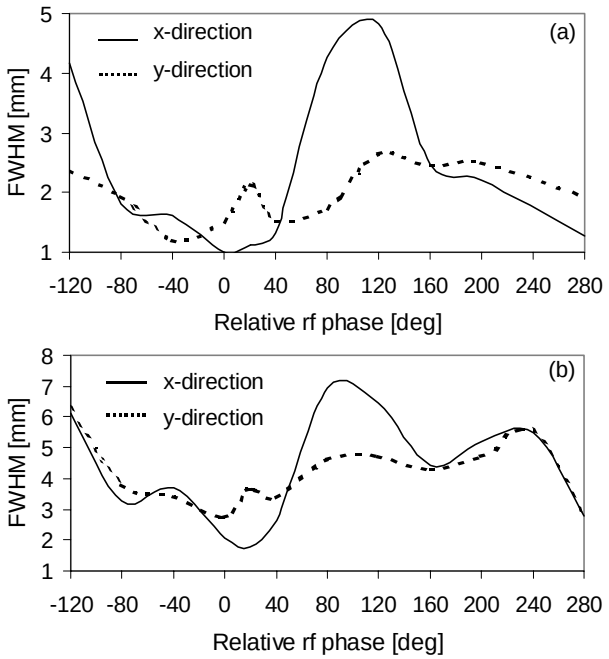

Figure 4. Measured beam dimensions at 284 mm (top) and 404 mm (bottom) distance from RFQ2 exit.

The calculated output beam size is shown in figure 5. There is good agreement between the measurements and the calculations. The smallest beam size is both predicted and observed in the high energy range, and is half the minimum value in the low energy range. The calculations indicate that at the maximum beam energy, the beam diameter is <1 mm at the exit of RFQ2.

The measurements indicate that the operation of the linac is very stable in the "acceleration" mode, where the beam has a well-defined energy with the smallest spatial dispersion. When operating with the relative rf phase outside these conditions, RFQ2 has both accelerating and decelerating modes as the beam passes through it. This results in significant beam energy spread and a larger beam spot size on the target.

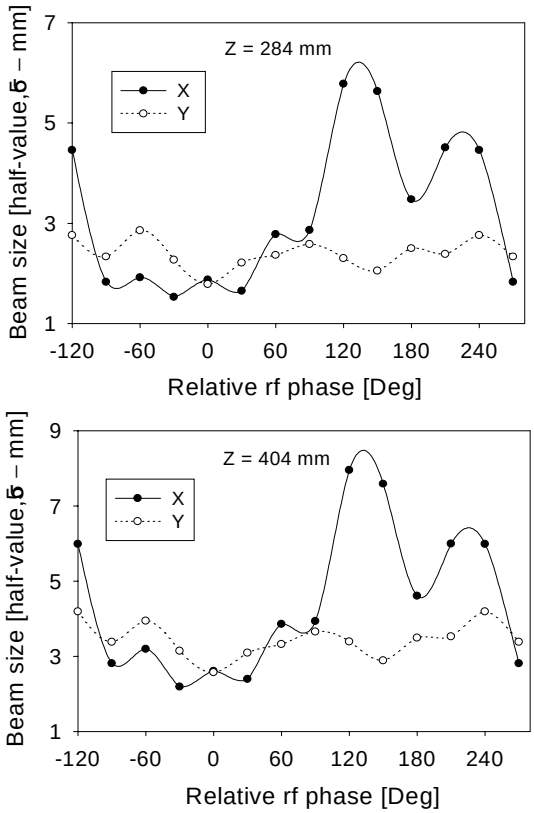

Figure 5. Calculated output beam dimensions at 284 mm (top) and 404 mm (bottom) from RFQ2 exit.

5 CONCLUSION

Output beam measurements on the LANSAR™ Model DL-5 variable energy RFQ linac have been performed and compared to PARMTEQ calculations. The experimental measurements are in good agreement with the beam dynamics calculations and prove that the system performance does indeed satisfy the stringent requirements imposed upon it as a dual energy neutron source. The system was installed in the spring of 1997 in a radiographic test facility in South Africa and has been in routine use for more than one year.

STATUS OF THE INFN HIGH CURRENT SC PROTON LINAC FOR NUCLEAR WASTE TRANSMUTATION

Abstract

INFN, jointly with ENEA, is working at the design study for an accelerator driven waste transmutation subcritical system, TRASCO. In particular, our group is studying the high energy section, above 100 MeV, of the high power (> 30 MW) proton linac driver at 352 MHz, following the guidelines we presented at the Linac'96 Conference. The funded activities include the overall conceptual design of the three section SC linac and the development and tests of prototypes for the cavities and cryomodules. An overview of the status and perspectives of these activities will be given in this paper.

1 THE TRASCO PROJECT

The TRASCO Project is a two year funded (10 M$) program in which INFN, jointly with ENEA and various Italian industries, will work on the design study of an accelerator driven waste transmutation subcritical system. TRASCO is an Italian acronym for Transmutation (TRAsmutazione) of Waste (SCOrie).

This program is in line with the growing European consensus, promoted by Carlo Rubbia through the idea of the Energy Amplifier, on a long term reconsideration of the civil use of nuclear power, based on a final solution of the waste accumulation problem. While similar programs are underway in the US and in Japan, in Europe the various national efforts are coordinating through the signature of Memoranda of Understanding, like the one recently signed by INFN, CEA and IN2P3 for a common effort in the accelerator technology development. Another MOU signed with the CERN group led by E. Chiaveri will give us the opportunity to make use of the wide experience gained so far in the production and commissioning of the LEP2 cavities. In particular, the cavity prototypes planned for TRASCO will be treated and tested at the CERN premises.

The aim of our specific effort in this preliminary, and short-termed, program is to set the feasibility of a high beam power proton linac based, whenever possible, on the "cheap" CERN technology developed for the LEP2 superconducting cavities. This is an extremely attractive option, since it allows the possibility to make use of large and expensive facilities, existing at CERN and at various European companies, for the studies on prototypes.

The low energy section of the machine, up to 6 MeV, is under study by others INFN groups (at LNL and LNS), in the framework of the collaboration with CEA and IN2P3. While a working prototype of the source is in operation at Saclay, the design and development of the CW, 6 MeV, RFQ, similar to the one developed for APT at LANL, is considered one of the major technological tasks.

The medium energy part, up to 100 MeV, is in study by INFN/LNL, and will take advantage of a contract signed with a qualified industry.

2 THE LINAC DESIGN

The reference linac design for the high energy section of the TRASCO linac has been set in Refs. [1] and [2]. The 100 to 1600 MeV linac is split three sections, with synchronous cavity β of 0.5, 0.65 and 0.85. Transverse focusing is provided by a periodic doublet lattice, with cell length of 8, 11.2 and 15.3 m, respectively.

2.1 Beam dynamics simulations

An intensive beam dynamics activity has started, in order to verify the performances of the linac design with multiparticle codes. An "ad hoc" simulation code has been developed for the beam dynamics in the elliptical shaped cavities, employing a fast 3D Poisson solver, based on multigrid algorithms, for the treatment of the nonlinear space charge fields. The results of this simulations are presented in a separate contribution to these Proceedings[3]. In Figure 1 we show the rms, 90% and 100% emittances along the linac for the nominal current of 25 mA, and a typical simulation of 100.000 particles. The cells at the transitions have been used for transverse and longitudinal matching across the three sections. The rms emittance growth is limited to below 10% and the total emittance increases by a factor smaller than 2.

The ratio between the beam aperture and the transverse rms beam size is well above 25 all along the linac. This, together with the small number of betatron wavelengths in the linac (few tens), gives us a great confidence that, with such a design, the halo formation in the SC linac would not be a serious problem.

The simulations were performed for a nominal current of 25 mA, the goal being that of a driver for a prototype transmutation plant. An increase of the linac current up to 100 mA has not been studied yet in full details.

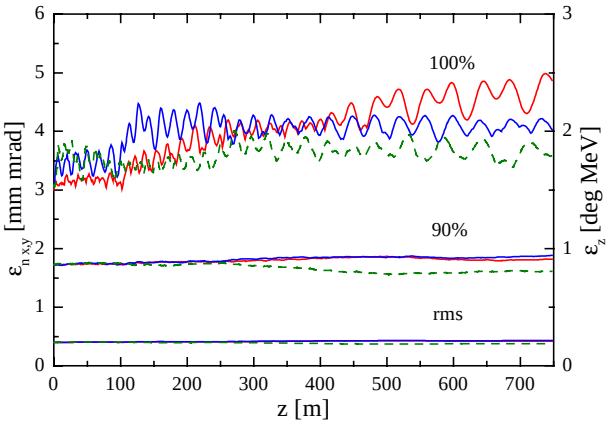

Figure 1: The rms, 90% and total (100%) emittances along the linac The solid curves are the transverse emittances, (left axis) and the dashed curve is the longitudinal emittance (right axis). The simulation has been performed with 100.000 particles.

However, to allow for this current increase it seems that either a shorter focussing period should be provided in the first linac section, or the normal conducting DTL to SC transition should be raised to higher energies.

2.2 Reliability of the proposed design

Having assessed that the basic design does not show serious limitations in achieving the objectives for a transmutation plant, we are now planning the inclusion of spare linac focussing cells in order to achieve full reliability in the case of klystron or cavity/coupler faults.

In spite of the demonstrated high reliability of the existing large scale superconducting RF accelerators (LEP, CEBAF, HERA and TRISTAN), a driver for a nuclear waste transmutation plant needs to satisfy the stringent requirements imposed by its specific use. In particular, a beam stop due to any failure of one of its components causes an interruption of the spallation neutron flux sustaining the subcritical system. If this interruption exceeds a fraction of an hour (the exact time depending on the details of the core design), the fuel bar poisoning rises: i.e. a new start up procedure needs to be performed and the waste cleaning process is partially lost.

For this reasons we are considering a linac design which includes two spare cryomodules for the low and intermediate energy sections. These two sections are the most critical, since they need to provide the correct transition energy to the following sections. A 10% spare contingency of three additional cryomodules is planned for the (less critical) high energy section. The lengthening due to the amount of contingency hardware is around 80 m, for a new total length of 800 m.

In the case of failure, a spare component will take the place of the faulty, and the beam will be back on the target in the time required by the reactor design. Some of the components, like the klystrons, could be repaired or replaced during the regular linac operation, while others, like the cavities or the RF couplers, will have to wait for the planned reactor maintenance shutdown.

The best use of these spare components when they are not needed (whether they are kept on or off at all times) needs to be analyzed on the basis of both capital and operational costs.

3 R&D ACTIVITIES ON THE SUPERCONDUCTING CAVITIES

The design of the three accelerating structures has been presented in detail at EPAC'98[4]. The geometry of a five cell cavity with an elliptical shape both at the iris and at the equator has been optimized in each linac section. The following design goals for the cavity operating conditions were chosen:

1. a peak surface electric field below 16 MV/m
2. a peak surface magnetic field below 40 mT
3. a good cell to cell coupling factor of 1.7%.

The cavities have been analyzed both with respect to the electromagnetic performances and with respect to the mechanical loads on the structures. Structural stiffening is required only for the lowest beta structure (β=0.5), and either a standard stiffening structure will be employed or a structural stiffening via copper spraying with a plasma jet (as proposed for the Tesla cavities[5]) will be performed.

Table 1 summarizes the main electromagnetic parameters of the TRASCO cavities, while Table 2 lists the geometrical parameters of the three structures. For an explanation of the symbols refer to the geometry sketched in Fig. 2.

The cavities will operate with an accelerating field of 4.6, 5.7 and 6.7 MV/m, respectively. A synchronous phase of 30 degrees has been chosen to provide the necessary longitudinal focusing.

Table 1: Main e.m. characteristics of the three structures.

β_c	E_p/E_{acc}	B_p/E_{acc} [mT/MVm^{-1}]	Cell to cell coupling [%]
0.5	3.4	8.1	1.8
0.65	2.7	6.5	1.7
0.85	2.3	4.6	1.7

Table 2: Geometrical parameters (in mm) for the internal cell geometry, at the working cryogenic temperature.

β_c	**0.5**	**0.65**	**0.85**
A	47.1	71.6	131.3
B	80.1	121.8	196.9
a	33.4	44.8	35.4
b	60.1	89.6	56.7
d	26.8	32.8	26.8
L	101.1	132.6	175.7
D	392.2	392.7	385.2
R_{iris}	99.4	109.3	114.3

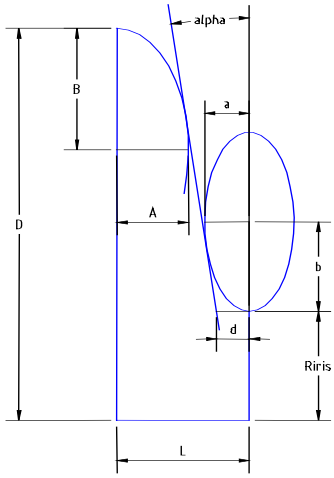

Figure 2: Reference geometry for the cavity shape.

3.1 Cavity prototypes

An agreement with CERN has been established in order to fabricate and test a full β=0.85 five cell cavity and a single cell test structure, on the basis of our design. The cavities will be ready for tests at CERN at the end of 98.

The Italian company Zanon will build a second β=0.85 cavity, a single cell Nb β=0.5 cavity and a complete copper model of the five cell structure. These additional cavities will be tested at CERN.

3.2 High order modes and multipactoring

An analysis of the high order modes distribution in the structure has been performed with the OSCAR2d code[6], showing modes with a very low R over Q. The choice of a beam tube diameter equal to the cavity inner irises helped in easing the behavior of the high order mode, since the field can freely propagate for any frequency above the tube cut-off. No trapped tube modes, like the ones measured on the LEP cavities, are possible.

Possible electron loading effects (multipactoring) were investigated, but the low magnetic fields and the elliptic shape of the equator resulted in a very safe cavity operation. In particular, the elliptical equator gives a stronger longitudinal component of the electric field along the surface, which pushes the electrons towards the equator, where the resonant condition for one point multipactoring is broken.

3.3 Preliminary design of the cryomodules

Based on the expertise gained in the design of the second and third generation of Tesla Test Facility cryostats we have started the design of the cryomodules for the superconducting linac. The design is still at a preliminary state, but various solutions have been chosen because of their success in the Tesla Test Facility design[7]. The cryostat will have a single thermal shield, made by self-sustained aluminum sheet or by a thin copper sheet kept by a stainless steel frame, and will be cooled by a finger welded pipe, to reduce production cost and assembling time. The cryomodule will be extremely modular, each module holding a single cavity in a titanium and stainless steel frame. The other guideline for the cryomodule design is a cost-effective solution, keeping in mind that extremely low thermal losses are not necessary when operating at 4.2 K. The vacuum vessel is open, similar to that one used in the LEP2, with a thin stainless steel sheet closing it, to guarantee easy access during the assembling and to reduce the assembling costs.

4 CONCLUSIONS

We have summarized here the status of the R&D activities for the TRASCO superconducting linac, aimed as a driver for nuclear waste transmutation and energetic applications. For sake of completeness we report in Table 3 an updated parameter list of the linac sections, where we explicitly indicated the necessary contingency for operational reliability.

Table 3: Summary of the SC TRASCO linac parameters.

	SI	**SII**	**SIII**
Section β_c	0.5	0.65	0.85
Section length [m]	96	146	475
Injection Energy [MeV]	100	190	428
Cell period [m]	8.0	11.2	15.3
# focussing cells/section	12+2	13+2	31+3
Max. ΔE/cavity [MeV]	4.0	6.5	10.0

DESIGN AND CONSTRUCTION OF THE BPL-RFQ

Deng-Ming Kong , Zi-Hua Luo, Ji-Min Qiao, Shu-Hong Wang and Wen-Wu Xu
Institute of High Energy Physics, Chinese Academy of Sciences
P. O. Box 918 , Beijing 100039, China

Abstract

BPL-RFQ is a four-rod type linac structure, currently under construction, that will be operated at a radio frequency of 201.25 MHz. According to the design, it can accelerate protons from 40 keV to 750 keV with a pulse beam current of 60 mA. BPL-RFQ is planned as the Beijing Proton Linac's injector instead of the present bulky Cockroft-Walton accelerator. This paper describes the general layout, dynamics design features, four-rod structure, field distribution measurements, and recent status of the BPL-RFQ.

1 INTRODUCTION

In August 1993, it was considered to construct an RFQ system as BPL's injector. Since then the design of beam dynamics, the design and the manufacture of a cold model had been done. The cold model of four-rod structure had been measured and tested. The mechanical design of RFQ structure, the construction of rf power supply, the reconstruction of the ion source have been done also. The formal electrode modules and the cavity is being assembled and tested. The control subsystem, emittance measurement devices, and solenoids have been tested also.

2 GENERAL LAYOUT AND DESIGN FEATURE

The construction of BPL-RFQ is based on the consideration for replacement of the present Cockroft-Walton accelerator, which has been used for BPL's injector near two decades. In order to meet the need as BPL's injector, some performance requirements for the BPL-RFQ had been proposed as follows: frequency of 201.25 MHz, output energy of 750 keV, pulse beam current of 60 mA, maximum repetition rate of 12.5 Hz, output transverse normalized emittance of less than 3 π-mm-mrad and the output energy spread of ±25keV.

BPL-RFQ system is composed of three sections:[1,2] including of RFQ section, IS-RFQ match section, and RFQ-DTL match section as shown in Fig.1.

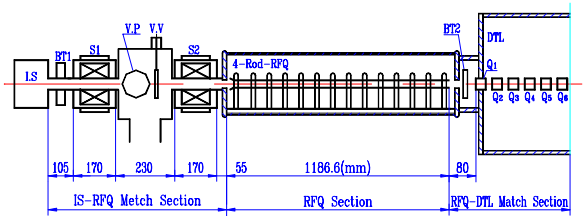

Fig.1: Scheme of the BPL-RFQ system

The RFQ is chosen to be a four-rod structure, because it has the advantages of easy manufacture and tuning, and the other features on feasibility of circular rods as electrodes giving very good mechanical as well as very good beam dynamic properties. Also four-rod RFQ has been successfully tested and used[3-5].

The RFQ beam dynamics design consists of four segments: the radial matcher, the shaper, the buncher and the acceleration. The first four cells is the radial matching segment , where the protons are gradually matched to the time dependent transverse focusing system. The next 51 cells is the shaper segment where the bunching process is initiated with a slow decrease of the stable phase from -90°to -77.2°and with a slow increase of the modulation parameter of m from 1 to 1.150. In the next 52 cells, the stable phase is reduced to -30°, the parameter of m is increased to 1.824, the protons are brought to 417 keV and fully bunched. The final 8 cells is the acceleration segment, the stable phase and parameter of m are kept constants of -30°and 1.824 respectively, the protons are accelerated to 750 keV by the end of RFQ. BPL-RFQ has a total of 115 cells and is 118.7 cm long. The main parameters of BPL-RFQ are listed in Table 1.

Table 1: Main Parameters of the BPL-RFQ

Particle	proton
Input energy	40keV
Output energy	750keV
Input pulse beam current	>100mA
Output pulse beam current	>60mA
Pulse length	180 micro-sec.
Input r.m.s. emittance:	
(x,x′)	<0.34 π-mm-mrad
(y,y′)	<0.32 π -mm-mrad
Output r.m.s. emittance:	
(x,x′)	<0.56 π -mm-mrad
(y,y′)	<0.54 π -mm-mrad
Frequency	201.25 MHz
Repetition rate	1-12.5 Hz
Maximum surface field (Es.max)	24.9MV/m
Inter-electrode voltage (V)	130.2kV
Characteristic radius	0.708 cm
Aperture radius (a)	1.962 - 0.492 cm
The length of electrode	~120 cm
Number of modules	13
Number of stems	14
Total number of cells (N_T)	115
Modulation parameter (m)	1-1.824
Trans. focu. parameter (B)	0.8-6.136
Stable phase	-90°— -30°

In the front of RFQ , there is an IS-RFQ matching section which consists of two solenoids and a beam transformer. Two solenoids are used for focusing and matching the beam into RFQ. Behind the RFQ there is an RFQ-DTL matching section which is composed of first six quadrupoles of DTL. In order to reduce the beam longitudinal mismatch, our RFQ is located very close to the DTL entrance. The distance between RFQ's electrode and first quadrupole of DTL is 8 cm only. The computer simulation for the 100 mA of beam motion from the exit of RFQ to the end of DTL had been done by PARMILA code. The simulation indicates that more than 98 mA of beam can be accelerated to the end of DTL.

The BPL-RFQ has some design features as follows:

- High transmission efficiency of 97% and 92% for the input beam current of 0 mA and 100 mA respectively.
- Low input energy of 40 keV even for an input beam current of 100 mA.
- The initinal focusing parameter of B_i and the radial matching cell number of N_{rm} have been chosen 0.8 and 4 respectively.
- The length of BPL-RFQ is short (~ 120 cm) . And the inter-electrode voltage is high (~130 kV).

3 FOUR-ROD STRUCTURE AND THE FIELD DISTRIBUTION MEASUREMENT

3.1 Four-Rod Structure

We chose a simplified structure (see Photo 1). The RFQ is brazed on a massive rail and can be aligned and tuned outside the cavity on a bench and then screwed into the cavity. The cylindrical electrodes with cones and cylinders of variable diameter have been used for our four-rod-RFQ.

Two pairs of the electrode rods form RFQ fields, each pair being held by seven stems. There are fourteen stems in total. The stems are equally spaced. Each electrode pair is supported by a common leg. The module geometry dimensions of our RFQ had been calculated by MAFIA.

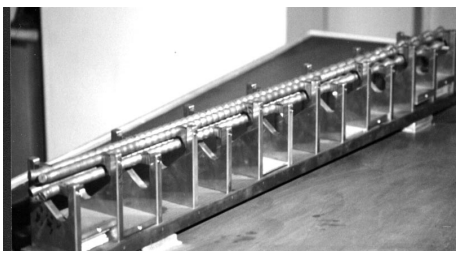

Photo 1: Electrodes and stems and substrate of the BPL-RFQ's model on the bench

3.2 Field Distribution Measurement

A cold model with full scale had been constructed for the field measurement and adjustment. Two kinds of electrodes, which are un-modulated and modulated, had been made and respectively assembled into the model. The field distribution had been measured by using bead pull perturbation method. When a bead is pulled into the cavity, the resonant frequency of the cavity will be shifted by a Δ f which satisfies the formula

$$\frac{\Delta f}{f} = -\left[\frac{\varepsilon}{\mu}\int_{v_b} E^2 dv - \int_{v_b} H^2 dv\right] / (2\int_{v_c} H^2 dv) \qquad (1)$$

where v_b and v_c are volumes of the bead and cavity respectively .

If the measurement is done at near beam axis where H apprixiates zero, so

$$(\Delta f / f) \propto \int_{v_b} E^2 dv \qquad (2)$$

The $\Delta f / f$ can be got by measuring the $\Delta\phi$ which satisfies $\Delta\phi = tg^{-1}\left[\frac{2\Delta f}{f} Q_L\right]$. We expect to look for a method to calculate the theoretical design values of $\int_{v_b} E^2 dv$ for the RFQ. For a RFQ, the electrical field components can be expressed by formula [6]

$$\left.\begin{aligned} E_z &= \frac{kAV}{2} I_0(kr)\sin kz.\sin(\omega t+\varphi) \\ E_r &= -\left[\frac{GV}{a^2} r\cos 2\theta + \frac{kAV}{2} I_1(kr)\cos kz\right].\sin(\omega t+\varphi) \\ E_\theta &= \frac{GV}{a^2} r\sin 2\theta.\sin(\omega t+\varphi) \end{aligned}\right\} \qquad (3)$$

where V–inter-electrode voltage, I_0 and I_1–modified Bessel functions

$$\left.\begin{aligned} k &= 2\pi / \beta\lambda \\ A &= (m^2-1)/\left[m^2 I_0(ka) + I_0(mka)\right] \\ G &= 1 - A I_0(ka) \end{aligned}\right\} \qquad (4)$$

According to the (3), the electrical field amplitude of E_m is given by

$$E_m^2 = E_{zm}^2 + E_{\theta m}^2 + E_{rm}^2 = L_{(r,\theta,Z,G,k,A)} V^2 \qquad (5)$$

where

$$L_{(r,\theta,z,G,k,A)} = \left[\frac{G}{a^2} r\cos 2\theta + \frac{kA}{2} I_1(kr)\cos kz\right]^2 + \\ + \left(\frac{G}{a^2} r\sin 2\theta\right)^2 + \left[\frac{1}{2} kA I_0(kr)\sin kz\right]^2 \qquad (6)$$

The L depends on the r,z,θ and the RFQ parameters of G,k,A. We are interested in field amplitude, so let's put (6) into the (2) and consider that V is constant for our RFQ, then

$$\frac{\Delta f}{f} \propto \int_{v_b} L_{(r,\theta,z,G,k,A)} dv \qquad (7)$$

Define $$\eta = \int_{v_b} L_{(r,\theta,z,G,k,A)} dv \qquad (8)$$

which indicates the field distribution at the position appointed and usually it is not constant. η is called the field distribution factor by us.

In the BPL-RFQ, the cell length is short and the variations of field near beam axis are very sharp. Therefore when we calculate the integration of the formula (8), the variation of field in the range of bead size can not be neglected. We do the measurement at the $\theta = \pm 45°$ and $\theta = \pm 135°$, because the calculations of η

are easy there.

For each cell of RFQ, there are maximum and minimum η at the positions of Z where coskz=1, sinkz=0 and coskz=0, sinkz=1 respectively. So

$$\eta_{\min} \approx 4\pi . r_b^3 \left[\frac{G^2}{a^4} \left(\frac{1}{3} r_a^2 + \frac{2}{15} r_b^2 \right) + k^4 A^2 \left(\frac{r_a^2}{48} + \frac{r_b^2}{40} \right) \right] \quad (9)$$

$$\eta_{\max} \approx 4\pi . r_b^3 \left[\frac{1}{12} k^2 A^2 + \left(\frac{G^2}{a^4} + \frac{1}{8} k^4 A^2 \right) \left(\frac{1}{3} r_a^2 + \frac{2}{15} r_b^2 \right) + \frac{k^6 A^2 r_a^2}{48} \left(r_a^2 + \frac{r_b^2}{5} \right) \right] \quad (10)$$

where r_b is the bead radius and r_a is the radial distance from bead center to the beam axis. The average of η, $\eta_{Av} = (\eta_{\min} + \eta_{\max}) / 2$, can be calculated also for each cell of RFQ. We like to use a relative normalized $\eta_{N,AV}$, because the calculated and measured field distribution are relative. The $\eta_{N,AV}$ can be as theoretical design values of field distribution, and it is shown in the Fig.3 for the BPL-RFQ.

In order to obtain a good result and to get a stronger signal for avoiding the noise perturbation and to reduce the image effect, it is important to choose an appropriate bead position, size, and material. We do measurement at the position off beam axis and use a dielectrical bead with a radius of 2mm . The measurement results are shown in the Fig.2 and Fig.3.

In the case of un-modulated electrodes, the results were: the field distribution unblance is less than ±1.5% azimuthally and the field flatness is less than ±4.0% longitudinally. In the case of modulated electrodes, the results were not so good as in the case of un-modulated one, but the measurement values correspondingly agree with theoretical values.

Fig.4 shows the measured field distribution of three modes in the case of un-modulated electrodes and without cavity shell. The nearest mode spacing is about 30 MHz.

4 OTHERS

4.1 RF Power Supply

There was a 50 KW rf power supply, which was initially used for a buncher supply of the BPL. We decided to upgrade it to satisfy the need of rf power for our RFQ by adding a new final power amplifier, which uses a TH-116 triode. Therefore the upgraded rf power supply system can provide the power output of more than 300 KW.

4.2 Ion Source

A dualplasma type ion source has been chosen for our RFQ system. A beam current of 140 mA has been reached under 40 kV.

4.3 Emittance Device

The emittance device is of "a slit and multi - wires" type. It is temporarily located behind of second solenoid for measuring the emittance at the entrance of RFQ.

4.4 Solenoids

Two pulsed solenoids had been made. The coil of the solenoid consists of 12 "cakes" with different inner diameters to obtain the wanted magnetic field shape. Two solenoids had been tested under the maximum magnetic field of 7.5 KGass. The measured effective magnetic length is 12.9 cm.

4.5 Status

The mechanical engineering for the BPL-RFQ is almost completed. It is being installed and commissioned.

5 ACKNOWLEDGMENT

Authors thank Prof. Dr. A. Schempp for the helpful discussion during the design and construction, and thank all staff of Proton Linac Division of IHEP for their work on the BPL-RFQ.

Abstract

A new 2 MeV 433 MHz RFQ has been built and tested with proton beam up to 15 mA. It has been fabricated from AMG-6 aluminium alloy and installed instead of previous 1.8 MeV RFQ. The results of frequency adjustment and field alignment are presented. There are significant improvements in field distribution and beam emittance of output injector in comparison with 1.8 MeV accelerator data. Simultaneously the working out of alternate phase focusing (APF) structure with input energy 2 MeV and output one 11 MeV was continued. Theoretical and experimental researches connected with different applications of 2 MeV linac or 11 MeV tandem RFQ and APF linacs are carrying out at NPK LUTS of the Efremov Institute last years. Methods and devices of elemental analysis and contraband detection system for 2 MeV linac and use of 11 MeV tandem for PET-system or as part of a big linac are discussed briefly.

1 INTRODUCTION

Since 1990 Linear Accelerators and Cyclotrons Division of the Efremov Institute (NPK LUTS) makes researches to create compact rf linear ion accelerators which may use as part of different complexes for applied purposes. Different output devices are worked out too. Choice of the working frequency is 433 MHz. There are five directions of researches:

- elemental express-analysis of materials or environment;
- contraband detection system (in particular detection of explosives and fission's);
- PET-system with ion rf linac;
- transported safe atomic station with undercritical nuclear reactor controlled by ion rf linac;
- rf linac as injector for medical proton synchrotron.

If one mean to use accelerated protons for all over these cases required range of final energies is from 2 up to 100 MeV.

2 ELEMENTAL ANALYSIS AND CONTRABAND DETECTION SYSTEM

Each of system consists of ion injector, 433 MHz RFQ, 433 MHz RF system, injector feed system, fast measuring and processing complex. Description of injector, RFQ and RF system was given in paper [1].

Neutron activation's analysis is used for express-analysis of environment. Maximal effect may be achieved by application of bicyclical registration method. Neutrons are produced by $Li_3^7(p,n)Be_4^7$ reaction and they are used as source of activating radiation. Pulsed sequence of radiation repeats sequence of accelerator's pulses. Tested sample, block of target change, neutron radiation monitor and semiconductor detector of induced g-ray are placed inside of interaction's chamber. There are two regimes of elemental analysis. Registration of short-lived isotopes (half live time 10^{-4} ...10^{-3} s) is produced between current pulses of accelerator. For determination long-lived isotopes is used standard neutron activation method. Detector is defended by protective gear from directed action of ionized radiation. Detector is blocked when neutron radioactive activation and thermolysation take place. Data process and spectral analysis are produced between blocking pulses. Sensitivity of different elements is 10^{-4} ...10^{-9} g/g. This method may be used for element analysis of isotopes that have atomic masses from 9 to 209.

Scheme of contraband detection complex is shown on fig.1. Explosive's detection is based on g-ray registration which is induced by non-elastic scattered fast neutrons and registration of induced activation on nuclei of specific elements (N,O,C) as result of thermal neutron capture. Fission's are registered by measuring of temporal neutron spectra. Specific change of neutron radiation's parameters permit to determine fission in observed object.

2 MeV RFQ is need for these purposes. In period 1993...1997 two RFQ had been fabricated and tested on laboratory stand at NPK LUTS. First of RFQ was fabricated from alloy D16. It had output energy 1.8 MeV. Results of it's tests were given in paper [1]. Second one was fabricated from aluminium alloy AMG-6, it's output calculated energy is 2 MeV. It was supposed to electroplate cavity's inner surfaces by copper but this plan was not fulfilled because financial and organizational prob-

lems. Testing of AMG-6 alloy RFQ showed correctness it's fabrication and tuning. Eigenfrequencies and field distributions of their oscillations in cavity were according to calculations ISFEL3D code [2]. Measuring of electrical field z-component along longitudinal axis showed accordance amplitude's meanings to theoretical meanings of effectiveness q. Field symmetrization of resonator's quadrants was better then 2%. Irregularity of field distribution along z-axis was less then ±2%. Convergence geometric and electromagnetic axes were less then 30 mkm along z. Dependencies of full current and energetical spectra on voltage vane were according to dynamics calculations although maximal beam energy was less then 2 MeV because bad quality of AMG surface and therefore additional electron load [3].

A new original 2 MeV RFQ is worked out now. Resonator is dismountable parallelepiped which has four rigid walls and two bottoms. Four copper vanes are placed inside parallelepiped together with plattings which are welded to vanes. Reliable mechanical contacts join the platting. Cavity's hermetization will be proved after receiving of geometric and electrodynamical parameters.

3 PET-SYSTEM

PET-system need accelerated protons of 11...16 MeV energy to produce four types of isotopes C^{11},N^{13},F^{18},O^{15}. It is evidently that first stage of accelerator is 2 MeV RFQ. But acceleration from 2 up to 11 or 16 MeV will be realized by accelerating structure with drift-tubes and crossed transversal holders (CTH) which was described in [2]. Distribution H-field of working type oscillation look like H-field in four-chamber's RFQ. CTH-structure have high shunt-impedance in energetical diapason from 2 up to 15 MeV. It is possible to use the same scheme of RF feeding for CTH-cavity as for RFQ. Using alternate phase focusing in CTH-structure permit to manage without magnetic lenses inside drift-tubes. Other advantages of this type resonators were described in [2]. If they are used as second stage accelerator and have the same working frequency as RFQ therefore here is not big problems to match RFQ then CTH-structure. 433 and 866 MHz CTH-cavities were successfully tested at NPK LUTS laboratory stands.

Required for PET's target and chemistry modules may be designed and fabricated by Efremov Institute and Main Science Research Radiological Institute at St. Petersburg in cooperation.

4 SAFE ATOMIC ENERGETICAL INSTALLATION

At the last time proposals to use accelerator as driver of under-critical reactor are discussed by many scientists. As rule there are considered schemes with big accelerators [4]. Their output beam power may be several megawatts or several tens of megawatts. Such power are need for driving of reactors with thermal power in few gigawatts. In these works cyclotrons are proposed to use as drivers. Output energy of these accelerators is supposed from 0.4 to 1 GeV. Aspiration for big accelerator drivers is explained by wish to obtain sufficient energetical gain (relation thermal power of reactor to beam power) 30 and higher. But for transported atomic installations main factor is safety. Their power may be several hundreds of megawatts. For example thermal power of transported station with ship reactor KH-3 is 300 MW. Therefore it may appear profitable that such energetical installations will be controlled by compact rf linac with about 300-500 kW beam power.

Comparison of electron, proton and deuteron beams as producers of neutrons under different targets was made in paper [5]. For produce the same quantity of neutrons power of the electron beam must be much more (approximately on order) then power of ion beams. On other hand efficiency of deuteron beam as neutron producer for energies more then 50 MeV just a little higher then proton beam one. Fabrication and exploitation of deuteron linac will be more expensive then proton linac. Therefore, best choice is proton rf linac as driver. Here is considered scheme of proton linac as energetical amplifier for reactor which works on high-enriched uranium 235. Following factors determine main parameters of accelerator. With energy's growth number of neutrons which are produced by only accelerated particle on target of total absorption are increased and compromise choice of final energy against average beam current is determined by allowable accelerator clearance and accelerating structure's acceptance which permits to pass required current without loss. For transported atomic station with thermal power 300 MW maximal proton energy 80-100 MeV will be good practice. Total density of neutron flow which proves normal working of reactor must be about 10^{14} neutron/sec×cm^2. Average linac current 3-5 mA is according to this flow density.

Accelerator-driver must be compact enough to work with reactor inside the compartment of limited sizes. 80 MeV proton linac with working frequency 433 MHz satisfies this condition. RFQ is used as first stage of accelerator which is accelerating particles up to 2 MeV and permit to capture about 100% ions into acceleration. For acceleration from 2 up to 10 MeV may use CTH-structure and alternate phase focusing. Modification of CTH-structure which has focusing magnetic lenses inside some of drift-tubes is used for acceleration from 10 up to 50...80 MeV. Pulsed mode must be used instead of CW-mode because scattered power inside cavity's walls will be too big to prove reliable thermal regime for CW-mode. If duty circle is 0.1 wall scattered power density will be 2 W/cm^2 and required cooling one may proves. It is expediently to build up RF system

multisectioned accelerator as separate amplificating lines. Dividing of RF power is made on low level. As output amplifier of line may be used klystron or endotron type devices to prove parameters

output pulse power	350-400 kW
average power	40 kW
pulse length	60 mks

Scheme of key blocks of accelerator-driver where is supposed dividing of the beam into seven ones before injection to reactor is given on fig.2.

Abstract

High accelerating gradients are very interesting for future machines, and, in particular, for high-current heavy-ion linac projects like the "Inertial Fusion Driver". In order to explore the maximum field achievable in an Interdigital-H type structure (IH), an experiment has been carried out at CERN with the Lead Ion Linac (Linac3). After the 1997 run, the RF amplifiers were rearranged in order to allow the feeding of the IH Tank number 2 (1.54 m long, 28 gaps, frequency of 202.56 MHz) with up to 2 MW pulsed RF power. After two weeks of conditioning at pulse lengths varying between 200 μs and 1 ms with a constant pulse repetition rate of 0.8 Hz, the maximum effective accelerating gradient achieved was 10.7 MV/m. This corresponds to a local field maximum of 75 MV/m, and to fields in excess of 50 MV/m (3.5 times the Kilpatrick limit) on large portions of the drift tube surfaces. This paper reports the conditioning procedure used, the measurements of field emission current at different voltages and pulse lengths, the determination of the surface field enhancement factor as well as the calculation of the electric field distribution for the gap with the highest surface fields.

1 SET-UP

For the normal Pb^{27+} operation of Linac3 [1], the IH Tank 2 requires 320 kW of RF power, which corresponds to a voltage gain of 9.09 MV. Its amplifier can deliver 800 kW, and during a test in 1996 the cavity was easily conditioned up to this power [2].

In order to increase the output power, a special amplifier arrangement has been prepared at the end of the 1997 Linac3 run. The tube TH170R, used in the final stages for Tanks 2 and 3, can deliver power levels up to 2.5 MW at a low duty cycle if enough power from the driver stage is available. By inserting the final amplifier stage of Tank 3 temporarily into the Tank 2 chain, between the driver and the final stage, more than 2 MW output RF power became available. The maximum pulse length in this configuration was 1 ms. This corresponds to a duty cycle of 0.08% at the Linac3 repetition rate of 0.8 Hz.

2 CONDITIONING

A two week period was made available for the high power tests, before the CERN winter shutdown. Part of this already short time was used for cabling the new amplifier arrangement, for improving the radiation safety of the installation (high X-ray levels were reached during the tests), and finally for some repairs to the amplifier electronics. The effective time available for conditioning amounted to 230 hours (i.e. slightly less than 10 days).

First of all, the power was gently increased with a pulse length of 200 μs. Breakdowns with associated strong degassing started from about 700 kW. The pumping rate of the vacuum system finally determined the acceptable number of breakdowns and therefore the speed of the conditioning process. Under normal conditions, the vacuum in Tank 2 is the best of the Linac3 complex, $4 \cdot 10^{-9}$ mbar. During the conditioning, it was noticed that the cavity was not able to recover from a series of breakdowns when the pressure entered in the 10^{-6} range, thus the power was reduced in order to stay within the 10^{-8} and 10^{-7} mbar region. The conditioning was done manually, but a computer was used to register the vacuum level at regular intervals, to log the breakdowns, and to calculate automatically cavity voltage, power levels and tube gains.

Figure 1 shows the integrated number of breakdowns (pulses where the cavity could not reach the programmed voltage) and the corresponding pressure during one night (15 hours at 780 kW) of the pre-conditioning phase.

After four days of pre-conditioning up to about 800 kW, the degassing from the surfaces decreased drastically, and the power could be pushed up more rapidly. Finally, a power of 1.21 MW was reached with only occasional breakdowns, however with dark current emission absorbing about 6% of the input RF power. At this point, instead of trying to push the field higher, the pulse length was increased to 500 μs. After 48 hours of reconditioning starting from 1 MW, the maximum stable level reached was as high as 1.3 MW. Beyond this input power level heavy sparking started with high degassing. Next, the pulse length was further increased to 1 ms and the conditioning restarted at 800 kW and reaching

1.2 MW after 3 days. Increasing the field beyond this level led again to heavy sparking with an almost immediate degradation of the vacuum.

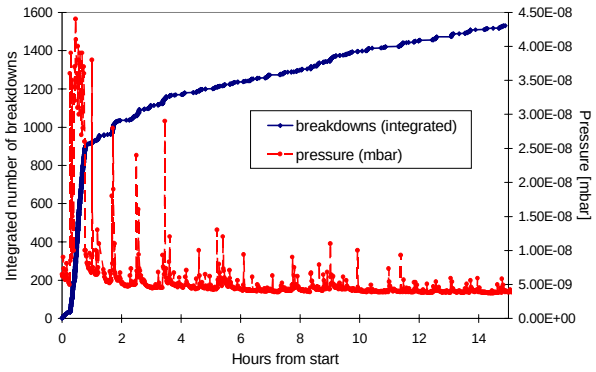

Figure 1: Integrated number of breakdowns and pressure during 15 hours pre-conditioning at 780 kW.

Figure 2 shows the power delivered to the tank as a function of time from the start of the tests. Table 1 gives the maximum gap voltage achieved, in units of the nominal voltage for Pb^{27+}, and the corresponding surface electric field at two positions, on the drift tube face and on the edges (see next Section).

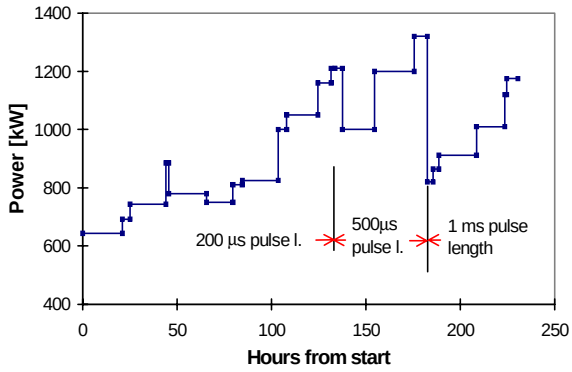

Figure 2: Conditioning history (RF power vs. time).

Table 1: Voltage and peak surface field achieved.

Pulse length	Voltage	*E*-field on tube	Max. *E* on tube	Eff. tank acc. field
[µs]	units of Pb^{27+} voltage	[MV/m]	[MV/m]	[MV/m]
200	1.71	51	70	10.1
500	1.82	54	75	10.7
1000	1.67	49	69	9.8

The radiation level (X-rays) during the tests was permanently monitored. The dose rates measured at 1.35 MW and 500 µs were about 5 mSv/h at 80 cm from the cavity axis and 2543 mSv/h at the tank surface [3].

3 SURFACE FIELD DISTRIBUTION

Figure 4 shows gap voltage and on-axis field distributions in Tank 2, derived from a bead-pull measurement scaled to the maximum voltage achieved during the tests (1.82 times the nominal). The electric field distribution in gap number 9, where the voltage is maximum, has been calculated with the code MAFIA to find the value of the surface field reached in the cavity during the tests. Figure 5 shows the calculated electric field in the plane of the stems and the value of the electric field at four representative points on the drift tube surface.

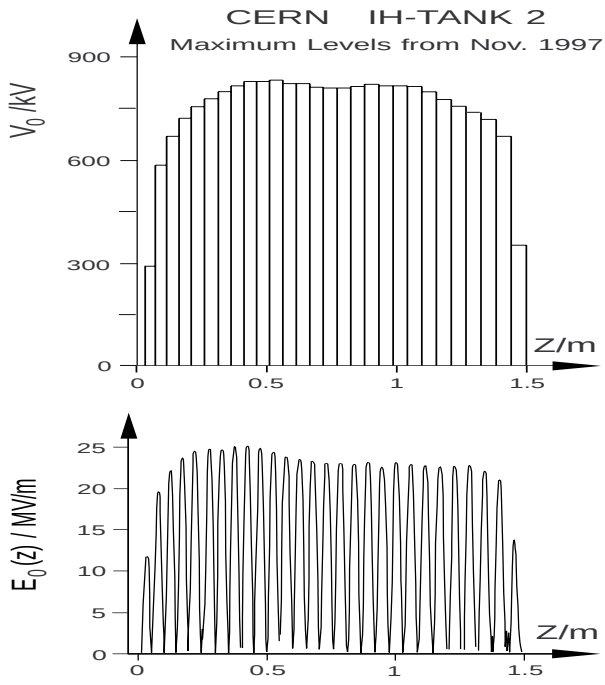

Figure 4: Voltage and electric field distribution (Tank 2).

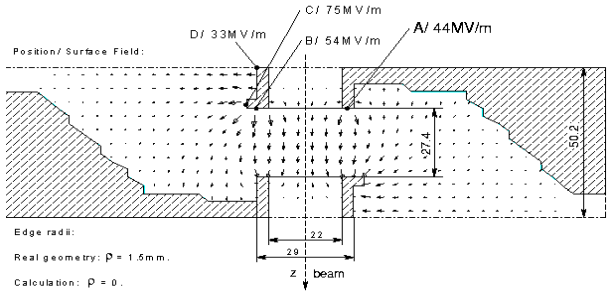

Figure 5: MAFIA calculation of field distribution in gap number 9 for 830 kV gap voltage.

In the MAFIA simulation the drift tube edges are not rounded, in contrast to the real geometry, and this leads to an underestimation of the field at point A (tube edge). At the other points, the values should be realistic, since they are calculated far enough from the square edges, as compared to the mesh step of 0.6 mm. Thus the field at point B can be taken as representative of the field on the

drift tube face, while point C represents a maximum field reached only on an area of about 0.5 cm^2 per drift tube.

In conclusion, fields of about 54 MV/m were reached on the drift tube face (~ 6 cm^2 per tube) in more than 20 gaps. This corresponds to 3.5 times the Kilpatrick level at 202 MHz (14.8 MV/m).

4 FIELD EMISSION MEASUREMENTS

The high electric field reached during the tests led to high levels of field-emitted current (dark current). The dark current level was measured at regular intervals by monitoring the cavity voltage for different RF input levels.

Without dark current, the power is proportional to the voltage squared, the coefficient being the inverse of the shunt impedance. When at high voltages dark current appears, the electrons are accelerated over the cavity gaps and extract an additional power $P=I\times U$ from the generator, I being the overall electron current and U the average gap voltage. The electron transit time factor is unity for the gap size and frequency of this case. When plotting P vs. U^2, the deviation from a straight line at high power gives the power driving the dark current; the dark current value is obtained by dividing this power by the average gap voltage. Figure 7 shows the measured dark current as a function of cavity voltage in units of the nominal Pb^{27+} voltage, at the end of the conditioning process for the three different pulse lengths. In all cases, appreciable dark current emission starts at 1.4 to 1.5 times the nominal voltage, and then rapidly grows with voltage. The highest dark current measured absorbed 9% of the input RF power.

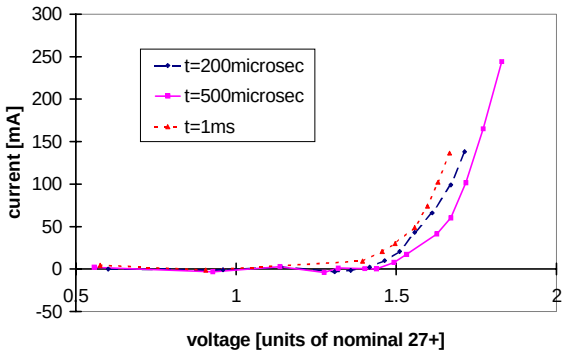

Figure 7: Overall field emission current vs. field level (units of nominal) for three pulse lengths.

The three measurements can be re-drawn in the usual "Fowler-Nordheim" form $\ln(I/E_s^{2.5})$ vs. $1/E_s$ (Figure 8), where field emission is represented by a straight line with a slope equal to the inverse of the surface field enhancement factor beta.

From the curves, it can be seen that β did not change appreciably during the conditioning process, being always between 100 and 114, values that indicate clean electrode surfaces. For comparison, β measured with the same technique on the CERN RFQ2 at different times ranged between 67 - very clean - and 920 – heavily polluted [4]. As expected, the conditioning process changed the intercept of the straight line, which is proportional to the overall emission, i.e. to the number of emitting spots on the surface. Between the first two measurements (200 μs and 500 μs pulse length) there is a reduction in the emitted current. When the pulse length was further increased to 1 ms, however, the emission went up again.

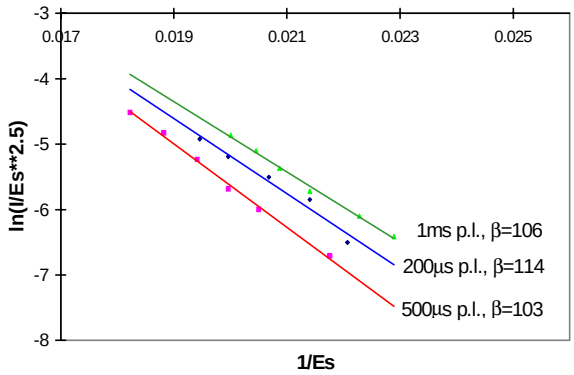

Figure 8: Fowler-Nordheim plot for the cases of Fig 7.

5 CONCLUSIONS

IH cavities of this type, with small diameter drift tubes, can stand fields of 50 MV/m (3.5 Kilpatrick) on large fractions of the drift tube surfaces, for low duty cycles and at pulse lengths up to 1 ms. Local maxima can be as high as 75 MV/m. These field levels were achieved after only a few days of conditioning with a cavity which has been in routine linac operation since 1994. Field emission was observed at surface field levels above 45 MV/m. Higher "clean" levels may be reached by applying an extended RF conditioning concept.

6 ACKNOWLEDGEMENTS

The authors are grateful to W. Pirkl who suggested the amplifier arrangement and to J.M. Hanon, R. Hajdas and R. Simitsch for their help during the tests.

Abstract

A 350MHZ, cw Radio-Frequency Quadrupole (RFQ) will be built to produce 20mA of proton beam at 3MeV for the KOrea Multipurpose Accelerator Complex (KOMAC) projects 1GeV linac. The beam dynamics and the engineering design of the RFQ linac are described. The length of the RFQ is 324cm long and the longitudinal stability is mitigated by the coupled-cavity concept. In order to minimize the power deposited on the cavity walls, the longitudinal variation of the width of the vane base is given. The peak temperature on the cavity wall is 50C, the displacement is about 18 μm.

1 INTRODUCTION

The Radio Frequency Quadrupole (RFQ) linac proposed for the Korea Multipurpose Accelerator Complex (KOMAC)[1-3]. Project is a cw linac which will produce a 20 mA beam of H^+/H^- with energy of 3 MeV. This paper addresses the physics and engineering design plus the present status of the KOMAC RFQ. The RFQ concept is shown on Figure 1 with the parameter values given on Table 1.

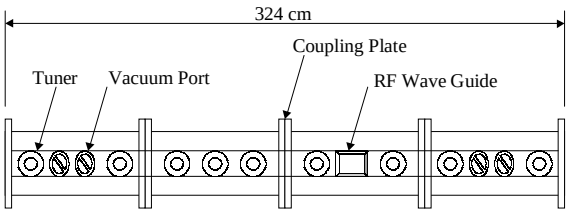

Figure 1. Preliminary drawing of a 3MeV 350MHz RFQ linac for the KOMAC.

The main focuses of this physics and engineering design in the KOMAC RFQ are as follows:

- To obtain the focusing required to match the H^+/H^- beam to the RFQ..
- To maintain a constant capacitance per unit length along the axis of the RFQ.
- To minimize the power dissipated on the cavity walls and the end region of the vanes.
- To stabilize the longitudinal mode in the structure.

The physics design study is presented in section 2. The physics design codes used for RFQ include space- and image–charge effects and have been proved against existing linacs [4-6]. The engineering design of the RFQ is described in Section 3. The thermal analysis is studied by ANSYS code. The section 4 describes the fabrication status of the KOMAC RFQ.

Table 1. RFQ linac parameters for the KOMAC

PARAMETER	VALUE
Operating frequency	350 MHz
Particles	H^+ / H^-
Input / Output Current	23 / 20 mA
Input / Output Energy	0.05 / 3.0 MeV
Input / Output Emittance, Transverse/norm.	0.02 /0.023 π-cm-mrad rms
Output Emittance, Longitudinal	0.246 MeV-deg
Transmission	95.4 %
RFQ Structure Type	4-vanes
Duty Factor	100 %
Peak Surface Field	1.8 Kilpatrick
Structure Power	350.0 kW
Beam Power	67.9 kW
Total Power	417.9 kw
Length	324.0 cm

2 PHYSICS DESIGN

The KOMAC system requires 20 mA of H^+/H^- beams from the 350 MHz RFQ. The proper energy needs for injection into the coupled cavity drift tube linac(CCDTL). The maximum vane voltage is given by the peak electric field that could cause sparking. In this design, the peak electric field was limited to 1.8 times the Kilpatrick criterion [7].

Figure 2 shows the various parameters defining the KOMAC RFQ design versus position. These parameters

were obtained by CURLI, RFQUICK, PARI, and PARMTEQM [4]. The curves labeled “V”, “Phase”, ”B”, “A”, “r”, “ a”, “m”, “E_z” and ”W” show the voltage difference adjacent vane-tips, synchronous phase, focusing strength, accelerating efficiency, average radius, aperture radius, modulation factor, average axial electric field and beam energy along the RFQ, respectively.

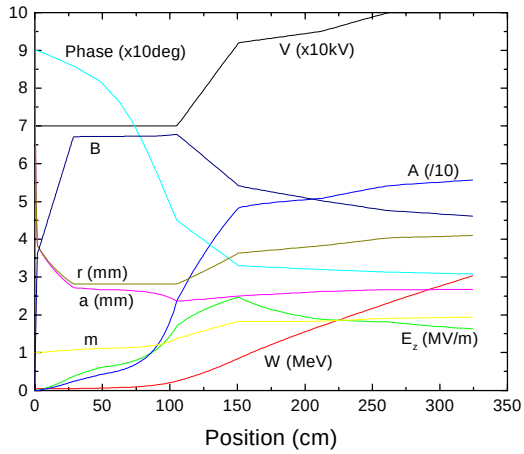

Figure 2. Various parameters defining the RFQ design versus position.

To obtain the focusing required to match the beam from LEBT to the RFQ requires a weaker focusing and a larger aperture at the entrance of the RFQ. However, the transmission rate of the beam decreases with the inverse of the aperture at the entrance of the RFQ. In order to design a radial matching section with a weak focusing and large aperture, we used CURLI and RFQUICK. The aperture in the KOMAC RFQ is smoothly reduced as it moves from the entrance to z=26.8 cm where the focusing strength is peak , as shown in Figure 2. In general, the end of the gentle buncher is a point where significant beam loss occurs. By the proper combination of V, a and B, the beam loss at the end of the gentle buncher was reduced. At about 104cm, the vane gap voltage, V, and aperture, a, start increasing and the focusing strength, B, starts decreasing. The increase in the vane gap voltage increases the accelerating gradient in the high-energy portion. The increase in the vane gap voltage also decreases the design length of the RFQ

Another important factor in the RFQ design is to maintain a constant capacitance per unit length along the axis of the RFQ. In order to maintain a constant capacitance, the average radius from the vane tip to the axis of the RFQ is changed, as shown in Figure 2. A change in the average radius would result in a change in the capacitance and in the local resonant frequency of the waveguide by a severe tilt in the fields. To maintain a constant capacitance per unit length, we fix the ratio of the vane tip transverse radius of curvature, ρ, to the average radius, r. For the KOMAC RFQ, the value of ρ/r is kept constant at 0.792. The resonant frequency is kept constant by varying the cavity cross-section by adjusting the width of the vane base while r changes. Because the power dissipated in the cavity walls will not be longitudinally uniform, this also minimizes the structure power.

We used PARMTEQM to match the beam into the CCDTL. Figure 3 shows the result of the PARMTEQM simulation. The percentage transmission is 95.4%.

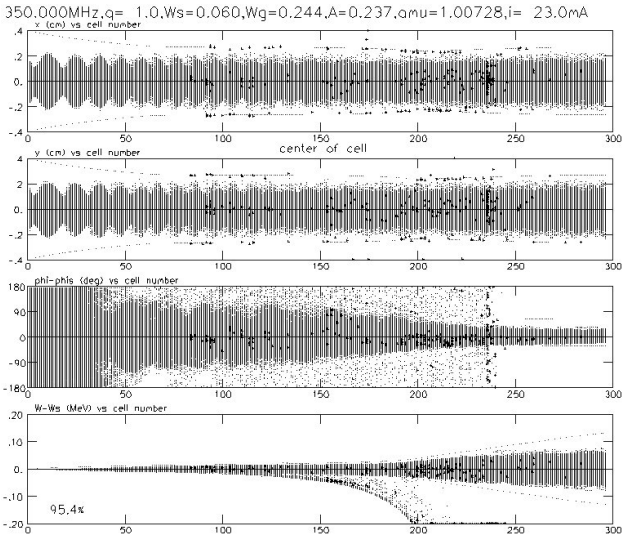

Figure 3. PARMTEQM simulation of the RFQ using 5000 particles. From top to bottom are: x, y, phase, and energy coordinates versus cell number. Bold black points indicate lost particles in the RFQ.

3 ENGINEERING DESIGN

The length of the KOMAC RFQ is 3.24 m long and consists of two resonantly coupled 1.62m sections. The length is determined by the final energy which is 3.0 MeV. The resonant coupling provides the longitudinal field stabilization and a stop band in the dipole mode, which is improved the transverse stability by eliminating dipole modes. In order to tune the resonant frequency of the end regions of the RFQ, we have used the three-dim. MAFIA code [8]. There is the rectangular undercut of the vanes. However, the exact shape of the undercut will be determined empirically by the cold model which is being fabricated into the aluminum alloy. The cavity cross-section is four triangular shape with the axial variation in the width of the vane base as shown in Figure 4. The vane-cavity will be joined longitudinally by a brazing. Thus the RFQ is the completed monolithic structure and the vanes are permanently aligned. This structure serves to mitigate the cost and to simplify the mechanical support system.

A serious problem in the design of the KOMAC RFQ with cw operation result from the rf thermal loads on the

cavity walls. The average structure power by rf thermal loads is 0.35 MW and the peak surface heat flux on the cavity wall is 0.13 MW/m^2 at the high energy end. In order to remove these heat, we consider 24 longitudinal coolant passages in each of the sections, as shown in Figure 4. Figure 4 also shows a temperature distribution of the cavity at the high energy end. The material is oxygen-free copper. The thermal loads was given by the SUPERFISH [9] analysis. The heat transfer coefficients is between 11kW/m^2-C to 15 kW/m^2-C. Because of the flow erosion of the coolant passages, we consider the maximum allowable bulk velocity of the coolant as 4.5 m/sec. From the thermal-structural analysis of ANSYS, the peak temperature on the cavity wall is 50C, the displacement is about 18 μm and the intensity stress .is 30 MPa.

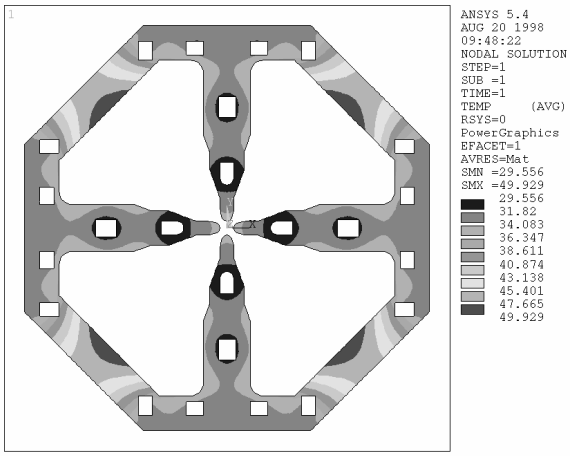

Figure 4. Temperature distribution of the cavity at the high energy end of the KOMAC RFQ.

4 PRESENT STATUS

A prototype of the RFQ is being machined at the Samsung Heavy Industies Co., Ltd and the Dae-Wung Engineering Co.. We are going to test a brazing of one section at next month.

Abstract

The first module of the REX-ISOLDE-Linac is a 4-Rod-λ/2-RFQ-structure, which is - together with the REX- IH-DTL - built up and tested at Munich.

In this Paper, the electrode design and the mechanical characteristics of the REX-RFQ are presented. Furthermore, the results and the principle of our low-level rf-measurements are discussed, and PARMTEQ-calculations for several measured voltage distributions are shown.

1 INTRODUCTION

At CERN a new concept for the efficient post-acceleration of radioactive ions will be realized with REX-ISOLDE [1]. REX-ISOLDE is a compact experiment, at which neutron-rich isotopes from the online mass separator ISOLDE are firstly accumulated, cooled and bunched in a Penning-Trap, afterwards charge breeded in an Electron-Beam Ion-Source (EBIS) and finally accelerated by a Linac to energies between 0.3 MeV/u and 2.2 MeV/u [2].

The Linac consists of a 4-Rod-RFQ and an Interdigital-H Drift-Tube-accelerator, followed by three seven-gap resonators for energy variation from 1.1 MeV/u to 2.2 MeV/u. The RFQ will accelerate the radioactive ions (design-ion: $^{36}Na^{8+}$) with an A/q of 3 - 4.5 from 5 keV/u to 300 keV/u. The according electrode-voltage is 28 to 42 kV, which will require an rf-power of about 30 to 40 kW. It has a total length of 3 m (18 stems) and operates at a resonant frequency of 101.28 MHz (duty-cycle: 10%).

Table 1: Parameters of the REX-RFQ, theoretical values are marked with '*'.

frequency	101.2 [MHz]
Input energy	5 [keV/u]
Final energy*	300 [keV/u]

2 ELECTRODE DESIGN

The calculations for the electrode-design of the REX-RFQ were made with a modified version of the multi- particle code PARMTEQ. For the input, an in both phase planes convergent beam (α=0.66) with emittances of 200 π mmmrad and a distribution with a randomly filled transverse phase-space, uniform phase and no energy spread was assumed. Because of the very low beam-currents at REX-ISOLDE (10000 particles per 100μs-EBIS-pulse), a zero-current electrode design could be generated, which was optimized to a high transmission (98%) and - due to the small longitudinal acceptance of the following IH-0°-synchronous phase structure - small energy spread (±1%).

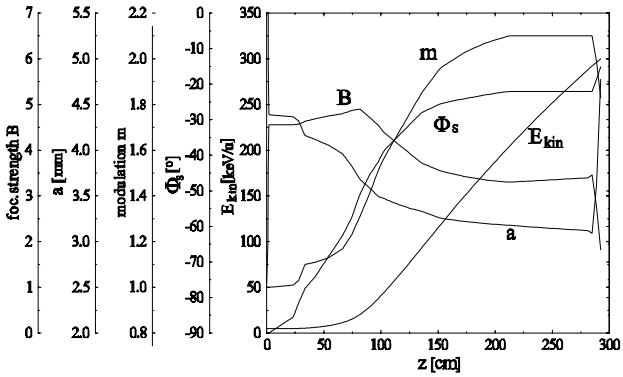

Figure 1: Electrode parameters calculated with the code PARMTEQ.

Figure 1 shows the electrode-parameters charted as a function of the accelerator-length. The strongly reduced focusing strength in the last three cells (which is the result of the increasing aperture: $B \propto 1/a^2$), corresponds to the matching-out section of the RFQ. By decreasing the phase in this section from -22° to -13° the energy spread could be kept constant. The simultaneous reduction of the modulation has simply mechanical reasons. Because of the increased aperture, a continuous modulation would have reached to close to the cooling channel inside the mini-vane profile (see below) of the electrodes.

The matching out section produces a decreased divergence of the output-beam, which reduces the required field strength of the following magnetic quadrupole lenses and avoids particle losses during the beam transport from the RFQ to the IH-structure. Fig. 2 shows the calculated output-emittances with (below) and without (above) matching-out section.

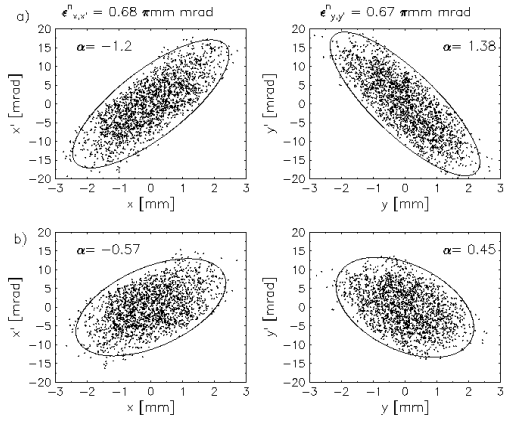

Figure 2: Output-emittances for $\varepsilon_{n,in}$=0.65 π mm mrad.

PARMTEQ calculations with the output emittance of the REX-ISOLDE mass-separator used as input emittance of the RFQ showed, that - due to the large acceptance of the given electrode design - the (in x-direction divergent) beam from the separator is matched and accelerated with the same excellent transmission and energy-spread as the design beam. Figure 3 shows the resulting RFQ-in- and output emittances. The separator output emittances have been calculated to third order with the COSY infinity code for an EBIS emittance of 14 πmmmrad [3].

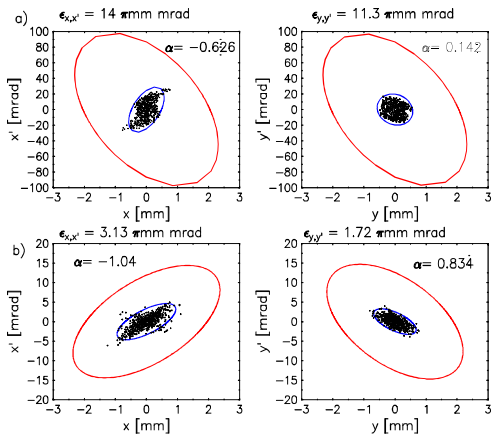

Figure 3: In and output emittances for the design beam (large ellipses) and the separator beam (small ellipses with α and ε specified).

3 MECHANICAL CHARACTERISTICS OF THE RESONATOR

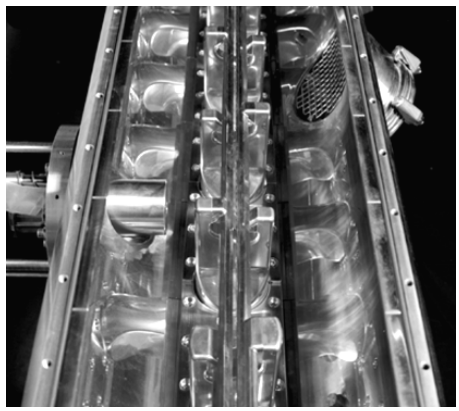

Figure 4: The inside of the RFQ tank (view from the low-energy end).

The resonator of the REX-RFQ is similar to the GSI High Charge-State-Injector- and to the Heidelberg High-Current-Injector-RFQ. Figure 4 shows a photo of the structure. The stems have a total height of 180 mm, the stem-foot (with circular cross-section) has a height of 40 mm, what defines the maximum thickness of the plates for frequency and Flatness tuning. For the quadrupole electrodes so called 'mini-vanes' with a cooling water channel inside (see Fig.6) were used. The mini-vanes allow a very good cooling of the electrodes, what avoids misalignment caused by heating.

The Flatness tuning is done with single plates, which are mounted between neighbouring stems. The plates are contacted to the stems by silver plated springs lying in a groove at the edge of the plates. The advantage of this principle is, that the deformation of the contact springs during operation of the resonator is reversible. Fig. 5 shows a tuning plate and the way it is contacted to the stems.

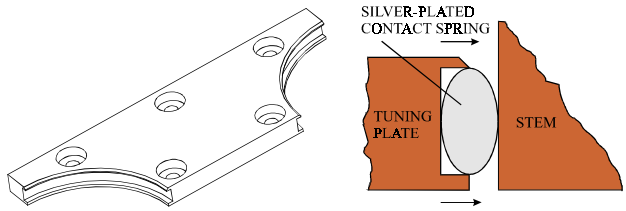

Figure 5: Tuning plate and contacting.

The channels for the water supply of the electrodes are drilled inside of the six waterleading stems. This design, which was developed for the Heidelberg High-Current-Injector-RFQ, avoids the (former used) little tubes on the outside, which turned out to be sensitive to corrosion and mechanical resonances. Figure 6 shows a Pro/E-Plot of a waterleading stem and a cross section of a stem with mounted electrodes. The electrode alignment is (because of the O-Ring between electrode-holder and stem) only

possible in the range ±1/10mm horizontally and ±5/10mm vertically.

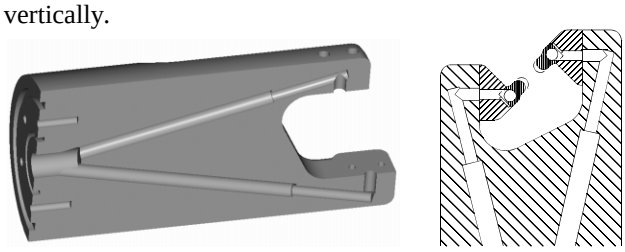

Figure 6: Waterleading-stem used in the REX-RFQ (see also Fig. 4 in the foreground).

4 MEASUREMENT OF THE RF-PARAMETERS

The measurement of the frequency and the quality factor resulted (with a distribution of tuning plates as seen in Fig. 7) in f=101.2 MHZ and Q=3894.

The theoretical description of the RFQ-resonator as a resonant circuit tells us, that the pertubation capacity, which is used for the measurement of the Rp-value must be small in comparison to the rod-capacity (≈190 pF). In this case $Rp=2Q\Delta f/\pi f^2\Delta C$, with ΔC being the pertubation capacity. Only if *all* values in this formula are kept constant, the electrode voltage is (because of the definition of the Rp-value: $U^2=Rp/N$) proportional to the square root of the frequency difference caused by the additional capacity.

To find out the upper limit of usable capacitors, and to investigate wether there is a convergence to the real voltage distribution when steadily smaller capacities are used, we measured the Flatness with three different pertubation capacitors.

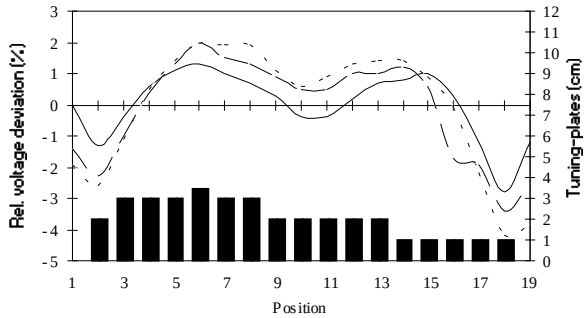

Figure 7: Voltage distribution of the REX-RFQ measured with 1.2pF (solid line), 2.2pF (dashed line) and 3.3pF (dotted line). The bars indicate the thickness of the Tuning-plates.

Figure 7 shows the expected steady increase of the 'Unflatness' at smaller capacitors. With an average Δf of the 1.2 pF measurement, the Rp-value of the REX-RFQ amounts to 171 kΩm.

In this context it is important to mention, that a Flatness and Rp-value measurement with the often used crocodile-clip-capacitor arrangements does not fit exactly to the theory. Because of the arrangement's own capacity (switch etc.), not the real Flatness is measured but the relative difference between f. ex. a 0.5 pF and a 1.2 pF measurement (analogue to Fig. 7). For the determination of the Rp-value this method provides strictly speaking no constant f in the above mentioned formula. The most accurate way of measurement is to contact the smallest available capacitor (≤ 1pF) directly to the electrodes and to determine its capacity as exact as possible (f. ex. with a capacity measurement-bridge).

The measured voltage distributions were used to calculate the influence of the Unflatness on the particle dynamics in the RFQ. Table 2. shows the results of the PARMTEQ-calculations. Note (from Fig. 7), that the maximum field deviation refers only to the end cells! On the average, the field deviation (except for the the untuned measurement) is around ±1%.

Table 2: Transmission and energy-spread for the untuned voltage distribution and for the tuned distri-bution measured with three different capacitors.

	max. field deviation	ΔE (90%)	Trans-mission	x,y-output-emittances ε_n
(untuned)	±20%	5.3%	97.9%	0.648; 0.659
3.3 pF	±2.8%	2.5%	97.3%	0.648; 0.659
2.2 pF	±3.4%	2.52%	97.15%	0.647; 0.658
1.2 pF	±4.2%	2.54%	96.95%	0.651; 0.656

5 PRESENT STATUS

Currently the REX-RFQ is on its test stand at the Munich accelerator lab ready for vacuum testing and final alignment of the electrodes. Two of the three piston tuners have been mounted (see Fig. 4), and provide (from a middle position) a frequency shift of ± 200 kHz. The vacuum test will take place after mounting of a cooled ground plate, which is the last missing component of the resonator. The electrode alignment was measured after mounting in the range of 1/10 mm, With the final alignment after the vacuum test, we want to reach an accuracy of 5/100 mm.

Abstract

The beam intensity available with the RIKEN heavy-ion linac (RILAC) has remarkably increased since the installation of a new injector in 1996, which consists of an 18-GHz ECR ion source and a variable-frequency RFQ based on a folded-coaxial resonator. Since August 1997, the maximum extraction voltage of the ECR ion source has been raised from 10 kV to 20 kV in order to upgrade the intensity further. The RFQ vanes were re-designed and replaced at the same time. Now the intensity has increased by about one or two orders of magnitude compared with those formerly available with the Cockcroft-Walton injector. The maximum power of the beam extracted from the RILAC and that from the ring cyclotron have reached 560 W and 2 kW, respectively. Another important result we have obtained is that the transmission efficiency through the RILAC is much improved by use of a prebuncher placed before the RFQ. Operational experiences of the RFQ as well as recent developments are described in this paper.

1 INTRODUCTION

As already reported[1], the new injector consisting of an 18-GHz ECR ion source (ECRIS) and a variable-frequency RFQ based on a folded-coaxial resonator has been working in the RIKEN heavy ion linac (RILAC) since August 1996. Figure 1 shows the RFQ along with the six tanks of the RILAC. Acceleration tests of the RILAC and the ring cyclotron (RRC) have been carried out continually using the beams from the new injector since the installation.

The beam intensity has remarkably increased owing to the high performance of the 18-GHz ECRIS[2]. In December 1996, we achieved the beam current of 1 pμA from the RRC for the first time using $^{36}Ar^{5+}$ beam supplied with the new injector.

One of the advantages of the new injector is that highly charged ions are readily generated with the ECRIS. The charge stripper between the RILAC and the RRC has become unnecessary for low-energy beams of medium-heavy ions such as Argon, so that the stability of the beam has been improved.

However, the extraction voltage of the ECRIS was quite low for the highly charged ions, because the maximum voltage was initially chosen to be 10 kV. The voltage was, for example, only 3 kV in the beam test mentioned above. This low voltage caused bad effects both on the intensity and the emittance of the extracted beams.

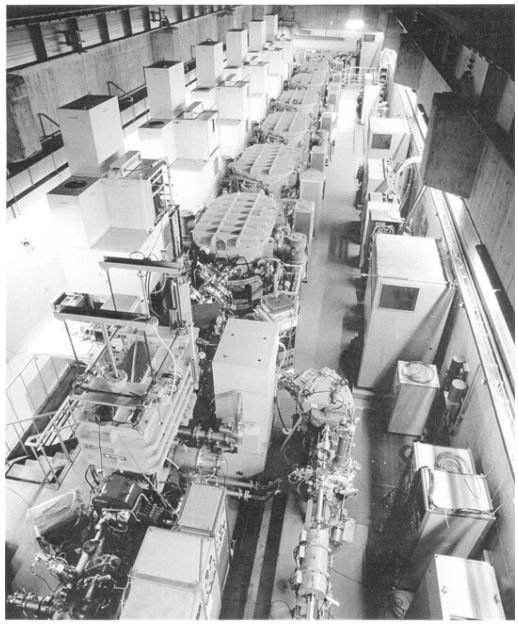

Figure 1: The RILAC and the RFQ seen from the upstream.

2 RECENT DEVELOPMENTS

2.1 New Vanes

Since August 1997, the maximum extraction voltage of the ECRIS has been raised to 20 kV in order to upgrade the beam intensity further. The RFQ vanes were re-designed and have been replaced.

The length of the initial sections of the vanes has increased, because the velocity of the input beam to the RFQ has become higher by about 40%. In order to keep the vane length less than the inner length of the resonator, we have raised the intervane voltage by about 5% and reduced the total number of the cells from 78 to 72. The mean aperture (r_0) have been slightly increased to reduce the capacitance between the vanes. All the parameters have been optimized by using the PARMTEQ code.

The vane parameters are listed in Table 1. Although the length has increased by 8%, the change of the frequency-

Table 1: Main Parameters of the RFQ

	~ 07.1997	08.1997 ~
Frequency (MHz)	17.7 - 39.2	17.4 - 39.0
Mass-to-charge ratio (m/q)	6 - 26	6 - 26
Input energy (keV/q)	10	20
Output energy (keV/q)	450	450
Input emittance(mm•mrad)	145 π	145 π
Vane length (cm)	142	153
Intervane voltage (kV)	33.6	36.8
Mean aperture (r_0:mm)	7.70	8.08
Min. aperture (a_{min}:mm)	4.17	4.67
Max. modulation (m)	2.70	2.41
Beam margin	1.7	1.6
Focusing strength (B)	6.8	6.8
Max. defocusing strength	-0.30	-0.30
Final synchronous phase	-25°	-30°

range could be made very small. The vanes were three-dimensionally machined within the accuracy of ±50 μm and aligned within the same accuracy.

2.2 Transmission Efficiency

At the same time of the replacement of the vanes, an additional Faraday cup was installed just after the RFQ, as shown in Fig. 2, for the measurement of the transmission efficiency through the RFQ alone. The efficiency is defined by the ratio of the measured beam currents with the two Faraday cups (FC-R1 and FC-R2) shown in Fig. 2.

The maximum efficiency ever achieved is 92 %, being good enough compared with the calculated value of 94 %. The typical efficiency is about 80 to 90%, which depends on the input beam emittance varying with respect to the ion species and the extraction voltage.

One of the problems annoying us is that the efficiency up to the entrance of the RILAC is not so good as expected. Although the best efficiency is 80%, only 50 to 70% of the beam entering the first Faraday cup (FC-R1) is usually transported to the entrance of the RILAC. This means that some portion of the beam is lost in the matching section between the RFQ and the RILAC.

The RFQ can accept a beam having an emittance larger

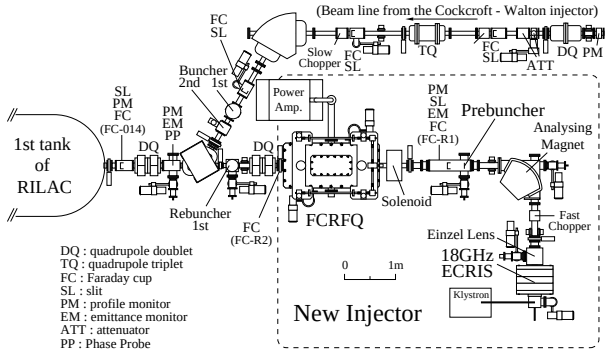

Figure 2: Schematic drawing of the new injector.

than the designed value of 145π mm•mrad, because the beam margin is large as shown in Table 1. However, the beam size exceeds the aperture diameter of the rebuncher when the input beam emittance is larger than the designed value or the beam ellipse does not match the designed ellipse. The aperture diameter of the rebuncher has been therefore enlarged from 40 mm to 50 mm, which does not help us so much. Additional devices such as quadrupole magnets is needed in the LEBT section to achieve more effective beam-transport.

2.3 A Prebuncher for the RFQ

As shown in Fig. 2, a prebuncher has been used in the LEBT section since the new injector was installed in the RILAC beam line. Its electrode consists of two mesh plates made of copper with a gap distance of 5 mm. A transformer is employed in the feeder line so that the termination register of 200 Ω matches the standard impedance of 50 Ω. The rf-power is supplied with a wide-band amplifier which transmits the maximum power of 1 kW in the frequency range from 5.5 MHz to 40 MHz.

This system was originally introduced to generate "single-bunch" beams by applying sub-harmonic (1/3 - 1/5 of the fundamental frequency) rf-voltage to the mesh electrode while a fast-chopper placed in the LEBT section sweeps the main part of the extracted beam from the ion source, based on the same method already established in the injection line of the AVF cyclotron[3]. It has been found that this method also works well in the RILAC.

On the other hand it has been reported elsewhere that the longitudinal emittance can be reduced by using the prebuncher with the fundamental frequency. We examined this effect by measuring the transmission efficiency through the RILAC, using Argon and Xenon beams from the new injector. In the test, the effect of the second and third harmonic components was also studied by adding these components to the fundamental rf-voltage.

A result measured with Ar^{5+} beam at the frequency of 18.8 MHz is shown in Table 2. As shown there, the transmission efficiency through the RILAC was much improved when the prebuncher was used, while that through the RFQ did not change so much. This result qualitatively agrees with the PARMTEQ simulation,

Table 2: Effect of the prebuncher on the transmission.

prebun.	FC-R1	FC-R2	FC-014*	FC-A02**
No Use	23.0μA (100%)	20.1μA (87%)	15.9μA (69%)	8.0μA (35%)
1f	23.0μA (100%)	20.1μA (87%)	16.9μA (73%)	12.1μA (53%)
1f - 3f	23.0μA (100%)	21.0μA (91%)	16.9μA (73%)	13.0μA (57%)

*The Faraday cup placed at the entrance of the RILAC (shown in Fig. 2).
**The Faraday cup placed at the exit of the analyzing magnet after the RILAC.

which shows little effect on the transmission efficiency through the RFQ but great reductions of longitudinal emittance of the accelerated beam.

It was hard to observe the effect of the higher harmonic components because the gap distance of the mesh electrode was too wide and the impedance-matching of the transformer in the high frequency region was not so good. Systematic study of the higher components as well as measurements of the longitudinal emittance are under preparation.

3 PRESENT STATUS AND OUTLOOK

The beam intensity from the ECRIS has increased by a few times since the extraction voltage was raised. The maximum current ever extracted from the RRC is 2 pμA for Argon and 200 pnA for Xenon. Comparing these values with the beam current formerly available with the Cockcroft-Walton injector, the intensity of Argon beams has increased by one order of magnitude. For Xenon beams, the intensity has become larger by two orders. The ions accelerated so far are summarized in Fig. 3.

Figure 4 shows the maximum transmission efficiency ever achieved up to the exit of the RILAC. It has become 1.5 times larger than that using the Cockcroft-Walton injector. Typical transmission efficiency from the ECRIS to the exit of the RRC is 10 to 20 %. The maximum beam power ever provided with the RRC is 2 kW (2 pμA of Argon at 24 MeV/u) and that with the RILAC is 560 W (13 pμA of Oxygen at 2.5 MeV/u). Considering the high beam power, the transmission should be further improved.

We are planning to construct an improved prebuncher system for the RFQ, which can generate "saw-tooth" wave-form. The design is under progress.

4 ACKNOWLEDGEMENTS

The authors are grateful to Dr. N. Tokuda at KEK for the usage of the program for vane-cutting. They are also grateful to the operating staffs for their efforts and cooperation.

Abstract

The ISAC RFQ is a 35 MHz, split-ring, four vane structure designed to accelerate ions of $A/q \leq 30$ from 2 keV/u to 150 keV/u in cw mode. When completed the RFQ will comprise 19 split rings and modulated electrodes in quadrature for a total length of about 8 m. The first 7-ring portion of the RFQ is being tested with beam in an interim configuration. A copper wall internal to the RFQ tank isolates the rf power to the electrode region. Electrostatic quadrupoles are installed in the remainder of the tank to transport the beam to a downstream diagnostic station. An injector composed of an ion source and an electrostatic LEBT and matching section delivers stable light ions to the RFQ. The beam is pre-bunched with an 11.7 MHz pseudo saw-tooth waveform across a single gap. The diagnostic station consists of Faraday cups, a fast Faraday cup, an emittance rig, and an analyzing magnet. The complete test set-up will be described and the results of commissioning the injector and testing the RFQ will be presented.

1 INTRODUCTION

A radioactive ion beam facility with on-line source and linear post-accelerator is being built at TRIUMF[1]. The accelerator chain includes a 35 MHz RFQ, operating cw, to accelerate beams of $A/q \leq 30$ from 2 keV/u to 150 keV/u.

The ISAC RFQ (Fig. 1) is a split ring 4-rod structure[2]. A total of 19 split rings, each feeding a 40 cm length of modulated electrodes, are housed in a square 1m×1m tank with a total length of almost 8 m. The gross specifications include a bore radius of $r_0 = 7.4$ mm, and a maximum inter-vane voltage of 74 kV corresponding to a power of 85 kW. Rings and electrodes are water cooled. A unique feature of the design is the constant synchronous phase of -25°[3]. The buncher and shaper sections of the RFQ have been eliminated in favour of a four-harmonic sawtooth prebuncher located ∼5 m upstream of the RFQ in the low energy beam transport (LEBT). This shortens the RFQ but in addition, injecting a pre-bunched beam yields a smaller longitudinal emittance at the expense of a slightly lower beam capture. The pre-buncher operates at a fundamental frequency of 11.7 MHz, the third sub-harmonic of the RFQ. This introduces an 86 nsec bunch spacing that is useful for some physics experiments. We expect 81% of the beam to be accelerated in the 11.7 MHz bunches, ∼4% accelerated in the two neighbouring 35 MHz buckets, with 15% of the beam unaccelerated.

It was decided to proceed with a two-stage installation. We have installed the first seven rings of the RFQ for an interim beam test subsequent to installation of the remaining twelve rings. The test allows us to perform rf measurements, establish alignment procedures, commission the injection line, determine matching conditions and establish capture efficiencies all well in advance of the RFQ completion in 1999.

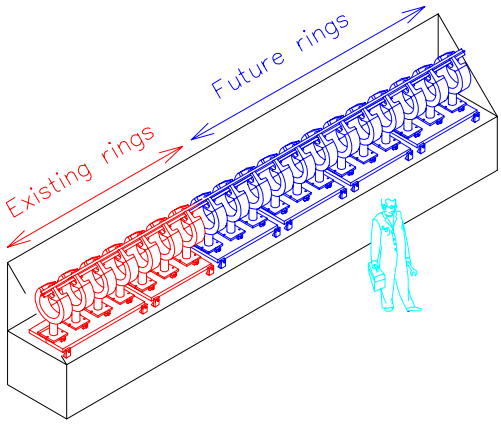

Figure 1: The ISAC 19 ring 35 MHz RFQ.

2 THE TEST SET-UP

A schematic of the test set-up is shown in Fig. 2. A copper wall installed downstream of the seven ring section provides rf containment. Beams produced in the ISAC off-line ion source (OLIS) are transported through a ∼15 m long LEBT section to arrive at the RFQ. The beam is accelerated

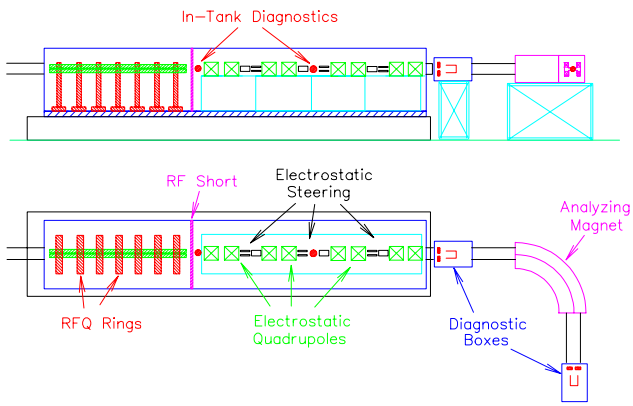

Figure 2: A schematic view of the RFQ and test station.

to 53 keV/u, then a series of eight electrostatic quadrupoles transports the beam to a diagnostic station just downstream of the RFQ tank.

2.1 OLIS and LEBT

A schematic of the ion source (OLIS) and injection line (LEBT) are shown in Fig. 3. Wire-scanners and Faraday cups are positioned throughout the line. In addition a transverse emittance rig is located after the OLIS analyzing magnet. A fast Faraday cup is located just upstream of the RFQ and was used to commission and tune the pre-buncher.

A 2.45 GHz micro-wave source with a magnetic cusp plasma confinement is installed. The LEBT consists of electrostatic elements; quadrupoles, steerers and spherical bends[4]. The source efficiently produces positive ions of gaseous species from Hydrogen to Argon. The ions for the initial RFQ tests are $^{14}N^{+}$ and $^{28}N_2^{+}$ with transverse emittances measured to be $20\pi\mu$m and $10\pi\mu$m respectively.

2.2 Pre-buncher Commissioning

The pre-buncher consists of two circular electrodes spaced 8 mm apart forming a single gap with a beam aperture of 7 mm radius. The fundamental frequency of 11.7 MHz and the first three harmonics are individually phase and amplitude controlled and combined at signal level. The signal is amplified by an 800 W broad-band amplifier that drives the two plates in push-pull mode with a peak voltage of about 200 V (400 V between plates). Optimization of amplitude and phase of each harmonic results in an almost saw-tooth modulation on the beam velocity. The variation in the gap-crossing efficiency for each harmonic means that the driving voltage is far from a sawtooth, being dominated by the higher, less efficient harmonics. In fact the present amplifier band width rolls off after 35 MHz and so initial testing was done with only three harmonics.

The time structure of the bunched beam as measured on a 50Ω co-axial fast Faraday cup[5] for one, two and three harmonic bunching are shown in Fig. 4. The buncher was tuned by setting the phase of each harmonic individually, then adjusting the voltage to previously calculated values followed by empirical optimization. The tuning was straightforward and the performance matches the predictions of simulation studies.

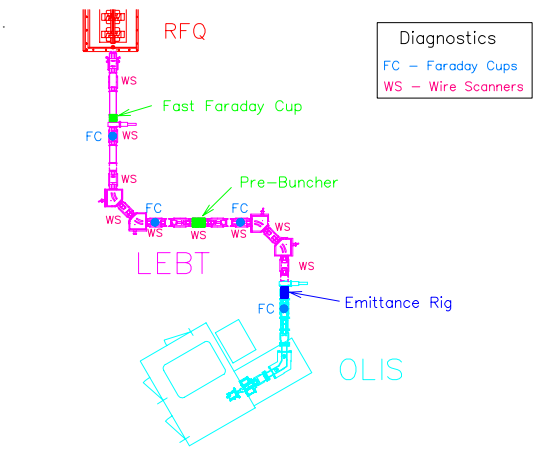

Figure 3: The layout of the off-line ion source (OLIS) and low energy beam transport (LEBT) upstream of the RFQ. The commissioning diagnostics are indicated.

2.3 In-Tank Beam Transport

The beam from the RFQ is brought to a double waist after the first four quadrupoles and again at the exit of the RFQ. The quadrupoles are each 30 cm long with a 2.5 cm half aperture and require maximum voltages of just under 10 kV for $A = 30$. For mechanical reasons the RFQ vanes are orientated at 45° to the horizontal. As a consequence the first four electrostatic quadrupoles are also at 45°. The transverse reference frame is rotated to the normal after the first double waist where the beam is round.

2.4 Diagnostic Station

The diagnostic station is designed around a $\rho = 1.5$ m analyzing magnet with a dispersion of 3 cm/%. [1] The magnet is placed symmetrically between horizontally defining object and image slits 1.5 m upstream and downstream of the magnet respectively. A Faraday cup upstream of the object slit measures the final beam intensity and when compared with the last Faraday cup in LEBT gives the relative beam capture. Unaccelerated beam is lost in the electrostatic quadrupoles. A Faraday cup just downstream of the image slit records the transmitted beam and the energy and energy spread are derived from the magnetic field. A slit and harp transverse emittance rig and fast Faraday cup have recently been placed upstream of the magnet.

3 RFQ BEAM TESTS

The initial set of rf and beam tests have been successfully completed. The RFQ was operated in cw mode for all beam tests. The operation of the RFQ at peak voltage (74 kV) is

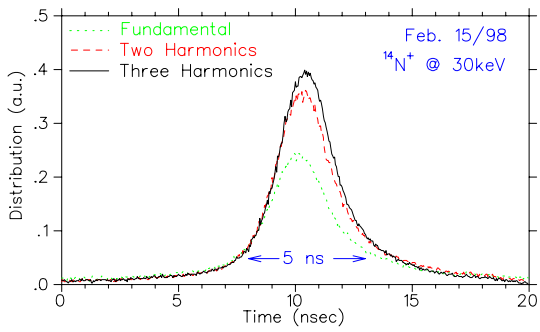

Figure 4: Beam bunches measured on the fast Faraday cup in LEBT for one, two or three harmonic bunching.

[1] The magnet was generously donated by the Nuclear Physics Institute in Rez, Czech Republic.

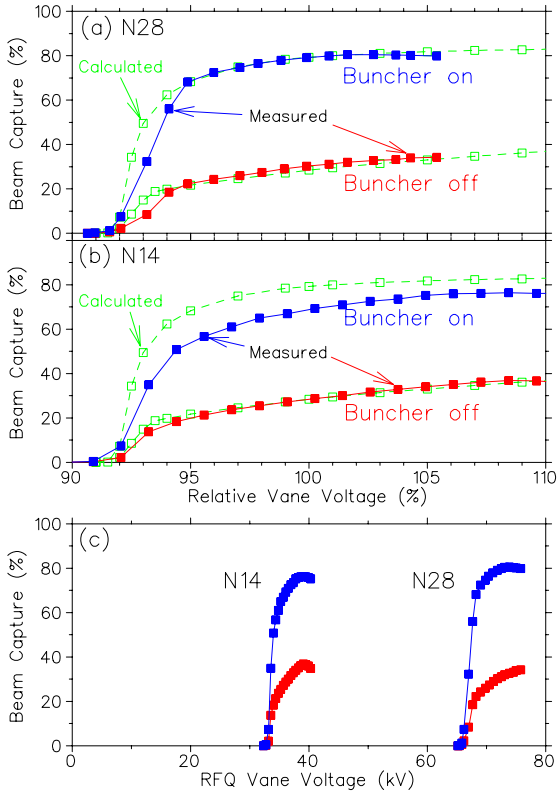

Figure 5: RFQ beam test results showing capture efficiency as a function of relative vane voltage for (a) N_2^+ and (b) N^+. The nominal vane voltage in each case was 71.9kV and 36 kV respectively. The beam capture for both bunched and unbunched initial beams are recorded (solid line) and are compared with PARMTEQ calculations (dashed lines). In (c) the results are plotted with respect to absolute vane voltage.

stable[2]. Beams of both N^+ and N_2^+ have been accelerated to test the RFQ at both low and high power operation.

Beam capture as a function of RFQ vane voltage measurements have been completed for each ion and for both unbunched and bunched input beams. The results are given in Fig. 5 (solid lines) along with predicted efficiencies based on PARMTEQ calculations (dashed lines). The N_2^+ capture efficiency at the nominal voltage is 80% in the bunched case (three harmonics) and 30% for the unbunched case in agreement with predictions. (The capture is lower than the 85% quoted earlier since we are presently operating with only three harmonics on the pre-buncher.) The capture for one harmonic and two harmonic pre-bunching are 63% and 74% respectively. The results for N^+ are somewhat lower in the bunched case (70%) due, we think, to the larger transverse emittance reducing the bunching efficiency. In theory the LEBT and RFQ have an acceptance of eight times the measured emittance of N^+ so this result may be significant. However it may also be the result of a poor LEBT tune generating a non-achromatic condition in the electrostatic bend. It warrents further investigation.

The energy of the beam as measured with the analyzing

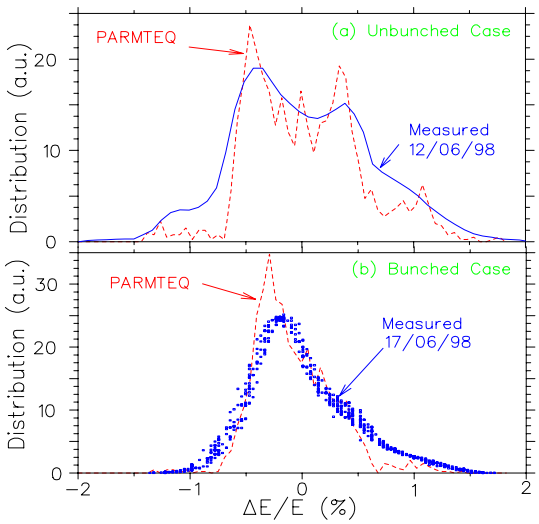

Figure 6: Results of energy spread measurements of accelerated N^+ beams for both (a) unbunched and (b) bunched cases. PARMTEQ simulation results are plotted for comparison.

magnet is 55 keV/u. The beam energy is higher than originally quoted since the RFQ test frequency is 2% higher than the design frequency. (The actual frequency is expected to drop with the addition of the remaining 12 rings.) The energy spread for the bunched and unbunched cases were measured at $\pm 0.4\%$ and $\pm 0.7\%$ respectively and compare well with PARMTEQ predictions (Fig. 6).

The results demonstrate a strong confirmation of both the beam dynamics design and the engineering concept and realization. We are presently installing diagnostics for a further set of tests [6] including measurements of longitudinal and transverse emittance and acceptance. These measurements will proceed through October 98 before we commence with the installation of the rest of the rings. Commissioning of the RFQ in the final configuration is expected in Fall 99.

Abstract

The VE-RFQ-injector for the cyclotron at HMI in Berlin is now in operation. The ECR-source together with the RFQ's [1,2] supply heavy ion beams with 90 - 360 keV/u for q/A > 0.15, matched to the isochronous cyclotron. Properties of the new injector and results of rf-measurements, high power tests and beam measurements are presented.

1 INTRODUCTION

The Ionen Strahl Labor (ISL), the former VICKSI-facility, at the Hahn-Meitner-Institut in Berlin has installed a second injector for the separated sector cyclotron. A combination of an ECR-ion source with a two stage 4-Rod-VE-RFQ (VE = variable energy) [3] replaces the former Tandem-injector to meet the demands of solid state physics [4,5] as shown in figure 1.

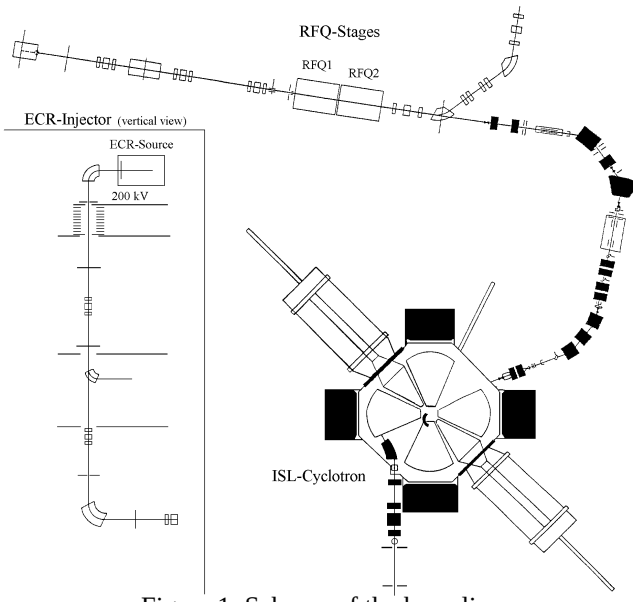

Figure 1: Scheme of the beamline

The VE-RFQ works at a high duty factor (cw-mode) and covers a frequency-range from 85 MHz to 120 MHz. It is designed to accelerate ions with an q/A from 1/8 to 1/2 with input energies from 15 to 30 keV/u to output energies between 90 and 360 keV/u. The final energies out of the cyclotron cover the range between 1.5 and 6 MeV/u [5]. Table 1 gives the parameters of the new injector and figure 2 shows a view of the RFQ.

To achieve this energy variation the RFQ is split into two stages. The second stage is designed to operate either as an accelerator or as an radial focusing transport channel [7,8,9] in an operational mode which has not been tested before with a bunched beam.

Figure 2: View into the two stage RFQ

After the assembly and first high power test at NTG in Gelnhausen the RFQ has been transported to ISL in December 1997 and has been installed at the cyclotron during the first half of 1998.

Length (split into two stages)	[m]	3
diameter	[m]	0.5
number of stems per stage		10
minimum aperture	[mm]	2
min/max Ein	[keV/u]	15.16/29.72
min/max Eout	[keV/u]	178.35/355.09
charge-to-mass-ration		1/8 - 1/2
frequency	[MHz]	85 - 120
duty factor		100% (cw)
max power consumption p. stage	[kW]	20

Table 1: ISL-VE-RFQ parameters

2 GAMMA-SPETROSCOPY

A first set of high power rf-tests was done to check the functionality after transport.

To ensure that the RFQ reaches the necessary electrode voltage and to calibrate the RFQ-probes several high power tests at different frequencies have been made. At a power-consumption of 10 kW the gamma-emission from the cavity has been measured and the results have been extrapolated for a power consumption of 20 kW.

Figure 3 shows the extrapolated electrode voltage and the necessary electrode voltage for minimum q/A proportion of the first RFQ stage.

The bend in the design voltage curve results from the limited preacceleration of 200 kV, so that the necessary injection energy into the RFQ could not be reached for all q/A proportions. The measurements show, that the design voltage can be reached for all frequencies.

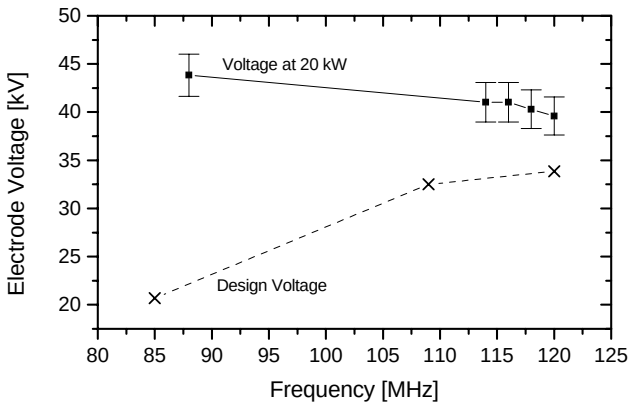

Figure 3: Electrode voltage as a function of RFQ frequency

3 BEAM MEASUREMENTS

The second set of tests were experiments with a beam from the ISL DC-injector. Figure 4 and 5 show the results of O^{4+}- and He^{+}-beams at a frequency of 120 MHz. The second RFQ has been operated in accelerating mode and in transport mode.

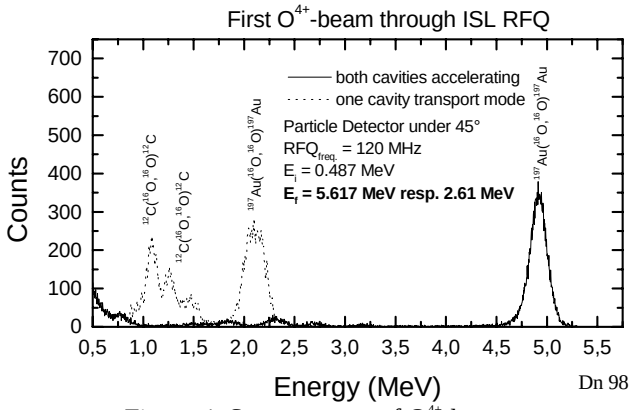

Figure 4: Spectroscopy of O^{4+}-beam

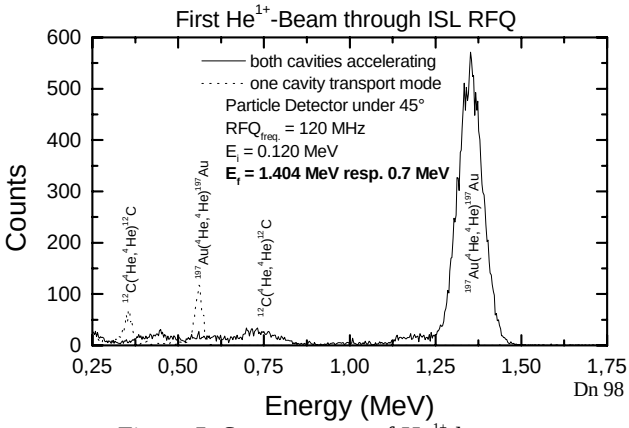

Figure 5: Spectroscopy of He^{1+}-beam

The results of the spectroscopy show that the RFQ works well and provides the calculated energies. It also shows, that the concept of using the second RFQ as a transport channel works, though more efforts on a better coordination between the two stages to improve the transmission in transport mode have to be done.

4 CONCLUSIONS

The series of high power and beam tests showed a good performance of the RFQ. The accelerator provides the correct energies and can be operated in the transport mode. More tests for an optimization of the transport mode have to be done.

At ISL the work is now focused on integrating the RFQ-system in existing controlsystem and on optimizing the rf-systems. In the beginning of September a first injection into the cyclotron is planned.

Abstract

An RFQ injector with a duty factor up to 10 % is planned for the spallation source ISIS at Rutherford Appleton Laboratory (RAL). The accelerator will be a Four-Rod RFQ with directly cooled electrodes, operating at 202 MHz.

The RFQ will provide a H^--beam current up to 50 mA with an output energy of 665 keV (input energy 50 keV). The beam dynamics, rf and mechanical designs are presented.

1 INTRODUCTION

The ISIS neutron source at the Rutherford Appleton Laboratory presently consists of a H^--Penning source (extraction voltage 35 kV), a Cockroft-Walton injector (output energy 665 keV), an Alvarez Drift Tube Linac (output energy 70 MeV), the ISIS synchrotron (final energy 800 MeV) and a heavy metal target (average beam current 0.2 mA, average beam power 160 kW) [1].

The Cockroft-Walton is now going to be replaced by a new RFQ accelerator [2, 3] with the same figures of energy. The resonance frequency of the RFQ will be the same as the one of the Alvarez linac, 202.56 MHz. The beam current will be 50 mA with high transmission, allowing a later upgrade to 100 mA with 85 % transmission.

ISIS has reached a maximum beam current of more than 55 mA with a stable operation at 2.5 % duty cycle in early 1997. The new RFQ is planned for 10 % duty cycle. These values are not far away from the proposed values for the next generation of neutron source, the European Spallation Source ESS, where 6.5 % and 5 MW beam power (1.34 GeV) are planned. So the ISIS upgrade is a test bench for the future ESS injector. The present plans for the ESS project provide 107 mA, achieved with two RFQs (54 mA each) at 175 MHz.

2 HIGH DUTY CYCLE RFQ

The HLI-RFQ at GSI Darmstadt is an operating RFQ with high duty cycle: It operates at 15 kW/m average power (duty cycle 25 %) [4]. Its resonance frequency is 108.5 MHz, lower than the frequency of the RAL RFQ (202.56 MHz). Lower frequencies go along with larger resonator structures and a distribution of the power to a larger surface. Such a higher thermal stress has been applied to a short test model (202.56 MHz) with 20 kW/0.3 m in c.w. operation. This model worked well and showed that an RFQ resonator with completely cooled electrodes works well even at 60 kW/m [5].

3 RF CALCULATIONS

MAFIA Calculations and experiments have been made to investigate the magnetic field distribution around the stems and for optimizing the input coupling loop. The magnetic field in a groove, milled into the surface of the copper stem, is very weak, compared to the field strength around the stem (<1%).

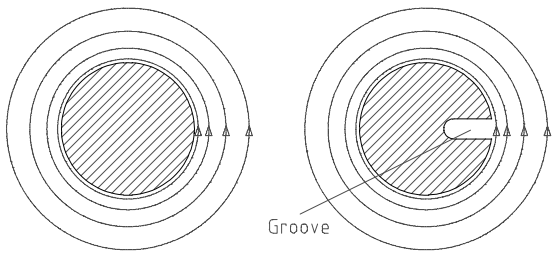

Figure 1: Magnetic field around stems.

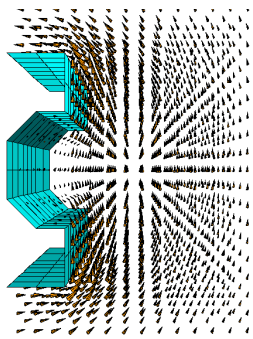

Figure 2: Magnetic field (arrows) on a grooved stem's surface.

To decrease the sensitivity of the loop, caused by the inhomogeneous magnetic field, the effect of a groove, milled into the stem has been tested. With this groove the loop can "dive" into the stem, thus giving a stronger coupling, as shown in figurs 1 and 2.

Another subject within the RF calculations was the influence of the electrode cooling pipes on the field distribution and the resonator properties.

It has been shown that multipole components of the electrodes with cooling pipes differ less than 0.1 % from the values of regular rods (circle shaped), and remain in the same range of difference from the hyperbolical (ideal) quadrupole geometrie, as shown in figure 3. The flatness (percentage rate of the intervane voltage) is shown in figure 4.

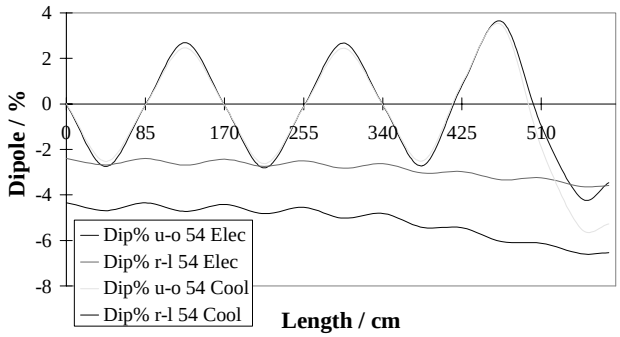

Figure 3: Influence of the cooling pipes on the field components.

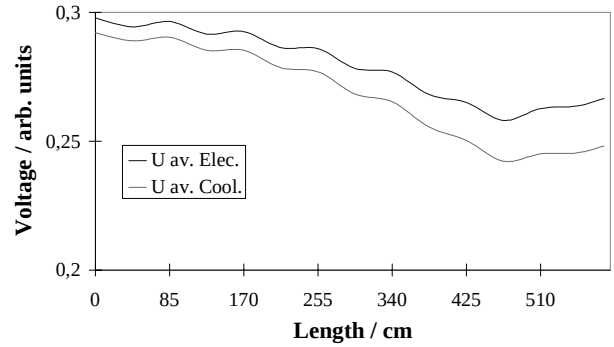

Figure 4: Influence of the cooling pipes on the field distribution along the beam axis.

The calculated values of Q-value and shunt-impedance differ less than 1 %, what is a negligible variation of change.

The geometry of the electrodes with the cooling pipes has an influence on the electric field distribution and the resonator properties. MAFIA calculations and measurements have been made to investigate that effect, particularly the ratio of aperture to rod radius is important for the capacitance of the electrodes, what has a big influence on the resonance frequency and the flatness and field distribution along the beam axis.

4 PARTICLE DYNAMICS

For the particle dynamics design, the methods for compact RFQs are used [6]. With adiabatic variation of parameters and 80 kV electrode voltage a high acceptance at large aperture is reached. The beam dynamics parameters are shown in table 1. Figure 5 shows results for simulations using the ideal two term potential.

Letchford [7] has developed a code which solves the field equations with respect to higher multipole components. The result was, that the design chosen for ideal shaped electrodes must be only slightly modified when it is used with rod electrodes, to match the properties of a hyperbolical shaped quadrupole.

Another special feature is used for this RFQ: The last cell consists of half an RFQ-cell and half a cell with a symmetrical output matcher to achieve a good output emittance matching [8].

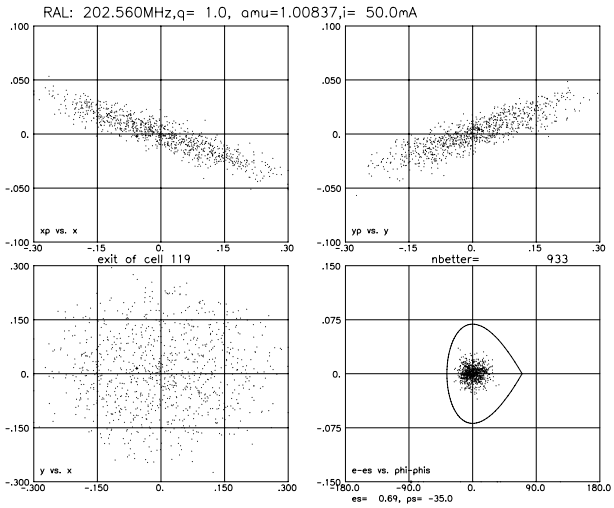

Figure 5: Particle Output Distribution.

5 MECHANICAL DESIGN

Results of MAFIA calculations have shown that 34 % of the power is lost on the electrodes, 44 % on the stems and 22 % on the ground plate. To get the temperature distribution on a stem, ANSYS calculations have been made. These calculations showed that a cooling of the end cells with only one coaxial cooling channel or with water flow split into two channels (figure 6) is not sufficient: So a "one way cooling channel" has been chosen, as shown in figure 7. The channel is milled into the stem and covered by a brazed plate, avoiding any direct water-to-vacuum seals [9, 10].

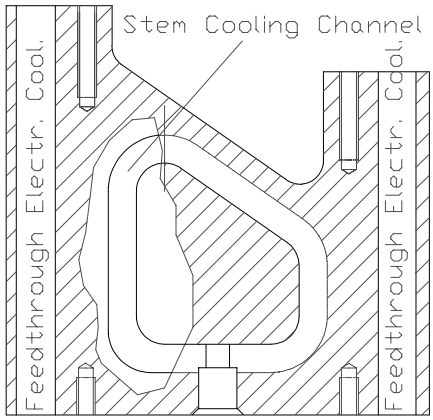

Figure 6: Cooling of the endstem with split water flow.

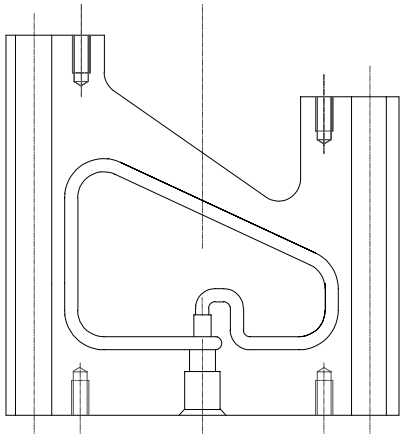

Figure 7: One way cooling channel of the endstems.

At present the tank is ready for copper plating. The parts of the RFQ insert should be ready in September, so that electrode alignment and cavity tuning can be done in Fall 1998.

ACKNOWLEDGEMENTS

We would like to thank the colleagues from RAL for collaboration and our group members for help and support.

Abstract

The Two-Beam Accelerator (TBA) is under active study both at Lawrence Berkeley National Laboratory (LBNL) and at CERN. In the TBA, an extremely intense low-energy electron beam is bunched at the desired operating frequency and, upon passing through resonant cavities, it generates radio-frequency (RF) power for accelerating the main beam. Among the different approaches to the production of a suitable drive-beam, the use of a free-electron laser has been proposed. Recently at CEA-CESTA, encouraging results in this direction have been obtained. To extend this work, we propose the use of the induction accelerator "PIVAIR" at CESTA (7.2 MeV, 3 kA) as a test stand for high power RF structure experiments at 30 GHz. Our research program for PIVAIR includes:

1 Production of a drive beam current profile designed to compensate beam loading,

2 High power tests of a CLIC Transfer Structure,

3 Tests of the 30 GHz RK-CLIC components.

1 INTRODUCTION

As a power source candidate for linear colliders, the highly developed klystron technology provides reliable and economic RF power at frequencies of order 3-12 GHz, but its extension to higher frequencies represents a difficult task. As alternatives to klystron technology, the TBA, suggested by A. Sessler at Lawrence Berkeley National Laboratory (LBNL) [1], is under active study both at LBNL [2] and at CERN, where the project bears the name Compact LInear Collider (CLIC) [3]. For multi-TeV TBA designs, both groups are considering operating frequencies around 30 GHz. Among the many technological difficulties in the TBA approach, the production of a suitable drive beam (DB) constitutes a major challenge. The research program outlined in the present document is devoted to a scheme of generating such a beam, based on the bunching that naturally occurs in a Free-Electron Laser (FEL) powered by an induction accelerator capable of producing kiloampere currents of electrons with energies in the several MeV range.

In a series of experiments performed at CEA/CESTA with the LELIA induction linac, the capacity of a FEL, powered by an induction accelerator, to generate an intense bunched beam has been demonstrated [4]. The next step, which is being pursued actively at CESTA, is the extraction of the bunched beam and its propagation into a resonant cavity [5]. The aim is to demonstrate the ability of this scheme to generate the required amounts of RF power by the passage of the bunched beam through the extraction cavity [6]. Although this program is proceeding as planned, a major difficulty must be surmounted, namely the tendency of a tightly bunched beam to debunch under the influence of longitudinal space charge forces. In the case of LELIA, the usual relativistic factor $\gamma = 5.3$, whereas at the nominal energy of the PIVAIR accelerator, $\gamma = 15.1$, and the correspondingly increased debunching distance is roughly an order of magnitude greater.

We propose here a continuation of the TBA R&D in a 4-year experimental program. This proposition is in fact a testbed for high frequency and high power RF acceleration. Many tests of interest are planned, thanks to the powerful PIVAIR accelerator [7], which is a unique tool capable of producing a bunched beam with specifications very close to the final DB for both TBA designs: CLIC and RK-TBA.

2 EXPERIMENTAL PROGRAM

The PIVAIR accelerator delivers a 3 kA, 7.2 MeV low emittance electron beam which will be transported to a high gain FEL amplifier operating at 30 GHz. A similar experiment was performed in the past at Lawrence Livermore National Laboratory at a beam energy of 6 MeV [8]. In the wiggler magnet, the beam undergoes the FEL process and becomes bunched at the resonant frequency. The interaction is stopped at a length where the bunching is maximum. The bunched beam is then ready to be used for various tests.

To compensate for transient beam loading effects in the accelerating cells, the front end of the current must be ramped with a profile adapted to produce the desired power extraction from the transfer cavity (TC). This shaping of the front end of the beam is necessary for the FEL to remain a viable candidate for DB production.

The PIVAIR energy is high enough to ensure bunched beam propagation through one or more TC. High power operation of the TC would permit us to test its operating limits. The breakdown threshold, dark current capture threshold, and maximum gradient are measurements of prime importance.

The RK-CLIC scheme is an extension to 30 GHz of the work in progress at LBNL for the RK-TBA project at 11.4 GHz. Idler and open cavities are its basic components. The coupling is stronger than in the other scheme and a re-acceleration of the electron beam is necessary by means of an induction cell. Tests of beam transport, high output power production, compact induction modules are proposed.

3 THE PIVAIR INDUCTION LINAC

A photograph of PIVAIR is displayed in Fig. 1. The high voltage pulse generator of the injector was developed by Pulse Science Incorporated (PSI) for the Dual Axis Radiographic Hydro-Test Facility (DARHT) and the diode was designed by Los Alamos National Laboratory (LANL). It is a single shot device whose repetition rate is once every 5 minutes. A 3 kA, 3.6 MeV electron beam is extracted from a velvet cathode with excellent reproducibility. Upon exiting the injector, the electron beam is accelerated to 7.2 MeV by 16 induction cells, which are fed by external high voltage generators producing 250kV, 75 ns pulses with 1% voltage spread. Each generator drives two induction cells. The beam energy spread is less than 1% over 60 ns and the normalized edge emittance is 1000 π-mm-mrad. PIVAIR has an excellent reliability when operating at 7.2 MeV.

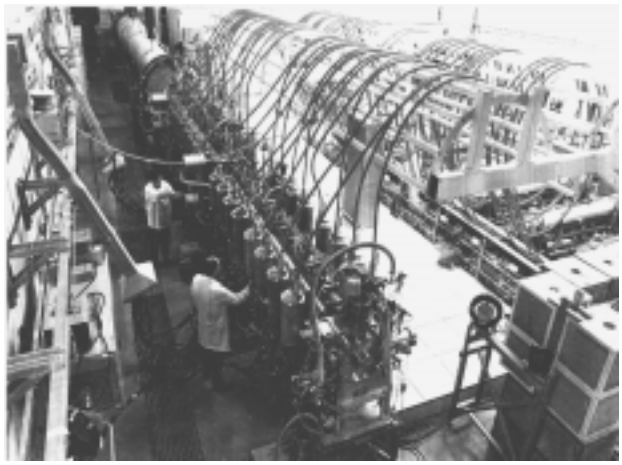

Figure 1: Photograph of the PIVAIR facility.

4 THE FEL AMPLIFIER AT 30 GHZ

In the proposed experiment the wiggler is a pulsed bifilar helix. The external EM wave is produced by a 30 GHz microwave source such as a magnetron or traveling-wave tube. Since the FEL efficiency varies slowly with the wiggler period, the length required to reach saturation does too. We choose a wiggler period short enough for the total length of the wiggler to be reasonable (a few meters).

FEL numerical simulations are performed using the code SOLITUDE. We present here the results obtained for a 7 m long wiggler with 6 adiabatic entrance periods, at 7.2 MeV. For these calculations, the beam current and beam radius have been chosen to be 1 kA and 1cm, respectively, while the waveguide diameter was 60 mm. Power levels close to 1 GW are expected at resonance for B_w = 1900 G. In Fig. 2, we have plotted the power as a function of the interaction length showing that saturation occurs at period 27 (5.40 m). The bunching is maximum just before this point with a maximum bunching parameter (average over the electrons phase in the longitudinal phase space) of 0.5. Consequently, the wiggler length should be around 5 meters to obtain the maximum bunching.

The beam is adiabatically extracted to remove the transverse momentum imparted by the wiggler field. Simulation with PARMELA indicates that the beam remains bunched at a significant level for a distance greater than 3 m permitting all the DB tests.

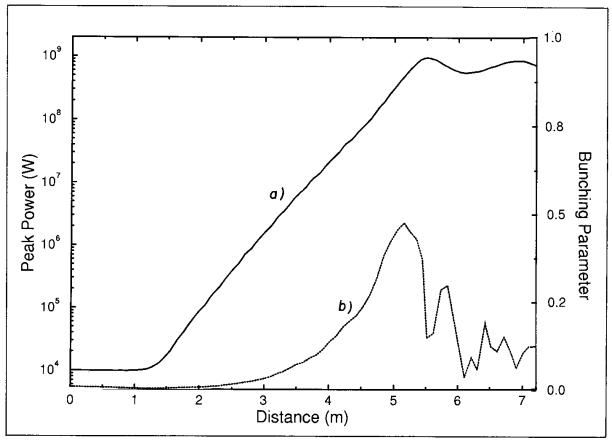

Figure 2: FEL simulations with the code SOLITUDE for the best resonant magnetic field (1900 G): a) power vs. z and b) bunching parameter vs. z.

5 PRODUCTION OF THE BEAM CURRENT PROFILE

Ramping of the current profile is a necessary requirement in any system that seeks to produce usable RF power to drive multi-bunch, high-gradient accelerating structures. Without any profiling, the transient response of the accelerating structure will cause an intolerable energy spread in the accelerated pulse train. By including an initial ramp to the drive beam, the transient filling of the accelerating structure will be accomplished before the main beam arrives, and constant transfer of energy will occur over the entire pulse train.

We propose the use of a pulsed quadrupole and a beam scraper to induce a ramped current profile. The quadrupole field is produced by a stripline device [9]. Initially, the beam is defocused in one plane by the quadrupole at the aperture position, and only a part of the total current is allowed to pass. As the quadrupole field decreases, the beam is more and more focused, until at zero field all the current is transported through the aperture. The quadrupole is pulsed and decays over a duration corresponding to the desired current ramp.

6 HIGH POWER OF A CTS

The multi-kiloamp PIVAIR beam current opens up interesting possibilities for testing future CTS. These would allow us to test both the extremely high field effects and long pulse periods that are required for multi-TeV colliders. At present, three CTS parameters sets have been studied in detail with MAFIA (See Table 1).

The electron beam requirements for full-field tests are easily calculated using the expression for structure output power.

$$P = \frac{(r/Q)q_d^2\omega}{2d}$$

where q_d is the beam charge passing through the structure during the drain time

$$d = (s/c)(1/\beta_g - 1)$$

The charge is supposed to be concentrated in infinitely short bunches spaced by $g=c/f$=1cm (f=30 GHz). The necessary beam charge per drain time is obtained from the above expression as:

$$q_d = \sqrt{\frac{2dP}{(r/Q)\omega}}$$

Furthermore, the charge per bunch (for a train of delta-function drive bunches) is obtained as $q_b = 2q_d/fd$. The Fourier analysis of a beam with these infinitely short bunches spaced in time by $1/f$ yields a peak current component at f of $I=2fq_b$. Note that the CTSs are tuned to the frequency component at f = 30 GHz. Assuming a RF current bunching factor of 0.6 at 30 GHz, the required PIVAIR beam DC current amplitude becomes $2fq_b/0.6$. Numerical values for the three drive beam cases are summed up in the table.

	1 TeV Single DB	1 TeV Multi DB	3 TeV Multi DB
CTS output power: P (MW)	550	309	600
CTS length: s (m)	0.92	1.028	1.028
Drain time: d (ns)	5	5.14	5.14
Relative group velocity: β_g	0.38	0.4	0.4
Beam charge / d: q_d (nC)	2325	673	798
r/Q of CTS (circuit Ω)	5.2	51.4	51.4
CTS peak deceleration (MV)	1.18	2.5	3.87
FEL mean current (A) (for delta-function)	465	123	155
Peak 30 GHz FEL current (A)	930	247	310
FEL mean current: (A) (for I_{rf} = 0.6 at 30 GHz)	1550	411	517

7 RK-CLIC STUDIES

The existing effort at LBNL seeks to realize the RK-TBA concept by construction and successful operation of a full-scale, prototype device [10]. This will be a 11.42 GHz version and will test all the key components and design elements of a complete system. PIVAIR operated as a test stand will provide a valuable resource in the effort to examine beam dynamics and to test designs of beamline components for a high frequency RK-TBA.

A key point in the beam dynamics of an RK-TBA is the stability of the bunching against space charge forces and longitudinal impedances. The RF cavities are designed to be 'inductively detuned' to provide a net re-bunching force on the beam as it travels through the structure, and to maintain stable synchrotron (longitudinal) oscillation. The cavities themselves are designed to act upon the beam to maintain stable bunches.

The induction cells may take on a very compact design, increasing the efficiency of the re-acceleration units. However, decreasing the beampipe diameter tends to increase the transverse impedance and peak surface electric field in the induction modules. Innovation is required in the cell geometry, induction core material, and high gradient insulation. These may all be tested at PIVAIR.

The RF cavities are the centerpiece in any RK-TBA system. Their microwave properties are crucial to the generation of useful power by the drive beam. The idler, standing-wave (SW) and travelling-wave (TW) output cavities all have unique interactions with the beam that need to be measured and analyzed experimentally. Important tests that need to be performed include: generation of high output power , high-voltage holdoff, low Q, longitudinal impedance characterization.

8 CONCLUSION

The PIVAIR accelerator is a useful research tool, capable of providing an intense high-quality electron beam of energy 7.2 MeV. This machine may be used in a variety of scientific and technological projects, among which figures prominently the generation of high-power, high-frequency microwaves. A major application of these consists in powering the next generation of linear colliders which will operate at high frequencies, such as 30 GHz. In the present project, we propose to use PIVAIR in conjunction with a FEL to produce an intense bunched beam, and to test structures designed to extract power at 30 GHz from such a beam.

Some of the technical aspects of our proposal have been contributed by members of different groups. We express to them our thanks, and acknowledge the helpful remarks offered by members of the CLIC collaboration and the RKTBA group.

FIRST ORDER DESIGN STUDY OF AN ACCELERATOR BEAMLINE FOR THE PEARL FEL

M. C. Lampel, G. H. Gillespie Associates, Inc., J. M. J. Madey, U. of Hawai'i, R. J. Burke, Arcata Systems

Abstract

The Pan-Oceanic Environmental and Atmospheric Research Laboratory (PEARL) consortium has proposed the deployment of a ship-based FEL facility in order to carry out advanced atmospheric and environmental research for a variety of applications. The FEL is intended to have an optical output from approximately 20 microns down to 1/3 micron, with up to 1 kW average power. The accelerator will operate over a wide range of beam currents and energies to meet these goals. Clearly, the proposed shipboard FEL must meet many design constraints in compactness and efficiency. The accelerator beamline, upstream of the FEL resonator, includes a 4.5 MeV rf gun, pulse length compression chicane, and four (4) 1.26 meter long traveling wave (TW) accelerator sections. First order focusing along the beamline is provided by quadrupole magnets. First order beam dynamics for this beamline are studied using TRACE 3-D with a self-consistent TW accelerator model incorporated into it. Parametric studies of current and beamloading effects on accelerator efficiency and beam transport are performed. Beamline layouts, taking into account the physical dimensions and operating parameters of the equipment will be studied to determine the baseline beamline design for further, higher order simulations, on the way towards an optimized design.

1 THE PEARL FEL

The PEARL consortium has proposed use of a powerful lidar system [1-3] for application to the problems of remote sensing and pollution monitoring. Air quality is affected by emissions of NOx, CO, CO_2, SO_2, hydrocarbons, CFCs, Ozone, and aerosols, etc. In addition there is an interest in detecting illegal drug manufacturing, chemical and biological warfare agents, and clandestine nuclear tests. Concentrations of the emissions of interest range from ppb to ppm, with a need for temporal and spatial resolution. Remote detection lidar processes available include Rayleigh scattering, Mie scattering, Raman scattering, absorption, and DIAL (differential absorption of two laser lines).

The FEL at the core of this lidar system is intended to have an optical output from approximately 20 microns down to 1/3 micron, with up to 1 kW average power. Macropulses of 3-5 microseconds, average currents of hundreds of milliamperes, and electron beam energies ranging from 20 MeV to 120 MeV are being considered as operating parameters of the accelerator/driver. In addition, high peak power requirements translate to a high micropulse current, 500-1000 Amps over 2-4 picoseconds. To begin translation of earlier system studies into specification of an accelerator beamline, several first order designs are being compared to gain insight into the problem. The remainder of this paper discusses four beamlines looked at using TRACE 3D. This version of TRACE 3D has been modified to incorporate traveling wave accelerator structures, both constant gradient and constant impedance [4].

2 THE BEAMLINES

The baseline accelerator design is taken from the 1 kW FEL concept of Cover, et. al. [5]. A 1.5 cell rf gun produces a 4.5 MeV electron beam [6]. This beam is

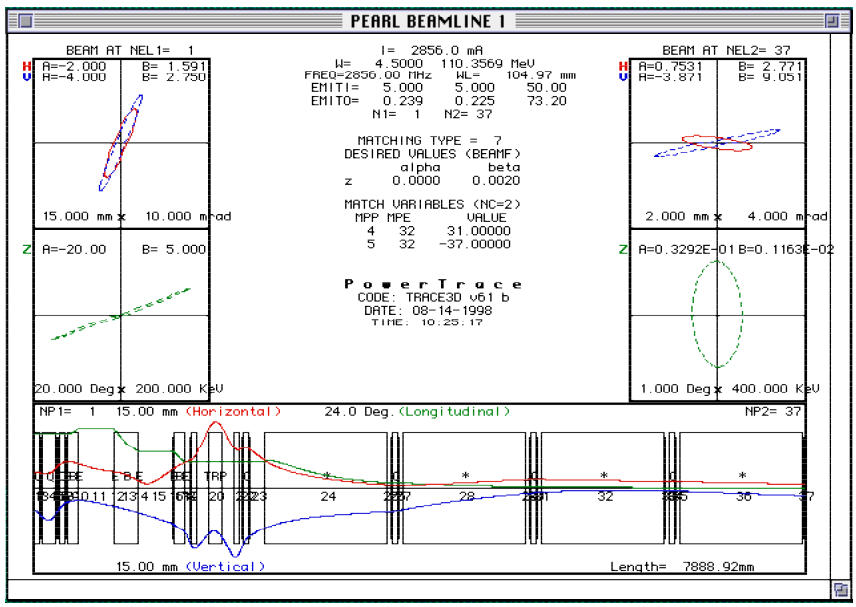

Figure 1: The Baseline PEARL Magnetic Chicane Buncher and Four Accelerator Structures

bunched in a variable magnetic chicane consisting of two 5" diameter dipole magnets placed about a large central magnet. The central magnet was designed to provide a path length equal to the combined path lengths of the two outside dipoles for any angle of entry. Bend angles up to 40 degrees can be accommodated, giving great flexibility in pulse compression. The beam is matched into the first of four 1.26 meter accelerator sections, which are derived from the SLAC 3 m structure. Three of them incorporate higher order mode outcouplers to extend BBU thresholds and limit emittance growth. Quadrupole magnets are placed in between the structures to provide focusing. Figure 1 illustrates this baseline, with a beam of 1 nC every eighth rf bucket accelerated to 110 MeV. Initial conditions for the TRACE 3D simulations are given in Table 1.

Table 2 summarizes the parameters for the different beamlines. Two beamlines use chicanes and two use six accelerator structures. This preliminary study indicates that, with the option to select phase lag for each accelerator structure individually, a chicane buncher is useful, but causes some emittance growth. However, a shorter, <20 psec pulse is probably needed out of the rf gun if the chicane is to be eliminated. Power requirements for the four beamlines are: 112, 104, 79, and 77 MW respectively.

Each beamline transports and accelerates the initial beam (see Table 1) to a final energy of 110 MeV. Parameters have been chosen to obtain this final energy and an upright longitudinal phase space ellipse at the end of the beamline. Table 3 summarizes final emittances and pulse lengths.

3 CONCLUSIONS

The four beamlines examined indicate that shorter and/or lower power alternatives can meet the operating parameters needed for PEARL. A chicane buncher provides greater flexibility at the expense of emittance growth. Future analysis will extend these preliminary results through higher order modeling.

Table 1: Initial Beam Parameters

Beam Kinetic Energy	4.5 MeV
Macropulse Beam Current	357 mA
Micropulse Charge	1 nC
Initial Pulse Length	20 (no ch.) 30 psec (w/ch.)
Correlated Energy Spread	125 - 210 keV
Longitudinal Emittance (z)	50 π deg-keV (eq. unif.)
Transverse Emittance (x,y)	5 π mm-mrad (eq. unif.)

FIRST LASING OF THE JAERI FEL DRIVEN BY THE SUPERCONDUCTING RF LINAC

E.J. Minehara, M. Sugimoto, M. Sawamura, R. Nagai, N. Kikuzawa,
T. Yamanouchi and N. Nishimori
Japan Atomic Energy Research Institute, Tokai, Naka, Ibaraki, 319-1195 Japan

Abstract

First and strong laser oscillation has been obtained in the wavelength ranging from 24 to 28μm using the JAERI (Japan Atomic Energy Research Institute, Tokai) 500MHz superconducting rf linac based FEL driver and far infrared FEL device. Electron beam energy and resolution are around 16MeV and 0.6%, respectively, the beam current between 2 and 4mA, and pulse width between 0.1ms and 0.9ms, respectively. A near-concentric optical resonator with a 52 period of 33mm length hybrid planer undulator (K=0.7) is 14.4m long, and uses Gold-coated Copper mirrors of 120mm diameter. The optical axes and distance of the mirrors are precisely adjusted by remotely controlled actuators in order to coincide with the electron beam and micro pulse repetition rate, respectively, before the oscillation. The power has been measured and scattered from 10^7 to 10^8 times higher than that of the spontaneous emission. During the first successful operation, the highest FEL power was measured to be about a hundred watts in average. The FWHM of the FEL spectrum is around the Fourier-transform limited value, and less than 0.09 μm, which corresponds to $\Delta\lambda/\lambda$=0.37%. The detuning curve of the cavity is asymmetrically-peaked over about 3 μm in the longer side, and spanned over about 15μm.

1 INTRODUCTION

A prototype for a quasi-cw or very long-pulse, and high-average power free electron laser(FEL) driven by the 15 MeV superconducting rf linac has been developed, and constructed at Tokai, JAERI (Japan Atomic Energy Research Institute) since 1989 [1-4]. Both high performances of cryogenic stand-by loss<3.5W at 4.5K and accelerating fields' Eacc < 8.3MV/m and Q < 2 x10^{+9} in the JAERI superconducting rf linac modules have been successfully realized as a so-called zero-boil-off and world-first transportable capabilities without any serious vibrational problem in the JAERI FEL accelerator vault.

Since modification and related maintenance of the cryogenic refrigerator system for the driver were completed in the middle of October 1995, the system has run with no trouble, and the driver has been continuously run very successfully up to now. The optical resonator system and related electron beam transport system were modified to realize larger acceptance than the old for both of the undulator radiation and energetic electron beam. An alignment and distance measurement system was newly developed, and successfully applied to actual preparatory measurement for lasing in the JAERI FEL. A far-infrared light transport line and detector room was built to realize a low-loss and low-noise measurement near the accelerator vault in April, 1996.

In order to realize the quasi-cw and very long-pulse operation, we have improved the electron gun grid-pulsar and high voltage power supply, and rf amplitude and phase control systems for the JAERI superconducting rf linac. The improvements in the electron gun and the related with the rf system are still under way.

A beam test and commissioning of the JAERI superconducting rf linac as an FEL driver was successfully performed to get an electron beam ranging from 10 to 23 MeV with a nearly full transmission and a full current, and relatively short macro pulse of 0.01ms. Strong and stable oscillation in the wavelength of around 24 μm have been observed by using the Ge(Cu) detectors with a home-made fast current amplifier system, commercially-available MCT detectors and thermopiles. As shown in Fig. 1, a sudden increase of the light signal were observed after a few tens of microseconds later from the onset of beam current pulse.

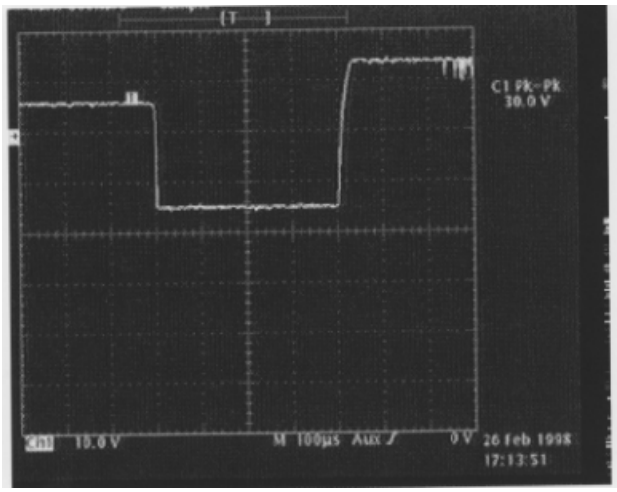

Figure 1: Stable oscillation in the wavelength of around 24 μm. The pulse duration is continued over 0.4ms, the beam current ranging from 2 to 4mA, and the maximum laser power about a hundred watts in average.

2 EXPERIMENT

Fig. 1 shows the first and stable laser oscillation with the JAERI superconducting rf linac based FEL. The average current for a macro pulse is measured to be around 4mA. The lower trace of the figure is a far-infrared light signal waveform of a Ge-Cu detector. The total cavity loss and the FEL gain are scattered between 1.1 and 1.9%, and estimated to be from 10% to 30%, respectively, which were obtained from decay and rising times of the output pulse.

Fig. 2 shows the e-beam current signal of the lower part and FEL light output signal of the upper over a half millisecond. As shown in Fig. 3, the FEL spectrum was measured with a grating spectrometer and a commercially-available pyroelectric line-sensor of 64 channels located at the focal plane during the operation.

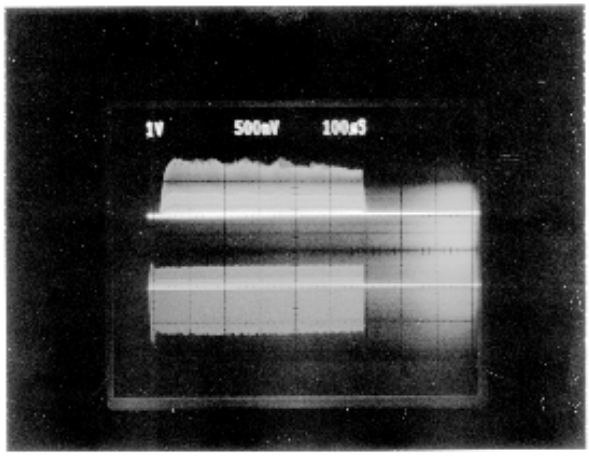

Figure 2: Electron-beam current signal of the lower part and FEL light output signal of the upper over a half millisecond.

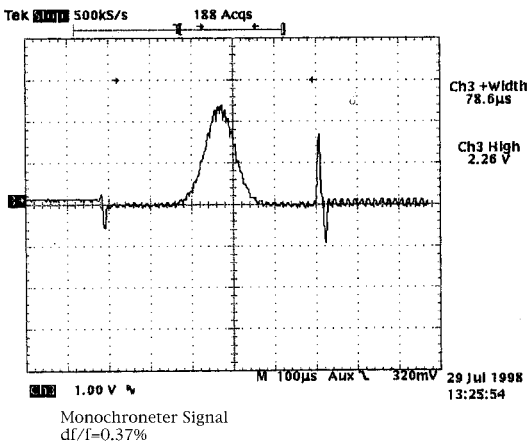

Figure 3: The FEL spectrum was measured with a grating spectrometer and a commercially-available pyroelectric line-sensor of 64 channels fixed at the spectrometer focal plane during the operation. The FWHM of the FEL spectrum is less than 0.09 µm, which corresponds to $\Delta\lambda/\lambda$=0.37%.

The FWHM of the FEL spectrum is less than 0.09 µm, which corresponds to $\Delta\lambda/\lambda$=0.37%. The tuning range of the cavity is spanned over about 15µm.

The detuning curve was measured reliably to be asymmetric, long-tailed in the shorter cavity-length side, and short-tailed or quickly-disappeared in the longer.

An FEL beam spot was observed using a pyro-camera fixed in the optical measurement room neighboring the FEL accelerator vault.

Divergence of the beam is estimated to be the same order of a diffraction limit value in the figure 4.

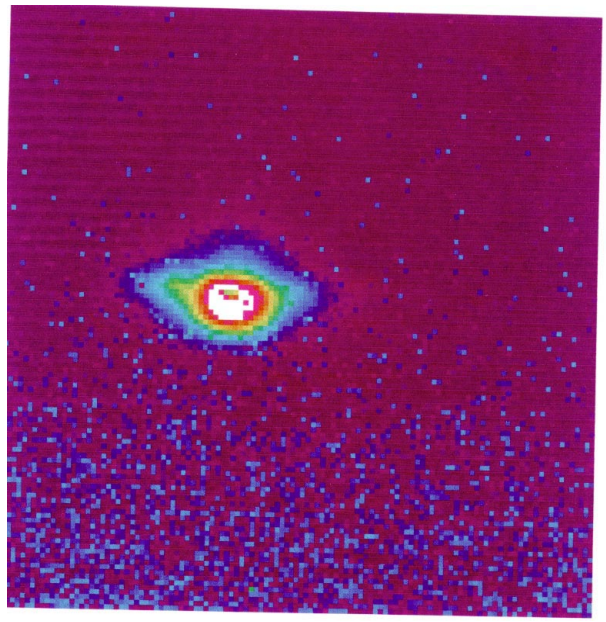

Figure 4: FEL beam spot observed using a pyro-camera fixed in the optical measurement room neighboring the FEL accelerator vault.

Stable laser oscillation has been obtained at a wavelength of 24µm using the JAERI superconducting rf linac based FEL driver. During the first successful operation, the highest FEL power was measured to be about a hundred watts in average. The JAERI superconducting rf linac operational parameters are summarized in the following; 1) Electron Beam Energy of 15.8 MeV from 0.1 to 0.9ms, 4) Beam current ranging from 2mA to 4mA, 5) Energy resolution around 0.6%, and 6)Repetition Rate 10.4125MHz.

A near-concentric optical resonator with a 52 period of 33mm length hybrid planer undulator (K=0.7) is 14.4m long and uses Gold-coated Copper mirrors of 120mm diameter. The optical axes and distance of the mirrors is adjusted by remotely controlled actuators in order to coincide with the electron beam and micro pulse repetition rate, respectively, before the oscillation. The power has been measured and scattered from 10^7 to 10^8 times higher than that of the spontaneous emission.

RECENT PERFORMANCE OF THE JAERI SUPERCONDUCTING LINAC FOR FEL

M. Sawamura, R. Nagai, N. Kikuzawa, N. Nishimori, E.J. Minehara
Japan Atomic Energy Research Institute (JAERI), Tokai, Ibaraki 319-1195 Japan

Abstract

Far-infrared FEL oscillation using the superconducting linac has succeeded in JAERI. The linac consists of a 250kV electron gun, a subharmonic normal-conducting buncher (SHB) of 83.3MHz, two single-cell and two 5-cell superconducting cavities of 499.8MHz. The gun was typically operated around 200 kV to reduce space charge effects.

The combination of the SHB and two single-cell cavities enabled high current beam of more than ten amperes by utilizing a thermionic cathode and a grid pulsing. Calculations utilizing the modified PARMELA code showed that the electron bunch of 3 ns from the electron gun was finally compressed to be 20-35 ps after the two single-cell cavities. FWHM bunch length and 80% emittance were measured to be 22ps and 35 pi mm mrad.

1 INTRODUCTION

Many kinds of free-electron laser (FEL) facilities exist in the world. Some are striving to develop a short wavelength FEL while others are trying to find applications in various fields, such as medical and scientific research. The purpose of the Japan Atomic Energy Research Institute (JAERI) FEL project is to develop a high-average-power, high-efficiency FEL for research and industrial use[1,2]. The stable FEL oscillation was achieved in March 1998. Figure 1 shows the schematic layout of JAERI superconducting linac. This paper describes the detail design of JAERI FEL linac and the measurement of bunch length and emittance.

2 CONCEPTUAL DESIGN OF THE JAERI FEL LINAC

The average power of an FEL is determined by multiplying the peak power by the repetition rate and pulse length. Thus, to create a high-average-power FEL, it is necessary to increase the peak power, the repetition rate, and the pulse length. The peak power is proportional to the peak current of the electron beam. The peak current of the linac is normally a few hundred amperes maximum for an RF linac. Though an RF gun and photocathode are used to obtain the high-current beam, it is difficult to

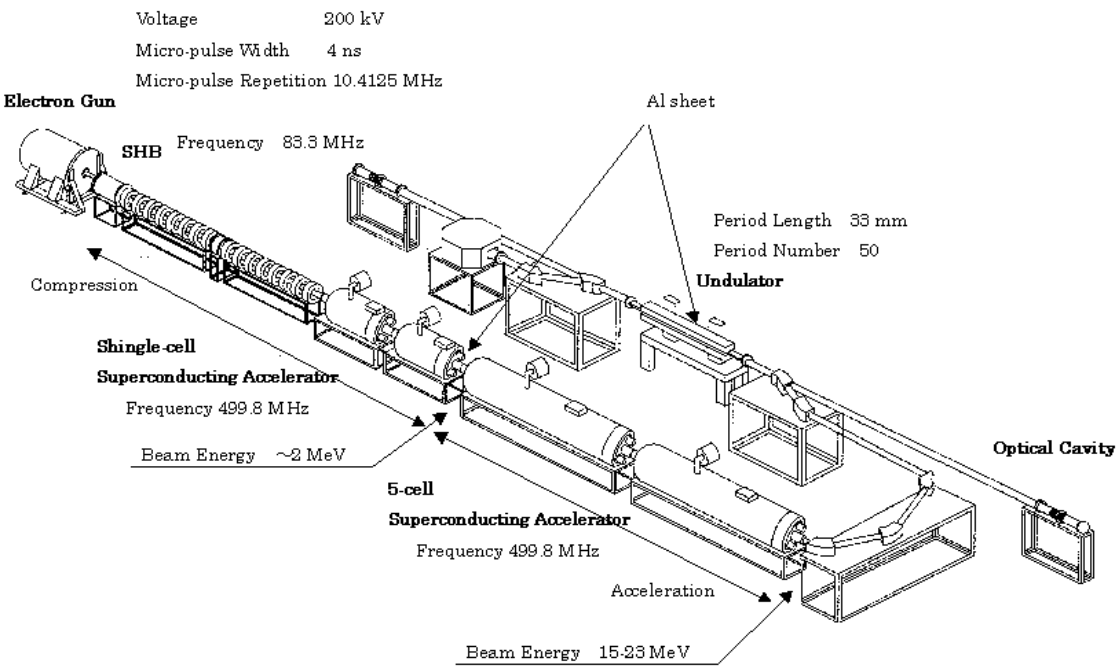

Figure 1: Schematic Layout of the JAERI Superconducting Linac

operate them with a high-repetition rate and a long pulse length. From this standpoint, a linac with a high repetition rate and a long-pulse or continuous-wave (CW) mode operation is suitable for a high-average-power FEL. Therefore, superconducting accelerators are superior.

The electron beam power is converted to laser power with an efficiency of only a few percent or less. When the electron beam is dumped, most electron beam power is wasted. Therefore the efficiency of an FEL is usually very low. Reusing the electron beam and reducing the RF loss increase the efficiency. Superconducting cavities have a very small RF power wall loss, which makes them superior to normal conducting cavities for a high-efficiency FEL linac.

Thus, we conclude that superconducting accelerators used as the main accelerating components are best to realize a high-power, high-efficiency FEL.

3 DESIGN DETAILS OF COMPRESSING SECTION OF THE JAERI FEL LINAC

For the electron gun, the thermionic cathode is the most acceptable choice presently available. However, it is difficult to obtain a high-current electron beam that has a current of more than a few hundred milliampere and also has good emittance. Therefore, a beam compressing system is necessary to produce a high-peak-current beam.

A frequency of 500 MHz was selected for the main accelerating components. A period of 500 MHz is 2 ns and at least half of that is unavailable for compressing the beam. Therefore, to compress the beam bunch of more than 1 nanosecond, a subharmonic buncher (SHB) is required. When the bunch length from the electron gun is 3-4 ns, the subharmonic frequency must be less than a quarter of the main frequency, 500 MHz. Though an SHB using lower subharmonics can compress a beam bunch to a shorter length than one using higher subharmonics, it requires a higher buncher voltage, which results in a larger RF loss in the SHB. Considering long-pulse or CW mode operation, low-power loss is desirable. We chose a subharmonic number of 6 for the SHB.

When the charge density increases by shortening the bunch length or when the beam current is originally high, beam compression with only the SHB does not work well because of the space charge effects. A means of resolving this problem is to install an additional element that works not only as a buncher but also as an accelerator that decreases the space charge force. Since we are considering a high-average-power, high-efficiency FEL, the accelerating section of the linac must be superconducting. If a multicell superconducting module is adopted for this element, it causes not only less effective acceleration but also an increase in the energy spread. When the phase in the first cell of a multicell is adjusted to enhance both compression and acceleration, the remaining cells are out of the phase of maximum accelerating. That causes an expansion of the energy spread because the accelerating field of the maximum accelerating phase has the smallest energy spread. Therefore, the multicell superconducting accelerator is unsuitable, whereas the single-cell element is suitable. Thus, two single-cell superconducting modules are installed after the SHB section to accelerate the beam to almost the speed of light.

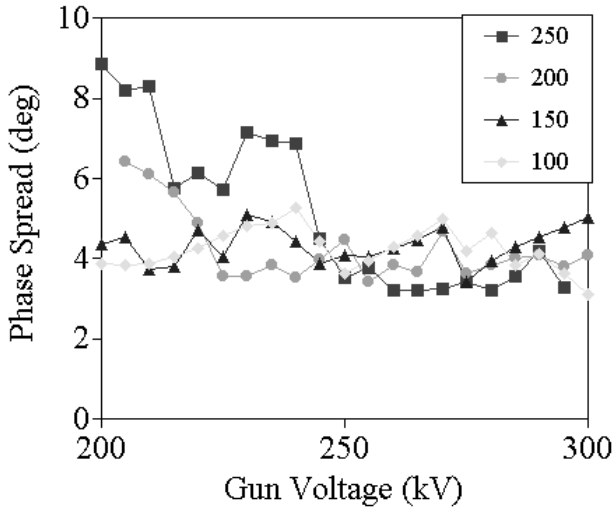

Figure 2: Calculated phase spread with different gun voltage and with different beam current.

The voltage of the electron gun influences the phase spread. Figure 2 shows the phase spread of the compressed bunch with the SHB and two single-cell cavities calculated with PARMELA. The initial phase spread was 3 ns. The 80 % phase spread was calculated by optimizing the phases of SHB and two single-cell cavities and the amplitude of SHB.

The figure shows that this compression system works well. For high beam current such as 200 mA and 250 mA, increasing the gun voltage has an advantage of making the beam spread small. For low beam current such as 100 mA and 150 mA, the phase spread does not change so much according to the gun voltage. Therefore, 200 kV gun voltage is sufficient for the beam current less than 150 mA.

4 MEASUREMENT OF THE BEAM BUNCH LENGTH AND EMITTANCE

The bunch length was measured at the middle of the undulator. The bunch length is estimated to be several tens picoseconds. The beam bunch length was measured with a steak camera made by Hamamatsu Photonics Co. An aluminum plate profile monitor was installed within the undulator duct. When the electron beam collided with an aluminum plate, optical transition radiation (OTR) was emitted. The bunch length was measured by detecting the OTR by the streak camera. Figure 3 shows the result of

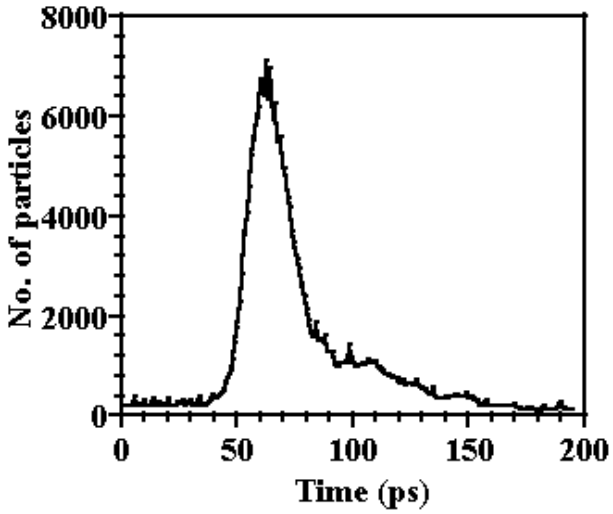

Figure3: Measured bunch length

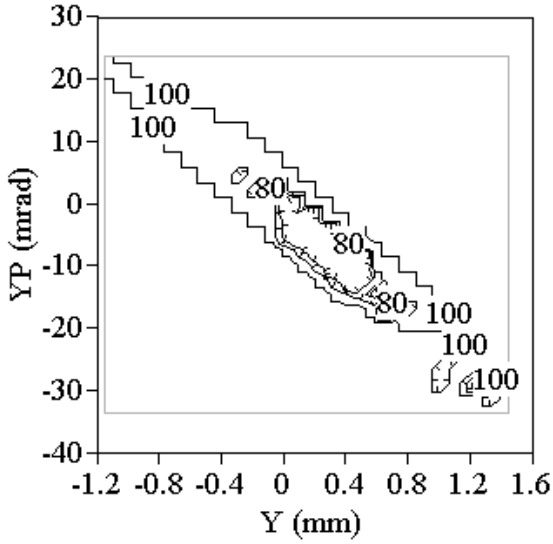

Figure 4: Reconstructed phase space contour of 100 % and 80 % emittance.

the bunch length measurement. It indicates a bunch length of 22 ps, which corresponds to 4.0 degrees.

The beam eminence was measured by measuring the beam distribution on the profile monitor with different quadrupole fields. Then the emittance was reconstructed with tomography method[3]. Figure 4 shows the result of the reconstruction. This indicates that 80 % normalized emittance is 35 pi mm mrad and that 100 % emittance is about 5.6 times larger than 80 %. This was achieved before the succession of the FEL oscillation and under adjustment of the accelerator parameters.

ELECTRON BEAM CHARGE STATE AMPLIFIER (EBQA)-- A CONCEPTUAL EVALUATION*

J. C. Dooling and J. A. Nolen
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

A concept is presented for stripping low-energy, radioactive ions from 1+ to higher charge states. Referred to as an Electron Beam Charge State Amplifier (EBQA), this device accepts a continuous beam of singly-charged, radioactive ions and passes them through a high-density electron beam confined by a solenoidal magnetic field. Singly-charged ions may be extracted from standard Isotope-Separator-Online (ISOL) sources. An EBQA is potentially useful for increasing the charge state of ions prior to injection into post-acceleration stages at ISOL radioactive beam facilities. The stripping efficiency from q=1+ to 2+ (η_{12}) is evaluated as a function of electron beam radius at constant current with solenoid field, injected ion energy, and ion beam emittance used as parameters. Assuming a 5 keV, 1 A electron beam, η_{12} = 0.33 for 0.1 keV, ^{132}Xe ions passing through an 8 Tesla solenoid, 1 m in length. Multi-pass configurations to achieve 3+ or 4+ charge states are also conceivable. The calculated efficiencies depend inversely on the initial ion beam emittances. The use of a helium-buffer-gas, ion-guide stage to improve the brightness of the 1+ beams [1] may enhance the performance of an EBQA.

1 INTRODUCTION--MOTIVATION FOR THE EBQA

The production and acceleration of radioactive nuclides far from stability is an area of significant interest in nuclear physics [2,3]. Generating these nuclides in specific charge states selectively and efficiently are important goals in the development of a cost-effective Radioactive Ion Beam (RIB) facility. To increase efficiency and reduce cost, it is desirable to strip singly-ionized species to higher charge states while still at low energy in the post-accelerator. RIBs typically employ low charge state ions (usually 1+) at the front end of the post-accelerator; these ions are often generated within Isotope Separation On-Line systems (ISOLs) [4]. For A>30-60 amu, higher charge states are desired to simplify the post accelerator. For example, ISAC [5] presently under construction at TRIUMF, requires a source capable of generating heavy ions with charge to mass ratios (q/A) greater than 1/30. Elevated charge states are available at low energy from Electron Cyclotron Resonance Ion Sources (ECRIS) [6] and Electron Beam Ion Sources (EBIS) [7]. The ISOL-MAFIOS [8] system combines properties of both ECRIS and EBIS by electrostatically "catching" singly-charged ions injected into the minimum B-field ECR region; stripped ions then effuse continuously. However, ECR sources tend to generate beams of relatively large emittance and produce a broad range of charge states. The EBIS is typically a pulsed machine which generates higher charge states by first trapping ions in an electrostatic well then "cooking" them in an electron beam for a period of time. A large EBIS is planned for the REX ISOLDE facility at CERN [9]. If the 1+ ions are first accelerated by a low q/A structure, such as an RFQ, they can be stripped afterwards to higher charge states. A post accelerator based on this concept is being developed at Argonne [2,10,11]. The EBQA concept discussed here is an alternative method of increasing the charge state of a DC beam at ion source energy.

The primary components of an EBQA are presented in Figure 1. Though in principle it should be possible for the EBQA to generate ions of arbitrarily high charge state by recirculating the beams, the present analysis focuses on advancing q from 1+ to 2+.

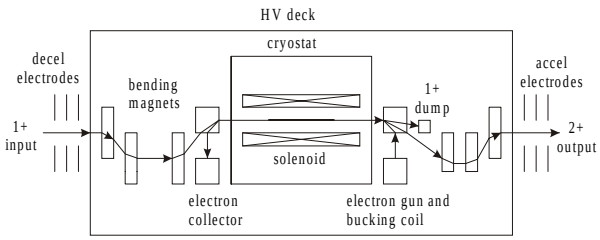

Figure 1: The EBQA in single-pass mode.

2 EBQA ANALYSIS

Simulating the detailed ion and electron orbits within the solenoid requires a full 4-D emittance distribution (e.g., f(x,x',y,y')). Angular momentum effects arise from xy' and x'y phase-space pairs. A Kapchinsky-Vladimirsky (K-V) distribution is chosen for the injected beam [12]. The solenoid is modeled as an ideal cylindrical coil. All ion trajectories are assumed to be near the axis; therefore, analytical expressions for B_z and B_r can be obtained.

2.1 Matching

To optimize stripping efficiency and minimize envelope oscillations, the ions and electrons must be

* Supported by U.S. DOE, Contract W-31-109-ENG-38

properly matched into the solenoid. Assuming the ion starts from a shielded source (**B**=0), the matched beam radius is just twice the Larmor radius, $r_m=2\rho_o$,

$$r_m = \left[\frac{2\varepsilon_n m_o c}{qB_{zo}}\right]^{1/2} \quad (1)$$

where the normalized emittance is $\varepsilon_n = \beta\gamma\varepsilon_o$. Note that the matched radius is not a function of injected energy.

2.2 Electron Injection

Magnetic field at the cathode plays an important role in determining the matched e-beam radius. Because of the relatively low electron energy and high field intensity, electron rigidity is low. The cathode immersion field can be used to control the beam size within the solenoid to maximize stripping efficiency or brightness. High field and low rigidity mean that both electron gun emittance and gun alignment errors must be small.

The EBQA requires a large perveance from the electron gun; thus, space charge neutralization must occur over a short distance. The doubling distance of a 5 keV, 1 A electron beam extracted through a 1 cm^2 aperture is approximately 4 cm. The necessary neutralization of the e-beam space charge is facilitated by dc extraction. Employing a background hydrogen gas at a pressure of 10^{-6} Torr, the neutralization time, $\tau_n=(n_b<\sigma_{01}v>)^{-1}$, is on the order of 1 ms for 5 keV electrons [13].

2.3 Stripping Efficiency--Analytical Results

Stripping efficiency in the EBQA depends upon solenoidal field intensity, beam energies, emittances, ion charge state, and stripping cross sections. Cross sections are estimated using empirical formula [14,15] or from data [16] where available. Multi-step ionization is ignored as are cross sections for excited states. Assuming uniform density profiles for both ions and electrons, stripping efficiency can be estimated. The stripping efficiency for singly-charged ions, fully immersed in the e-beam can be expressed as,

$$\eta_s(t_i) = 1 - \exp\left[-\frac{L_s\sigma_{12}I_e\beta_e}{e\pi r_e^2\beta_i c\beta_{e\|}}\right] \quad (2)$$

To determine actual efficiency, overlap of the electron and ion beams must be included (this does not take into account orbital effects). For a matched ion beam radius, r_m the efficiency is given as,

$$\eta_{12} = \eta_s(t_i)\frac{r_e^2}{r_m^2} \qquad r_e < r_m \quad (3a)$$

$$\eta_{12} = \eta_s(t_i) \qquad r_e > r_m \quad (3b)$$

The effect of nonlocalized charge on stripping efficiency is discussed in the following section with simulation results. In the limit where stripping efficiency is relatively weak (<10 percent) and $r_e \le r_m$, the efficiency can be approximated by Equation 4. In this case, the efficiency is roughly independent of r.

$$\eta_{12} \approx \frac{L_s\sigma_{12}I_e\beta_e}{e\pi r_m^2\beta_i c\beta_{e\|}} \quad (4)$$

Continued stripping of the 2+ beam to higher charge states must also be considered. If interest is in q=2+ only, ions stripped to higher charge states would be considered lost. The time it takes to maximize the q=2+ state may be expressed as,

$$t_{max} = \frac{\ln(\sigma_{12}/\sigma_{23})}{n_e\beta_e c(\sigma_{12}-\sigma_{23})} \quad (5)$$

Using ^{132}Xe as an example, $\sigma_{12}=1.5\times10^{-21}$ m^2 and $\sigma_{23}=0.84\times10^{-21}$ m^2 at 5 keV, t_{max}= 215 μs (r_e = 0.7 mm). Inserting t_{max} into the 2+ rate equation, the maximum efficiency for the production of Q=2+ is 47.9 percent; at this time the density of q=3+ is 21.4 percent. In the single-pass mode, this represents the maximum theoretical efficiency; however, in a multipass system, one could do better if trying to attain q>2+.

2.4 Stripping Efficiency and Orbit Effects

Stripping efficiency is found to be maximized when electron and ion beam diameters are the same; however orbital effects complicate the picture. Figure 2a shows an x-y projection of two ion orbits entering the solenoid.

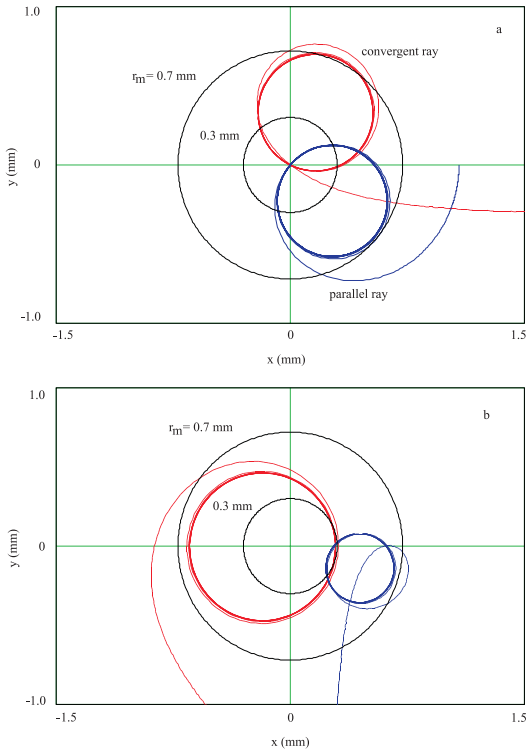

Figure 2: a) End-on view of matched orbits within the solenoid (x-y plane) starting with zero angular momentum, and b) with finite angular momentum.

The electron beam is contained within a circle of radius r_e. The ion trajectories are matched into the solenoid with a radius r_m=0.71 mm. Both trajectories enter the solenoid with zero angular momentum; however, they are separated in phase space to indicate maximum displacement and divergence. In Figure 2b, trajectories are shown which include angular momentum satisfying the K-V distribution. Stripping can only take place while ions are within the region occupied by the electron beam; i.e. $r<r_e$. Because of the complex orbits that result from the inclusion of angular momentum, it is necessary to use a numerical model to determine the stripping efficiency within an EBQA.

3 NUMERICAL MODEL

A random number generator is used to produce a set of Cartesian input phase space coordinates satisfying the K-V distribution. A predictor-corrector algorithm is employed to step each trajectory through the solenoid; this method has been benchmarked against a Runge-Kutta algorithm to insure accuracy. Depending upon initial positions in phase-space, some ions never encounter the e-beam and therefore cannot be stripped. For those ions that do enter the e-beam, a finite stripping probability is assigned. Total efficiency is determined by summing the probability for all trajectories and then dividing by the total number of particles. The trajectories possessing a nonzero stripping probability are used to calculate the emittance of the stripped, doubly-charged beam. Stripping efficiencies, determined in simulations of 2000 particles per electron beam radius are presented in Figure 3 for ion beam emittances of ε_n=0.005, 0.010, and 0.020 π-mm-mrad (ε=39, 77.5, and 155 π-mm-mrad at 1 keV, A=132 amu). The results in Figure 3 are obtained for constant e-beam current and energy (1 A, 5 keV) assuming a stripping cross section of 1.5×10^{-21}m^2. In the case of 0.1 keV injection into an 8 T field, the maximum efficiency is 38.6 percent with a charge state distribution of 33.4 percent in 2+, 4.9 percent in 3+, and 0.3 percent in 4+ and above. The stripping efficiency is seen to be inversely proportional to injected ion beam emittance.

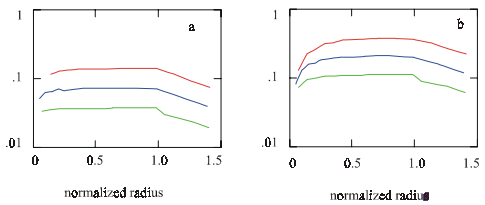

Figure 3: Stripping Efficiency versus electron beam radius at 0.005, 0.010, and 0.020 π mm mrad a) 1.0 keV, 8 T and b) 0.1 keV, 8 T.

A comparison of numerical and analytical stripping efficiency is presented in Figure 4. In this case, the injected ion beam energy and emittance are 1.0 keV and ε_n=0.005 π-mm-mr and the solenoid field strength is 8 T. Efficiency is plotted against electron beam radius assuming constant current. Near the matched radius, good agreement exists between both efficiency models; however, away from matched radius, the numerical result is larger. The deviation of the numerical result from Eq. 3 is indicative of orbital effects within the solenoid. Similar behavior is observed for the other injection cases.

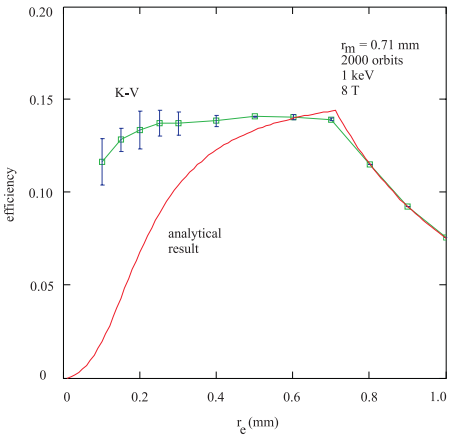

Figure 4: Comparison of numerical and analytical stripping efficiency models with electron beam radius.

4 ACKNOWLEDGEMENTS

The authors would like to thank Drs. P. Schmor, P. Van Duppen, and M. Reiser for their valuable comments.

LONG RANGE PLAN PROPOSAL FOR AN EXTENSION TO ISAC

R. Baartman, R. Laxdal, L. Root, TRIUMF, Vancouver, Canada

Abstract

A radioactive ion beam facility, ISAC, is presently under construction at TRIUMF. The post-accelerator comprises a 35 MHz RFQ to accelerate ions of $A/q \leq 30$ from 2 keV/u to 150 keV/u and a post-stripper room temperature 105 MHz DTL to accelerate ions of $3 \leq A/q \leq 6$ to a final energy fully variable up to 1.5 MeV/u. Both linacs are required to operate in cw mode. For the next five year plan, it is intended to increase the final energy above the Coulomb barrier (roughly 6.5 MeV/u) and broaden the mass range up to roughly $A = 150$. The ISAC-2 proposal will utilize the existing RFQ. Masses higher than 30 will require ECR ion sources and/or charge boosters. The optimum design consists of an IH linac to reach a 400 keV/u stripping energy, and superconducting modules to reach the final energy. The superconducting option is preferred because the short modules allow significantly higher energy – up to 13 MeV/u – for light ions. In this paper we compare the various ISAC2 options and present first order linac designs and staging scenarios.

1 INTRODUCTION

The ISAC facility currently under construction at TRIUMF[1] (ISAC1) will have the capability of accelerating singly-charged radioactive ion masses up to 30 atomic mass units ($A = 30$) to an energy of 1.5 MeV per amu (MeV/u). As a next step, experimenters would like to go to the Coulomb barrier (roughly 6.5 MeV/u) with masses up to roughly 150.

One option considered[2] was to take the singly-charged ions up to 12 keV/u with a low frequency RFQ (11.67 MHz), use a gas stripper to reach $A/q = 60$, then with a combination of RFQ and IH linac accelerate to 0.55 MeV/u, strip to $A/q = 6$ and finally accelerate to 6.5 MeV/u using more IH linacs. Although this is an intensity-efficient option, it is expensive, requiring 60 m of linac.

Ions of mass A can be accelerated in ISAC1 if their charge is greater than $A/30$. The first step in an upgrade is therefore to upgrade to a higher charge state. ECR ion sources can easily reach the required $A/q = 30$. Such sources which can withstand the radiation fields due to the 500 MeV, 10-100 μA primary beam are already under development at TRIUMF. Another possibility is a device which boosts the charge state of the 60 keV beam from the ion source. Such charge state boosters are under intensive development at GANIL/Grenoble[3]. For example, from singly-charged initial ions they have achieved Kr^{9+} with an efficiency of 9% and Zn^{7+} with an efficiency of 2%.

An attractive option is to develop a charge state booster which would give $A/q \leq 6$. This would obviate the need for any stripping and the ISAC1 stripper could be discarded. Subsequent linacs could then be optimally short and inexpensive. However, there is no guarantee that such high charge states ($q = +25$ for $A = 150$) can be obtained. Moreover, experiments indicate that the higher the charge state, the longer the 'cooking' time needed in the charge booster: up to 100 ms for very high charge states. This obviously would make it difficult to use isotopes far from stability in ISAC2.

Although ISAC1 would allow acceleration of all masses to 1.5 MeV/u, intensities for masses beyond ~70 would be too low to be useful. The reason is that the stripper in ISAC1 is at an energy of 0.15 MeV/u and $A/q \leq 6$ required for the Drift Tube Linac (DTL) cannot be achieved for masses beyond about 70. This rules out a simple extension to the ISAC1 DTL to take the ions from 1.5 to 6.5 MeV/u, unless the ISAC1 MEBT and DTL are upgraded to higher A/q. The drawback of this approach is that approximately an order of magnitude in intensity would be lost because a second stripper would be needed after ISAC1 to lower the A/q else the 1.5 MeV/u to 6.5 MeV/u linac would be too expensive.

A better approach would be to optimize the total design to use only one stripper to reach 6.5 MeV/u while keeping the total linac length to a minimum. In that case, the optimum stripping energy is 0.4 MeV/u with a maximum $A/q = 7$ for $A = 150$. A higher stripping energy makes the pre-stripper linac (where A/q is 30) too long. A lower stripper energy does not strip to a high enough charge state, making the post-stripper linac too long.

2 ISAC2 DESIGN

2.1 Acceleration from 0.15 MeV/u to 0.4 MeV/u

A cost effective configuration to reach 400 keV/u is to continue the acceleration straight north of the RFQ MEBT1 line (Fig. 1). This would require an addition to the present building to widen it northward. The energy gain of 0.25 MeV/u requires a total rf voltage of ($0.25 \times 30 =$) 7.5 MV. A DTL very similar to the ISAC1 DTL IH linac[4] would be about 5 m long assuming an average gradient of 1.5 MV/m and could be placed downstream of the first MEBT bender after a short matching section.

After the new DTL, the beam would go through a beam

transport system (MEBT2) consisting of a short matching section, stripping foil, a 90° bend for charge selection and a matching section to the post-stripper linac.

2.2 Acceleration from 0.4 Mev/u to 6.5 MeV/u

To reach 6.5 MeV/u from 0.4 MeV/u with $A/q = 7$ requires a total voltage gain of 42.7 MV. A room temperature linac should be composed of long, many-gap modules (like the ISAC1 IH DTL), else the rf power supply and running costs become prohibitively large. Such a structure running cw would have a gradient of 2.2 MV/m and including the required focusing quadrupoles between tanks would therefore be at least 28 m in length. Higher electrical gradients are possible in principle, but in cw operation rf power dissipation in the drift tubes becomes a limiting factor. These problems disappear if we instead use superconducting cavities. In that case, an accelerating gradient of 3 MV/m is conservative (5 MV/m has been achieved).

Superconducting technology is technically more difficult than the room temperature IH structure but would offer a shorter more flexible accelerating structure. Typically superconducting booster linacs are composed of two- to four-gap cavities. Two gaps give a larger velocity acceptance at the expense of a reduced voltage gain per cavity when compared to three- and four-gap cavities. Two-gap cavities have been made in both a spiral and QWR (quarter wave resonator) configuration. Three-gap cavities have been made in a split-ring structure. The four-gap cavities are constructed in a QWR geometry. The QWR shape has been found to be inherently more stable than the ring structures[5]. Acceleration efficiencies (= energy gain/($q \times$ peak voltage)) are more than 80% for the velocity range $0.81 \leq \beta/\beta_0 \leq 1.60$ for two-gap cavities and $0.85 \leq \beta/\beta_0 \leq 1.34$ for three-gap cavities.

2.3 Cavity Dimensions

A zeroth order linac concept is presented here as an example. Obviously a full optimization considering cavity type, stability, cost, etc, is required to achieve a first order design. This example consists of three different cavity geometries. The three models have design velocities of 3.5%, 7% and 11% respectively with the lowest velocity cavity being a two-gap resonator and the other two models being three-gap resonators. The two-gap cavity is chosen in the low velocity section because of its broader velocity acceptance but also because the device is inherently more phase stable and the longitudinal emittance in this region is relatively large. Cavity details are presented in Table 1, Table 2 and Table 3. In Table 1 ($A/q = 7$) and Table 2 ($A/q = 3$) the efficiency of acceleration can be determined from the ratio of the velocity to the cavity design velocity. The regions have been chosen to yield at least ∼80% acceleration efficiency for acceleration of the higher masses ($A/q = 7$). In Table 2 the particle velocity is estimated for the case where $A/q = 3$ assuming a flat velocity acceptance for the cavities. This shows that energies of 15 MeV/u can still be accelerated with reasonable efficiency.

Table 1: Energy range, velocity range and maximum voltage gain required for the three cavity types for $A/q = 7$.

Cavity	Cells	E (MeV/u)	β (%)	ΔV (MV)
1	2	0.4 – 1.5	2.9 – 5.6	7.7
2	3	1.5 – 3.5	5.6 – 8.6	14
3	3	3.5 – 6.5	8.6 – 11.7	21

Table 2: Energy range, velocity range and voltage gain for $A/q = 3$ assuming a flat effective energy gain for the three cavity types.

Cavity	Cells	E (MeV/u)	β (%)	ΔV (MV)
1	2	0.4 – 3.0	2.9 – 8.0	7.7
2	3	3.0 – 7.7	8.0 – 12.8	14
3	3	7.7 – 14.7	12.8 – 17.6	21

In Table 3 the cell structure for each cavity type is given assuming rf frequencies of 105, 140 and 175 MHz (resp. 3, 4 and 5 times the RFQ frequency). The rf frequency can be increased down the line as the relative longitudinal emittance is reduced. (The frequencies are conservative compared to the room temperature equivalent due to the higher Q and possible resultant reduction in longitudinal acceptance.) The length of the two-gap cavity is $L_2 = \beta\lambda$ and of the three-gap cavity is $L_3 = 3\beta\lambda/2$. A conservative gradient of 3 MV/m is assumed to calculate the effective voltage gain per cavity.

Table 3: Specifications for the three cavity types. The effective voltage assumes an accelerating gradient of 3 MV/m.

Cavity	Cells	β_0 (%)	f (MHz)	L (cm)	V_{eff} (MV)
1	2	3.5	105	10	0.3
2	3	7.0	140	22.5	0.68
3	3	11.	175	28.2	0.85

The proposed structure was used to estimate expected final energies. Assuming a conservative gradient of 3 MV/m, ISAC2 could reach 13 MeV/u for the lightest ions decreasing monotonically to 10 MeV/u at $A \sim 60$ and to 6.5 MeV/u at $A = 150$.

3 STAGING

The flexibility of short superconducting modules has other advantages as well. Since they are short and have wide

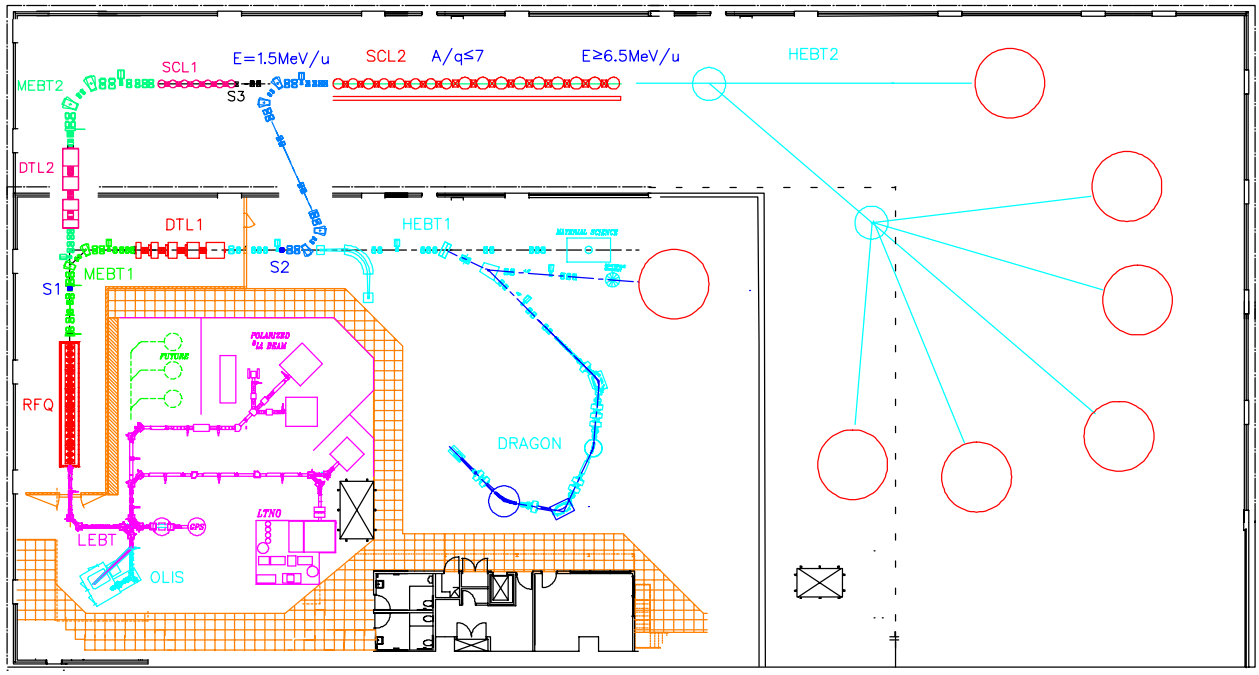

Figure 1: ISAC2 layout, including link from ISAC1, as would be needed for a 2-stripper stage

velocity acceptance, they can be built and tested even before the building addition for ISAC2 (see Fig. 1) is completed. Modules can be installed downstream of DTL1 as they become available and before the building needs to be expanded. At reduced, but usable intensity, masses up to 60 and energy up to 7 MeV/u could be available with an outlay of as little as 1/3 the cost of the complete ISAC2. This is stage 1 in Fig. 2.

Intensity for masses higher than 60 are low in stage 1 because the ISAC1 DTL requires $A/q \leq 6$ and the stripping energy is 0.15 MeV/u. However, by pushing the DTL voltage, raising the top fields of the MEBT dipoles and the DTL quads by a factor of 7/6, $A/q \leq 7$ becomes possible. This allows acceleration by ISAC1 up to mass 110 before intensity drops off. Accordingly, the ISAC1 design has been upgraded from $A/q = 6$ to 7. This is stage 2 in Fig. 2. In this stage, the building would have the expanded size shown in Fig. 1, the superconducting modules would be installed in their final location in preparation for ISAC2, and a transfer line would be used to bring the beam from DTL1 to SCL2.

Finally, DTL2 and MEBT2 would be installed to allow stripping at 400 keV/u to reach $A = 150$. This is stage 3 in Fig. 2.

Abstract

The Radioactive beam Experiment (REX-ISOLDE) [1] a pilot experiment testing a new concept of post acceleration of radioactive ions at ISOLDE/CERN is under progress. Radioactive singly charged ions delivered by the on-line mass separator ISOLDE are accumulated in a Penning trap, then charge bred to A/q < 4.5 in an electron beam ion source (EBIS) and finally accelerated in a LINAC from 5 keV/u to a final energy between 0.8 and 2.2 MeV/u. The resonant structures of the LINAC consist of a Radio Frequency Quadrupole (RFQ) accelerator, a 3-gap split ring buncher, an interdigital H-type structure and three 7-gap spiral resonators, which allow to vary the final energy. New beam line calculations of the mass separator and the matching section between the RFQ and the IH-structure have been done. A test beam line including a duoplasmatron ion source, an electrostatic quadrupole lens system and a prototype of a diagnostic box is assembled. The vacuum tank of the IH-structure is in production as well as the buncher. The RFQ is assembled and ready for first vacuum tests. The first 7-gap resonator is almost completed and first tests are sheduled. The present paper describes the status of the separator and the REX-ISOLDE LINAC.

1 INTRODUCTION

REX-ISOLDE is a first generation Radioactive Ion Beam (RIB) project to explore the structure of neutron rich Na, K, Ca and Mg isotopes and the possibilities of an effective post acceleration of exotic ions due to charge breeding with dedicated state of the art machines. The frame parameters of the LINAC are an operation frequency of 101.28 MHz which is the half frequency of the CERN proton LINAC II, the timing of the extraction and a repetition rate of up to 50 Hz require a maximum duty cycle of 10%. To be flexible in the kind of experiment and for different ion species the exit energy has to be variable between 0.8 and 2.2 MeV/u. [2]. The radioactive ions are injected into the LINAC with an A/q-ratio between 3 and 4.5. The used structures is a 4-rod RFQ similar to the first RFQ of the Heidelberg high current injector [3] using mini-vanes as electrodes.

* Work supported by the BMBF under contract 06 LM 868 I / TP:4 and 06 HD 802 I

In addition an IH-structure is used as a booster structure which is a small version of the tank1 of the lead LINAC-IH-structure at CERN [4]. For matching the phase spread of the ion beam out of the RFQ to the longitudinal phase acceptance of the IH-structure a 3-gap split ring resonator is used. The energy variation is done by three 7-gap spiral resonators similar to the structures used at the Heidelberg high current injector [5]. The complete experiment is shown in Fig.1 including the beam optics and the target region.

2 HARDWARE STATUS

All resonance structures of the LINAC are now in production or already delivered. Hence an overview of the hardware status can be given. The installation of the LINAC at ISOLDE takes place in the next shut down period. The Penning trap is fully assembled and first tests of the injection system have been done [6]. The beam line trap-EBIS has been calculated and is now under construction. The cryostat of the EBIS was damaged after a He-quench test and is now in repair. The vacuum system of the EBIS as well as the collector and the gun are completed and shipped to CERN.

2.1 The q/A separator

The ion beam leaving the EBIS contains impurities from residual gas inside the EBIS. Therefore a q/A-separator is required with a resolving power of about 150. In order to be independent in the resolving power from the energy spread of the ions due to the potential depression of the electron beam of the EBIS an achromatic system was chosen, where the resolving power is dependent on the EBIS emittance [7]. The amount of radioactive isotopes from ISOLDE can be down to 100 times lower than the number of residual gas ions. Thus the overlap of the mass peaks at the mass separation slit must not be higher than 0.01%. Therefore the EBIS emittance has to be lower than 10 π mm mrad (2σ) to get a resolving power of 150. The hardware of the separator is in production, the vacuum system is delivered. The electrostatic quadrupole quadruplet (EQQ1) is completed and built into the test beam line.

The deflector tank is in production as well as the deflector. The construction of the electrostatic lenses is

completed. The deflecting magnet with a maximum field of 0.2 T is ordered.

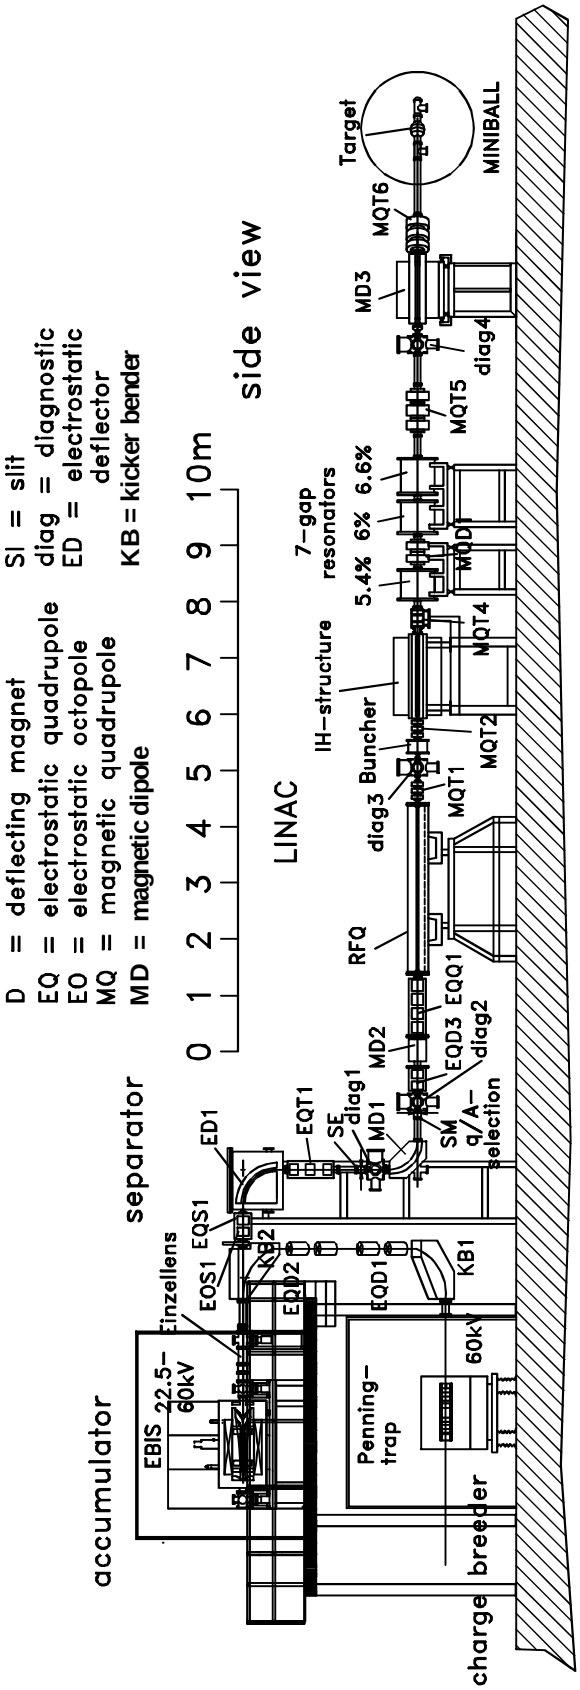

Figure 1: Layout of REX-ISOLDE.

This magnet has the possibility to shape the exit pole face for higher order corrections by iron fingers mounted at the mirror plates.

2.2 The four-rod RFQ

The REX-ISOLDE-RFQ has been assembled and a first frequency tuning has been done. In these measurements the flatness of the rod voltage, the quality factor and the shunt impedance have been determined. The resonator is ready for the first vacuum test. For the power test the water cooled ground plates have to be mounted and the final alignment has to be done. More details about the RFQ are presented in [8] on this conference.

2.3 The buncher

The vacuum tank for the Split Ring Buncher has been manufactured and leak checked. Next step is copper plating at GSI. An 1:1 model of the resonator has been built and tuned to the proper frequency. The final drift tube assembly has been manufactured. Fig.2 shows a view of the present tank with the split rings.

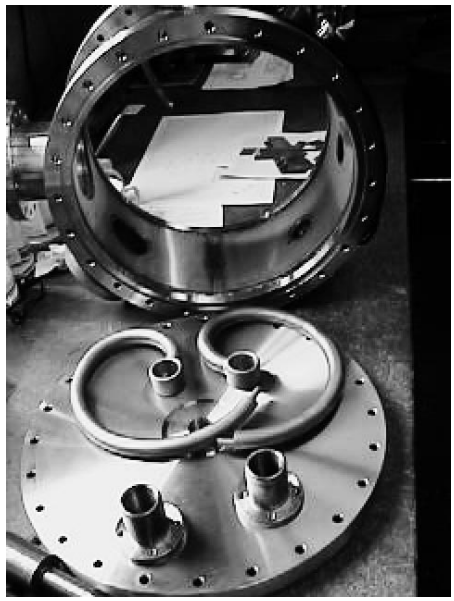

Figure 2: Vacuum tank of the buncher and the split ring structure.

2.4 The IH-Structure

The booster part of the LINAC is a short IH-structure with a maximum resonator voltage of 5.04 MV. Identical to the twin brother structure tank1 of the CERN lead LINAC the REX-ISOLDE-IH-structure consists of a center frame which carries the drift tubes and two half shells which are double walled for water cooling reasons. In fig.3 one can see the two walls of both half shells and the center frame with the support of the drift tubes. The photo was taken before the frequency tuning via the half shell length has been done. The big holes in the half shells are for the pumping flange, the incoupling loop and the inner-tank triplet lens. The triplet lens mounted in the IH-

vacuum tank is now completed and will be delivered from DANFYSIK within the next three weeks. After the final production of the tank all parts will be copper plated until the end of the year. The drift tubes will now be brazed to the supports and both will than be copper plated.

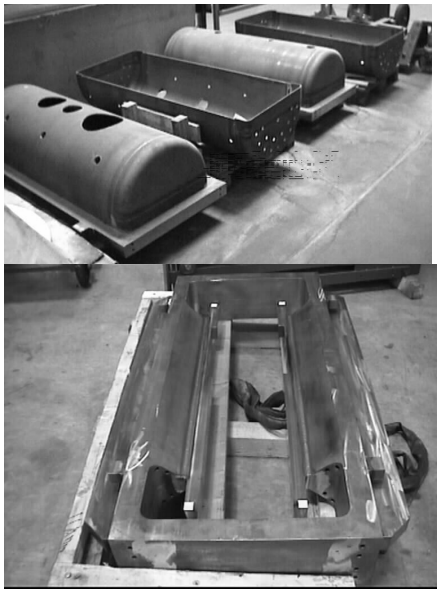

Figure 3: Half shells and center frame of the IH-structure before the final assembly at the company NTG.

2.5 The 7-gap resonators

The high energy section of the REX-ISOLDE LINAC consists of three 7-gap resonators each with a single resonance structure. It consists of a copper half shell to which three copper arms are attached on each side. Each arm consists of two hollow profiles, surrounding the drift tubes and carrying the cooling water. Copper segments on both sides allow to tune the resonator to the required frequency. The optimization of all model resonators is finished. The resonators will achieve the design voltage of 1.75 MV at 90 kW incoupled rf-power.

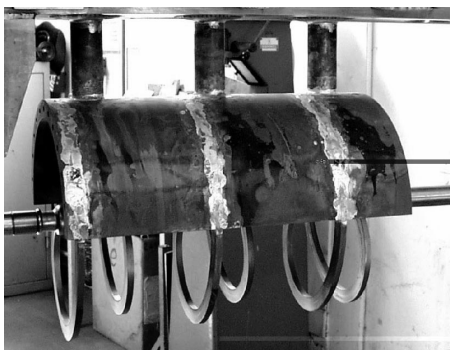

Figure 4: Resonance structure of the 5.4% power resonator directly after brazing of the arms into the half shell.

All components of the power resonators (tank, half shells, arms and drift tubes) are in production (fig.4) or already finished. The first half shell (5.4% resonator) is brazed and will be assembled into the tank after cleaning and polishing of the surface. After the tuning to the right frequency the resonator will be ready for vacuum, power and beam tests. The production of the resonators are well within the time schedule, expecting the first accelerated beam in 1999.

3 TEST BEAM LINE

In order to test the RFQ as the first acceleration stage, an injection system as well as an ion source are required. Therefore a duoplasmatron ion source has been borrowed from the university of Frankfurt. For the present geometry the calculated current of 1^+ He-ions is about 38 μA assuming 20 kV extraction voltage. This current will be reduced by collimators and slits down to 1 μA in order to reduce the emittance to the EBIS emittance. For beam diagnostic the prototype of a diagnostic box for REX-ISOLDE developed at KU Leuven will be used. In order to get the right beam slope in both transverse directions for the injection into the RFQ the electrostatic quadrupole quadruplet of the mass separator will be used. In the first stage the beam leaving the RFQ will be examined. Later the matching section will be included and the buncher will be tested with the He-beam as well.

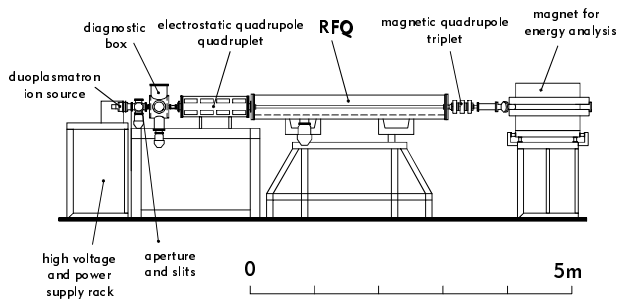

Figure 5: Lay-out of REX-ISOLDE test beam line for beam analysis of the RFQ beam

Abstract

The technical challenge for making two-beam accelerators into realizable power sources for high-energy colliders lie in the creation of the drive beam and in its propagation over long distances through multiple extraction sections. This year we have constructed a 1.2-kA, 1-MeV, electron induction injector for the RTA accelerator. The electron source will be a 8.9 cm diameter, thermionic, flat-surface cathode with a maximum shroud field stress of approximately 165 kV/cm. The injector's pulse length should be over 120-ns flat top (1% energy variation) with a normalized edge emittance of less than 300 π-mm-mr. Details of the design and performance of the injector, beam line, and diagnostics will be presented.

1 INTRODUCTION

Induction accelerators are a unique source for high-current, high-brightness, electron beams. A collaboration between the Lawrence Livermore National Laboratory (LLNL) and Lawrence Berkeley National Laboratory (LBNL) has been studying rf power sources based on the Relativistic Klystron Two-Beam Accelerator (RK-TBA) concept for several years [1, 2]. Demanding beam parameters are required of the electron source, an induction injector, to achieve the transport goals. A test facility, called the RTA, has been established at LBNL [3] to verify the analysis used in the design study. The primary effort of the facility is the construction of a prototype RK-TBA subunit that will permit the study of technical issues, system efficiencies, and costing. In this paper, we will discuss the development of the RTA electron source and it's pulsed power system, which has recently been constructed and is now undergoing testing. Figure 1 is a photograph of the gun undergoing initial tests. Beam tests will be performed this fall.

2 RTA GUN

A major part of our effort during the past year has been towards the design of a low emittance electron source for RTA accelerator. We expect to produce an electron source with a much lower emittance than typical induction guns. The electron source will be a 8.9-cm-diameter, thermionic, flat-surface M-type cathode with a maximum shroud field stress of approximately 165 kV/cm. An emission density of 20 A/cm^2 is required from the cathode to produce a 1.2 kA beam.

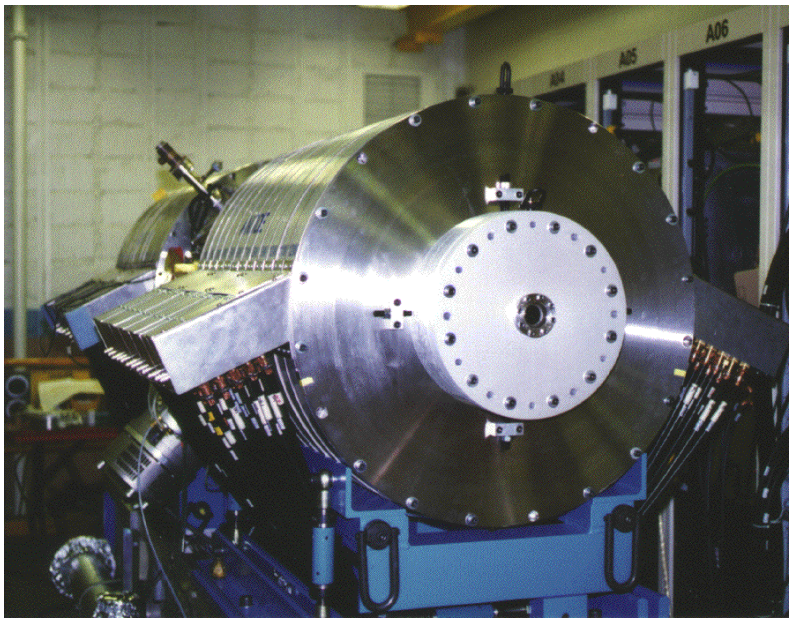

Figure 1. RTA Gun during pulsed power test.

The RTA gun has 72 induction cores, each driven at 14 kV. The voltage from the cores are summed across the A-K gap to produce 1 MV. The cells are segmented radially to reduce the individual aspect ($\Delta r/\Delta z$) ratio of the cores. The lower aspect ratio reduces the variation in core impedance during the voltage pulse simplifying the pulse forming network (PFN) design.

We have done high-voltage tests on the gun. In operation a 500 kV potential is developed across each of the two 30-cm-ID PYREX insulators producing a 5.1 kV/cm average gradient along the insulator. The maximum fields at the triple points, the intersection of insulator, vacuum, and metal, is less than 3.5 kV/cm. Maximum surface field in the cathode stalk of the gun is about 85 kV/cm. The maximum field is about 116 kV/cm on the anode stalk.

Initial beam focusing in the gun is accomplished by large-bore air-core solenoids installed on the central pumping spool. The first solenoid is operated to null the magnetic field from the other solenoids at the cathode front surface. With a flat cathode a high dB/dz is needed to prevent the beam from hitting the anode surfaces. The magnetic field at a distance of 20 cm from the cathode is about 650 gauss. There are seven smaller solenoids located within the anode stalk to provide additional focusing to transport the beam to the end of the gun.

2.1 Pulsed Power System for the RTA Gun

The pulsed power system for the gun consists of a 20-kV High-Voltage Power Supply, 6-kJ Energy Storage Bank, two Command Resonant Charging (CRC) Chassis, 24 Switched Pulse Forming Networks, and four Induction Core Reset Pulsers. Each PFN will drive a single 3-core induction cell of the gun.

Segmenting the core in the induction cell and driving the individual core segments avoids a high-voltage step-up transformer. This reduces the developmental effort needed to achieve a "good" flattop pulse (minimal energy variation) with fast risetime and improves the efficiency of the overall pulsed power system. Our system of low-voltage PFNs driving multiple core induction cells is similar to the system envisioned for the full scale RK-TBA design. For the gun core material we choose 20-μm-thick 2605SC METGLAS. In the RTA main extraction section we will use a lower loss 2714AS METGLAS for the induction cores.

Design of the switched PFNs follows easily from published METGLAS core loss data [4]. For the RTA induction cells, a flux swing of 2.6 T in 400 ns (FWHM) results in a magnetization rate of 6.5 T/μs. At this rate, a loss density of 1800 J/m^3 translates into 30 J lost in a cell with $16.7x10^3$ cm^3 of 2605SC METGLAS. For a cell input voltage of 14 kV applied for 400 ns, these losses require that 5900 A be supplied to the three radial cores. An additional 3600 A is required to supply beam current (1200 A x 3 cores/cell), resulting is a total current of 9 kA. The required drive impedance for a cell is then 1.5 Ω, which is provided by the PFN module.

An area of concern was the variation of the energy loss for different METGLAS cores. Experience [5] with the 72 cores in the gun leads us to believe that for a large RK-TBA, matching cell cores should permit acceptable energy loss variation.

2.1 Gun Voltage Waveform

Achieving the fast risetime necessary to minimize the volt-seconds required for the injector cores presented a challenge. Budget constraints coupled with the large availability of EEV CX1538 thyratrons from the ATA program at LLNL made these tubes an attractive option. However, their poor time rate of current change (4 kA/μs rating) made them questionable for this application, which requires about 40 kA/μs. A variety of techniques were tried to decrease the risetime. In a 1.5 Ω system, stray circuit inductances must be maintained at or below 100 nH to achieve a 10-90% risetime of 150 ns. This was accomplished by placing the thyratron between two current sheets connecting the PFN output to the output cables. The ionization time of the thyratron was substantially reduced by applying a 1-2 A pre-pulse to the keep-alive grid 300-400 ns prior to the arrival of the main control-grid pulse. Faster risetimes were achieved with Triton F-130 ceramic thyratrons. An upgrade of the current thyratrons in the gun pulsed power system should allow us to achieve the design 100-ns risetime.

At the 1-MV, 1.2-kA operating conditions we hope to produce a ±1% gun voltage flat waveform for 120 ns. We will need to adjust the number of turns in appropriate sections of individual PFNs to achieve this goal. Insertion of ferrite material in the center of the inductors coils will allow additional small corrections to the waveform.

2.3 Diagnostics for the RTA Gun

A variety of diagnostics [6] will be used to determine the performance of the gun, both permanently installed monitors for general operations and temporary diagnostics specific to the injector commissioning and troubleshooting. Planned diagnostics include an isolated cathode with resistive divider for direct measurement of current emission, resistive-wall and magnetic probe current monitors for measuring beam current and centroid position, capacitive probes for measuring A-K gap voltage, an energy spectrometer, and a pepper-pot emittance diagnostic.

The majority of the diagnostics will be installed after the gun. The first 1.4 m of beam line after the gun will

include two beam position and current monitors to allow the offset and angle of the beam at the exit of the injector to be measured. A pop-in probe will be incorporated in a pumping port to allow the beam profile to be viewed.

The current density profile will be measured using Cherenkov and/or optical transition radiation from intercepting foils. A primary concern with using foils is possible damage from beam energy deposition. Average heating of the foil can be controlled by adjusting the repetition rate of the injector. The difficulty is the single shot heating where material can be melted and ejected before the heat is conducted away. As an example, to avoid damage for a thin quartz foil, the beam diameter must be larger than 2 cm for a 1-kA, 300-ns, relativistic electron beam. The significant levels of energy deposited in the foil could affect the dielectric constant or generate a surface plasma that could be confused as a variation in beam parameters.

Three different methods may be used to determine the A-K voltage and beam energy. The first method involves measuring the applied voltage to the induction cores at the connection of the power feeds to the induction cells. Capacitive dV/dt pickup probes [6] are used for a more direct measurement of the A-K gap voltage and also to provide greater bandwidth with respect to the resistive dividers. We also hope to employ a conventional energy spectrometer comprised of an on-axis collimator, dipole magnet, scintillator, and viewing port to directly measure the beam energy.

2.4 Emittance measurement for the gun

We plan to use a pepperpot emittance diagnostic to help characterize the beam. Measuring the beam emittance is expected to be very difficult as the beam is highly space charged dominated. Our aperture plate will consist of a rectangular pattern of 121 (11x11) 250-μm apertures with 7 mm spacing on a 500-μm thick tungsten plate. The emittance term that is responsible for spot size growth of the beamlets after the aperture plate is approximately an order of magnitude larger than the space charge term.

Another serious problem concerns the effect of the conductive aperture plate on the beam. It has been demonstrated [7] that, while the local distribution in phase space can be determined, the global x–x' curve is dominated by the non-linear focusing of the aperture plate. EGUN simulations performed for our beam parameters indicate that the beam emittance determined from the pepperpot data will be as much as six times the actual emittance in the absence of the aperture plate. This effect can be accounted for in the analysis. However, the accuracy in the final emittance value will suffer.

3 ACCELERATOR SECTION DESIGN

Design of the full-scale RK-TBA system has an accelerator section after the gun that raises the beam energy from 1 MeV to 2.5 MeV before starting to bunch the beam at 11.4 GHz. In the full-scale RK-TBA system we expect to use a pulse power system similar to that demonstrated in the gun system for this section. The accelerator cells will be segmented to reduce the required drive. However, to reduce RTA's cost we are planning on using a 120-kV MARX spark-gap pulsed power system to drive 16 unsegmented accelerator cells in this section of RTA. The design is not acceptable for the full-scale machine because of the high gap erosion rates. The spark-gap system can provide a faster risetime than the thyratron system which will reduce the required cross sectional area of the induction cores. The volt-second rating of the accelerator cores (operated at 120 kV) will limit the flat top of the beam pulse in the RTA. Installation of additional cells (future upgrade), and operating all the cells at a lower voltage, will increase the useful duration of the current pulse. We also plan to test a High-Gradient Insulator [8] in the first of these accelerator cells. If successful we would like to construct the 16 cells for RTA accelerator section using High-Gradient Insulators.

4 ACKNOWLEDGEMENTS

The work was performed under the auspices of the U.S. Department of Energy by LLNL under contract W-7405-ENG-48, and by LBNL under contract AC03-76SF00098. We thank Andy Sessler and Swapan Chattopadhyay for their support and guidance and thank Wayne Greenway, William Strelo, Bob Benjegerdes and Bob Candelario for their excellent technical support

ACHROMAT WITH LINEAR SPACE CHARGE FOR BUNCHED BEAMS

D. Raparia, J.G. Alessi, Y. Y. Lee and W. T. Weng
Brookhaven National Laboratory
Upton, NY 11973, USA

Abstract

The standard definition for an achromat is a transport line having zero values for the spatial dispersion (R16) and the angular dispersion (R26). For a bunched beam with linear space charge this definition of achromaticity does not hold. The linear space charge in the presence of a bend provides coupling between (a) bunch spatial width and bunch length (R15) and (b) bunch angular spread and bunch length (R25). Therefore, achromaticity should be redefined as a line having zero values of the spatial dispersion (R16), the angular dispersion (R26), and matrix elements R15 & R25. These additional conditions (R15=R25=0) can be achieved, for example, with two small RF cavities at appropriate locations in the achromat, to cancel space charge effects. An example of the application of this technique to the Spallation Neutron Source (SNS) high energy beam transport line will be presented.

1 INTRODUCTION

A transport line is said to be achromatic if spatial & angular widths of the beam are independent of its momentum spread. In other words, the spatial dispersion (R16) and the angular dispersion (R26) have zero values. The spatial & angular widths are also independent of the bunch length in absence of linear space charge. The beam ellipse is upright in the x-z plane. A property of an achromatic bend is that the total phase advance should be $n\pi (n = 1, 2 \cdots)$ if all dipoles in achromat bend the beam in the same direction, or $2n\pi$ if some of the dipoles in achromat bend the beam in the opposite direction. In the presence of linear space charge the transport line no longer remains achromatic for two reasons. (1) The total phase advance is no longer $n\pi$ or $2n\pi$ due to tune depression. The total phase advance can be changed back to $n\pi$ or $2n\pi$ by readjusting quadrupoles in achromat. (2) When beam passes through the bend it is no longer upright in x-z plane because space charge provides coupling between (a) bunch spatial width and bunch length (R15) and (b) bunch angular width and bunch length (R25). The beam ellipse can be made upright in x-z plane by introducing two rf cavities in the achromat.

2 ACHROMAT WITH LINEAR SPACE CHARGE FOR BUNCHED BEAM

2.1 Linear Space Charge for Bunched Beams

Following the formulism of TRACE3D [1], the electric field components due to a uniformly charged ellipsoid are given by [2]

$$E_x = \frac{1}{4\pi\epsilon_0}\frac{3I\lambda}{c\gamma^2}\frac{(1-f)}{r_x(r_x+r_y)r_z}x,$$

$$E_y = \frac{1}{4\pi\epsilon_0}\frac{3I\lambda}{c\gamma^2}\frac{(1-f)}{r_y(r_x+r_y)r_z}y,$$

$$E_z = \frac{1}{4\pi\epsilon_0}\frac{3I\lambda}{c}\frac{f}{r_x r_y r_z}z,$$

where r_x, r_y and r_z are the semi-axes of a ellipsoid, I is the average electrical current over one RF period, λ is the free-space wavelength of the RF, c is the velocity of light, and ϵ_0 is the permittivity of the free space. The form factor f is a function of $p \equiv \frac{\gamma r_z}{\sqrt{r_x r_y}}$ given by

$$f(p) = \begin{cases} \frac{1}{1-p^2} - \frac{p}{(1-p)^{3/2}}\cos^{-1}p & \text{if } p < 1 \\ \frac{p\cosh^{-1}p}{(p^2-1)^{3/2}} - \frac{1}{(p^2-1)} & \text{if } p > 1 \\ \frac{1}{3} & \text{if } p = 1 \end{cases}$$

where $\cosh^{-1}p = \ln\left(p + \sqrt{p^2-1}\right)$.

The space charge is applied in the kick approximation as a change in the normalized momentum components as the beam traverses Δs, and is given by

$$\Delta(\beta\gamma)_u = \frac{qE_u\Delta s}{m_0c^2\beta}$$

where u represents x, y, or z. This kick formulation is correct as long as the ellipsoid is upright in local x-y, y-z, and z-x planes. When beam traverses the bend the ellipsoid is tilted in the local x-z plane. To calculate the space charge kick first one has to transform to the coordinate system in which the ellipsoid is upright. The ellipsoid is transformed back to the local coordinate system after applying the space charge kick. The transfer matrix for the space-charge kick is

$$R_S = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ \frac{qE_x\Delta s}{m_0c^2\beta} & 1 & 0 & 0 & 0 & \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & \frac{qE_y\Delta s}{m_0c^2\beta} & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & \frac{qE_z\Delta s}{m_0c^2\beta} & 1 \end{pmatrix}.$$

2.2 *Coupling Between Bunch Length and Bunch Spatial & Angular Widths*

This coupling is induced by linear space charge, which can be shown as follows. The transfer matrix of a bending magnet for bend angle α and length L is

$$R[xx]_B = \begin{pmatrix} \cos(k_x L) & \frac{1}{k_x}\sin(k_x L) \\ -k_x \sin(k_x L) & \cos(k_x L) \end{pmatrix}$$

$$R[xz]_B = \begin{pmatrix} 0 & \frac{h(1-\cos(k_x L))}{k_x^2} \\ 0 & \frac{h\sin(k_x L)}{k_x} \end{pmatrix}$$

$$R[yy]_B = \begin{pmatrix} \cos(k_y L) & \frac{1}{k_y}\sin(k_y L) \\ -k_y \sin(k_y L) & \cos(k_y L) \end{pmatrix}$$

$$R[zx]_B = \begin{pmatrix} \frac{-h\sin(k_x L)}{k_x} & \frac{-h(1-\cos(k_x L))}{k_x^2} \\ 0 & 0 \end{pmatrix}$$

$$R[zz]_B = \begin{pmatrix} 1 & \frac{-1}{\rho^2 k_x^3}(k_x L\beta^2 - \sin(k_x L)) \\ & +\frac{L}{\gamma^2}(1 - \frac{1}{\rho^2 k_x^2}) \\ 0 & 1 \end{pmatrix}$$

$$R[xy]_B = R[yx]_B = R[yz]_B = R[zy]_B = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

where

$$h = \frac{1}{|\rho|}\frac{\alpha}{|\alpha|}$$

$$k_x = \sqrt{(1-n)h^2}$$

$$k_y = \sqrt{nh^2}$$

$$L = |\rho|\,\alpha$$

$$\rho = \frac{m_0 c\beta\gamma}{qB_y}$$

$$n = -\left(\frac{\rho}{B_y}\frac{\partial B_y}{\partial x}\right)_{x=0,y=0}$$

When space-charge is included in the calculation for the bending magnet in the kick approximation, the two matrices R_S and R_B are multiplied, and the resultant matrix R_{SB} will have $R_{SB}15$ and $R_{SB}25$ non-zero and given by

$$R_{SB}15 = R_B16 * R_S65 = \frac{h(1-\cos(k_x L))}{k_x^2} \times \frac{qE_z L}{m_0 c^2 \beta}$$

$$R_{SB}25 = R_B26 * R_S65 = \frac{h\sin(k_x)L}{k_x} \times \frac{qE_z L}{m_0 c^2 \beta}.$$

Even after applying the usual conditions for an achromat, R16=R26=0, the system is not achromatic. To completely remove coupling between x-x' and z-z' planes, not only the determinant of sub-matrix R[xz] has to be zero, but all of its elements have to be zero. If any element of this sub-matrix is non-zero, it means that beam is not upright in the x-z plane. The coupling provided by the space charge will effectively produce dispersion (R16), angular dispersion (R26) and non-zero matrix elements R15 & R25. The beam ellipse can be made upright in x-z plane by introducing two rf cavities in the achromat.

3 EXAMPLE

As shown, all four elements of the R[xz] sub-matrix should have zero values for a transport line to be achromatic. We will use as an example proposed Spallation Neutron Source (SNS) high energy transport line [3]. This transport line is about 180 meters long and has an achromat which is six cells long, with a total phase advance of 360 degrees. The layout of HEBT is shown in Figure 1, and the corresponding amplitude and dispersion functions are shown in Figure 2.

The transfer matrix of the achromat in the HEBT for the zero current (using TRACE3D) is

$$R_{acro} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1.305 & 0 & 0 \\ 0 & 0 & 0.01778 & 0.98846 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 14.15989 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

with the following units

$$\begin{pmatrix} 1 & m & 1 & m & 1 & m \\ m^{-1} & 1 & m^{-1} & 1 & m^{-1} & 1 \\ 1 & m & 1 & m & 1 & m \\ m^{-1} & 1 & m^{-1} & 1 & m^{-1} & 1 \\ 1 & m & 1 & m & 1 & m \\ m^{-1} & 1 & m^{-1} & 1 & m^{-1} & 1 \end{pmatrix}$$

The R[xz] sub-matrix of the achromat plus the following two cells, for zero current, is

$$R[xz]_{acro+2c} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

The R[xz] sub-matrix for the achromat, with 28 mA current, is

$$R[xz]_{acro} = \begin{pmatrix} 0.133349 & -0.18495 \\ 0.00469 & 0.8130 \end{pmatrix}$$

Now one can apply the conditions R16 = R26 = 0, by adjusting two families of quadrupoles in the achromat, and the resultant R[xz] sub-matrix of the achromat is

$$R[xz]_{acro} = \begin{pmatrix} 0.14278 & 0 \\ 0.00339 & 0 \end{pmatrix}$$

The R[xz] sub-matrix of the achromat plus the following two cells, for the 28 mA, is then

$$R[xz]_{acro+2c} = \begin{pmatrix} -0.00608 & -0.68454 \\ -0.01605 & 0.01919 \end{pmatrix}$$

This shows the condition R16 = R26 = 0, will not yield a achromatic system if one includes space charge. Figure 3 shows the space charge induced dispersion at end of the SNS achromat as function of half bunch length at beginning of the HEBT.

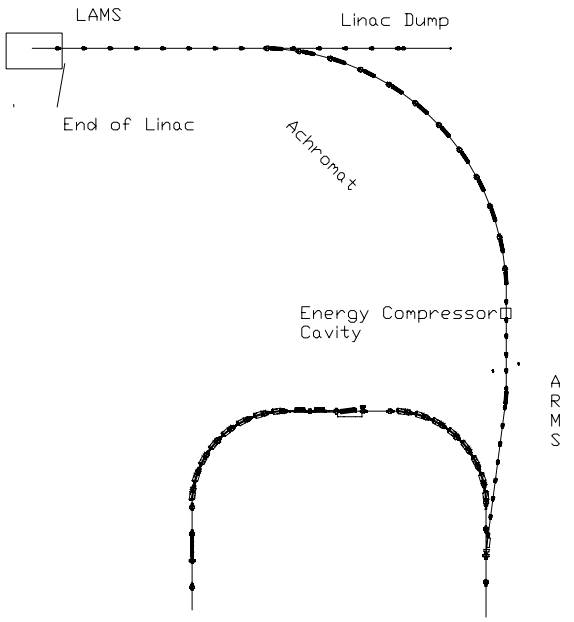

Figure 1: Layout of the SNS HEBT line.

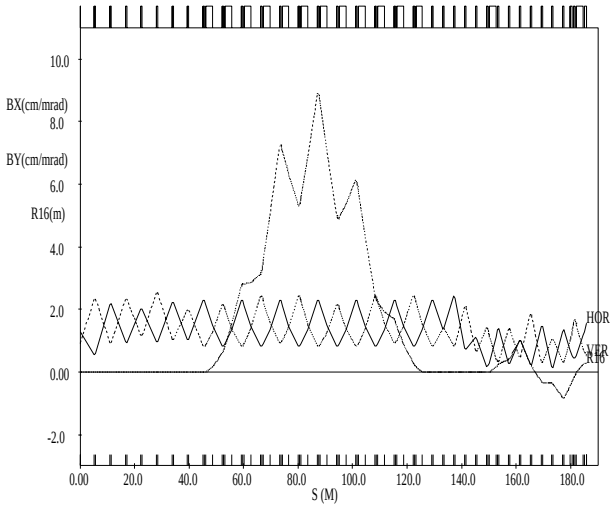

Figure 2: TRANSPORT output for the amplitude (β) functions and dispersion function (η) along the SNS HEBT.

Next, one can apply the conditions R16 = R26 = R15 = R25 = 0 (instead of R16 = R26 = 0) by adjusting the two families of quadrupoles in the achromat, and adding two small 1 meter RF cavities in the 2nd and 5th cells of the achromat set at appropriate voltages. One can then get the following R[xz] sub-matrix, similar to the zero current case.

$$R[xz]_{acro} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

For this case, however, the R[xz] sub-matrix for the achromat plus the following two cells, for 28 mA, is

$$R[xz]_{acro+2c} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

Therefore, for bunched beams achromaticity should be redefined as a line having zero values of matrix elements R15, R25, R16 and R26. The additional condition can be achieved with two small rf cavities.

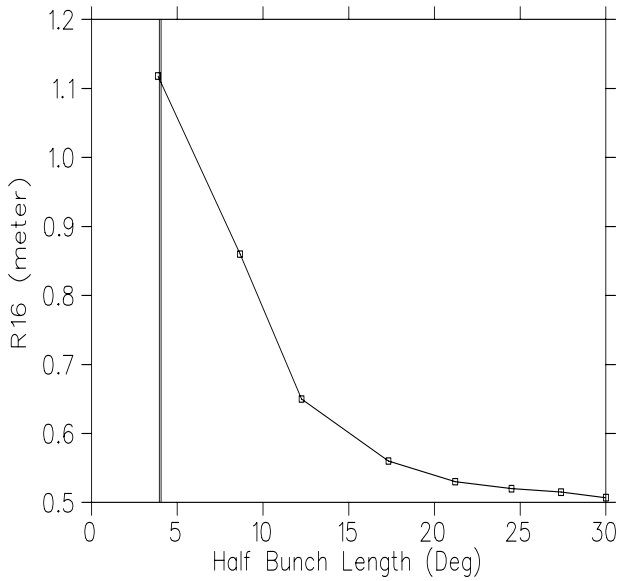

Figure 3: Space-charge induced dispersion (R16) at the end of the SNS achromat as a function of bunch length at the beginning of HEBT. Vertical line shows the design bunch length.

A POSSIBLE PARTICLE-CORE APPROACH TO MISMATCHED BEAMS IN A PERIODIC FOCUSING CHANNEL

M. Ikegami and M. Mizumoto
Proton Accelerator Laboratory, Japan Atomic Energy Research Institute
Tokai-mura, Naka-gun, Ibaraki-ken, 319-1195 JAPAN

Abstract

A method is derived for applying the particle-core analysis to mismatched beams in a periodic focusing channel. By carefully choosing the parameters to yield a favorable core frequency, Poincaré surface of section plots are obtained. The plots for a periodic solenoid channel exhibit a striking resemblance with the continuous focusing case, while those for an FODO channel exhibit strong chaosity which is not seen in the corresponding continuous situation. Some typical numerical results and a way to find adequate parameters are presented.

1 INTRODUCTION

In recent years, halo formation in intense ion beams has been extensively studied in both theoretical and numerical ways. In these studies, the so-called *particle-core model* [1] has been frequently used. In this model, we usually consider a beam propagating in a continuous focusing channel and assume that its core has the Kapchinskij-Vladimirskij (KV) distribution. In the macro-particle simulation studies of the continuously focused beams, features such as the separatrix and fixed point locations are found to be in good agreement with those obtained with the particle-core model [2].

The halo properties in periodically focused cases have also been studied self-consistently, and a close resemblance to the continuous focusing cases is found for a periodic solenoid channel unless instabilities due to structure-driven resonances occur [3]. Though the role of the particle-core resonance in periodic focusing situations can be directly investigated by applying the particle-core model, it has never been done in mismatched cases mainly due to the difficulty in finding the fundamental frequency of the system. In the particle-core model, Poincarémapping technique is an essential tool to examine the stability properties of test particles, but we need to know the fundamental frequency of the system to use this technique. It is generally difficult to know the fundamental frequency in periodic focusing cases because there are two sources of periodicity, namely; the external focusing field periodicity and that due to initial beam-size mismatch. As the envelope is known to be stable with a reasonable choice of parameters, we try to obtain the fundamental core frequency restricting our interest to the cases where core oscillation is stable.

2 PERIODIC SOLENOID CHANNEL

Assuming the axial symmetry of the focusing channel, the time evolution of the beam envelope is governed by the envelope equation,

$$\frac{d^2 R_b}{ds^2} + \kappa(s) R_b - \frac{K}{R_b} - \frac{\varepsilon^2}{R_b^3} = 0, \qquad (1)$$

where R_b is the beam radius, $\kappa(s)$ is the periodic function representing the external focusing field strength, K is the generalized perveance, ε is the rms emittance of the beam, and independent variable s is the distance measured along the beam line. Then, in terms of dimensionless variables, Eq. (1) becomes

$$\frac{d^2 R}{d\tau^2} + \vartheta(\tau) R - \frac{\Gamma}{R} - \frac{1}{R^3} = 0, \qquad (2)$$

where $\tau = s/S$ is taken as the independ variable with S being the focusing period. The function $\vartheta(\tau)$ is related to the zero-current phase advance σ_0, and Γ is related to the tune depression η, namely, the ratio of the space-charge depressed phase advance to the zero-current phase advance. The matched solution R_0 of Eq. (2) can be obtained with the help of an optimization code. For later reference, we here introduce a mismatch factor defined as

$$M = \left[R(0) - R_0(0)\right] / R_0(0). \qquad (3)$$

It should be noted that $R_0(0)$ corresponds to the maximum of the matched beam radius since the origin of the coordinate τ is located at the center of a focusing solenoid. With use of the smooth-approximation, Eq. (2) can be written as

$$\frac{d^2 R_s}{d\tau^2} + {\sigma_0}^2 R_s - \frac{\Gamma}{R_s} - \frac{1}{R_s^3} = 0, \qquad (4)$$

where R_s is the scaled beam radius in the approximation. In weakly mismatched cases, the phase advance of the breathing mode oscillation of the envelope can be approximated by

$$\sigma_m = \sqrt{2\left(1+\eta^2\right) + \frac{1}{2}\left(1+9\eta^2\right) M^2}\,\sigma_0, \qquad (5)$$

where we use a combination of a simple perturbation method and an averaging method.

We here assume that the oscillation of the core can be approximated by a simple composition of two oscillation modes, namely; one is excited by the initial beam-size mismatch (*mismatch mode*) and the other is excited by the periodic nature of a focusing structure (*structure mode*). Based on the smooth-approximation analysis above, the phase advance of the mismatch mode is expected to be σ_m. On the other hand, the fundamental period of the structure mode is apparently synchronized with the focusing structure. Thus, it is obvious that if $\sigma_m/2\pi$ is a rational number *n/m*, the mismatched envelope is exactly periodic in τ with the period of *m* times a focusing period. In such cases, we can easily obtain a Poincaré surface of section plot by plotting test particle location every *m* focusing periods. That is our strategy to apply the particle-core method to mismatched beams in a periodic channel.

Finally, we write down the equation of motion for a test particle. Assuming that the core has a KV distribution and test particles have no augular momentum, the equation of motion in terms of the dimensionless variables is given by

$$\frac{d^2x}{d\tau^2} + \vartheta(\tau)x - \frac{\Gamma}{R^2}x = 0 \quad (|x| \le R), \tag{6a}$$

and

$$\frac{d^2x}{d\tau^2} + \vartheta(\tau)x - \frac{\Gamma}{x} = 0 \qquad (|x| > R). \tag{6b}$$

Figure 1 shows an example in which we consider a periodic solenoid channel having σ_0=45° and a 50% filling factor, and the beam parameters are set to be η=0.5 and M=0.3. These parameters are determined to yield σ_m=360/5=72° by Eq. (5) with the help of an optimization code. As shown in Fig. 1, the fundamental period of the core oscillation coincide with five focusing periods with a very good accuracy. We can also see in Fig. 1 that the core oscillation is almost dominated by the mismatch mode, and the contribution from the structure mode is fairly small. Plotting the single particle position every five focusing periods, we successfully obtain a Poincaré surface of section shown in Fig. 2, which exhibits a striking resemblance with continuous focusing cases.

3 FODO CHANNEL

The same method is also applicable to the beams in channels without an axial symmetry such as FODO channels. Assuming that the zero-current phase advance and emittance are the same in the horizontal and vertical directions, the envelope equations are given in terms of dimensionless variables as

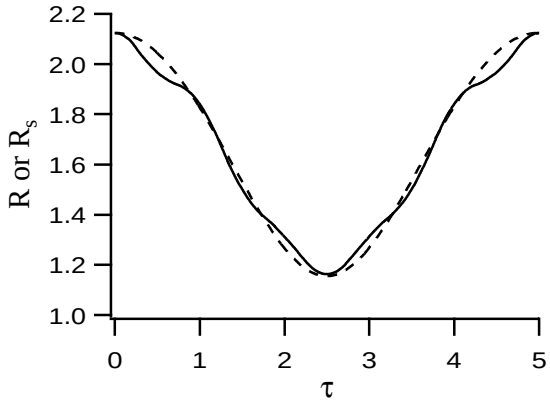

Figure 1: Time-evolution of the beam envelope in a periodic solenoid channel. Solid line: periodic solenoid channel. Broken line: smooth-approximation.

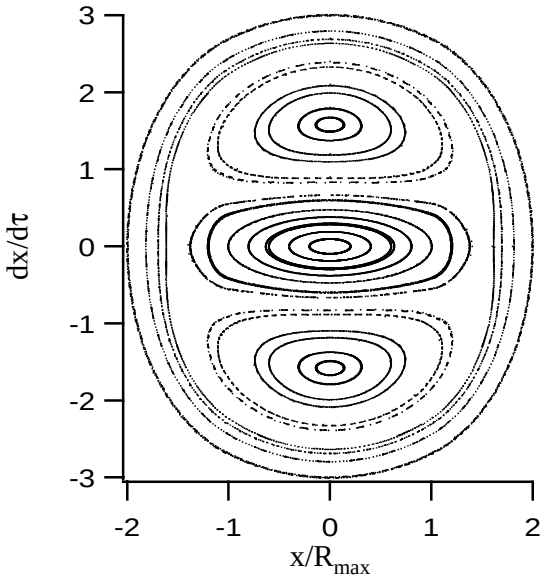

Figure 2: Poincaré surface of section plot for a periodic solenoid channel. The same parameters with Fig. 1 are employed.

$$\frac{d^2X}{d\tau^2} + \vartheta(\tau)X - \frac{2\Gamma}{X+Y} - \frac{1}{X^3} = 0, \tag{7a}$$

and

$$\frac{d^2Y}{d\tau^2} - \vartheta(\tau)Y - \frac{2\Gamma}{X+Y} - \frac{1}{Y^3} = 0, \tag{7b}$$

where X and Y are, respectively, the scaled beam half-width for the horizontal and vertical directions.

Note here that not only the breathing but also quadrupole mode oscillation can be excited in an FODO channel. For the quadrupole mode oscillation, the frequency of the mismatch mode is given by

$$\sigma_m = \sqrt{1+3\eta^2+5\eta^2 M^2}\,\sigma_0 . \qquad (8)$$

The equations of motion for a test particle initially located on the horizontal plane can be written [4] as

$$\frac{d^2x}{d\tau^2} + \vartheta(\tau)x - \frac{2\Gamma}{X(X+Y)}x = 0 , \qquad (|x| \le X) \text{ (9a)}$$

and

$$\frac{d^2x}{d\tau^2} + \vartheta(\tau)x - \frac{2\Gamma}{x^2 + |x|\sqrt{x^2+Y^2-X^2}}x = 0 . \ (|x| > X) \text{ (9b)}$$

First, we will consider the case where the breathing mode oscillation of the core is excited. Figure 3 shows an example in which we consider an FODO channel having σ_0=45° and a 50% filling factor, and the beam parameters are set to be η=0.5, and M=0.3. We can see in Fig. 3 that the modulation of the core oscillation due to the periodic nature of the focusing field is much larger than in periodic solenoid cases. A Poincaré surface of section plot is obtained as shown in Fig. 4.

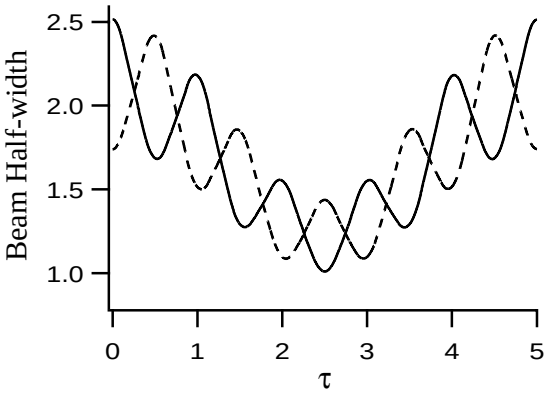

Figure 3: Time-evolution of the beam envelope in an FODO channel (breathing oscillation case). Solid line: horizonral half-width. Broken line: vertical half-width.

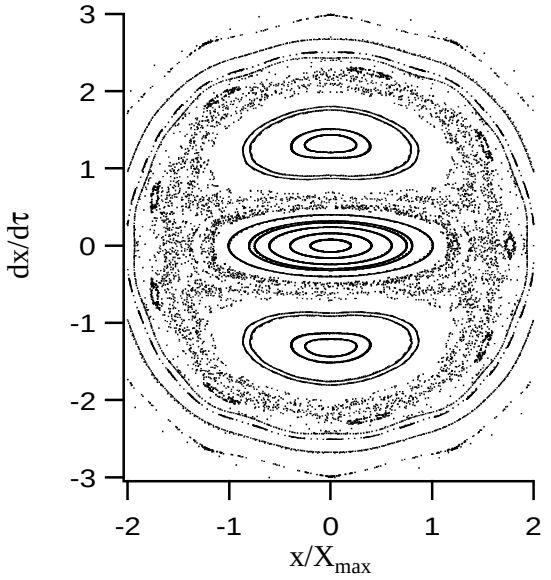

Figure 4: Poincaré surface of section plot for an FODO channel (breathing oscillation case). The same parameters with Fig. 3 are employed.

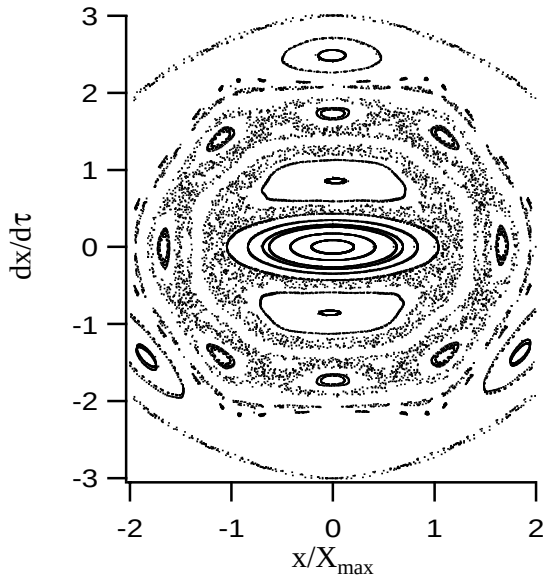

Figure 5: Poincaré surface of section plot for an FODO channel (quadrupole oscillation case).

Second, we consider the case where the quadrupole mode oscillation is excited. Figure 5 shows the Poincaré plot for a core executing the quadrupole mode oscillation. An FODO channel having σ_0=52° and a 50% filling factor is considered, and the beam parameters are set to be η=0.5, and M=0.3. These parameters are determined again to yield σ_m=72°.

Both pictures show strong chaosity which is not observed in solenoid cases. It suggests that the strong modulation of the core oscillation due to an alternating-gradient focusing field affects test particle stability, and causes an increase of the halo intensity.

4 ACKNOWLEDGEMENTS

We thank Dr. R. A. Jameson and Dr. S. Machida for helpful discussions on several points in this paper.

HALO FORMATION BY MISMATCH FOR HIGH INTENSITY BUNCHED BEAMS

K. Bongardt, M. Pabst, FZJ, Jülich, Germany
A. Letchford, RAL, Didcot, U.K.

Abstract

In high intensity proton linacs even small particle loss causes activation of the accelerator components [1]. Minimizing the losses is therefore a major task of the beam dynamical design. Losses are strongly correlated to the formation of a halo around the beam core. Monte Carlo simulations are presented for bunched beam transfer lines with varying tune depressions and equipartitioning ratios showing halo formation by mismatch due to parametric resonance excitation. For large tune depressions and/or quite unequal transverse and longitudinal temperatures substantial halo formation even for a matched beam occurs due to temperature exchange and/or exciting a higher order mode instability. An envelope instability can be excited in addition. A conservative criteria is presented for identifying parameters for reduced halo formation due to mismatch.

1 INTRODUCTION

In recent years substantial progress has been achieved by identifying the parametric resonance conditions as a major source of halo production in DC and bunched beams [2]. For realistic particle distributions with nonlinear space charge forces particles inside the core have a tune spread. Parametric resonances can occur between single particle tunes and the frequency of the oscillating mismatched beam core.

In this presentation the one dimensional parametric resonance model is generalized to bunched beams. Due to one longitudinal and the two transverse bunch dimensions, 3 eigenmodes exist for the mismatched envelopes.

The three eigenmodes of bunched beams are described in section 2. Correlation between enhanced halo production due to mismatch and parametric resonances are verified by Monte Carlo simulation in section 3. In section 4, halo production even for a matched beam due to the excitation of an envelope or higher order mode instability or as a result of temperature exchange is demonstrated. A conservative criteria is presented for identifying parameters for reduced transverse and longitudinal halo formation due to mismatch.

2 THE THREE ENVELOPE MODES OF MISMATCHED BUNCHED BEAMS

For the analytical approximation of the eigenfrequencies (modes) of the mismatched envelopes it is assumed that the beam is of ellipsoidal shape with uniform charge density giving linear space charge forces. In the rest frame of the bunch, the bunch radii are denoted by a_x, a_y and a_z. The bunch length b in the laboratory system is given by $b = a_z/\gamma$, where γ is the relativistic mass factor. The external forces for are assumed to be linear and periodic in the longitudinal direction s with period length L. The envelope equations are given by

$$a_x'' + k_{xo}^2 a_x - \frac{IK_x}{a_y b} - \frac{\epsilon_t^2}{a_x^3} = 0,$$

$$a_y'' + k_{yo}^2 a_y - \frac{IK_y}{a_x b} - \frac{\epsilon_t^2}{a_y^3} = 0,$$

$$b'' + k_{zo}^2 b - \frac{IK_z}{a_x a_y} - \frac{\epsilon_z^2}{b^3} = 0.$$

Here k_{xo}, k_{yo} and k_{zo} are the external periodic force constants. K_x, K_y and K_z are proportional to the elliptical formfactors and depend on the bunch dimensions too. I is the bunch current and ϵ_t and ϵ_z are the transverse and longitudinal emittances. This system of nonlinear coupled differential equations exhibits oscillating stable or unstable solutions. 'Matched' solutions have the same periodicity as the external focusing system. The oscillation of small mismatched solutions can be characterized by three eigenfrequencies, a pure transverse **quadrupolar mode**

$$\sigma_{env,Q} = 2\sigma_t$$

and a **high** and **low mode** which couple the transverse and longitudinal directions

$$\sigma_{env,H}^2 = A + B,\ \sigma_{env,L}^2 = A - B$$

with

$$A = \sigma_{to}^2 + \sigma_t^2 + \frac{1}{2}\sigma_{lo}^2 + \frac{3}{2}\sigma_l^2$$

and

$$B = \sqrt{\left(\sigma_{to}^2 + \sigma_t^2 - \frac{1}{2}\sigma_{lo}^2 - \frac{3}{2}\sigma_l^2\right)^2 + \left(\sigma_{to}^2 - \sigma_t^2\right)\left(\sigma_{lo}^2 - \sigma_l^2\right)}.$$

The mismatch mode tunes are expressed by the full and zero current transverse and longitudinal tunes σ_t, σ_{to}, σ_l and σ_{lo}.

The high mode represents a 'breathing' of the ellipsoidal bunch [3]. For the low mode, the bunch breathes in the transverse direction, but the oscillation in the longitudinal direction is of opposite phase.

In Fig. 1, the optical elements and the three matched beam radii are shown for a bunched beam transportline corresponding to the first period at 70 MeV of the coupled cavity (CCL) of the proposed European Spallation Source (ESS). By varying the beam current, the transverse and longitudinal emittance and the quadrupole gradient, a range

of full and zero current tunes can be obtained. The radii shown in Fig. 1 correspond to the 214 mA ESS bunch current and 60^o transverse full current tune.

3 HALO FORMATION BY PARAMETRIC RESONANCE EXCITATION

It is important to do multiparticle calculations of the bunched beam transfer line and compare the results with the model as due to phase space filling the multiparticle simulations have nonlinear space charge forces included. However the rms quantities are mainly determined by the linear part of the space charge forces. Monte Carlo simulations are done with 20 000 particles which interact fully in 3d. A 6d waterbag distribution is used as input.

Due to the nonlinear space charge forces, particles have tunes which are distributed between the full current and zero current tune. Due to oscillation of the mismatched radii single particles can experience parametric resonances. The condition for exciting a parametric resonance either radially or longitudinally is given by

$$\frac{\sigma^p_{t,l}}{\sigma_{env}} = \frac{m}{n} = \frac{1}{2}, \frac{1}{3}, \ldots$$

with

$$\sigma_t \leq \sigma^p_t \leq \sigma_{to},$$
$$\sigma_l \leq \sigma^p_l \leq \sigma_{lo}$$

where σ_{env} is one of the three envelope tunes of the mismatched radii and $\sigma^p_{t,l}$ the single particle tune.

The low order resonances are the most dangerous ones. For the radial direction the 1/2 parametric resonance is always excited by the quadrupolar mode. The high or low mode can excite a parametric resonance either in the transverse or longitudinal direction. The frequency of the high mode should be limited below 180^o in order to avoid an envelope instability.

Figs 2 and 3 are the results of Monte Carlo simulations of the bunched beam transfer line in Fig. 1. Shown is the 99.9% total to rms emittance ratio in x-direction. The transverse and longitudinal rms emittances stay constant for a 20% initial mismatch. In Fig. 2 the matched case is compared to a 20% quadrupolar mode excitation. An increase of the 99.9% emittance is visible due to exciting the 1/2 parametric resonance. Fig. 3 compares the matched case with a 20% radially and 30% longitudinally excited high mode with a numerically determined mode frequency of 168^o. No halo formation due to mismatch is visible here as no single particles have a transverse tune of 84^o. The full current transverse design tune is 60^o.

4 STABILITY CRITERIA FOR HALO FORMATION DUE TO MISMATCH

Halo production due to mismatch gets complicated if the rms emittances are changing. Reasons for emittance

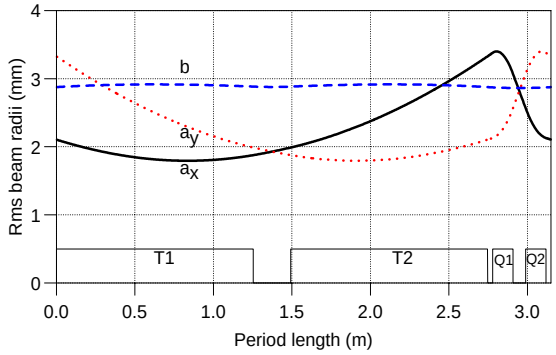

Figure 1: The matched beam radii along one period. T1, T2 bunching cavities, Q1, Q2 quadrupoles

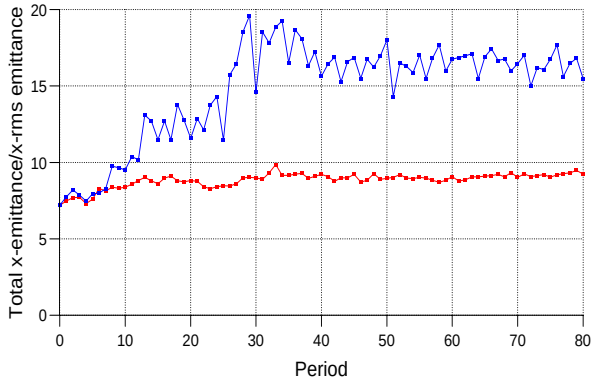

Figure 2: 99.9% total to rms emittance ratio for a matched (bottom) and a quadrupolar mode excited case (top)

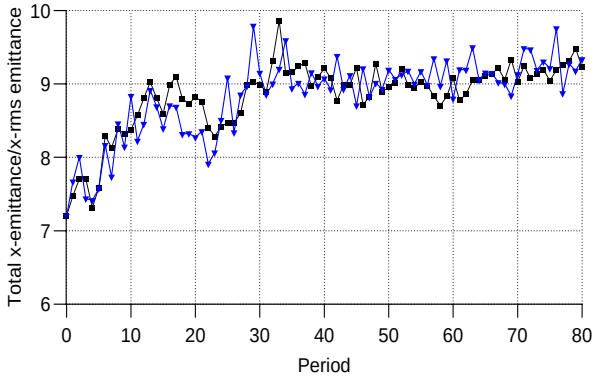

Figure 3: 99.9% total to rms emittance ratio for a matched (squared) and a high mode excited case (triangles)

change can be an envelope instability, temperature exchange or particle redistribution under high space charge forces. Substantial halo production even for a matched beam will occur in these cases.

4.1 High Mode Envelope Instability

The coupled set of bunched beam envelope equations with linear space charge forces can have unstable solutions due to the periodic external focusing. This is expected to hap-

pen if one of the envelope tunes is close to or above 180^o. Fig 4 shows a Monte Carlo simulation for an unstable bunched beam transfer line, which has a high mode frequency of almost 180^o. Clearly visible is a dramatic increase of the transverse total emittance.The transverse rms emittances grow by a factor of 4.

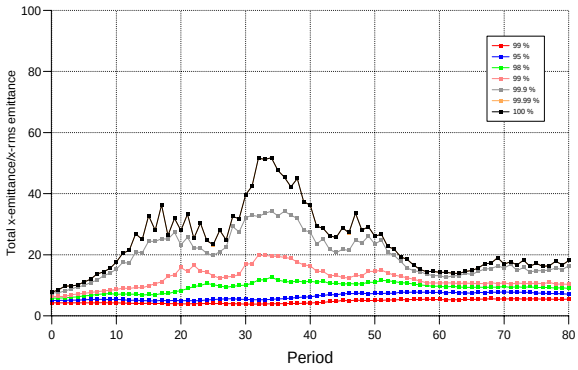

Figure 4: Excitation of the high mode envelope instability.

4.2 *Temperature exchange*

In Fig. 5 the transverse and longitudinal rms emittances are shown for an initially matched beam, where the transverse temperature is chosen to be a factor 2.3 higher than the longitudinal one. Visible is an exchange of emittance at the beginning, followed by damped oscillation afterwards. The ratio of total to rms emittance stays constant in all three planes. This is consistent with a temperature exchange [4,5].

4.3 *Higher Order Mode Instability*

Results of Monte Carlo simulations for an initially matched, equipartitioned beam with transverse and longitudinal tune depressions below 0.4 are shown in Fig. 6. Visible is the excitation of a higher order mode instability [6,7]. The total emittance growth is earlier and much more pronounced than the rms emittance growth which is not shown.

4.4 *Stability Criteria for Halo Formation due to Mismatch*

Based on Monte Carlo simulations for designs of bunched beam transferlines, a conservative stability criteria for halo fromation due to mismatch can be given. If the high mode envelope instability is avoided then a linac design insensitive to mismatch is given if the tune depressions are above 0.8 and the transverse to longitudinal temperature ratios between 1/3 and 2. The asymmetric temperature boundary reflects the situation of a bunched beam. Two hot transverse temperatures feeding one cold longitudinal are more dangerous than vice versa.

It should be pointed out that 'islands of stability' for a matched beam can exist outside this boundary [8] but they may suffer from substantial halo production due to mismatch. For a larger initial mismatch, pronounced halo formation has been observed in DC beams [9] and for equipartitioned, self-consistent bunched beams [10].

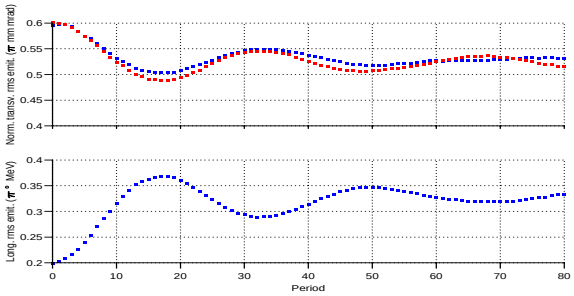

Figure 5: Rms emittances showing temperature exchange from the transverse (top) to the longitudinal (bottom) plane

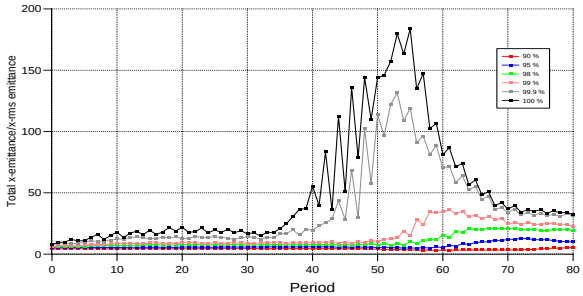

Figure 6: Excitation of a higher order mode instability

Abstract

In order to prevent activation of the beam pipe walls and components of a high power ion accelerator, beam loss must be minimized. Here we present self-consistent, 3D particle-in-cell simulations of longitudinally mismatched beams, including the effects of rf non-linearities, using parameters based on the Accelerator Production of Tritium linac design. In particular, we explore the evolution of the longitudinal halo distribution, i.e. the distribution of particles in longitudinal phase space with oscillation amplitudes significantly larger than amplitudes of particles in the main body or "core" of the beam. When a particle reaches a sufficiently large amplitude longitudinally, it can be lost from the rf bucket, and consequently loses synchronism with the rf wave. Such particles will lose energy and so be poorly matched to the transverse focusing field and consequently can be lost transversely. We compare the present simulations, in which all particles contribute self-consistently to the self-field, to predictions of a core/test particle model, in which the core distribution has uniformly distributed charge and does not evolve self-consistently. Effects of self-consistent, non-linear space-charge forces, non-linear rf focusing on envelope mismatch induced beam halo are explored through comparisons of both models.

1 INTRODUCTION

Requirements on accelerator activation in high power proton linacs, have led to stringent limits on particle loss from the beam. Transverse mismatches have been shown to lead to large transverse particle oscillation amplitudes, leading to large apertures (up to a factor of 20 rms in conservative designs) to avoid intercepting the transverse beam halo (cf. refs.[1]-[4]). In the longitudinal case, the width of the stable rf bucket replaces the physical aperture as the dimension which determines when a particle can be lost from the beam. Since the half-width of the bucket can be as small as 2.3 longitudinal beam radii, a careful understanding of longitudinal halo is also warranted. Recently, the development of halos in the longitudinal direction has been explored using core test-particle models (cf. ref. [5],[6]), and using 3D PIC simulations, (ref. [7], and [8]) using rf fields which varied linearly with distance from the bunch center. In this paper we focus on the effects of the non-linear rf-focusing field, and compare numerical results of a 3D PIC code, known as Langevin3d, to the core-test particle code (CTP) reported on in references [5] and [6].

2 PARAMETERS USED FOR EXAMPLES

For concreteness, we will refer to a design of the Accelerator Production of Tritium (cf. ref. [9]) for numerical examples (see table). The undepressed synchrotron wavenumber, k_{s0} represents the zero-current oscillation wavenumber of a particle at infinitesimal amplitude about the synchronous phase, k_s/k_{s0} is the tune depression due to space charge. Also, $k_{\beta 0}$ is the zero current transverse betatron frequency, and $k_\beta/k_{\beta 0}$ is the transverse tune depression. The quantities $r_{\perp 0}$ and r_{z0} are $\sqrt{5}$ times the rms radius in the transverse and longitudinal directions, respectively in the lab frame. The quantity α represents the ratio of transverse to longitudinal radius in the comoving frame, and is the quantity of physical relevance when evaluating the fields (cf.ref[5]). Note that although the beam is nearly spherical in the lab frame at the 500 MeV point, in the comoving frame $\alpha = 0.68$ and at other energies it is even more elongated. $\Delta z_{max} \cong \beta_s c(-\phi_s)/2\pi\nu$ and $\Delta z_{min} \cong \beta_s c(2\phi_s)/2\pi\nu$ are the approximate rf-bucket half-widths longitudinally, where ϕ_s is the synchronous phase, $\beta_s c$ is the velocity of the synchronous particle, and ν is the rf frequency.

Energy (GeV)	0.1	0.5	1.0	1.8
k_{s0} (rad/m)	0.285	0.107	0.055	0.030
k_s/k_{s0}	0.31	0.31	0.23	0.20
$k_{\beta 0}$(rad/m)	0.474	0.160	0.151	0.147
$k_\beta/k_{\beta 0}$	0.35	0.32	0.48	0.65
r_{z0} (mm)	6.53	4.61	4.90	4.62
$r_{\perp 0}/r_{z0}$	0.53	1.04	0.62	0.46
$\alpha \equiv r_{\perp 0}/\gamma_s r_{z0}$	0.48	0.68	0.30	0.16
$\Delta z_{max}/r_{z0}$	2.34	5.87	6.37	7.26
$\lvert\Delta z_{min}/r_{z0}\rvert$	4.68	11.7	12.7	14.5

Table APT parameters in superconducting coupled cavity linac, at four representative points along the linac.

3 CORE-TEST PARTICLE CODE, CTP

In the code CTP (refs. [5,6]), test particles are allowed to evolve from both external and space charge fields, in all three spatial directions (although the fields themselves are cylindrically symmetric). The external longitudinal field is a sinusoidally varying rf electric focusing field with the intrinsic non-linearity of a sine wave, and the external transverse field is assumed to be uniform focusing, representing the effects of the quadrupoles, in an average sense. The

space charge field is that of a uniformly charged spheroid, calculated for arbitrary α (prolate, oblate or spherical). The spheroid is set to oscillate in linearized normal modes of the coupled transverse and longitudinal envelope equations, at the linearized mode frequencies, each with assumed sinusoidal time dependence. Arbitrary amplitudes and phases of the two envelope modes are allowed. Particles are typically loaded with radial coordinate $r = 0$, and distributed in longitude either over a bunch length or a bucket length, although more complicated loads are also possible. Stroboscobic plots of particle energy and phase relative to the synchronous particle are made at the same phase of each envelope period. CTP is well suited for studying particle resonances and the overall structure of the phase space.

4 3D PIC CODE, LANGEVIN3D

The code Langevin3d (see ref. [10,7] for details) is a Particle-In-Cell (PIC) code that allows 3D space charge field calculations as well as 3D particle orbits. The boundaries are placed at infinity by using the method of ref. [11], which is a good approximation in accelerators with large beam pipe radii. One option in the code uses a modified symplectic integrator, to allow inclusion of artificial damping and diffusion. Use of this feature drives beams to a Boltzmann distribution, to allow thermal equilibrium initial conditions. The parallel processing architecture of Langevin3d permits the use of large particle numbers, which minimizes statistical fluctuations and maximizes accuracy. Typical results displayed here were run with 0.5 million particles, but runs with several million particles are not extraordinary. Phase space plots of a randomly chosen fraction of all the particles can be viewed at a fixed time or test particles can be viewed stroboscopically. Plots with a "density cut" can be viewed which display particles up to a specified maximum density. This feature allows viewing the low density halo regions without saturating the higher density core.

5 COMPARISON OF RESULTS

Figure 1, shows a comparison between the longitudinal phase space ($d\Delta z/ds$ vs. Δz generated by Langevin3d (top two plots) and CTP (lower plot). Here Δz is the longitudinal particle position relative to the synchronous particle, and s is distance along the accelerator. In the top plot, a density cut was made allowing the details of the halo to be observed. The relative intensity of the halo is better characterized by the middle plot, in which the density of particles displayed is proportional to the actual distribution. In the lower plot the solid line represents the position of the equilibrium bunch, with dotted lines indicating the extent of the excursions from the beam mismatch. It is apparent that the main two-lobe structure (due to the resonance between the particle oscillation frequency and half the envelope frequency) in phase space is clearly visible in the results of both codes. The extent of the halo in both Δz and $d\Delta z/ds$ is also quite similar for both CTP and Langevin3d. Higher order resonances appearing within the beam in the CTP plots do not appear to be as significant in the self-consistent simulations.

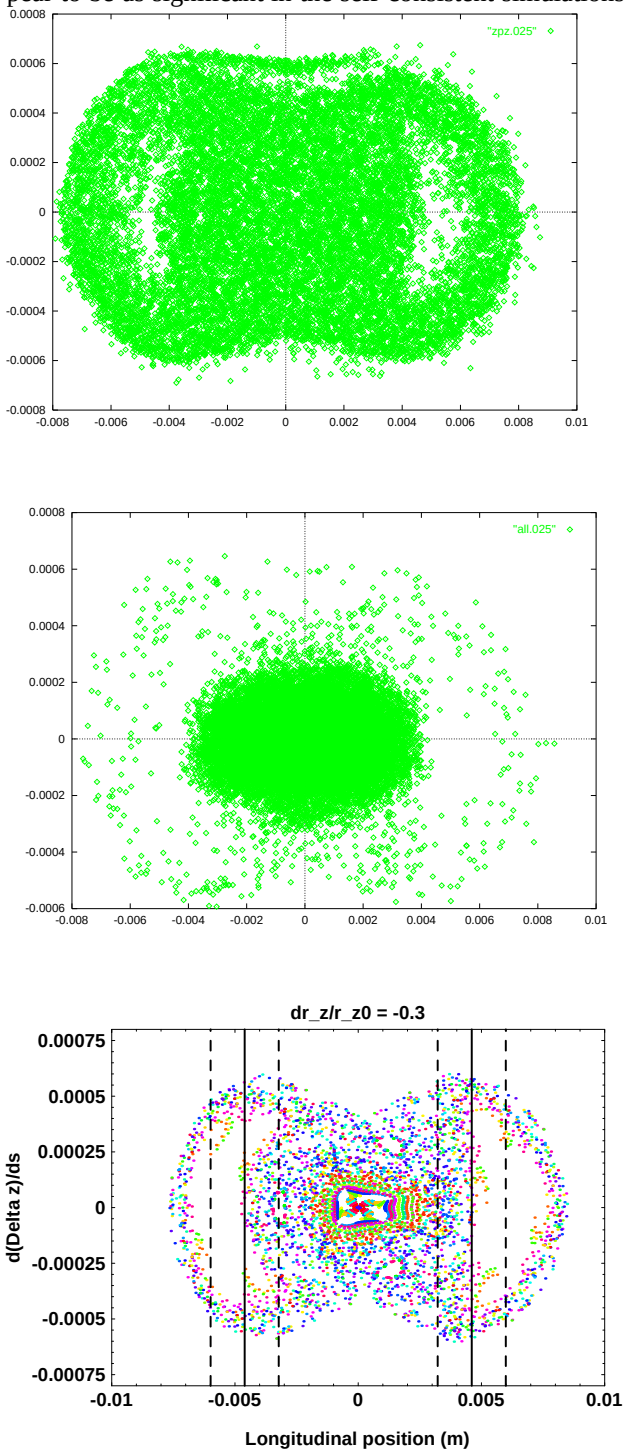

Figure 1 Comparison of Langevin3d (top, middle) and CTP results (bottom) of $d\Delta z/ds$ versus $\Delta z(\mathrm{m})$ for a 30% mismatched beam at the 500 MeV point in the APT linac. Top: Density cut; Middle: Full distribution; Bottom: Stroboscopic test particle plot.

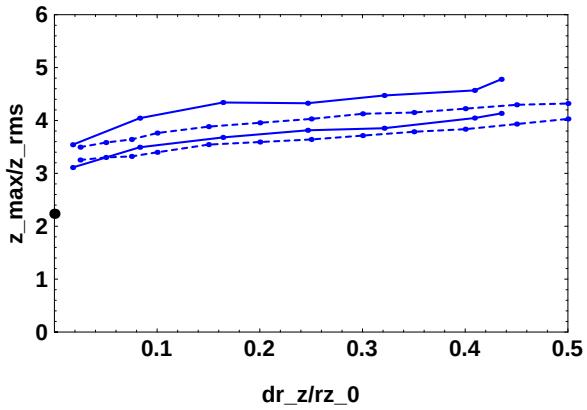

Figure 2 Comparison of the maximum longitudinal excursion in CTP and Langevin3d simulations as a function of mismatch parameter $\delta r_{z0}/r_{z0}$ using parameters from the 500 MeV point. Dashed lines indicate CTP results; solid are from Langevin3d. The upper curve of each pair is the absolute value of the negativemost excursion in Δz, the lower is the maximum of the positive particle excursion.

Figure 2 indicates that CTP tracks the Langevin results well as a function of envelope mismatch amplitude, although the maximum excursion is somewhat less than that found in Langevin3d. Note that the particles all remain within the stable bucket, and so no particles were lost at these amplitudes.

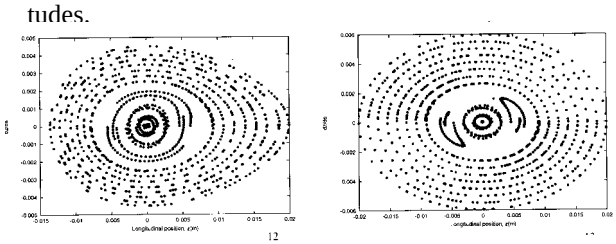

Figure 3 Langevin3d stroboscopic test particle plots for an average current per bunch of 5 mA (rather than 200 mA) but otherwise parameters for the 100 MeV APT normal conducting linac tabulated in ref.[5], loaded over the width of the bucket, with $d\Delta z/ds = 0$. Left: with non-linear rf-focusing; Right: with linear focusing.

6 NON-LINEAR RF HALO SUPPRESSION

In ref. [6] it was shown that for fixed focusing strengths and emittances, at very low or high currents the resonance disappears. Because the rf focusing field varies sinusoidally, the particle oscillation frequencies do not tend to an asymptotic frequency as they would in a strictly linear external focusing field. Rather, a maximum oscillation frequency is reached at some radius generally outside the bunch, and the frequency decreases for larger amplitudes. If that maximum frequency lies below half the longitudinal envelope frequency no resonance is possible. Parametrically it was found that at very low and high currents (when focusing and emittance is held fixed) the maximum frequency is below half the envelope frequency and simulations with CTP found an absence of resonance. Simulations using Langevin3d verified that for a low current case the resonance indeed vanished. Figure 3 illustrates this effect, by showing the phase space with linear focusing in which the resonance persists and sinusoidal rf focusing which suppresses the resonance.

7 CONCLUSIONS

We have performed 3D PIC simulations of beams with longitudinal mismatches, and have found general agreement between PIC simulations and the Core/Test Particle model, particular with respect to the size of the resonant region. The suppression of the envelope-particle resonance by the sinusoidal rf field under certain conditions predicted using CTP has been confirmed using Langevin3d. Using both codes, no particle loss through the rf bucket has been observed for mismatch amplitudes below 0.5.

ANALYTIC MODEL OF ION EMISSION FROM THE FOCUS OF AN INTENSE RELATIVISTIC ELECTRON BEAM ON A TARGET

George J. Caporaso and Yu-Jiuan Chen
Lawrence Livermore National Laboratory, Livermore, California 94550 USA

Abstract

Advanced radiographic systems for stockpile stewardship require very small x-ray sources to achieve the required resolution. Focusing multi-kiloampere beams to diameters on the order of 1 mm onto a Bremsstrahlung target leads to the generation of axial electric fields on the order of several MV/cm which act to extract ions out of the surface plasma and accelerate them upstream into the beam. These backstreaming ions act as a distributed electrostatic lens which can perturb the focus of the electron beam in a time varying manner during the pulse. An analytic model of the ion extraction is presented for a particular target geometry along with scaling laws for the perturbation of the focal spot.

1 INTRODUCTION

High resolution x-ray radiography requires the production of a small (≈1 mm diameter) spot on the surface of a Bremsstrahlung converter target by a relativistic electron beam of at least several kiloamperes [1]. A mechanism that might possibly disrupt the focal spot was proposed by D. Welch [2]. Bombardment of the target by a high power electron beam would lead to the rapid formation of a surface plasma. A large axial electric field would appear at the surface due to the charge redistribution on the target arising from cancellation of the beam's *radial* electric field. This axial field would expel the ions into the beam. These *backstreaming* ions would acquire energies on the order of the space charge depressed potential of the beam and would propagate upstream at very high speeds where they would act as an electrostatic focusing lens. The focusing due to these moving ions would cause the electron beam to pinch upstream of the target and then rapidly diverge. The result would be a spot size that would rapidly increase in time at the converter target.

An analytic model is presented for a "beer can" geometry in which a close fitting conducting tube surrounds the beam right up to the target. A beam envelope equation is used to derive scaling laws for the effect of the backstreaming ions on the focal spot size at the target.

2 TARGET GEOMETRY AND MODEL

We will model the "beer can" geometry shown in Figure 1. In this target arrangement, a conducting tube with the same radius as the electron beam is connected to the target. The presence of the tube limits the space charge depression of the beam which will in turn reduce the emitted ion current.

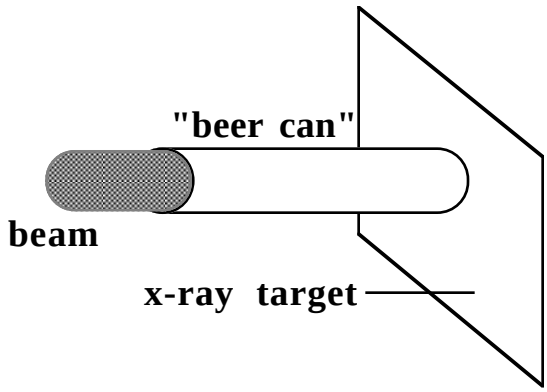

Fig. 1. "Beer can" geometry proposed to reduce the space charge depressed potential of the beam which would reduce the backstreaming ion current.

We will assume that the target surface is sufficiently rich in ions that flow will be space charge limited. The steady state emission is determined by Poisson's equation for the electrostatic potential (in c.g.s. units)

$$\nabla^2\Phi = -4\pi\rho \tag{1}$$

where ρ is the sum of the beam's charge density and the density of the emitted ions. Since the target (and the tube) are assumed to be grounded, we may use the conservation of energy to obtain the ion velocity as

$$v_i = \sqrt{-2e\Phi / M} \tag{2}$$

where M is the ion mass and e is the ion charge. The ion charge density is given by

$$\rho_i = J(r) / v_i \tag{3}$$

where J(r) is the ion current density.

Equation [1] is two dimensional (r and z). A great simplification is made possible by choosing the beam profile to be of the form

$$\rho_b = -\rho_o J_o(\alpha r) \tag{4}$$

where J_0 is the zeroth order Bessel function and $\alpha = x_{01} / a$. Here a is the radius of the beer can, x_{01} is the first root of J_0 and $-\rho_0$ is the on-axis charge density of the beam.

Let us seek solutions which have the following form:

$$\Phi(r,z) = -\psi(z) J_o(\alpha r) \tag{5}$$

and

$$J(r) = \Lambda_o J_o^{3/2}(\alpha r) \tag{6}$$

where $\psi(z)$ and Λ_o are to be determined.

Substitution of Equations [2] through [6] into Equation [1] yields

$$\psi - \frac{d^2\psi}{d\zeta^2} = -\frac{4\pi\rho_o}{\alpha^2} + \frac{4\pi\Lambda_o}{\alpha^2}\sqrt{\frac{M}{2e}}\frac{1}{\sqrt{\psi}} \tag{7}$$

where we have defined a dimensionless axial coordinate $\zeta=\alpha z$. If we multiply Equation [7] by $d\psi/d\zeta$ we can obtain a first integral

$$\left(\frac{d\psi}{d\zeta}\right)^2 = \psi^2 - \frac{8\pi\rho_o}{\alpha^2}\psi + \frac{16\pi\Lambda_o}{\alpha^2}\sqrt{\frac{M}{2e}}\sqrt{\psi} \tag{8}$$

where we have used the condition for space charge limited emission to eliminate the constant of integration (i.e., $d\psi/d\zeta=0$ at the emitting surface $\zeta=0$ where $\psi=0$).

To proceed further we define a dimensionless variable Ω and a dimensionless constant μ as

$$\Omega \equiv \sqrt{\alpha^2\psi / 8\pi\rho_o} \tag{9}$$

and

$$\mu \equiv \frac{16\pi\Lambda_o}{\alpha^2}\sqrt{\frac{M}{2e}}\left(\frac{\alpha^2}{8\pi\rho_o}\right)^{3/2}. \tag{10}$$

With these definitions we may solve Equation [8] as (we choose the positive root since we expect ψ to increase with ζ)

$$\int_0^{\Omega}\frac{\sqrt{\Omega'}}{\sqrt{\Omega'^3 - \Omega' + \mu}}d\Omega' = \frac{\zeta}{2}. \tag{11}$$

We expect that as $\zeta \to \infty$, Ω will approach a finite asymptotic value corresponding to the space charge depressed potential of the beam. Thus μ must have a value such that the integral in Equation [11] $\to \infty$ as $\Omega \to \overline{\Omega}$ the asymptotic value. We note that the radical in the denominator of Equation [11] must be real for a physical solution to exist. Let us find its minimum. Defining the radicand as χ we have

$$\chi \equiv \Omega^3 - \Omega + \mu \tag{12}$$

and

$$d\chi / d\Omega = 3\Omega^2 - 1 = 0 \tag{13}$$

so that

$$\Omega_o = \pm\sqrt{1/3}. \tag{14}$$

From the derivative of Equation [13] we see that the positive root of Equation [14] will correspond to a minimum of the radicand

$$\chi_{\min} = -2/3\sqrt{3} + \mu. \tag{15}$$

Note that if this minimum value is greater than zero then the integral will be finite regardless of the upper limit of integration in Equation [11] and thus will not be a solution. Therefore μ must have a value such that $\chi_{\min} = 0$. That is, we must have

$$\mu = 2/3\sqrt{3} \quad \text{and} \quad \overline{\Omega} = \Omega_o = 1/\sqrt{3}. \tag{16}$$

Using this result we can solve Equation [11]. The solution is shown in Figure 2. Note that the potential changes rapidly over a distance of order the beam radius.

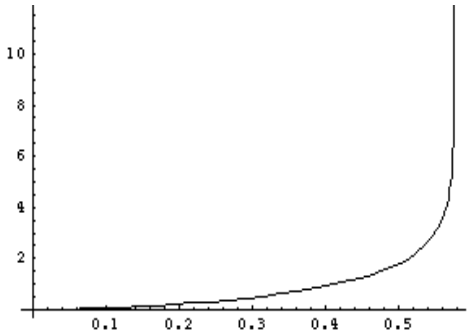

Fig. 2. Solution of Equation [11]. ζ is plotted vs. Ω.

With the solutions given by equation [16] we can immediately determine the asymptotic potential as

$$\psi \to \psi_{\max} = 8\pi\rho_o / 3\alpha^2 \tag{17}$$

and the ion current constant as

$$\Lambda_o = \frac{2}{3\sqrt{3}}\frac{\alpha^2}{16\pi}\sqrt{\frac{2e}{M}}\left(\frac{8\pi\rho_o}{3\alpha^2}\right)^{3/2} \propto \frac{\psi_{\max}^{3/2}}{a^2}. \tag{18}$$

Note that the final result for the ion current resembles the classical Child-Langmuir law for a diode with a potential given by the beam potential and an "A-K gap" given by the beam radius.

By integrating over the beam profile we find that

$$\psi_{\max} = \frac{4}{3}\frac{I}{x_{01}J_1(x_{01})c} \cong 32.04 I_{kA} \text{ (kV)} \tag{19}$$

and that the asymptotic neutralization fraction of the beam by the ions is

$$\rho_{ion}(r, z\to\infty) / \left|\rho_{beam}(r)\right| = 1/9\sqrt{3} = 0.064. \tag{20}$$

The potential gives rise to an asymptotic ion speed given through Equation [2] as

$$v_{\max} = 2.48x10^8\sqrt{I_{kA}Z/A} \text{ (cm/sec)} \tag{21}$$

where Z and A are the charge state and atomic number of the ions respectively.

3 FOCUSING EFFECTS OF BACKSTREAMING IONS

Examination of Equation [21] reveals that substantial motion of backstreaming ions is possible during a single electron beam pulse. For example for a 4 kA beam protons will propagate approximately 50 cm upstream after 60 ns, singly charged carbon ions would travel 14 cm in the same time and singly charged tantalum ions (a typical target material) would move only about 3.5 cm.

These propagation distances are comparable to the focal length of the final focusing lens in radiography systems and so would be expected to exert a substantial focusing force on the electron beam.

An estimate of the effects of these ions can be obtained by using an envelope equation for the beam. By computing the radial electric field produced by the ions and averaging the product of this field with radius over the beam profile it is possible to derive a simple equation for the rms (root mean square) radius of the beam [3]. Assuming a uniform distribution for the beam profile and using the Lapostolle emittance (E) we can then obtain an equation for the edge radius R of the beam (without space charge) as

$$R'' = \frac{E^2}{R^3} - \frac{2 f_n I}{\gamma\beta^2 I_o R} \qquad (22)$$

where f_n is the neutralization fraction (given in the "beer can" model by Equation [20]), $I_o = mc^3/e \approx 17$ kA and E is the Lapostolle emittance.

As the ions propagate upstream we expect the type of behavior shown in Figure 3a to occur. Equation [22] can be solved for different "slices" of the beam corresponding to different distances from the head of the beam. Each slice will experience an ion column of different length and so will have a different history of R vs. z. If the head of the beam is arranged to hit the target at a waist then ion backstreaming will initially lead to a smaller spot on target as the additional electrostatic focusing in close proximity to the target pinches the beam. However, as the ions move further upstream this pinching will occur progressively farther upstream leading to a divergent beam at the target. The behavior of the focal spot at the target as a function of time is shown in Figure 3b. The time at which the spot radius equals R_S, the spot size at the head of the beam is the *disruption time* τ_d.

By numerically solving a dimensionless, scaled version of Equation [22] the length of uniform ion column required to disrupt the focal spot is found to be

$$z_o \approx R_s \sqrt{\pi\gamma\beta^2 I_o / f_n I} \qquad (23)$$

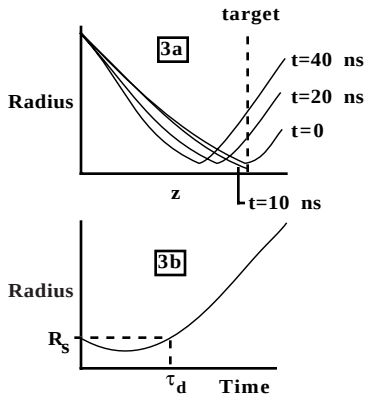

Fig. 3. (a) Trajectories of different beam "slices". (b) Radius as a function of time at the target plane.

and the disruption time follows from Equations [21] and [23] as

$$\tau_d = z_o / v_i \approx 29.5 R_s \sqrt{\gamma\beta^2 A / f_n Z} / I_{kA} \text{ (ns)}. \qquad (24)$$

For example if R_S=0.05 cm, I=2kA and γ=12.7 we find that z_o=3.64 cm and τ_d=10.4 ns for proton emission.

4 CONCLUSIONS

We have provided an exact analytic solution to the problem of the space charge limited flow of ions off the surface of a target surrounded by a tight fitting cylindrical tube of the same diameter as the electron beam. The effects of these ions have been treated with an envelope equation and the scaling laws for the disruption of the focal spot have been derived.

TRAPPING BACKSTREAMING IONS FROM AN X-RAY CONVERTER USING AN INDUCTIVE CELL

J. McCarrick, Y.-J. Chen, T. L. Houck, B. R. Poole
Lawrence Livermore National Laboratory, Livermore, California 94550 USA

Abstract

High current electron beams have been used as x-ray drivers for x-ray radiography. Typically, several thousand amperes of electron beam current at 20 MeV is focused to a millimeter spot size on a x-ray converter. Within a single pulse, the heating of the target by the electron beam will lead to rapid desorption of surface contaminants. The space charge potential of the electron beam will pull ions out of this plasma layer upstream into the beam. These backstreaming ions can act as a focusing lens which cause the beam to be overfocused at a waist upstream. The final beam spot size on the target would then be larger than intended, and the x-ray radiography resolution is reduced. We have designed a self-biased ion trap for the Experimental Test Accelerator (ETA-II) beam by using an Advanced Test Accelerator (ATA) inductive cell to prevent the backstreaming ions from moving upstream and forming a long ion focusing channel. We have studied the effects of this type of ion trap on the final focusing of the electron beam with the ETA-II beam parameters. Simulation results will be presented.

1 INTRODUCTION AND MOTIVATION

The use of electron beams in high-resolution x-ray radiography requires that a high-current beam be focused on a millimeter-sized spot for the duration of the beam pulse. The energy deposited in a small volume of target material is enough to generate a plasma of heavy target material, along with any lighter species that contaminated the target surface, such as hydrogen or carbon. Once these light ions are present, they are rapidly accelerated upstream in the strong axial electric field produced by the beam at the metallic surface of the target, in a process called "backstreaming." The presence of this excess positive charge in the beam upsets the balance of electric repulsive forces and magnetic pinching forces which determine the radius of the beam. The radial electric force is reduced, causing the magnetic forces to pinch the beam to a premature focus and then expand well past the desired spot size at the target. This reduces the achievable resolution of the radiographic image and is an undesirable effect.

Only a small quantity of positive charge is required to have an impact on the target spot size. We can compare the extraction of ions from the target plasma to the operation of an ion diode under the conditions of space-charge limited (SCL) flow. The accelerating potential is that of the beam with respect to the grounded metallic target, which has the well-known form

$$\phi_o = 30I\left(1 + 2\ln\frac{r_w}{r_b}\right) \tag{1}$$

where r_w is the beampipe radius, r_b is the beam radius, and I is the beam current. For the ETA-II accelerator with a millimeter spot radius, 3 cm beampipe radius, and 2 kA of beam current, this potential is 468 kV. Assuming that the extracted ion current satisfies the Child Law for SCL conditions, and neglecting the small initial thermal energy of the ions compared to the beam potential, the neutralization fraction f of ion space charge to beam space charge is given by

$$f = \frac{r_b^2\left(1 + 2\ln\frac{r_w}{r_b}\right)}{9d_{eff}} \tag{2}$$

where d_{eff} is the effective diode gap. Consideration of Poisson's equation in the vicinity of the target shows the potential has the approximate form [1]

$$\phi(r=0,z) \approx \phi_o\left(1 - e^{-z/d}\right) \tag{3}$$

where the scale length d is approximately the beam diameter. Choosing $d_{eff} \sim 3d$ as the total acceleration gap in the ion-diode model gives a neutralization factor of 2.5%, corresponding to a number density of $\sim 10^{17}$ m^{-3}. Thus, a 25 cm channel of hydrogen ions requires a mere 2.5×10^{11} atoms, easily supplied by surface contaminants. At ETA-II parameters the asymptotic velocity for protons is $\sim 9.5 \times 10^6$ m/s, so that this channel can form in about 25 ns, about the mid-point of a pulse.

The effect of such an ion channel on the beam radius can be estimated by a simplified form of the envelope equation:

$$\frac{d^2R}{dz^2} = \frac{\varepsilon^2}{R^3} + \frac{k}{R}\left(\frac{1}{\gamma^2} - f\right) \quad (4)$$

where R=R(z) is the radius of the beam, ε is the un-normalized beam emittance, γ is the usual relativistic factor, f is the neutralization fraction, and the constant k is γ^2 times the generalized perveance of the beam. A comparison of beam envelope with and without the ion channel is shown in figure 1. This behavior is also seen in self-consistent PIC simulations which capture other effects such as emittance growth [2], and has been seen experimentally based on recent data from the ETA-II accelerator [3].

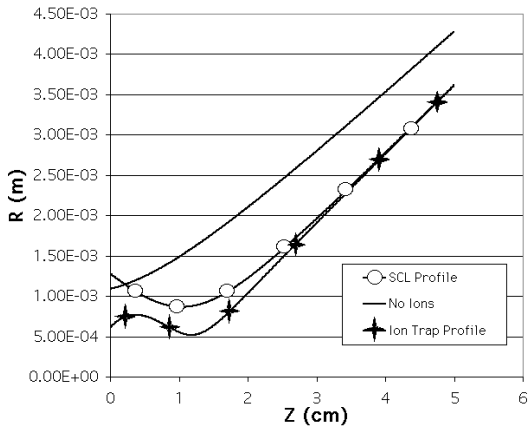

Figure 1. Beam envelope in the presence of no ions, ions with a SCL profile, and ions with the inductive trap profile.

2 APPLICATION OF AN INDUCTIVE ION TRAP

To preserve the minimum spot size of the beam throughout the pulse, it is desirable to either prevent ion emission altogether, or at least confine the ions to a sufficiently small channel such that the net effect on the beam is small. It is not feasible to bias the target with an external DC voltage due to the magnitude of the beam potential; however, it is possible to use the beam current as a "self-biasing" source. One method involves using an induction cell where the accelerating gap (or "decelerating gap", in this case) is formed between the target material and an annular electrode placed slightly upstream in the beampipe. Such a cell has been designed for ETA-II, based on an induction cell used in the Advanced Test Accelerator (ATA) [4]. A schematic of the cell is shown in figure 2.

During a beam pulse, the large inductance of the core will prevent the return current of the beam from traveling the preferred DC path A+B, forcing it instead through the shunt resistor in path A+C and causing the voltage $I_{beam}R$ to appear across the gap. This potential drop serves a dual purpose. Firstly, for a sufficiently high value of R, the sum of the cell potential and the beam potential will form a well, trapping ions in a channel of length the order of the gap size. Secondly, as charge builds up in the channel, the net electric field at the surface of the target will decrease and lower the rate of subsequent ion emission.

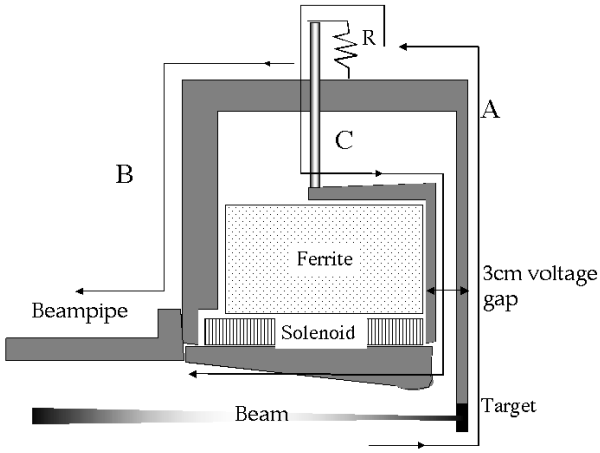

Figure 2. Schematic of Inductive-Cell Ion Trap.

There are difficulties associated with such a design. The potential provided by the cell must be of the same order as the beam potential, and the gap size must be kept as small as possible to minimize ion channel length. Such gradients could cause the electric fields in the gap to exceed the breakdown voltage. In addition, expansion of the plasma of target material could cause conducting plasma to fill the gap, causing a short. The present design has a gap size of 3 cm and a maximum desired voltage of 450 kV, producing electric fields of magnitude 150 kV/cm. By placing high-gradient insulator in the portions of the gap away from the beam, these parameters should be achievable [5].

3 NUMERICAL RESULTS

During the flattop of the current pulse, the inductive voltage across the gap should remain approximately constant, allowing it be modeled as a simple DC voltage. PIC simulations have been run on space-charge limited proton emission from the target in a 2 kA, 1mm spot radius ETA-II beam, with the ion trap operating at 400 kV. Note this value is less than the "bare" beam potential because of the ameliorating effect of the ion space charge which builds up in front of the target.

The simulation is run for 20 ns, allowing enough time for the ions to complete a full round-trip in the potential well. To reduce computation time, the electron beam particles are fixed in time, so that the effect of the ions on the beam is not simulated. The geometry along with the distribution of ions at 5ns and 20ns is shown in figure 3; note almost all of the ions have collected within the gap region, with only a small stream managing to escape the trap. Figure 4 shows the axial positions of all 50,000 particles in the simulation at 20ns; 94% of the particles are trapped within about 2.5 cm of the target.

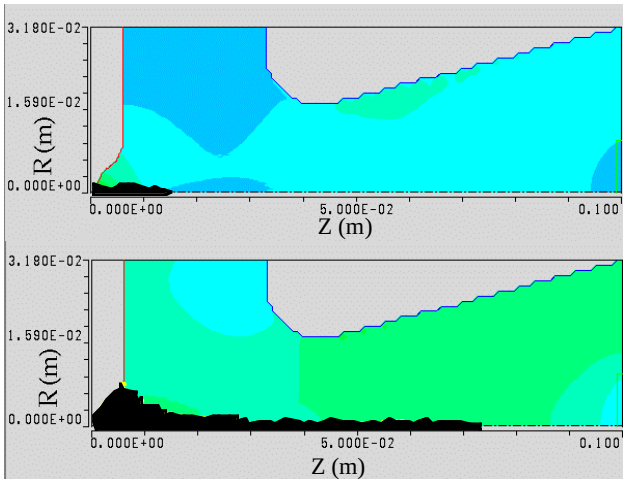

Figure 3. Inductive trap simulation geometry, showing ion distribution at 5ns (top) and 20ns (bottom) after onset of emission.

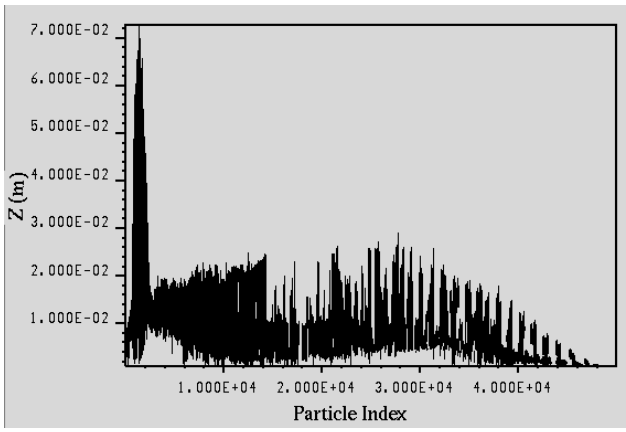

Figure 4. Axial coordinate of each particle at 20ns, showing 2.5cm trapping length.

However, figure 5 shows that ion charge density in the gap is much higher than the unconfined SCL value. The electron beam charge density is about 2 C/m^3, meaning that the neutralization "fraction" is in fact much greater than unity. Using a smooth approximation to this profile in an envelope-equation calculation yields the third curve in figure 1, showing confined oscillations of the beam envelope below the nominal profile. While these results suggest that such a tailored profile of high-density ions could prevent the growth of the beam spot, the varying divergence angle of the beam as it enters the target is not desirable for radiographic purposes. In addition, such constant-emittance envelope calculations are questionable in the presence of beam oscillations, and complete self-consistent PIC simulations including the electron beam are required.

4 CONCLUSIONS

The presence of backstreaming ions from target material in high-current electron accelerators causes undesirable growth in beam size, reducing the achievable resolution of radiographic images. We have examined the use of an inductive ion trap to confine the length of the backstreaming ion channel. PIC simulations show that an ion trap based on an ATA induction cell will confine 94% of emitted protons in the ETA-II accelerator. However, the resulting density of ions in the confinement region is much higher than the unconfined value. Preliminary envelope calculations show that this density profile confines the beam envelope to oscillations below the nominal beam radius. However, further PIC simulations which include the electron beam self-consistently must be performed to confirm this behavior. In addition, the radiographic quality of such an oscillating beam may not be acceptable.

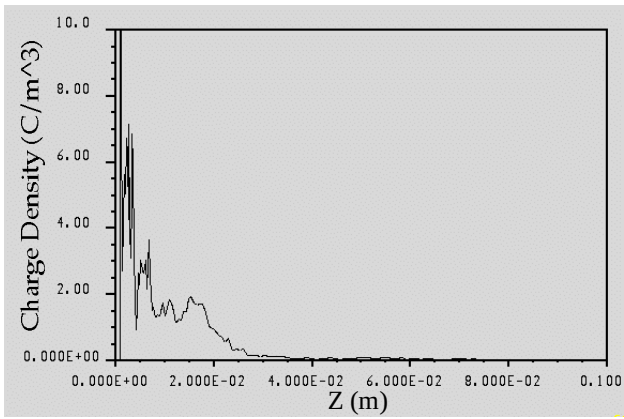

Figure 5. Ion charge density along beam axis. Beam density is 2.12 C/m^3

ANALYSIS OF THE FREQUENCY DEPENDENCE OF THE LONGITUDINAL COUPLING IMPEDANCE OF A SMALL HOLE IN A COAXIAL LINER *

Alexei V. Fedotov, Robert L. Gluckstern
Physics Dept., University of Maryland, College Park, MD 20742

Abstract

We recently developed a general analysis for an azimuthally asymmetric rectangular slot in the inner conductor of a coaxial liner, which allowed us to investigate the coupling impedance numerically. In the present paper we obtain analytic expressions for a small hole of arbitrary shape. Specifically, we go beyond the quasi-static (Bethe) approximation to explore and understand the structure of the impedance in the frequency region near the cutoffs of the inner beam pipe and outer coaxial structure. Finally, we extend our analytic analysis to a hole in a wall of finite thickness.

1 INTRODUCTION

In an earlier work, Gluckstern and Neri [1] analyzed the impedance of a small azimuthally symmetric pill-box in a beam pipe at frequencies of the same order as the cutoffs of the TM_{0n} modes in the pipe. They found that the admittance could be written as the sum of a term depending primarily on the pill-box width and thickness, and a term depending primarily on the pipe radius. In fact, the broad resonance used frequently by others to describe the behavior near cutoffs, was shown to be due to a change of sign of the imaginary part of the admittance.

We recently constructed a variational form for the impedance of a rectangular hole in the wall of a coaxial liner [2]. Our analysis allowed us to study numerically the frequency dependence of the coupling impedance of a transverse rectangular slot, small square hole [2] and a longitudinal rectangular slot, including the resonances due to the slot length [3]. However, it is possible to obtain an approximate analytic expressions, analogous to that obtained in [1], for a small hole of arbitrary shape which would allow us to understand the structure of the impedance in the frequency region near the cutoff of the beam pipe. In the case of a narrow pill-box the dominant contribution comes from the magnetic portion of the problem; therefore, in [1], only the magnetic part was considered. In the present paper we extend the analysis to the azimuthally asymmetric problem of a hole in the wall of a coaxial liner. We also consider both the electric and magnetic portions of the problem. Finally we extend our analysis to a hole in a wall of finite thickness.

2 THE LONGITUDINAL COUPLING IMPEDANCE

The source fields in the frequency domain generated by the driving current

$$J_z(x,y,z;k) = I_0\delta(x)\delta(y)e^{-jkz} \tag{1}$$

are the following:

$$E_r^{(s)}(r,z;k) = Z_0 H_\theta^{(s)}(r,z;k) = \frac{Z_0 I_0}{2\pi r}e^{-jkz}, \tag{2}$$

$$E_z^{(s)}(r,z;k) = 0, \tag{3}$$

where $Z_0 = 120\pi\ [\Omega]$, $k = \omega/c$. The definition of the frequency dependent longitudinal coupling impedance of any obstacle can be taken to be

$$Z_\parallel = \frac{-1}{I_0}\int_{-\infty}^{\infty} dz e^{jkz} E_z(0,\theta,z;k), \tag{4}$$

where $E_z(r,\theta,z;k)$ is the axial electric field in the frequency domain, with frequency dependence $\exp(j\omega t)$, where $\omega = kc$. This expression can be rewritten as

$$\frac{Z_\parallel(k)}{Z_0} = -\frac{1}{2\pi a Z_0 I_0}\int dS E_z(a,\theta,z;k)e^{jkz}, \tag{5}$$

where the surface integral is only over the hole, since E_z vanishes on the liner wall. Since the driving current on axis is proportional to $\exp(-jkz)$, the problem is simplified by obtaining results for an even driving current $\cos kz$ and an odd driving current $-j\sin kz$ separately [2]. We use the superscript (e) for the even problem and the superscript (o) for the odd problem. The field matching is performed at the radius of the inner conductor (liner) in the opening. We call the region inside the inner conductor $r \le a$ the "pipe region" and the region outside the inner conductor $a \le r \le b$ the "coaxial region".

3 THIN WALL ANALYSIS

3.1 Odd Part

We now assume that the hole dimensions are small compared to the wavelength, and we can use the quasi-static solutions for the field components in the vicinity of the hole. For the odd part of the impedance we obtain

$$\frac{Z_\parallel^{(o)}}{Z_0} = -\frac{jk}{8\pi^2 a^2}\chi\Big[1 + \frac{\chi}{8\pi^2}W\Big], \tag{6}$$

with W being defined as

$$W = \sum_n \Big(\int dq[q^2 P_n(q) - \frac{n^2 k^2}{\kappa^2 a^2} Q_n(q)] \Big), \qquad (7)$$

where κ, defined by $\kappa^2 = k^2 - q^2$, is the radial propagation constant, χ is the electric polarizability of a hole, and symbol n stands for the azimuthal index of the modes. Functions P_n and Q_n contain Bessel functions and their derivatives and can be found in [2]. For a small hole, the term proportional to χW will be small compared to 1 and we can write an expression for the admittance as

$$Z_0 Y_{\parallel}^{(o)} = \frac{j8\pi^2 a^2}{k\chi} - \frac{ja^2}{k} W. \qquad (8)$$

3.2 Even Part

Similarly to the odd part we obtain

$$\frac{Z^{(e)}}{Z_0} = \frac{jk}{8\pi^2 a^2} \psi_\theta \Big[1 - \frac{\psi_\theta}{8\pi^2} V \Big], \qquad (9)$$

where ψ_θ is the transverse magnetic susceptibility of a hole, and V is defined as

$$V = \sum_n \Big(\int dq[k^2 P_n(q) - \frac{n^2 q^2}{\kappa^2 a^2} Q_n(q)] \Big). \qquad (10)$$

As before, for $\psi_\theta V \ll 1$ we can write

$$Z_0 Y_{\parallel}^{(e)} = -\frac{j8\pi^2 a^2}{k\psi_\theta} - \frac{ja^2}{k} V. \qquad (11)$$

We can also combine Eqs. (6) and (9) to obtain the expression for the total impedance

$$\frac{Z_{\parallel}}{Z_0} = \frac{jka}{8\pi^2 a^3} \Big(\psi - \chi - \frac{1}{8\pi^2} (\psi^2 V + \chi^2 W) \Big). \qquad (12)$$

The structure obtained in Eq. (12) is similar to the one presented in [4], but we now have additional contribution from the modes in the coaxial region.

3.3 Discussion

We now examine our results in Eqs. (8) and (11). One sees that each admittance separates into a part which includes the geometry of the hole (parameters ψ and χ), and the term involving the pipe and the coaxial region. In the present case the real part includes dependence on parameters b and a (where b is the radius of the outer pipe), and is present even below all possible cutoffs because of the existence of the TEM mode in the coaxial region. Additional energy is lost when other outgoing propagating modes are generated in the "coaxial" and the "pipe" region. In fact, experience with [1] suggests that these expressions are valid in the region of the mode cutoffs where ka and $k(b-a)$ are of the order of 1. This speculation is confirmed by the numerical studies [5].

3.4 Numerical Implementation

It is clear from Eq. (12) that the departure from the usual small hole (Bethe) approximation is contained in the quantities W and V defined in Eqs. (7) and (10). The real parts of W, V contribute to the imaginary part of the impedance. From numerical studies [5] we find that for low frequencies $V_r, W_r \sim k^2$, and that below all possible cutoffs imaginary part of $V, W = \pi/[ln(b/a)]$, with additional energy being lost when other outgoing propagating modes are generated.

To compare the frequency behavior of the admittance of a small hole with the one presented for a pill-box [1], we perform numerical calculations for the square hole with the following parameters $b/a = 1.3125$, $w/a = 0.25$. Results are shown in Figs. 1 and 2 for the imaginary and real part of the admittance, respectively. Figure 2 clearly shows the steps which occur as ka passes the cutoffs corresponding to the TM amd TE modes. For the odd part one sees the cutoffs corresponding to the $\mathrm{TE}_{11}^{(coax.)}$, $\mathrm{TE}_{21}^{(coax.)}$, $\mathrm{TE}_{11}^{(pipe)}$, $\mathrm{TE}_{31}^{(coax.)}$ modes, while for the even part one sees the cutoff corresponding to the $\mathrm{TM}_{01}^{(pipe)}$ mode. This leads to the conclusion that, for a small hole, the odd (electric) part primarily couples to the TE modes, while the even (magnetic) part primarily couples to the TM modes near the cutoffs. This behavior can be also shown analytically (see for example [6]). We also confirmed numerically that this behavior holds for slots with $l/a < 1$ and $kl < 1$, in agreement with [6]. If one goes to very high frequency ($kl \sim \pi$), the imaginary part of the admittance in Fig. 1 eventually crosses the zero axis and changes sign. This behavior corresponds to a resonance due to the hole length. Note that the resonances occur at different frequencies for the odd and even parts.

4 THICK WALL ANALYSIS

When the field is incident on a hole in a wall of finite thickness the usual approach is to split it into two components: one with an asymmetric potential and one with a symmetric potential about the midpoint of the wall [7]. The parameters ψ and χ come from both the symmetric and antisymmetric problems. We then define the magnetic susceptibility and electric polarizability seen within the liner as

$$\psi_{in} = \psi^s + \psi^a, \;\; \chi_{in} = \chi^s + \chi^a, \qquad (13)$$

while the susceptibility and polarizability outside the liner are defined by

$$\psi_{out} = \psi^s - \psi^a, \;\; \chi_{out} = \chi^s - \chi^a. \qquad (14)$$

4.1 Even Part

For the even part of the impedance we obtain [5]:

$$\frac{Z^{(e)}}{Z_0} = \frac{jk}{8\pi^2 a^2} \psi_{in} \Big[1 - \frac{\psi_{in}}{8\pi^2} \tilde{V} \Big], \qquad (15)$$

where

$$\tilde{V} = \sum_n \int dq \Big[k^2 \Big(\frac{J_n'(\kappa a)}{\kappa a J_n(\kappa a)} - \frac{\psi_{out}^2}{\psi_{in}^2} \frac{F_n'(\kappa a)}{\kappa a F_n(\kappa a)} \Big)$$

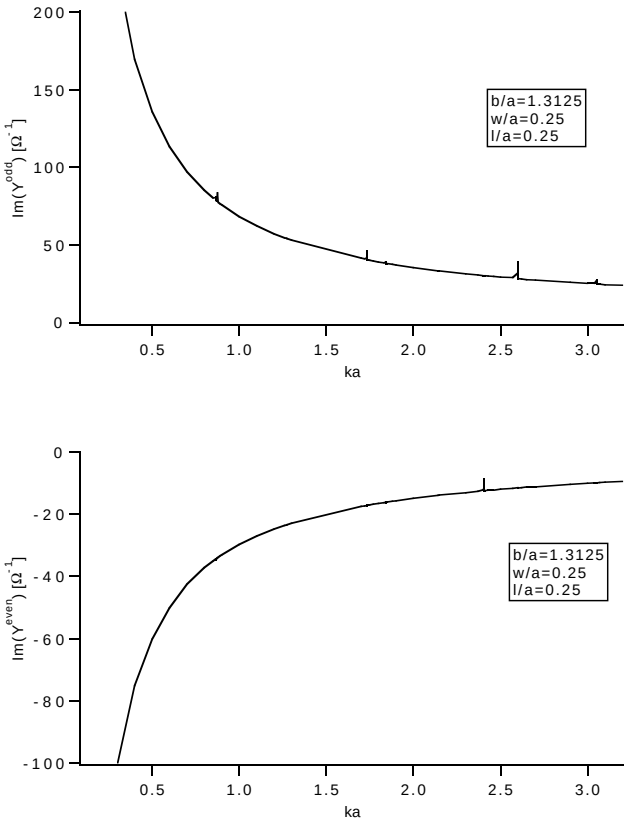

Figure 1: Imaginary part of the admittance near the cutoff frequencies.

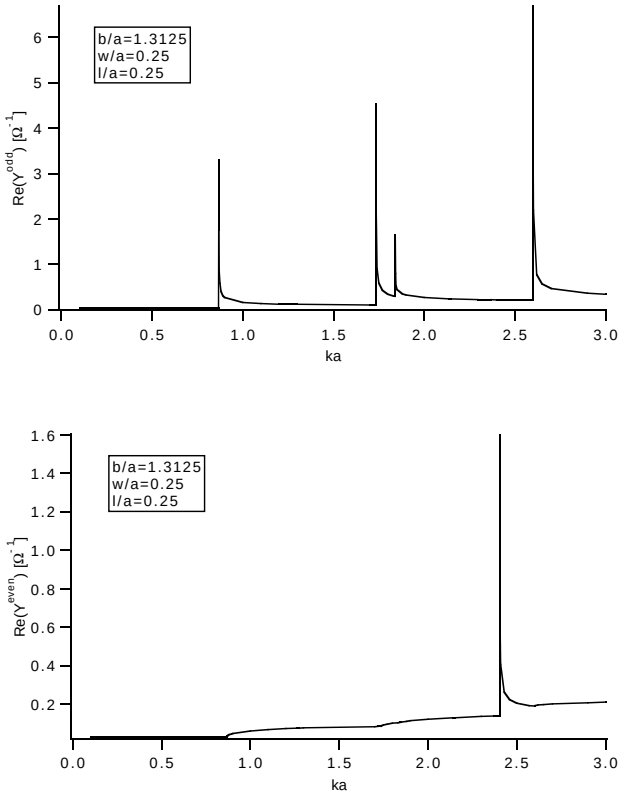

Figure 2: Real part of the admittance near the cutoff frequencies.

$$- \quad \frac{q^2 n^2}{\kappa^2 a^2}\Big(\frac{J_n(\kappa a)}{\kappa a J_n'(\kappa a)} - \frac{\psi_{out}^2}{\psi_{in}^2}\frac{G_n(\kappa a)}{\kappa a G_n'(\kappa a)}\Big)\Big]. \quad (16)$$

4.2 Odd Part

For the odd part of the impedance we obtain [5]:

$$\frac{Z^{(o)}}{Z_0} = -\frac{jk}{8\pi^2 a^2}\chi_{in}\Big[1 + \frac{\chi_{in}}{8\pi^2}\tilde{W}\Big], \quad (17)$$

where

$$\tilde{W} = \sum_n \int dq \Big[q^2\Big(\frac{J_n'(\kappa a)}{\kappa a J_n(\kappa a)} - \frac{\chi_{out}^2}{\chi_{in}^2}\frac{F_n'(\kappa a)}{\kappa a F_n(\kappa a)}\Big) - \frac{k^2 n^2}{\kappa^2 a^2}\Big(\frac{J_n(\kappa a)}{\kappa a J_n'(\kappa a)} - \frac{\chi_{out}^2}{\chi_{in}^2}\frac{G_n(\kappa a)}{\kappa a G_n'(\kappa a)}\Big)\Big]. \quad (18)$$

Expressions for $\tilde{V}$ and $\tilde{W}$ include the parameters ψ and χ; and, therefore, for the case of a wall of finite thickness, the admittance does *not* separate into a part which includes only the geometry of a hole and a term which includes the geometry of a pipe. But this separation *is* still valid for a thin wall ($\chi_{out} = \chi_{in}$, $\psi_{out} = \psi_{in}$) and for a very thick wall ($\chi_{out} = \psi_{out} = 0$).

5 SUMMARY

We obtained analytic expressions for the impedance of a small hole which includes effects of energy propagation along the inner beam pipe and/or outer coaxial pipe. This allow us to understand the structure of the impedance in the frequency region near the cutoffs of the inner beam pipe and outer coaxial structure. We then extended our analytic treatment to a wall of finite thickness and discussed the resulting expressions, and concluded that the admittance could no longer be separated into a part depending only on the pipe geometry and a part depending primarily on the hole geometry.

BEAM DYNAMICS SIMULATIONS OF THE LANSCE LINAC

Frank Merrill and Lawrence Rybarcyk
LANSCE Division, Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

Detailed beam dynamics calculations of the LANSCE Linac have been performed using multi-particle simulation codes. The LANSCE accelerator produces both H^+ and H^- beams and is comprised of Cockcroft-Walton injectors, a 100 MeV drift-tube linac and an 800 MeV side-coupled linac. Several improvements to the simulations of H^+ and H^- beams have recently been made. These include the use of more accurate input distributions and a better estimate of beam neutralization in the low-energy beam transport. Better estimates of the accelerating fields in the drift-tube linac have also been determined through measurements and modeling. With these improvements better agreement has been achieved between the predictions and measurements of RMS beam parameters and beam losses for both beams. The details of the simulations along with predictions are presented in comparison with measurements for both H^+ and H^- beams.

1 INTRODUCTION

The LANSCE accelerator begins with two Cockcroft-Walton injectors that accelerate H^+ and H^- beam to 750 keV. Each beam is transported in a separate low-energy beam transport (LEBT) to a common LEBT that transports both beams to the drift-tube linac (DTL). The DTL operates at 201.25 MHz and accelerates the beams from 0.75 to 100 MeV. The transition region (TR) consists of two beam lines, one for H^+ and the second for H^-, and transports both beams from the DTL to the Side-Coupled Linac (SCL). The SCL operates at 805 MHz and accelerates the beams to 800 MeV.

Each LEBT contains quadrupole magnets set to transport and transversely match each beam into the DTL. A single-cell 201.25 MHz buncher in each upstream LEBT, referred to as the pre-buncher, and an identical buncher in the common LEBT, referred to as the main buncher, are used to prepare the longitudinal phase-space of the beams for DTL injection.

The DTL consists of four tanks, referred to as modules 1 through 4. Each DTL tank is driven by a separate rf power source. Quadrupole magnets inside the DTL drift-tubes are used to establish a singlet FODO lattice.

The two beam lines in the TR each contain four quadrupole magnets for transporting and transversely matching the beams into the SCL. The SCL is made of 44 modules, each fed by a separate rf power source. The SCL modules 5 through 12 accelerate beam from 100 to 211 MeV and consist of four bridge-coupled tanks each with 32-36 cells. Modules 13 through 48 accelerate from 211 to 800 MeV and consist of two bridge-coupled SCL tanks with 49-61 cells. Quadrupole doublets between tanks provide the focusing lattice required for transport of the beams through the SCL.

During typical LANSCE operation an average current of 1 mA of H^+ is delivered to one experimental area while an average current of 76 μA of H^- is transported to the Proton Storage Ring (PSR) for compression and subsequent delivery to a neutron spallation target. The 1 mA of H^+ beam is presently achieved by accelerating a peak current of 16.5 mA at a pulse rate of 100 Hz and a pulse length of 625 μs. The 76 μA of H^- is delivered at 20 Hz and 575 μs length with a 9.5 mA peak current. The H^- beam must also be "chopped" for injection into the PSR with a chopping duty factor of ~70%.

2 SIMULATION TECHNIQUE

A modified version of PARMILA was used to model the beam transport through the LEBT, DTL and TR. The beam transport through the SCL was modeled using a modified version of CCLDYN, a PARMILA-like code used to model beam dynamics through coupled-cavity linacs. These simulation codes were used in previous studies[1] of the LANSCE linac and were modified to incorporate more of the details of the beam transports and accelerator.

Both the H^+ and H^- simulations were performed using 1×10^5 macro-particles to represent 6.2×10^8 H^+ ions or 3.7×10^8 H^- ions at DTL injection. The two-dimensional mesh used by PARMILA and CCLDYN to calculated space-charge forces consisted of 800 mesh points, 20 radial points and 40 longitudinal points.

2.1 Input Distributions

The transverse phase-space input distributions were derived from measurements made at TDEM1, a slit-and-collector emittance station upstream of the DTL. To discriminate between signal and noise on the collector wires only those data bins above 2% of the peak were included in the generation of the input distribution. The measured distributions were then normalized and used as a discrete probability distribution for the Monte-Carlo creation of the horizontal and vertical input distributions.

The longitudinal phase-space input distributions were estimated with PARMILA by transporting mono-energetic, unbunched H^+ and H^- beams through their

respective pre-bunchers and the common main buncher to the slit of TDEM1.

The transverse and longitudinal phase-space distributions were combined without correlations to produce the final input distributions. The resulting H^+ and H^- input distributions at the entrance to the DTL are shown in Fig. 1 and 2, respectively.

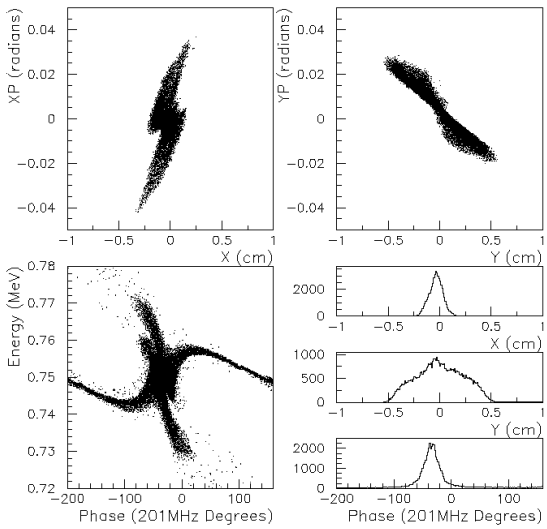

Figure 1: The simulated transverse and longitudinal H^+ beam distributions at injection to the DTL.

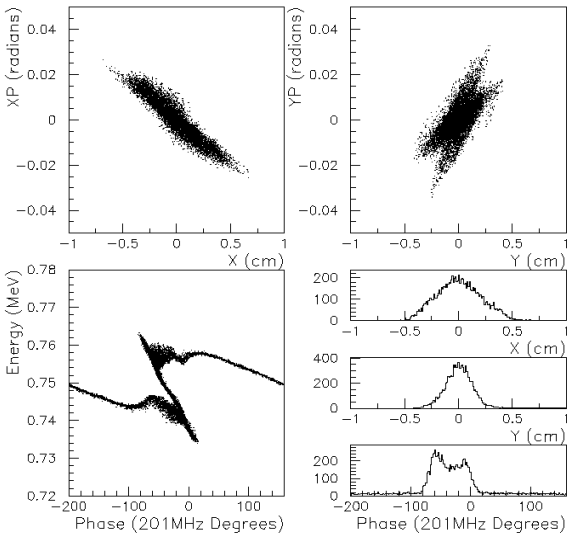

Figure 2: The simulated transverse and longitudinal H^- beam distributions at injection to the DTL.

2.2 Space-Charge Neutralization

The effects of space-charge neutralization in the common LEBT were estimated for both H^+ and H^- beams from measurements made with TDEM1. For each beam the horizontal and vertical phase-space distributions at the slit position were measured along with the beam profiles at the collector position. The measured phase-space distributions were used as input in a PARMILA calculation to predict the beam profiles after a drift to the collector location. An iterative search routine was used to determine the effective charge of the beam that resulted in the best agreement between the measured and predicted profiles. An effective peak of 85% of the measured H^+ peak current and 75% of the measured H^- peak current were found to best reproduce the measured data.

The measured H^+ and H^- currents were used in the DTL and SCL since the large magnetic and electric fields in these structures would quickly remove electrons or ions from the beam column. No neutralization effects were included in the simulations of the TR.

2.3 LEBT, DTL, TR and SCL Parameters

The field strengths of the quadrupoles in the LEBT, DTL, TR and SCL were determined from field-map data and present operating set points.

The phase and amplitude of the rf fields in the buncher and DTL cavities were determined through a combination of measurements and simulations. For these estimates a version of the PARMILA code was modified to include an option for simulating "phase scans". This phase scan procedure uses an absorber-collector diagnostic to measure the transmitted beam current above an energy threshold versus the cavity rf phase. The phase centroid and width of the resultant distribution are related to the phase and amplitude of the rf fields in the cavity. For the bunchers, phase and amplitude settings were adjusted until measured phase scan results matched simulations that were based upon desired operating set points. For the DTL, phase scan simulations were performed for a range of amplitude and phase values that produced the desired output energy. Phase scan measurements were then performed with the DTL tanks at their production settings. Simulation results were interpolated to these measured phase scan parameters to extract an operating amplitude relative to the design amplitude for each tank. Simulations were then performed with these amplitudes and compared with measurements to obtain the operating phase set points of each of the DTL tanks.

The design phase and amplitude set points of the rf fields in each SCL module were used in the simulations.

3 SIMULATION RESULTS

The simulations were performed with beam started in the 750 keV LEBT and transported through the DTL and TR to the exit of the SCL at 800 MeV. Particle distributions were saved at various locations along the accelerator for analysis and comparison to measurements.

3.1 DTL Capture

The DTL capture ratio is the percent of the injected beam that is properly accelerated to 100 MeV through the exit of the DTL. This ratio is primarily determined by the longitudinal distribution at injection into the DTL and the settings of the DTL parameters. The two-buncher system

used at LANSCE results in a complicated longitudinal phase-space distribution at injection to the DTL. The simulated longitudinal H^+ and H^- distributions at injection are shown in Fig. 1 and 2, respectively.

Simulations have shown that the structure of these distributions is primarily determined by the rf field strengths in the bunchers and the level of space-charge neutralization in the LEBTs. With the estimates of these parameters, described in section 2, the simulations accurately predict the capture for both H^+ and H^- beams. The H^+ capture was measured to be 82±1% while simulations predict 80%. For the H^- beam a capture ratio of 81±1% was measured while the simulations predict a ratio of 80%.

3.2 Beam Emittance

The measured transverse phase-space distributions at TDEM1 were used as input distributions for both H^+ and H^- beam simulations. The next two emittance stations that were used for comparison with the simulations are located in the TR. Station one (TREM1) is located at the exit of the DTL and station two (TREM2) at the entrance to the SCL. The simulated and measured normalized RMS emittances at these locations are summarized in Table 1.

Table 1: Comparison of simulated and measured normalized RMS emittances for H^+ and H^- beams in horizontal (H) and vertical (V) planes.

Emittance Station		H^+ RMS Emittance (π cm-mrad)		H^- RMS Emittance (π cm-mrad)	
		Sim.	**Meas.**	**Sim.**	**Meas.**
TDEM1	H	$.93\times10^{-2}$	$.93\times10^{-2}$	1.9×10^{-2}	1.9×10^{-2}
	V	$.92\times10^{-2}$	$.92\times10^{-2}$	2.5×10^{-2}	2.5×10^{-2}
TREM1	H	5.2×10^{-2}	3.1×10^{-2}	3.2×10^{-2}	2.8×10^{-2}
	V	2.7×10^{-2}	2.8×10^{-2}	5.1×10^{-2}	3.4×10^{-2}
TREM2	H	5.2×10^{-2}	3.7×10^{-2}	3.2×10^{-2}	2.9×10^{-2}
	V	2.7×10^{-2}	2.0×10^{-2}	5.0×10^{-2}	2.6×10^{-2}

Although the simulated and measured RMS emittances agree, the higher order moments of the beam distributions in phase-space are different. The 95% emittance, which is the emittance value that includes 95% of the beam, includes information about these higher order moments. The predicted 95% emittance of the H^+ beam in the TR is 2 times larger than the measured 95% emittance and the H^- 95% emittance in the TR is 1.5 times larger than the measured value.

3.3 TR and SCL Losses

The simulations also predict the expected level of losses and the distribution of these losses along the SCL. Measurements of total losses have been made with current monitors that measure average current with an accuracy of ~1 μA. The loss distribution along the linac has also been measured with loss monitors located along the SCL. A comparison between simulation and typical measured losses is shown in Table 2. The simulated and measured distribution of these losses is plotted in Fig. 3. Relatively good agreement has been achieved between simulation and measured losses, although the measured trend of increasing H^- losses along the linac has not yet been understood.

Table 2: Comparison of simulated and measured losses for H^+ and H^- beams.

Between Modules	H^+ Losses		H^- Losses	
	Sim.	**Meas.**	**Sim.**	**Meas.**
3-12	0.04%	0.1%	0.15%	< 1%
12-48	0.28%	< 0.1%	0.24%	< 1%

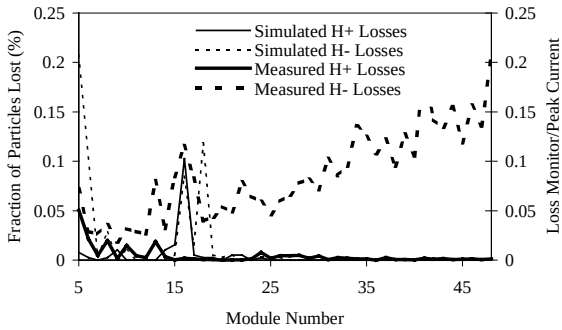

Figure 3: Fraction of particles lost versus module number from simulations (plotted against left axis) and measured losses scaled by peak current (plotted against right axis).

4 CONCLUSIONS

The recent improvements made to the beam dynamics simulations of the LANSCE linac have resulted in better agreement between simulation results and measurements. The most important of these were the use of input distributions derived from measurements, better estimates of space-charge neutralization effects in the LEBTs and the use of accurate estimates of the phase and amplitude of the DTL rf fields.

Because of the improved agreement between simulations and measurements this new model has been used to investigate upgrade scenarios with more confidence. The model is also presently being used to investigate possible sources of the smaller than predicted 95% emittance for both beams in the TR and possible effects that create the observed H^- losses along the SCL.

THE NONLINEAR TRANSERVERSE RF FIELD EFFECTS ON THE BEAM DYNAMICS*

Sun Xiang and Lin Yuzheng
Department of Engineering Physics, Tsinghua University, Beijing 100084, PRChina

Abstract

The nonlinear transverse RF field effects on the low energy and emittance dominated electron beams are investigated theoretically including the bunching and accelerating. Without any external magnetic focusing devices and in pursuit of high shunt impedance, the nonlinear transverse RF field effects should not be neglected. The evolution of the beam phase space distribution in asymmetric cavity is studied by taking into account the nonlinear transverse RF fields. As a result of the nonlinear transverse RF field effects, the emittance growth occurs mainly in the first cavity of bunchers and is associated with the relative position of the particles deviating from the axis, the nonlinearity of the RF fields and the synchronous state of the beam. A few formulas for energy, phase and emittance growth are derived.

1 INTRODUCTION

Low energy electron linacs used for industry, medicine and research need the higher quality beam. The nonlinearity of RF fields, magnetic focusing fields and space charge will cause the phase space tearing and emittance growth. And this distortion of the phase space can not be corrected.

The RF fields in S-band low energy electron linacs are considered as linearity and this approximation are good enough due to a smaller ratio of beam size to beam aperture. In order to get higher breakdown threshold and shunt impedance, higher microwave frequencies should be used (e.g. X-band linacs). Then the nonlinearity of RF fields becomes serious. With the increasing of RF frequencies, $r/(\beta_p\lambda)$ (r: the particle radial position; λ: the RF field wavelength; β_p: the relative phase velocity) increases and a decreases correspondingly (a: the iris radius). The cavities are optimized for higher shunt impedance by decreasing a and r/a is larger. In the meantime the magnetic focusing lens is not used to keep linac size small and r/a can not decrease. The condition of paraxial beam is no long satisfied in our case.

In NLC design, the beam sizes are microns and the iris radius is 4 mm, so the cubic term is down by about $(10^{-3})^2$ from the linearity[1]. But in our case, the beam radius is about 1 mm and the iris radius is no larger than 2 mm.

The nonlinear effects of magnetic focusing fields and space charge have been studied[2][3]. An approximate theory of electron beam dynamics in laser-driver RF guns has been developed[4] and the emittance growth due to the effects of nonlinear RF fields in laser-driver RF guns has been studied by simulations[5].

In low energy and low current SW linacs, the electron beams are emittance dominated. The beams are bunched in the first a few cavities and accelerated along the tube. Contrary to the laser-driver RF guns, the initial phase region of captured particles is very large (e.g. 120^0) and usually in the decelerating region. In the following discussion, the influence of initial phase should be considered. The initial emittance is set to zero and the space charge forces are turned off. There is no magnetic focusing lens and the beam is not paraxial.

2 RF FIELDS IN SW LINACS

In order to represent the fields near the axis of a multi-cell π-mode structure, the RF fields are approximated by a power expansion truncated after r^3, yielding

$$E_z = \sum_{n=1}^{\infty} a_n Sin\left(\frac{nkz}{\beta_p}\right) + \frac{k^2 r^2}{4}\sum_{n=2}^{\infty} a_n Sin\left(\frac{nkz}{\beta_p}\right) \quad (1.1)$$

$$E_r = -\frac{kr}{2\beta_p}\sum_{n=1}^{\infty} n a_n Cos\left(\frac{nkz}{\beta_p}\right) - \frac{k^3 r^3}{16\beta_p^3}\sum_{n=2}^{\infty} n\left(n^2-1\right) a_n Cos\left(\frac{nkz}{\beta_p}\right) \quad (1.2)$$

$$H_\theta = \frac{jkr}{2\mu_0 c\beta_p}\sum_{n=1}^{\infty} a_n Sin\left(\frac{nkz}{\beta_p}\right) + \frac{jk^3 r^3}{16\mu_0 c\beta_p^3}\sum_{n=2}^{\infty}\left(n^2-1\right) a_n Sin\left(\frac{nkz}{\beta_p}\right) \quad (1.3)$$

where, $a_i = \frac{2}{D}\int_0^D E_z(r=0) Sin\left(\frac{kz}{\beta_p}\right) dz$; $D = \frac{\beta_p \lambda}{2}$ is the cell length; $i = 1,2,3,\cdots$.

It is because the coefficient of the first harmonic nonlinear term is zero that the π-mode structure is used. If we use symmetric cavities, the coefficient of the second harmonic nonlinear term is zero.

So called symmetric cavity is the one that has a symmetry plane perpendicular to the axis and asymmetric cavity is the one which has not such plane.

3 ANALYSIS OF LONGITUDINAL BEAM DYNAMICS

The low energy linacs consist of a first cavity, bunchers and relativistic cavities. In analysis, the first cavity is the phase oscillation section and bunchers and relativistic cavities are the quasi-synchronous section (shown in Fig. 1). For convenient, we neglect the nonlinear of longitudinal electric fields.

*Work supported by the National Science Foundation of China

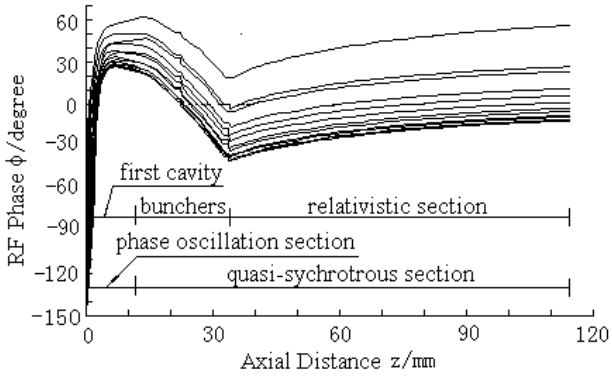

Fig. 1 Schematic of linac distributions

Because the particles are in the decelerating region when they are injected, we assume D_0 is the length of decelerating region (shown in Fig. 2) and $\overline{\beta}_{e0}$ is the average velocity over D_0. ϕ_0 is the initial phase of particles and γ_0 is the initial relativistic factor. γ_i and ϕ_i are the relativistic factor and the phase at the exit of *ith* cavity separately. D_i is the cell length of *ith* cavity. $\overline{\beta}_{ei}$ is the average velocity in the *ith* cavity except $\overline{\beta}_{e1}$ which is the average velocity over $(D_1\text{-}D_0)$ in the first cavity.

We assume $\frac{k}{\overline{\beta}_{e0}} D_0 + \phi_0 = 0 \Rightarrow D_0 = -\frac{\overline{\beta}_{e0}}{k}\phi_0$.

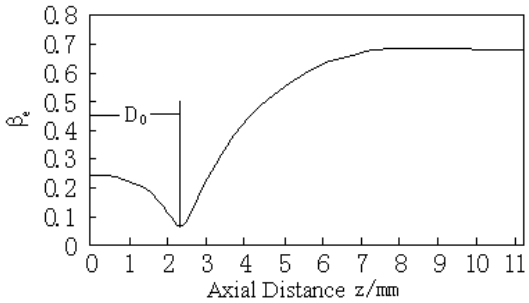

Fig. 2 Schematics of β_e in the first cavity

The average relative velocity is assumed to be constant over its integral region below. At the exit of the first cavity, the relativistic factor particles is

$$\gamma_1 = \gamma_0 + \int_0^{D_0} \frac{e}{m_0 c^2} E_z(z) Sin(\omega t + \phi_0) dt + \int_{D_0}^{D_1} \frac{e}{m_0 c^2} E_z(z) Sin(\omega t + \phi_0) dt$$

$$= \gamma_0 + \frac{e}{m_0 c^2}\frac{\overline{\beta}_{e0}}{k}\left[\sum_{n=1}^{\infty} a_n \frac{Sin\left(\frac{n\overline{\beta}_{e0}}{\beta_{p1}}\phi_0\right) - \frac{n\overline{\beta}_{e0}}{\beta_{p1}} Sin(\phi_0)}{1-\left(\frac{n\overline{\beta}_{e0}}{\beta_{p1}}\right)^2}\right]$$

$$+ \frac{e}{m_0 c^2}\frac{\overline{\beta}_{e1}}{k}\sum_{n=1}^{\infty} a_n \left[\frac{-Cos\left(\frac{\overline{\beta}_{e0}}{\overline{\beta}_{e1}}\phi_0\right) Sin\left(\frac{n\overline{\beta}_{e0}}{\beta_{p1}}\phi_0\right)}{1-\left(\frac{n\overline{\beta}_{e1}}{\beta_{p1}}\right)^2}\right.$$

$$\left. + \frac{n\overline{\beta}_{e1}}{\beta_{p1}} \frac{(-1)^n Sin\left(\frac{\beta_{p1}}{\overline{\beta}_{e1}}\pi\right) + Sin\left(\frac{\overline{\beta}_{e0}}{\overline{\beta}_{e1}}\phi_0\right) Cos\left(\frac{n\overline{\beta}_{e0}}{\beta_{p1}}\phi_0\right)}{1-\left(\frac{n\overline{\beta}_{e1}}{\beta_{p1}}\right)^2}\right] \quad (2)$$

Corresponding, the phase at the exit of the first cavity

$$\phi_1 = k\int_0^{D_1}\frac{dz}{\beta_{e1}} + \phi_0 = k\int_0^{D_0}\frac{dz}{\overline{\beta}_{e0}} + k\int_{D_0}^{D_1}\frac{dz}{\overline{\beta}_{e1}} + \phi_0 = \frac{k}{\overline{\beta}_{e1}}(D_1 - D_0) \quad (3)$$

In the quasi-synchronous section,

$$\gamma_i = \gamma_{i-1} + \int_0^{D_i}\frac{e}{m_0 c^2} E_z(z) Sin(\omega t + \phi_{i-1}) dt$$

$$= \gamma_{i-1} - \frac{e}{m_0 c^2}\frac{\overline{\beta}_{ei}}{k}\frac{\overline{\beta}_{ei}}{\beta_{pi}}\sum_{n=1}^{\infty} n \frac{Sin\left(\frac{\pi}{\left(\overline{\beta}_{ei}/\beta_{pi}\right)} + \phi_{i-1}\right) + Sin\phi_{i-1}}{1-\left(\frac{n\overline{\beta}_{ei}}{\beta_{pi}}\right)^2} \quad (4)$$

$$\phi_i = k\int_0^{D_i}\frac{dz}{\beta_{ei}} + \phi_{i-1} = \frac{k}{\overline{\beta}_{ei}}(D_i - D_{i-1}) + \phi_{i-1} \quad (5)$$

4 ANALYSIS OF TRANSVERSE BEAM DYNAMICS

In the following, the radius r and the average relative velocity are assumed to be constant over their integral region. After the first cavity,

$$\Delta P_{r1}\big|_{non} = \int_0^{D_0}\frac{F_r\big|_{non}}{m_0 c\overline{\beta}_{e0} c} dz + \int_{D_0}^{D_1}\frac{F_r\big|_{non}}{m_0 c\overline{\beta}_{e1} c} dz$$

$$= \frac{\pi^2 D_1 e}{2m_0 c^2}\left(\frac{r}{\beta_{p1}\lambda}\right)^3\left(\frac{1}{\beta_{p1}} - M_0^2\right)\sum_{n=2}^{\infty}\frac{n(n^2-1)a_n}{1-(nM_0)^2}\left[Cos(nM_0\phi_0) - Cos(\phi_0)\right]$$

$$- \frac{\pi^2 D_1 e}{2m_0 c^2}\left(\frac{r}{\beta_{p1}\lambda}\right)^3\sum_{n=2}^{\infty}\frac{(n^2-1)a_n}{1-(nM_1)^2}\left\{M_1\left(\frac{n^2}{\beta_{p1}} - 1\right)Sin\left(\frac{M_0}{M_1}\phi_0\right)Sin(nM_0\phi_0)\right.$$

$$\left. + n\left(\frac{1}{\beta_{p1}} - M_1^2\right)\left[-(-1)^n Cos\left(\frac{\pi}{M_1}\right) + Cos\left(\frac{M_0}{M_1}\phi_0\right)Cos(nM_0\phi_0)\right]\right\} \quad (6)$$

where $M_0 = \overline{\beta}_{e0}/\beta_{p1}$, $M_1 = \overline{\beta}_{e1}/\beta_{p1}$. $\Delta P_{r1}\big|_{non}$ is the transverse momentum changing due to the nonlinear components of RF fields through the first cavity.

From eq.(6), the nonlinear transverse effects come from three facts.

(1) $(r/\beta_{p1}\lambda)^3$ expresses the relative radial position of particles.

(2) a_n indicates the nonlinear components of RF fields. They are determined by the shapes of the cavities. $a_{2n}=0$ in the symmetric cavities. But the RF fields in the asymmetric cavity lift slowly along the axis and the decelerating force exerted on the particles in the asymmetric cavity is smaller than the force exerted on the particles with the same initial phase in the symmetric cavity over the decelerating region. The synchronous state of particles in the asymmetric cavity is better than in the asymmetric cavity over the decelerating region.

(3) M_0, M_1 and ϕ_0 show the synchronous state between particles and RF fields. We can change the synchronous state by changing injecting voltage and RF field amplitude in the first cavity.

After one cavity in quasi-synchronous section,

$$\Delta P_r\big|_{non} = \int_0^D \frac{F_r\big|_{non}}{m_0 c\beta_e c}dz = -D\frac{2e}{m_0c^2\pi}\frac{\pi^3}{2}\left[\frac{1}{\beta_p}-\left(\frac{\beta_e}{\beta_p}\right)^2\right]\left(\frac{r}{\beta_p\lambda}\right)^3 \bullet$$

$$\bullet\left\{\frac{2\cdot 3a_2}{1-\left(\frac{2\beta_e}{\beta_p}\right)^2}Sin\left[\frac{\pi}{2\left(\frac{\beta_e}{\beta_p}\right)}+\phi\right]Sin\left[\frac{\pi}{2\left(\frac{\beta_e}{\beta_p}\right)}\right]\right.$$

$$\left.+\frac{3\cdot 8a_3}{1-\left(\frac{3\beta_e}{\beta_p}\right)^2}Cos\left[\frac{\pi}{2\left(\frac{\beta_e}{\beta_p}\right)}+\phi\right]Cos\left[\frac{\pi}{2\left(\frac{\beta_e}{\beta_p}\right)}\right]+...\right\} \quad (7)$$

where $(\beta_e/\beta_p) \to 1$, $\beta_p \to 1$, $\phi \to 1$,. So $\Delta P_r|_{non} \to 1$ in quasi-synchronous section.

From eq.(6) and (7), the nonlinear transverse effects occur in the first cavity and the nonlinear transverse effects in the bunchers are more serious than in relative section.

5 EMITTANCE GROWTH

The rms normalized transverse emittance is

$$\varepsilon_{xn} = 4\pi\sqrt{\langle P_{xn}^2\rangle\langle x^2\rangle - \langle P_{xn}x\rangle^2}$$

where <> denotes an average over *N* particles at *z*.

For convenient, $p_{xn0}=0$ is assumed at the entrance of one cavity, or $\varepsilon_{xn0}=0$.

After one cavity which length is $\beta_p\lambda/2$, we have

$$P_r = \Delta P_r = L(\phi_0)\left(\frac{r}{\beta_p\lambda}\right) + N(\phi_0)\left(\frac{r}{\beta_p\lambda}\right)^3 \quad (8)$$

from eq.(6) and (7), where $L(\phi_0)$, $N(\phi_0)$ is the function of ϕ_0 alone. Then,

$$P_x = \Delta P_x = L(\phi_0)\left(\frac{1}{\beta_p\lambda}\right)x + N(\phi_0)\left(\frac{r}{\beta_p\lambda}\right)^2\left(\frac{1}{\beta_p\lambda}\right)x. \quad (9)$$

$$\Delta\varepsilon_{xn} = \varepsilon_{xn} - \varepsilon_{xn0} = 4\pi\left(\frac{1}{\beta_p\lambda}\right)^3|N(\phi_0)|\sqrt{\langle r^4x^2\rangle\langle x^2\rangle - \langle r^2x^2\rangle^2} \quad (10)$$

If the distribution of electrons is uniform distribution at the plane which is perpendicular to the axis,

$$\Delta\varepsilon_{xn} = 4\pi\left(\frac{R}{\beta_p\lambda}\right)^3|N(\phi_0)|\times 0.06R \quad (11)$$

where *R* is the envelope radius of the beam.

From eq.(11), $\Delta\varepsilon_{xn}$ and ΔP_r are the same form. So the analysis and conclusion about ΔP_r can apply to $\Delta\varepsilon_{xn}$ too.

6 CONCLUSION

A simple theory to investigate the nonlinear transverse RF field effects on the emittance dominated beam in low energy SW electron linacs has been performed. The nonlinear transverse effect of RF fields on the beam is associate with the relative radial position of particles, the nonlinear components of RF fields and the synchronous state between particles and RF fields. The nonlinear transverse effects of RF fields on the beam and the emittance growth mainly occurs in the first cavity, especially over the decelerating phase region. These effects weaken quickly and vanish in the quasi-synchronous and synchronous section. In the symmetric π mode cavities, the nonlinear components of RF fields are least. But the nonlinear effects on the beam in an asymmetric first cavity can be less than on the beam with the same initial phase in a symmetric one. It is because the radial RF fields lift slowly in an asymmetric first cavity than in a symmetric one that the synchronous state of particles over the decelerating region in an asymmetric first cavity is better than in a symmetric one, even though the nonlinear components of RF fields in asymmetric cavity are larger.

A few formulas for longitudinal and transverse dynamics have been derived including bunching, accelerating and higher space harmonics. They should be useful in design the low energy SW linacs operating in higher frequencies. The comparison of this theory with the simulation is reported in ref.[6] and they are agreement on the whole.

Abstract

An advanced graphic user interface (GUI) is being developed for use with the particle optics code MARYLIE. MARYLIE is based on a Lie algebra formulation of charged particle trajectory calculations and is particularly useful for particle tracking and the analysis of linear and nonlinear lattice properties. The GUI for MARYLIE uses the Multi-Platform Shell for Particle Accelerator Related Codes, a software framework developed specifically to support accelerator modeling and simulation. Transport element icons are selected from a palette and assembled into beamlines by graphical construction. Optical cells and lattices composed of element groups may be defined as sublines, and any element or subline can be replicated using an alias element. The icon-based beamlines generate entries for the #beam, #menu and #lines components of the MARYLIE Master Input File (MIF). Frequent computations, such as creating maps or generating particle distributions, are encapsulated into interactive GUI commands which create corresponding entries in the #menu, #lines and #labor components of the MIF. An icon-based description of procedural processes is being developed to support the more complex MARYLIE analysis tasks that utilize the #lumps and #loops components. Progress on the development of this GUI for MARYLIE is described and illustrations from the Windows95/NT GUI implementation are presented.

1 INTRODUCTION

The Multi-Platform Shell for Particle Accelerator Related Codes (S.P.A.R.C. MP) software technology provides a framework for implementing cross platform graphical interfaces. The software architecture was designed to run on different operating systems including 32-bit Windows, UNIX/X-Windows and the Mac OS. The approach to developing the cross platform code is to implement platform specific interface libraries, each of which encapsulates an individual operating system. These interface libraries provide a common application programming interface (API) between the S.P.A.R.C. MP source code (C++) and each target operating system. The API libraries, which are a collection of basic functions utilizing OS native routines, provide a means of interacting with the different platform specific operating systems to maintain the native "look and feel" of the graphic interfaces associated with each platform, while providing a single programming interface to all supported platforms. This approach yields a single version of the S.P.A.R.C. MP source code for all platforms. Platform specific executable applications are created by linking the compiled S.P.A.R.C. MP code with the appropriate API for that platform.

S.P.A.R.C. MP was developed to interface with a variety of accelerator modeling and simulation programs. The software uses a modular approach that allows new programs to be added to the framework, without affecting the functionality of existing programs. This paper summarizes progress on the interfacing of the MARYLIE [1] code with S.P.A.R.C. MP.

2 GRAPHIC USER INTERFACE (GUI)

The graphic interface for MARYLIE is patterned after that developed for the Particle Beam Optics Laboratory (PBO Lab™). The PBO Lab [2,3] has four major components: (1) a graphic user interface shell, (2) a graphic beamline construction kit, (3) a set of physics and technology tutorials, and (4) modules for various charged particle optics computation engines. Each component is described elsewhere [2,3,4,5]. A MARYLIE Module is being developed to provide significant new optics modeling and simulation capabilities.

A principle requirement for the GUI is to assist users in the set up and running of MARYLIE without requiring any knowledge of the format, syntax, or similar requirements of the input. Beamlines are graphically constructed on the computer screen using drag and drop icons. Default parameters are incorporated for all required inputs so that both the topology of the beamline and a complete set of input data are defined automatically during the graphical construction. Setting up a specific problem then involves editing the values of parameters. The S.P.A.R.C. MP graphic user interface shell and the beamline construction kit [3] provide this capability for the MARYLIE GUI. Figures 1 and 2 illustrate selected windows for the GUI running under Windows 95.

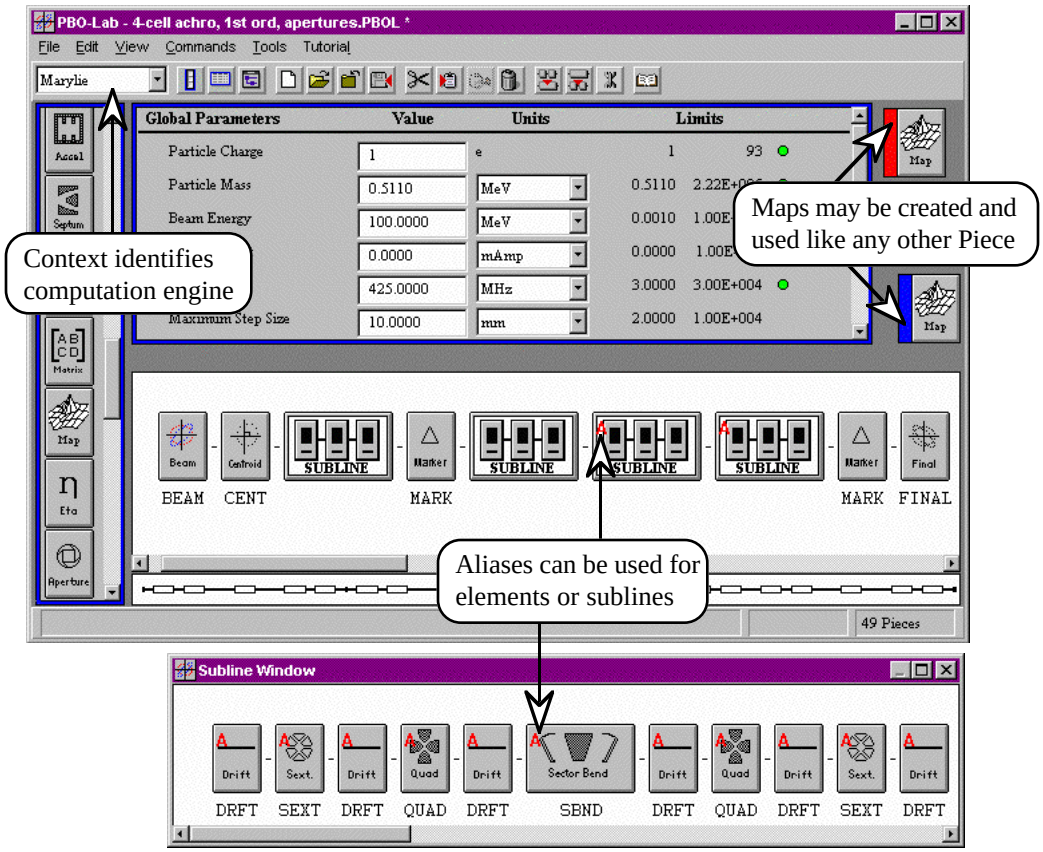

Figure 1. Example Document Window and Subline Window of the graphic user interface for MARYLIE.

Several new GUI features have been added in order to support the extensive capabilities of MARYLIE. Figure 1 illustrates the second-order achromat described in [5] in a new version of the Document Window [2,3] developed for MARYLIE. Figure 1 also illustrates two new elements of the GUI developed for MARYLIE: Alias Pieces and Map Pieces.

The Map Piece is an important new element of the GUI for MARYLIE. Its full functionality is still being defined, but currently the Map Piece can be used to enter a user specified map, to create a map from a given selection of Pieces or Sublines, and to save a map for later use.

The Alias Piece is one of the components of an innovative object model [6] that has been developed to describe beamlines. S.P.A.R.C. MP beamlines can be modeled using hierarchical (Sublines), flat (individual Pieces), or mixed representations that contain both Sublines and individual Pieces. This object model provides the basis for the functionality of the beamline construction kit. An alias in this object model is a Piece or Subline which is represented by a persistent link to another Piece or Subline, and is also capable of storing deviations from the original parameters without duplication of redundant data. The Alias Piece thus provides an element that can be used to efficiently replicate any other Piece, including Sublines: the only persistent data is a pointer to the original Piece or Subline. However, Alias Pieces can also contain deviations (e.g. to represent errors) from the original data. Figure 1 illustrates an example of Alias Subline use, where the second Subline (describing the 2nd cell of the achromatic) has been used to define an Alias which is then replicated to define the 3rd and 4th cells. Alias Sublines contain Aliases to individual Pieces or Sublines.

Figure 2 illustrates an Alias Window for a magnetic bend, together with the Piece Window [3] for the original bend element. In the example illustrated, a deviation of 0.1% of the magnetic field has been entered. Figure 2 also shows some of the new features that have been added to the Piece Windows for all elements to support MARYLIE. The new features for magnetic elements include tab panels for additional data that describe fringe fields, magnet geometry parameters and beamline location (position and orientation) information.

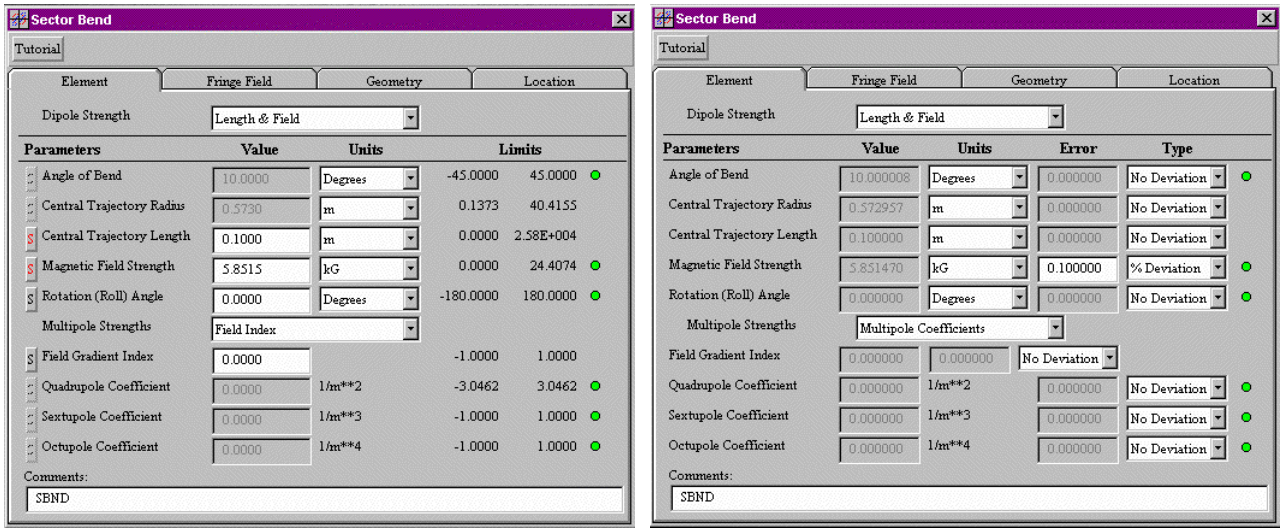

Figure 2. Example of Piece Window (left) and Alias Window (right) for editing parameters of a magnetic bend element.

3 MARYLIE MASTER INPUT FILE

MARYLIE is executed with a Master Input File (MIF) which contains six components referred to as #beam, #menu, #lines #lumps, #loops and #labor [1]. The requirements for the GUI to provide for all of these components are still under development, but the central features can be summarized. The graphic interface writes to each component all of the necessary data to accomplish a given task. The Global Parameters generate entries in the #beam component, and individual Pieces generate entries in the #menu component. Commands and other data also create entries in the #menu component, since this component defines all data used in subsequent components. Commands determine most of the structure of the #labor component. Sublines generate entries in the #lines component. Aliases (with no deviations) are utilized in the data for the #lines component, and the complete beamline also creates an entry in the #lines component. Map Pieces create entries in the #menu component, but may be used in a number of different ways, for example to create an entry in the #lumps component.

4 SUMMARY

A graphic user interface is being developed for MARYLIE that promises improved productivity for researchers working on the design and analysis of accelerators and beamlines. Substantial progress has been made in developing a MARYLIE Module for integration with S.P.A.R.C. MP.

Abstract

Two-dimensional modeling of klystron output cavity coupler is presented. The coupler is considered to be the mode converter between TE10 mode of the rectangular waveguide and TM0*0 mode of the cavity cell. The components of the scattering matrix are calculated using MAFIA eigenmode solver. For the simulation by MAGIC2D 2.5 dimensional particle-in-cell code, finite-conducting material is set in the coupler region to match S11. Output powers, which are calculated from the Poynting vector, are compared with the measured values of KEK XB72K#9 and SLAC XL-4 klystrons.

1 INTRODUCTION

Development of X-band (11.424GHz) klystrons capable of 120MW(XB72K series) is undergoing at KEK [1-3]. To reduce the maximum electric field in the output cavity, traveling wave type structures are used. Output structures of XB72K#8 and #9 were designed at BINP using one dimensional simulation code DISKLY [4]. Due to the limitation of one-dimensional design, not enough powers were extracted with these output structures. MAGIC2D [5], a 2.5 dimensional particle-in-cell code, was introduced in KEK in 1997 for the design of the next klystron XB72K#10 with a 4-cell traveling wave type output cavity. Since the coupler of the output cavity is not axisymmetrical, the structure cannot be simulated directly by 2 dimensional codes. To make it possible, the notion of scattering matrix is introduced, and is calculated using the eigenvalue solver of MAFIA [6] codes. Output powers calculated by MAGIC2D are compared with the measured values of KEK XB72K#9 and SLAC XL-4 [7] klystrons. In section 2, calculation of scattering matrix is shown. In section 3, output cavity simulation by MAGIC2D is presented. Design of XB72K#10 klystron output structure is briefly discussed in section 4.

2 SCATTERING MATRIX

Though there are many modes around operating frequency with the multi cell output structure, the field pattern around the output cell of these modes are similar to TM0*0 mode. The phasor of the electric field in the region can be approximated as the following,

$$E_{CAV} = a_{1in} H_0^{(1)}(kr) + a_{1out} H_0^{(2)}(kr), \quad (1)$$

where H is the Hankel function, $k=\omega/c$ is the wave number. Time dependence of the electric field is assumed to be $\exp(-i\omega t)$. The electric field in the waveguide can be described as,

$$E_{WG} = a_{2in} \exp(-ik_g y) + a_{2out} \exp(ik_g y), \quad k_g = \sqrt{(\omega/c)^2 - (\pi/a)^2}, \quad (2)$$

where a is the width of the rectangular waveguide, y is the distance from the center of the coupler. If the output coupler is considered as the mode converter between TM0*0 of the cavity cell and TE10 mode of the rectangular wave guide, the scattering matrix can be defined as follows,

$$a_{1out} = S_{11} a_{1in} + S_{12} a_{2in}, \quad a_{2out} = S_{21} a_{1in} + S_{22} a_{2in.} \quad (3)$$

The variables $\xi_1$and ξ_2 are defined as the ratio between the amplitudes of the incoming and outgoing waves,

$$\xi_1 = a_{1out} / a_{1in}, \ \xi_2 = a_{2out} / a_{2in}. \quad (4)$$

Using (4), (3) becomes

$$(S_{11} - \xi_1)(S_{22} - \xi_2) = S_{12} S_{21} \quad (5)$$

If the values of three (ξ_1,ξ_2) pairs are known, S_{11}, S_{22} and $S_{12}S_{21}$ can be calculated.

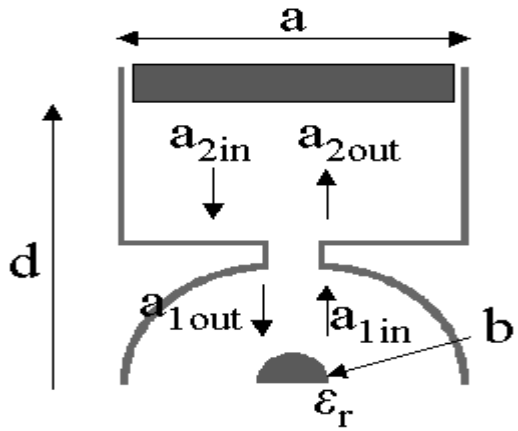

Figure 1: Configuration for MAFIA calculation.

MAFIA eigenmode solver is used to calculate three (ξ_1,ξ_2) pairs. As shown in figure 1, the waveguide is short at distance d, and the dielectric material is set at the center of the cavity cell. Since the electric field on the plane y=d is zero, ξ_2 is,

$$\xi_2 = -\exp(-2ik_g d). \quad (6)$$

By putting dielectric material at the center of the coupler cell, the parameter ξ_1 can be varied as,

$$\xi_1 = \frac{kJ_0(k'b)H_1^{(1)}(kb) - k'J_1(k'b)H_0^{(1)}(kb)}{k'J_1(k'b)H_0^{(2)}(kb) - kJ_0(k'b)H_1^{(2)}(kb)}, \quad (7)$$
$$k' = \sqrt{\varepsilon_r}\,\omega / c,$$

where b is the radius of the dielectric material, ε_r is the relative dielectric constant, J is Bessel function.

From the energy conservation, the following equations

$$|S_{11}| = |S_{22}|, S_{11}S_{22} - S_{12}S_{21} = S_{22}/S_{11}^*, \quad (8)$$

are obtained. These are used to check the calculation of scattering matrix.

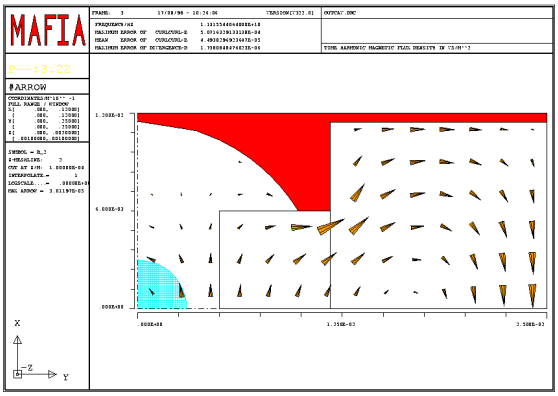

Figure 2: An example of MAFIA calculation.

Figure 2 shows the example of eigenmode solver calculation using MAFIA. The structure is from KEK XB72K#9. Three relative dielectric constants ε_r=1,3,5 are used to obtain three different ξ_1. The distance d is changed to find the frequency dependence of the scattering matrix. Reflection coefficient S_{11} for XB72K#9 output cavity coupler is shown in figure 3.

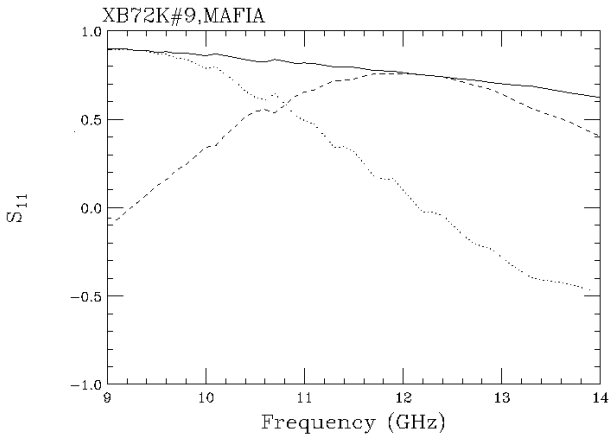

Figure 3: Reflection coefficient S_{11} as a function of frequency. Dotted and broken lines are real and imaginary parts, respectively.

3 MAGIC2D SIMULATION

Since the reflection coefficient r at the rectangular waveguide looked from the center of the cell is usually designed to be zero, the reflection coefficient at the coupler looked from the center of the cell can be assumed to be S_{11}. If the reflection coefficient r is not negligible, S_{11} should be replaced by the parameter S, which is defined by,

$$S = S_{11} + S_{12}(r + r^2 S_{22} + r^3 S_{22}^2 + \cdots)S_{21} = S_{11} + rS_{12}S_{21}/(1 - rS_{22}). \quad (9)$$

In order to realize the reflection coefficient S_{11} in the MAGIC2D simulation, a finite conducting material is set in the coupler region as shown in figure 4.

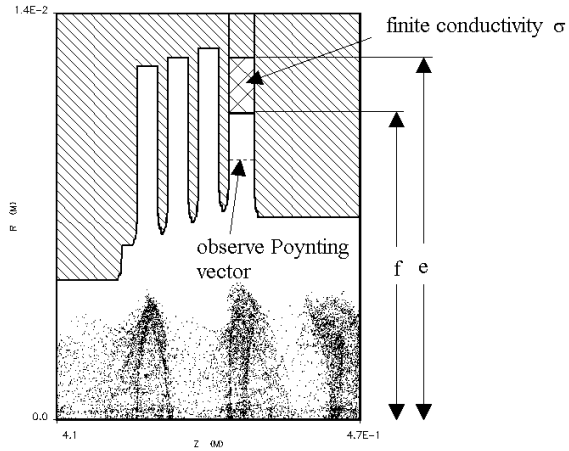

Figure 4: An example of MAGIC2D simulation. A finite conducting material is set in the coupler region to match S_{11}. Output power is calculated by time average of the area integral of Poynting vector. This structure is KEK XB72K#9 output cavity.

With this configuration, S_{11} is,

$$S_{11} = \frac{k\alpha H_1^{(1)}(kf) - k''\beta H_0^{(1)}(kf)}{k''\beta H_0^{(2)}(kf) - k\alpha H_1^{(2)}(kf)},$$
$$\alpha \equiv H_0^{(1)}(k''e)H_0^{(2)}(k''f) - H_0^{(2)}(k''e)H_0^{(1)}(k''f),$$
$$\beta \equiv H_0^{(1)}(k''e)H_1^{(2)}(k''f) - H_0^{(2)}(k''e)H_1^{(1)}(k''f),$$
$$k'' = \sqrt{(\omega/c)^2 + i\mu_0\sigma\omega}, \quad (10)$$

where e is the outer radius, f is the inner radius, σ is the electric conductivity, of the material. The reflection coefficient S_{11} in (10) is fitted to the value calculated from (5) at operating frequency 11.424GHz by changing three parameters (σ, e, f) with the aid of Mathematica [8]. Since number of unknown parameters (σ, e, f) are three, and number of known parameters (Real(S_{11}), Imag(S_{11})) are two, one parameter is free. In many cases, the outer radius e is fixed to one of the outer radii of the upstream cells in order that Courant stability criterion,

$$\sum_i \frac{\beta c \Delta t}{\Delta x_i} < 1, \quad (11)$$

is satisfied in the MAGIC simulation. In this equation, βc is the velocity of the particle, Δt is the time step, Δx_i is the grid size of i-th coordinate. For XB72K#9, the parameter e is fixed to the outer radius of the second cell, as can be seen in figure 4. The conductivity σ should be small so that the skin depth

$$\delta = \sqrt{2/\mu\sigma\omega} \qquad (12)$$

is larger than the grid size. Since the conductivity is chosen to be 2.5/Ωm in case of XB72K#9, skin depth is 3mm, which is larger than the grid size of 0.2mm. Figure 5 shows the frequency dependence of S_{11}, which is calculated from (10).

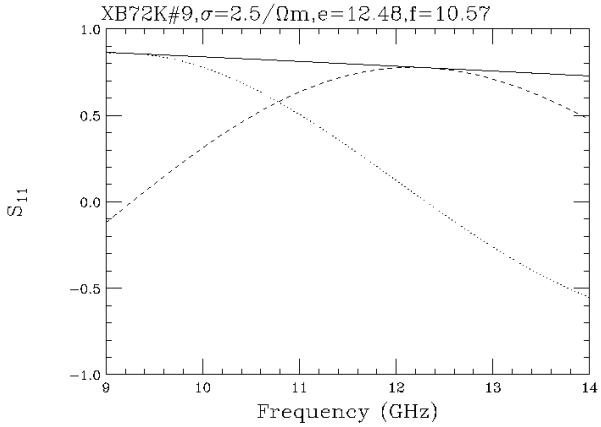

Figure 5: Frequency dependence of the S_{11} calculated from (10). Parameters of the conductor are obtained by fitting S_{11} at the operating frequency of 11.424GHz.

Output cavity simulations are done with imported bunches and space-charge waves, which are created by buncher section simulation [3]. Output power is calculated from time average of Poynting vector just below the finite conductor, as shown in figure 4. Saturated output powers of XB72K#9,10 and SLAC XL-4 are shown in figure 6. For SLAC XL-4, simulation results and measured values are consistent within a few percent. For XB72K#9, simulation results are about 10 percent lower than measurements. We think that accuracy of the measured cathode voltage is not good due to the capacitance in gun region. We have a plan to test XB72K#9 again with longer pulse.

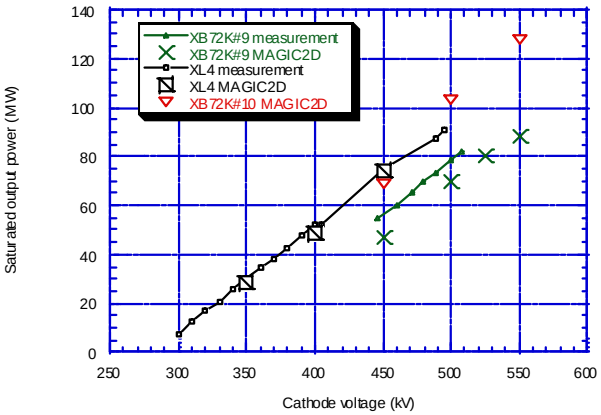

Figure 6: Saturated output power as a function of cathode voltage for XB72K#9,10 and SLAC XL-4.

4 DESIGN OF XB72K#10 OUTPUT STRUCTURE

How to reduce the maximum electric field in 120MW output structure design is the problem. By choosing 2π/3-like mode instead of π/2, we can make the width of the cells wider than that of SLAC XL-4. Since the electric field was high at the disk between third and fourth cell, we increased the width of the disk. After hundreds of simulations, we decided the approximate structure, which has the maximum electric field less than that of SLAC XL-4. The structure was slightly changed in order to separate the resonant frequencies of transverse deflecting modes from the operating frequency. Figure 7 shows one example of the MAGIC2D simulations of XB72K#10 output structure. Saturated output powers by MAGIC2D simulation are plotted in figure 6. XB72K#10 is being manufactured at TOSHIBA. We will test it in November this year.

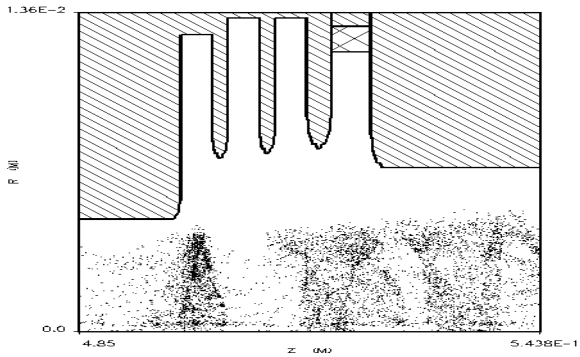

Figure 7: An example of MAGIC2D simulation of XB72K#10 output structure.

Abstract

For applications like ion implantation, rf linacs using double-gap structures with external resonators can be used because they are practical at low frequencies. However, since the two gaps associated with a given resonator cannot be individually phased, it is not obvious how to build a linac that can efficiently accelerate particles having different mass/charge ratios. This paper describes the beam dynamics of double-gap rf linacs and shows how to maximize the range of mass/charge ratios. Our theory also tells us how to rescale a linac tune (i.e., reset the voltages and phases) so that a new particle, having a different mass or charge, will behave similarly to the original particle.

1 INTRODUCTION

Eaton Corporation builds high-energy ion implanters for semiconductor device fabrication. These machines are rf linear accelerators that accelerate ions to energies up to several MeV. Recently, Eaton has been working with Los Alamos to study ways to improve their machines to meet the future needs of Eaton's customers[1]. The main requirements for a near-future ion implanter linac are

- Various ion species. From $^{11}B^{+}$ to $^{75}As^{+}$.
- Variable energies. Up to several MeV.
- High current. Several mA.
- Short length. Not more than about 2 m long.

Additional requirements are low power consumption and low energy spread. This project consists of analyzing the present Eaton linac, studying new approaches for improved performance, and determining the best design based on present double-gap technology. The main part of this paper describes a new theory and design procedure, which we developed to determine the maximum performance of double-gap structures.

2 BACKGROUND

2.1 Study of Present Eaton Machine

The Eaton linac uses 13.56 MHz rf cells to accelerate and provide longitudinal focusing. Each cell consists of a drift tube, fed by an external helical resonator, in a grounded cavity. This provides two rf gaps per cell and is a practical way to get a compact and efficient structure at low frequencies. Electrostatic quadrupole lenses, in an alternating-gradient arrangement, provide transverse focusing. In general, accelerator performance can be limited by weak focusing, poor matching, or poor bunching. We found that the present machine has adequate focusing for accelerating $^{11}B^{+}$ at 3 mA but transmits only about a third of the particles injected. The losses are caused mainly by emittance growth in the rf gaps. This is a nonlinear effect caused by different particles seeing different rf phases as they cross the rf gaps. Improved bunching and matching could double the output current. To further increase the current or to get good performance for heavier ions, we need to improve the transverse focusing.

2.2 Study of New Approaches

New structures and focusing A single-gap rf structure (resonant cavity) has the advantage that we can phase each gap independently. We investigated the feasibility of resonant cavities at low frequencies (40 MHz). While it is possible to get a cavity of reasonable size at this frequency, we found the efficiency to be low. We studied variable-frequency radio frequency quadrupole (RFQ) structures. The high cost of variable-frequency rf power is a problem. The high transmission of most RFQ linacs is the result of adiabatic bunching. However, this is not practical for an ion implanter because of the length constraint. A segmented RFQ or an RFQ with a separate buncher may turn out to be feasible. We studied modifications to the drift tube noses in a gap structure to introduce quadrupole fields that would contribute to transverse focusing. We also studied alternating phase focusing (APF). As in previous investigations, we found that the acceptance of such machines is low.

Improved bunching A well-designed linac with a conventional (single frequency) buncher can accelerate about 75% of the particles injected. While multiple-frequency bunchers are probably not worthwhile, two separated cavities are desirable even for a single-frequency approach, because of the range of particle velocities associated with different particle masses.

Scaling studies We determined optimum quadrupole strengths and period lengths required for an alternating gradient focusing system, taking into account the defocusing

effect of the rf gaps. We also verified that we can reduce the length of the linac by raising the frequency while maintaining the electrostatic and rf voltages. This is beneficial when the quadrupoles and the rf gaps are voltage (not field) limited.

3 IMPROVED DOUBLE-GAP DESIGNS

We developed a new theory (see [2] for earlier version) and design procedure for linacs having double-gap resonators and electrostatic quadrupoles. Our goal is to determine the maximum performance using technology proven at Eaton. The basic idea is that we design the linac for a certain design-reference particle. Then we scale the design-reference tune (voltages and phases) to new particles.

3.1 Theory for Double-Gap Structures

The new theory is useful for the situation in which we are voltage rather than field limited. In existing machines, power limitations limit maximum gap voltage.

In each double-gap resonator, the two gaps are separated by a distance of

$$L = \frac{\beta_o \lambda}{2\pi}(\phi_{o2} - \phi_{o1} + \pi), \tag{1}$$

where β_o is the velocity of the design-reference particle and ϕ_{o1} and ϕ_{o2} are the synchronous phases at the two gaps. As we will see, we need the flexibility to allow the two synchronous phases to be different, even for the design-reference particle.

Once the machine is designed and built, we can no longer change any of the L values, but we are free to retune the machine, i.e., to change gap voltages and phases and to inject different particles.

To see how a new particle of different mass, charge, or velocity will behave,[1] let us define some ratios, which are various quantities relative to their values for the design-reference-particle design. The focusing ratio refers to the focusing strength of the rf gaps.

$$\begin{aligned}
k_{m/q} &= \frac{m/q}{m_o/q_o} && \text{(mass/charge ratio)} \\
k_q &= \frac{q}{q_o} && \text{(charge ratio)} \\
k_\beta &= \frac{\beta}{\beta_o} = \frac{\Delta\beta}{\Delta\beta_o} && \text{(velocity ratio)} \\
k_W &= \frac{W}{W_o} = \frac{m\beta^2}{m_o\beta_o^2} && \text{(energy ratio)} \\
k_f &= \frac{1/f_e}{1/f_{eo}} && \text{(focusing ratio)} \\
k_v &= \frac{VT}{(VT)_o} && \text{(voltage ratio)}
\end{aligned} \tag{2}$$

[1] We are including the situation in which the "new" particle is the same as the design-reference particle but run at a new velocity (energy).

We assume all ratios are the same at every cell in the linac. (A constant velocity ratio β/β_o implies the velocity ratio equals the velocity-gain-per-cell ratio $\Delta\beta/\Delta\beta_o$.)

We assume all the ratios of Eq. 2, except for k_v, as given and determine the new rf voltage and phase required to achieve them. The change in energy in crossing the two gaps is given by

$$\Delta W = qeVT(\cos\phi_1 + \cos\phi_2), \tag{3}$$

where ϕ_1 and ϕ_2 are the synchronous phases on the two gaps, V is the gap voltage, and T is the transit-time factor. We assume that V and T are the same for both gaps. By evaluating Eq. 3 for both the design-reference and the new particles, and using $\Delta W = mc^2\beta\Delta\beta$, we get the following expression for the voltage ratio:

$$k_v = k_{m/q}k_\beta^2\frac{\cos\phi_{o1} + \cos\phi_{o2}}{\cos\phi_1 + \cos\phi_2}. \quad \text{(acceleration condition)} \tag{4}$$

Once we set the phase at the first gap, the phase at the second is determined by the gap separation and the velocity.

$$\phi_2 = \phi_1 - \pi + \frac{1}{k_\beta}(\phi_{o2} - \phi_{o1} + \pi). \tag{5}$$

The effective longitudinal focusing strength (reciprocal of focal length) of the two gaps is given by

$$\frac{1}{f_e} = -\frac{2\pi qeVT}{\beta^3\lambda mc^2}(\sin\phi_1 + \sin\phi_2), \tag{6}$$

where we have added the two strengths and neglected the fact that the two gaps are separated. The focusing strength in the transverse direction is one-half of the value given by Eq. 6 and of the opposite sign. Thus the focusing ratio is the same for both transverse and longitudinal focusing.

If we compute the focusing strengths for the design-reference particle and for the other particle, take their ratio, and rearrange, we get the following expression:

$$k_f = \frac{k_v}{k_{m/q}k_\beta^3}\,\frac{\sin\phi_1 + \sin\phi_2}{\sin\phi_{o1} + \sin\phi_{o2}}. \quad \text{(focusing condition)} \tag{7}$$

If we eliminate $k_v/k_{m/q}$ in Eqs. 4 and 7, we get the following expression for how to set the phase of the first gap for the new-particle tune.

$$\tan\phi_1 = \frac{(1-c_o)k_f k_\beta S + s_o C}{(1-c_o)C - s_o k_f k_\beta S}, \tag{8}$$

where

$$\begin{aligned}
c_o &= \cos\left(\frac{\phi_{o2} - \phi_{o1} + \pi}{k_\beta}\right), \\
s_o &= \sin\left(\frac{\phi_{o2} - \phi_{o1} + \pi}{k_\beta}\right), \\
C &= \cos\phi_{o1} + \cos\phi_{o2}, \\
S &= \sin\phi_{o1} + \sin\phi_{o2}.
\end{aligned} \tag{9}$$

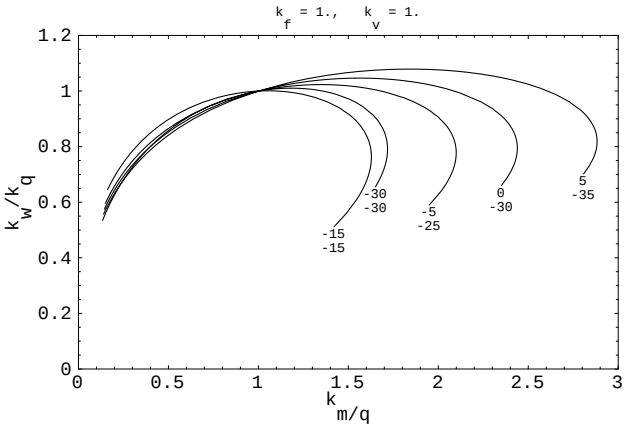

Figure 1: This shows how the energy changes when we retune a linac to a new particle. The quantity k_W is the energy ratio, k_q is the charge ratio, and $k_{m/q}$ is the charge/mass ratio. For a fixed charge, therefore, the curves show the energy as a function of mass. All ratios are relative to the design-reference particle, which is the particle for which the synchronous phases at the two gaps are ϕ_{o1} and ϕ_{o2}. The curves are labeled by the values of these phases.

Knowing ϕ_1, we determine the new voltage from Eq. 4.

Now let us determine over what range of mass/charge values a given design will work. Because we want the new particle to behave similarly to the design-reference particle, we set the focusing ratio to k_f=1. Assume our accelerator was designed to work at the maximum rf gap voltage. As a result, we want to fix the voltage ratio at k_v=1, as we cannot go any higher in voltage for the new particle. Now if we eliminate ϕ_1 in Eqs. 7 and 8 (we can do this numerically), we get a relation between the velocity ratio and the mass/charge ratio, with ϕ_{o1} and ϕ_{o2} as parameters. Figure 1 shows the result, which we express in terms of the energy instead of velocity.

There are five curves in the figure. Each curve is labeled by the values of the synchronous phases at the two gaps for the design-reference particle, ϕ_{o1} and ϕ_{o2}. Notice the large mass range over which an accelerator with phases of (5°,-35°) can operate. The cases (-5°,-25°) and (0°,-30°) have the same rf focusing strength as (5°,-35°) but work over a more restricted range of mass values. What is happening here is that making the synchronous phase on the first gap positive reduces the distance between the two gaps, which is beneficial for heavier (slower) particles. Figure 1 shows that we can accelerate particles over a mass/charge range of about three to one to about the same energy as the design-reference particle. Quite low masses can also be accelerated, but only to somewhat lower energies.

Now consider the electrostatic quadrupoles and space charge. The quadrupoles can be set to provide the same focusing strength for the new particle by setting the voltage according to

$$qV_q/W = \text{const.}, \qquad (10)$$

where V_q is the voltage on the quadrupole electrodes.

For a focusing ratio k_f of unity, and with the quadrupoles set according to Eq. 10, the beam bunch size will be the same as for the design-reference particle if the emittance of the new particle is the same. In this case, the space-charge effects will be the same for the new particle. If we change the beam size by changing the emittance or focusing strength, we can maintain space-charge effects the same as before by adjusting the beam current.

3.2 New Design Procedure

We start with the TRACE 3-D code with user-defined elements for electrostatic quadrupoles and the double-gap rf cells. These elements operate in two modes. In the design mode, the code sets the rf gaps automatically to get the specified synchronous phases. Also, the quadrupole lengths and the gap voltages are automatically set to achieve the specified phase advance per focusing period in all three directions. We do this for each focusing period, getting the maximum focusing possible without exceeding the voltage limits of the gaps and taking care to avoid cell-to-cell discontinuities. In the retune mode, an existing design is retuned to a new particle according to our theory. Once we have a TRACE 3-D design, we use the PARMELA particle-tracking code to determine the fraction of the beam transmitted by the machine. We finish our design by using an optimizing version of PARMELA to fine tune the quadrupole and buncher settings. We find that our new designs have substantially improved performance while still using proven technology.

4 DISCUSSION

The new approaches need further study. However, we found that the present approach of using double-gap resonators and electrostatic quadrupoles can provide ion implanters of substantially improved performance over a wide range of mass/charge values. The design procedure we developed ensures we get the good bunching, matching, and the maximum transverse focusing. Improvements in the rf resonators could further improve performance. The rf gap voltage limitation makes it impossible to obtain significantly higher energies within the length constraint.

Abstract

The next generation of radiographic machines based on induction accelerators require very high brightness electron beams to realize the desired x-ray spot size and intensity. This high brightness must be maintained throughout the beam transport, from source to x-ray converter target. The accelerator for the second-axis of the Dual Axis Radiographic Hydrodynamic Test (DARHT) facility is being designed to accelerate a 4-kA, 2-μs pulse of electrons to 20 MeV. After acceleration, the 2-μs pulse will be chopped into a train of four 50-ns pulses with variable temporal spacing by rapidly deflecting the beam between a beam stop and the final transport section. The short beam pulses will be focused onto an x-ray converter target generating four radiographic pulses within the 2-μs window. Beam instability due to interaction with the accelerator cells can very adversely effect the beam brightness and radiographic pulse quality. This paper describes the various issues considered in the design of the accelerator cell with emphasis on transverse impedance and minimizing beam instabilities.

1 INTRODUCTION

A DARHT Second Axis Technology Options Study (TOS) was initiated in September 1996 to determine if advances in technology since the design of the first axis induction accelerator warranted a new design for the second axis. The "Long Pulse" option, an induction accelerator that would produce a 2-μs, 4-kA electron beam pulse that could be divided into several shorter pulses, was eventually selected to be the basis for a new design [1]. A preliminary accelerator cell design for the "Long Pulse" option had been presented to the TOS Committee. This preliminary design evolved into the "initial" design described below as detailed engineering design work and beam transport studies were accomplished.

The principle issues necessitating changes to the preliminary cell design involved the material for the vacuum interface insulator and the transport solenoidal magnet field strengths. The dielectric constant for the current insulator is about three times larger than that for the original insulator. The cross sectional area also changed to accommodate fabrication. These changes altered the rf characteristics of the cell and the mode damping scheme for was revised. A more important issue involved the solenoid fields required to transport the beam from the injector into the accelerator. The growth in the beam's transverse centroid motion (instability) is strongly influenced by the transverse impedance of the cell and the transport solenoids' magnetic field strength. See equation (2). Very low solenoidal fields at the front of the accelerator placed a severe constraint on the maximum impedance.

Nearly half of the transverse motion growth occurred in the first 10% of the accelerator with the preliminary design. Thus, it was decided to increase the cell inner radius to reduce the transverse impedance and alter the gap/insulator design to shift the impedance spectrum for the first eight cells. The new gap/insulator design proved to be more compact longitudinally and offered some mechanical advantages over the initial cell design. This design is now the "current" design described below for the first eight larger bore cells and the main accelerator.

2 INITIAL DESIGN

This design evolved directly from the TOS "Long Pulse" design. Improvements were made in vacuum surface field stresses, transverse impedance, fabrication ease, and vacuum integrity. Figure 1 is a schematic of this initial accelerator cell design.

2 .1 General Design Criteria

The cross sectional area of the induction cores was set by the required voltage, V, pulse duration, $\Delta\tau$, and core material: $V \cdot \Delta\tau = \Delta B \cdot A \cdot pf$, where (1)
ΔB is the magnetic flux swing, A is the cross sectional area, and pf is the packing fraction of the core material.

The desired maximum growth in the traverse instability and number of cells was used to estimate the maximum transverse impedance. A minimum inner radius consistent with this impedance was then chosen. The following equations are pertinent [2]:

$$\Gamma = \frac{c}{2}\frac{Z_\perp}{l}\frac{I}{I_o}\int_0^L \frac{dz}{B_z}, \text{ and} \quad (2)$$

$$Z_\perp = 120\frac{W}{r_p^2}\eta \ (\Omega/\text{m}), \text{ where} \quad (3)$$

Γ is the number of e-folds of growth, $Z_\perp$ is transverse impedance, l is the cell longitudinal length, I is beam current, I_o is 17 kA, L is length of the accelerator, B_z is solenoid field strength, r_p is beam pipe radius, W is cell gap width, and η is a form factor of order unity. Note that

*The work was performed under the auspices of the U.S. Department of Energy by LLNL under contract W-7405-ENG-48, and by LBNL under contract AC03-76SF00098.

W is approximately the total energy gain of the accelerator divided by number of induction cells and maximum vacuum surface electric field stress. Constraints on the length of the accelerator limited flexibility in determining the outer radius of the induction core.

Determining the optimum B_z involves simulating the beam transport from source to x-ray converter and requires information on expected current and energy variation, location/alignment of components, and cell impedance. This process requires several iterations as the accelerator design matures. The preliminary design assumed the transport fields would be similar to those planned to be used for the first axis accelerator and a conservative value, 12.7 cm, was chosen for r_p.

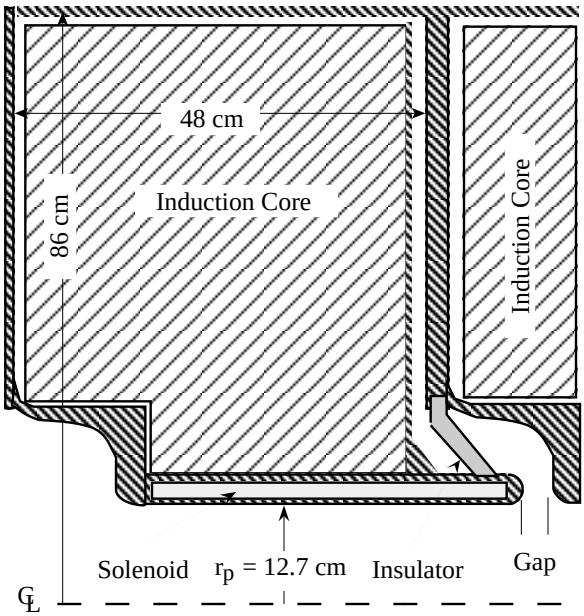

Figure 1. Schematic of the initial accelerator design.

2 .2 Insulator and Field Stress Issues

The insulator has to provide a mechanical interface between the beam line vacuum and the cell insulating oil while withstanding the applied voltage pulse of, in this instance, about 200 kV. It is highly desirable for the insulator to be hidden from line-of-sight view of the beam. See reference [3] for an alternative approach. The simplest design would have been to locate the insulator at the outer radius of the induction cores. Unfortunately, insulating materials, e.g. plastics, that could be fabricated with the required large inner radius, presented an unacceptable gas load due to the large surface area.

A shielded gap design, illustrated in Fig. 2, was used as it permitted the insulator to be placed at a smaller radius (less surface area) while preventing direct line-of-sight with the beam. Rexolite was initially chosen as the insulator material based on performance in operating, short pulse (~100 ns), induction accelerators. However, during long pulse, high-voltage testing performed at LBNL, a Rexolite insulator did not fully recover after experiencing an electrical arc. The insulator was changed to Mycalex to remove any concerns related to insulator performance for long pulses.

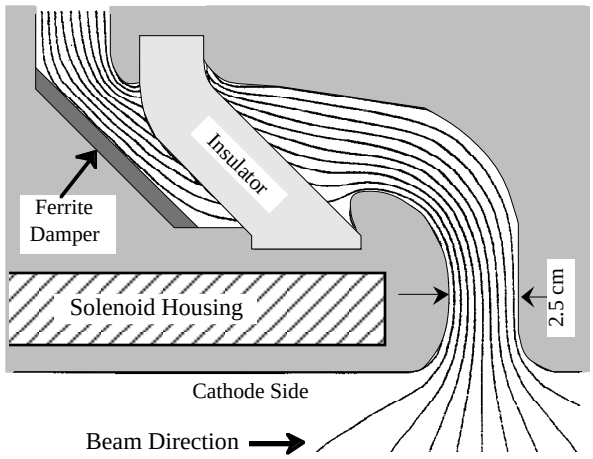

Figure 2. Illustration of the insulator and gap in the initial design. Equipotential lines are shown for the vacuum and oil regions. Each line represents ~20 kV potential change.

Design goals were for vacuum surface electric fields (negative polarity) to be ≤ 100 kV/cm and insulator surface fields ≤ 40 kV/cm. The primary limitation on positive polarity surfaces was to maintain ≤ 100 kV/cm during pulsed power reversals. As the maximum reversed voltage expected is less than 30% of the forward, this was not a difficult requirement. Care was taken to minimize electric fields at triple points (vacuum, metal, and insulator interfaces). Equipotential lines generated by Poisson are shown in Fig. 2 for the vacuum and oil regions of the cell. Maximum fields for the negative polarity (cathode) side of the gap occurred towards the top of the gap nose and were about 100 kV/cm. The maximum field across the insulator occurred towards the top and was about 40 kV/cm. Maximum stress on the positive polarity surfaces was about 130 kV/cm along the curve surfaces approaching the top of the insulator.

2 .3 Transverse Impedance

The transverse impedance of the induction cell was calculated using the AMOS Code [4]. Cell damping was simulated with ferrite, modeled after the TDK PE11B used in the DARHT first axis induction cells, located in the oil region after the insulator as shown in Fig. 2 and on a small section of the outer radius of the core material (not shown). The simulations results are shown in Fig. 3.

3 CURRENT DESIGN

The large radius and low B_z transport fields needed to match the beam from the injector into the accelerator argued for increasing the accelerator bore in the first eight-cell block. Increasing the cell inner radius to 17.8 cm was expected to reduce the impedance by half. See eq. 3.

Desire to reduce the length of the accelerator, while also including more longitudinal space for beam diagnostics,

encouraged compactness in the gap/insulator design. The current cell design, shown in Fig. 4, has been adopted for both the larger bore cells and the main accelerator. The notch in the beam pipe wall downstream of the gap is a recess for diagnostics. This design with diagnostic recess has about the same cross section as the initial design.

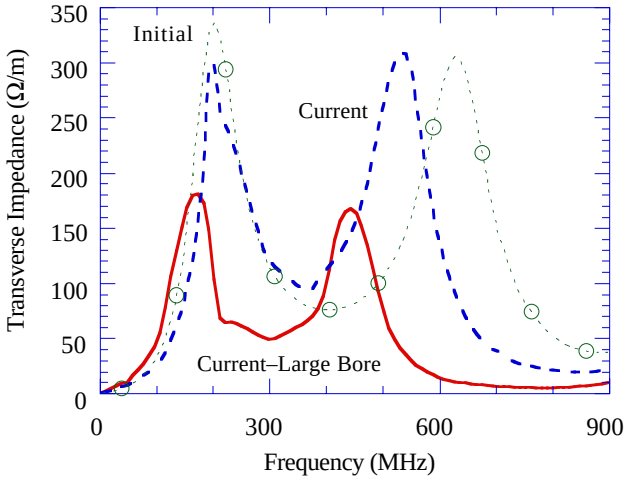

Figure 3. Calculated transverse impedances, $Z_{\perp}$, for the initial and current designs. $Z_{\perp}$ for the first eight larger bore cells using the current design is also shown.

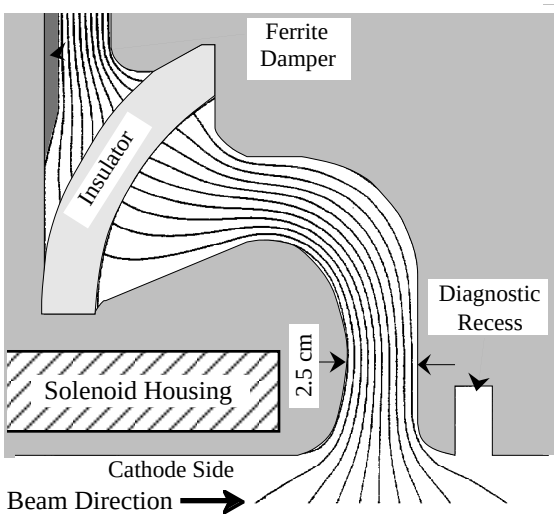

Figure 4. Illustration of the insulator and gap for the current design. Equipotential lines are shown for the vacuum and oil regions. Each line represents ~20 kV potential change.

3 .1 Field Stresses

The first step in arriving at the current design was a series of electrical field stress calculations using Poisson. The current cell design, with equipotential lines plotted, is shown in Fig. 4. The angle of the insulator with respect to the equipotentials was the most significant departure from the initial design with respect to electrical field stress management. Tests with relatively short pulses have determined that the maximum field stress across an insulator can be increased significantly if the electric field makes an angle of 30-45° with respect to the insulator surface [5]. The initial cell design took advantage of this phenomena. It is believed that the field stress in the current design is sufficiently low, < 35 kV/cm for the main accelerator and < 30 kV/cm for the large bore cells, that insulator breakdown will not occur. All conducting surfaces have field stress levels below 100 kV/cm.

3 .2 Transverse Impedance

The transverse impedance of the current induction cell design was also calculated using the AMOS Code and modeling the ferrite damping material as TDK PE11B. The simulations results are shown in Fig. 3. Modest lowering of the impedance can be seen at 200 MHz. The impedance for the larger, 17.8 cm, radius cell is lowered by about half, as expected, and shifted in frequency.

4 SUMMARY

The basic induction cell design for the DARHT second axis accelerator has remained essentially unchanged from the preliminary "Long Pulse" option design. However, the gap/insulator configuration evolved as the engineering design of the accelerator matured, comprehensive beam dynamics simulations were completed, and developmental testing performed. Two gap/insulator configurations have been proposed, a conservative design with respect to the electric field stress on the insulator and a longitudinally compact design. For both configurations, the first eight cells have a larger bore, inner radius of 17.8 cm, than the main accelerator cells, inner radius of 12.7 cm. The compact design is preferred, but the final selection will be made after high-voltage testing of both designs.

5 ACKNOWLEDGMENTS

A very large number of people associated with the DARHT program contributed towards the cell design. In particular, we thank D. Birx, R. Briggs, G. Caporaso, D. Prono, C. Peters, D. Vanecek, and G. Westenskow.

THE PERFECT BOUNDARY APPROXIMATION TECHNIQUE FACING THE BIG CHALLENGE OF HIGH PRECISION FIELD COMPUTATION*

Abstract

Computational tools for the design of accelerating structures are in use since decades. While highly accurate methods exist for quasi two dimensional cavities, fully three dimensional modeling with high precision is still a 'big challenge'.

The most widely used computer code in this area is MAFIA, basing on the Finite Integration Theory (FIT, [1,2]). While being well known for its robustness and reliability, MAFIA nevertheless suffers somewhat from a deficiency in being able to model very complicated 3D-cavities including curved boundaries with high precision.

In this paper we present two recently developed algorithms, facing this challenge within FIT: the usage of generalized non-orthogonal computational grids (NO-FIT), and the so-called Perfect Boundary Approximation (PBA) technique. Both methods represent consistent extensions of FIT, preserving all important properties as second order accuracy and stability of the transient solver. Especially the PBA technique reveals to be a highly efficient method, as it combines easy-to-use Cartesian grids with a perfect approximation of boundaries.

We compare MAFIA with the PBA technique for typical accelerator components, and it turns out, that the PBA technique is more than one order of magnitude faster than the conventional method if many non Cartesian metallic boundaries appear inside the modeled structure.

1 INTRODUCTION

The most common disadvantage of the Finite Integration Technique in three dimensions is the usage of Yee-type [3] cartesian meshes (cf. Fig. 1a), being quite inflexible, if complex, non-orthogonal structures have to be discretized. Even with the concept of triangular fillings (cf. Fig. 1b), not only the local electric and magnetic field, but sometimes also global quantities like resonance frequencies and Q-values suffer from the modeling errors along curved boundaries.

In the field of the FDTD-method, which is equivalent to FIT for transient calculations, several approaches have been published in the last years, trying to overcome this problem. Most of these algorithms, however, either suffer from stability problems, or do not show the same high efficiency properties as FDTD referred to both memory and CPU-time requirements. In this paper we present two algorithms, which can handle curved boundaries and are not only provably stable, but also highly accurate and efficient. Included in the matrix-formalism of the FIT, these algorithms are not only applicable to RF-problems, but also to the calculation of static fields, time-harmonic fields, the interaction with charged particles, and other related problems.

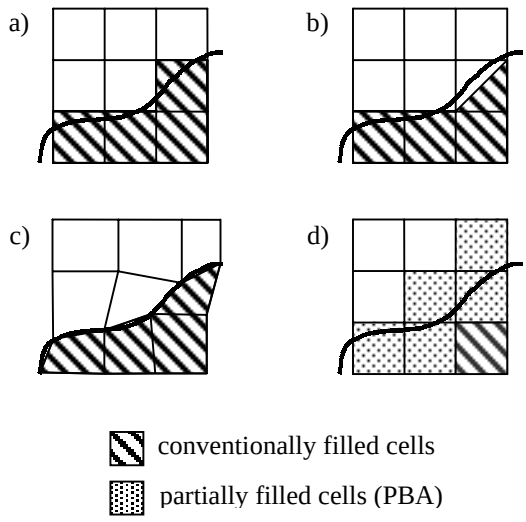

Figure 1: Grid approximations of rounded boundaries: Standard (a), triangular (b), non-orthogonal (c), PBA

2 ALGORITHMS

2.1 FIT on Non-Orthogonal Grids

The most general approach to handle curved boundaries is to allow generalized non-orthogonal grids (Fig. 1c). The basic idea to extend the FDTD-method on such grids has already been formulated in 1983 [4], including a local interpolation scheme for field components. Fulfilling the symmetry-condition in this interpolation process, we get an explicit time-stepping method with proven stability properties [5].

* Work of B. Krietenstein supported in part by DESY, Hamburg.

The non-orthogonal algorithm has been implemented in MAFIA (experimental status), and successfully applied to several transient RF-calculations, as well as to 2D and 3D eigenvalue computations. As the method reduces to standard FIT for orthogonal meshes, interfacing orthogonal with non-orthogonal grids is trivial. The numerical cost is increased by the interpolation scheme by a factor between 2 and 3 for 2D- or 3D-problems, respectively.

2.2 Perfect Boundary Approximation Technique

The application of the non-orthogonal algorithm is sometimes limited by the increase of the numerical cost, and, last but not least, by the requirement to supply a body-fitted, structured, non-orthogonal grid.

As an even more efficient approach we implemented the Perfect Boundary Approximation (PBA) Technique. In this method, the (orthogonal) computational grid does not have to be conformal to the rounded boundaries (Fig. 1d). Instead, also sub-cellular information is taken into account, leading to an algorithm with second order accuracy for arbitrary shaped boundaries. Except for a somewhat more complicated preprocessing, there is only slightly additional numerical cost during the iteration (the factor being near to one). Moreover, the grid generation becomes very easy, as there is no need for a highly resolved mesh near by non-orthogonal shapes. In most cases, even equidistant meshes produce highly accurate results. However, adaptive mesh generation has been implemented to achieve the highest possible accuracy for a given number of mesh cells, including user defined accuracy requirements.

The application of the PBA-technique to several problems from microwave- and accelerator-components is presented in the next chapter.

3 NUMERICAL EXAMPLES

3.1 Twisted Waveguide

In the first example, the reflection parameter S11 at the input port of a twisted waveguide has been calculated. Fig. 2 shows the discrete model using a non-orthogonal mesh, and in Fig. 3 the broadband results for three grid resolutions are shown. All three curves are very close

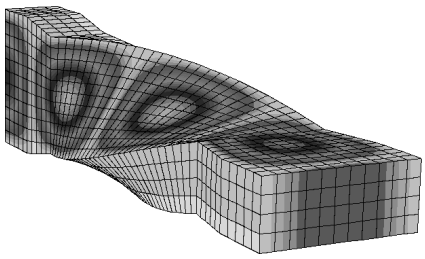

Fig. 2: Twisted Waveguide: non-orthogonal grid-model and electric field (steady state).

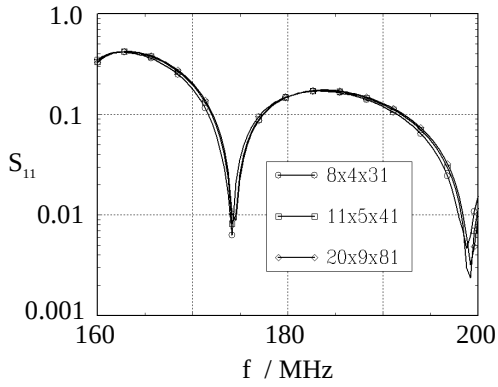

Fig. 3: Twisted Waveguide: reflection coefficient S_{11} for different grid resolutions

together. The result is already well converged for the coarsest grid.

3.2 TESLA Input Coupler

This example (cf. Fig. 4) shows a planned new input coupler for the TESLA superconducting cavities[1]. A rectangular coupler in-between two cavity cells is connected to an elliptical waveguide. A ceramic window is located

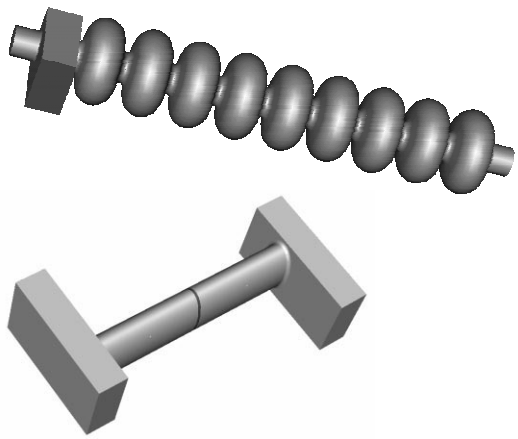

Fig. 4: TESLA 9-cell cavity with planned input coupler structure.

in the middle of the elliptical guide, followed by a second rectangular waveguide.

Fig. 5 shows the geometry of the transition of the rectangular guide to the elliptical one. The connection be-

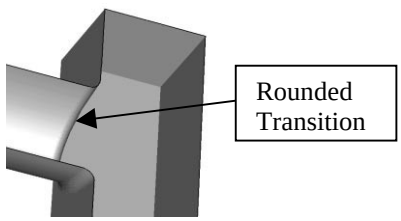

Fig. 5: Transition rectangular to elliptical waveguide.

[1] Design by M. Dohlus and A. Jöstingmeier (DESY)

tween the two waveguides was rounded with a rounding radius of 1cm.

Some more geometric details, the dielectric window and two matching rods (radius 2mm) inside the elliptic waveguide, are shown in Fig. 6.

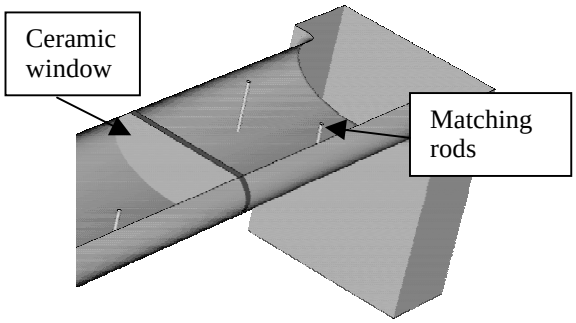

Fig. 6: Details inside the elliptical waveguide.

After a transient field simulation including an on-line DFT transformation we obtain the entire spectrum for the S-parameters, as shown in Fig. 7:

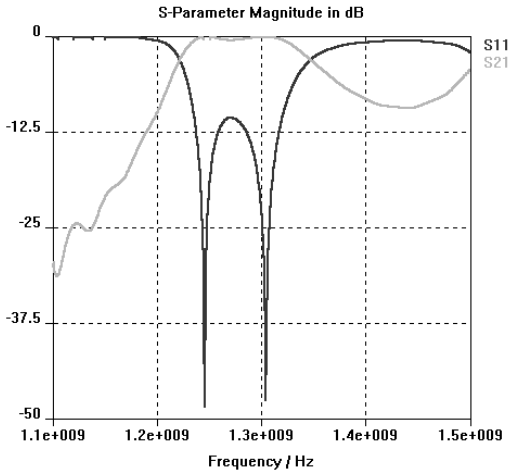

Fig. 7: S-Parameter of the Waveguide Transition.

The design shows a very good reflection property at the design frequency of 1.3 Ghz, although it was not yet optimized and was meant to serve here only as a demonstration example for the new PBA-algorithm.

3.3 Coax to Waveguide Coupler

The last example is the (mismatched) coax to waveguide coupler structure shown in Fig. 8. It has been simulated with both the new PBA-technique and standard MAFIA.

The results for the transmission coefficient demonstrate the high accuracy of the PBA-method: even the calculation with the coarsest grid resolution (10 mesh steps per wavelength) yields a S_{12}-curve close to the final result, whereas the standard method needs more than 60 steps/λ to achieve a comparable accuracy. The numerical cost of the simulation thus can be reduced by about two orders of magnitudes, which is a typical result for structures containing many non Cartesian geometrical details.

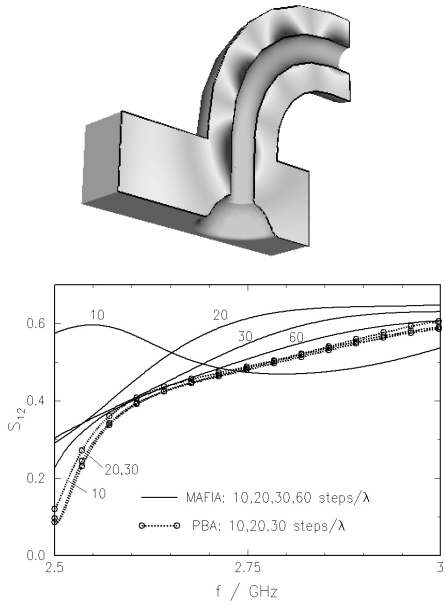

Fig. 8: Coax to waveguide coupler (with electric field in steady state), transmission coefficient for different grid resolutions (MAFIA and PBA results).

4 CONCLUSION

The Finite Integration Theory, combined with either non-orthogonal computational grids or with the newly developed Perfect Boundary Approximation Technique, is able to model structures with very fine geometric details with high accuracy. The application especially of the PBA-technique to typical accelerator devices demonstrates the high efficiency of the method compared to conventional FD- or FE-approaches.

Abstract

The major challenges in operating a photocathode RF gun based injector are its stability and reliability. This report discuss two important subjects which affect the performance of photocathode RF gun, high efficiency photocathode and experimental technique characterizing the RF gun injector. A Mg cathode was manufactured and routinely operated at 100 MV/m field with quantum efficiency on the order of 10^{-3}. By measuring the photoelectron charge as function of RF gun phase, we can monitor the RF gun driving laser pulse length variation, and measuring the laser arrive time variation on the cathode with Pico-second accuracy.

1 INTRODUCTION

The superior performance of photocathode RF gun based injectors have been experimentally demonstrated in many laboratories [1-3], all proposed fourth generation light source, such as X-ray and UV free electron lasers are based on the photocathode RF gun injector [4-6]. The performance of those future light sources will be determined by the photocathode RF gun injector. One of most challenging area in photocathode RF gun research is to improve the stability and reliability of its operation.

Brookhaven Accelerator Test Facility (ATF) is a facility dedicated to the beam physics and advanced accelerator physics research. It is one of few user facilities based on photocathode RF gun injector. It has a unique opportunity to address those challenges, demonstrate the feasibility of photocathode RF gun based user facility. The reliability and stability of the photoinjector are determined by the RF gun and its driving laser. The procedure developed in manufacture and operating RF gun reach in such stage that, it is mainly determined by the photocathode. The stability and reliability of the laser system for photocathode RF gun is the area much improvement is needed. Develop high efficiency, reliable photocathode, and laser diagnostic techniques, specially the longitudinal profile measurement, are critical to improve the stability and reliability of the photoinjector. We will first present experimental results of Mg cathode measurements at the ATF. Then we discuss a simple technique to study the laser longitudinal profile and laser intensity front variations on the cathode.

* Work supported by U.S. DOE

2 MAGNESIUM PHOTOCATHODE

As we pointed out earlier, photocathode is one of the critical links to improve the RF gun operation for both metal and semiconductor materials. The life time and quantum efficiency (QE) stability of the cathode is the major concern for a user facility. We choose metal cathode at the ATF mainly due to its robustness. Magnesium (Mg) has demonstrated relative high QE under modest vacuum condition [7,8]; the challenge is to find reliable way to attach Mg cathode to the Copper. Many techniques were tested, such as press fitting and sputtering, to attach the Mg cathode to the Copper. The Mg cathode made of press fitting suspect to the temperature variation due to vacuum bake out, while sputtered Mg can be damaged by RF break down. We were able to work with NCT Inc of Connecticut to develop a frictional welding technique to attach the Mg to the Copper with reliable vacuum seal. The Mg cathode was prepared according to the procedure we have developed [9], the cathode surface was polished using three different sizes diamond polishing compound, as polish progressing, the diamond in the polishing compounds were reduced from 9 μm, to 6 μm, then to 1 μm. The polished surface was rinsed with Hexane before immersed in the Hexane bath for 20 minutes ultra-sound cleaning. After the cathode surface was blowed dry with dry nitrogen, it was placed inside a UHV vacuum chamber for 200 °C bake out. It was installed on the RF gun under dry nitrogen (Fig.1).

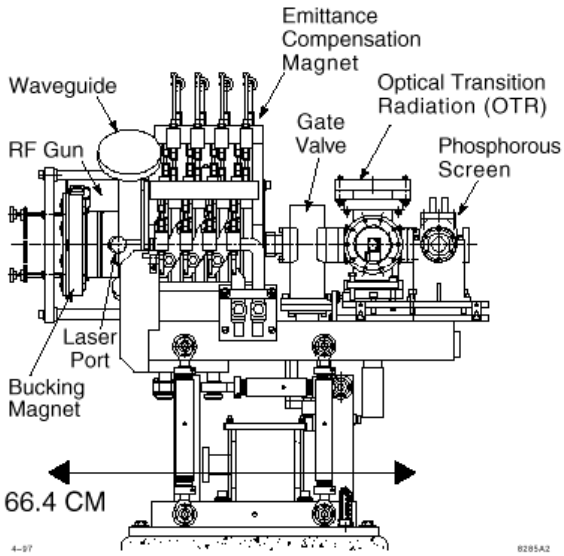

Figure 1: Layout of the ATF photoinjector.

Fig.1 shows the ATF photocathode RF gun injector. The RF gun was mounted directly on the emittance compensation solenoid magnet. There is a Electron beam diagnostic station, which is a multi-function device can be used as a beam profile monitor (BPM) and Faraday cup for photoelectron charge measurement. Fig. 2 is the measurement of photoelectron charge as function of the laser polarization and QE improvement after laser cleaning. The laser energy density used for the cleaning is about 7 mJ/cm^2. One of the most important improvement with frictional welding Mg cathode is its stability comparing to the sputtered Mg cathode [8], which decays by an order of magnitude after couple days operation. The QE measured is on the order of 10^{-3} for a peak field of 100 MV/m after laser cleaning.

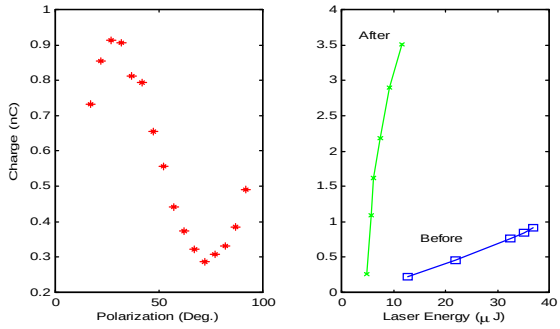

Figure 2: Photoelectron charge as function laser polarization (left) and laser cleaning (right).

3 LONGITUDINAL LASER PROFILE STUDIES

The photoinjector driving laser stability is determined by its energy fluctuation, point stability, timing jitter, transverse and longitudinal longitudinal profiles distribution. Develop experimental technique to characterize those laser properties are critical to improve laser performance. We have developed a technique to study laser longitudinal profile variation and timing jitter by measuring the photoelectron charge as function of the RF gun phase.

The photoelectron current density can be described by the following formula,

$$j = AI(t)(h\nu - \varphi + \alpha\sqrt{\beta E(t)})^2$$

Where I (t) is the time dependent laser intensity, hν is the photon energy, φ is the cathode work function, E(t) is RF field, and β is the field enhancement factor. Using frequency quadrupled Nd:Yag laser (266 nm), the first two terms in above equation is much smaller than the last term for Copper and Mg, so the photo-emission is dominated by the so called Schottky effect. The total photoelectron charge as function of the RF gun phase is,

$$Q(\phi) = \int_{-\infty}^{\infty} d\tau AI(\tau)(h\nu - \varphi + \alpha\sqrt{\beta E(\phi - \tau)})^2$$

The above equation shows that, the charge $Q(\phi)$ is the convolution of the laser intensity distribution $I(\tau)$ and RF field $E(\phi)$. So in principle, we could deduce the laser longitudinal distribution by measuring the photoelectron charge through deconvolution.

Measuring the photoelectron charge as function of the RF gun phase is one of the simplest, but most import measurement in photocathode RF gun operation. Fig.3 is the experimental measurement for both Copper and Mg cathodes. We could obtain following information from Fig.3,

- **Absolution RF gun phase:** both photoelectron beam transverse emittance and bunch length are the function of the RF gun phase [10], accurate measure of the absolute RF gun is essential any stable photoinjector operation. For Schottky effect dominated photoemission, the peak of $Q(\phi)$ corresponding to the RF field crest (90 deg).
- **Timing Jitter:** taking advantage of $Q(\phi)$ dependency on the RF gun phase, we can measure the timing jitter between the RF system and RF gun driving laser. Notice the asymmetry in Fig.3, the falling edge of the $Q(\phi)$ curve is much more sensitive to the laser timing jitter. For a maximum charge of 1.5 nC, the sensitivity of the measurement can be 35 pC/deg. For a S-band RF gun, one degree RF phase is almost equal to 1 ps, this easily allows us to measure femto-seconds timing jitter between the laser and RF system if laser energy fluctuation can be simultaneously take into consideration. To deduce the laser system timing jitter, the timing jitter dependency on the RF gun phase must be taken into consideration [11].

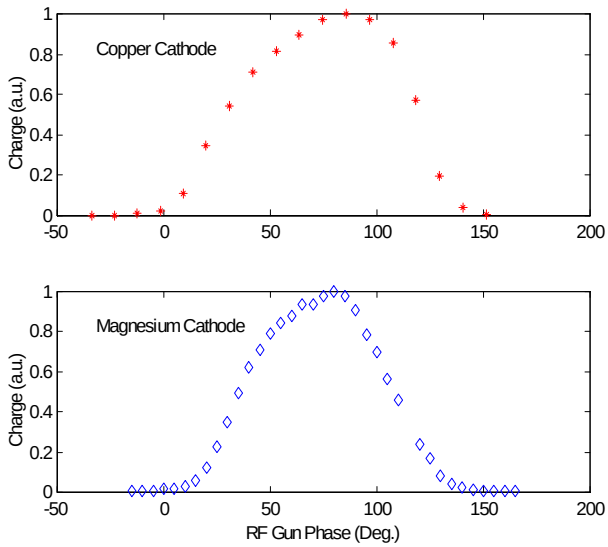

Figure 3: Photoelectron charge as function of RF gun phase for different cathode materials.

The $Q(\phi)$ curve was extensively used at the ATF for photocathode RF gun injector stability studies. We have measured the effect of the frequency doubling crystal on the longitudinal profile distribution of the RF gun driving

laser system (Fig.4). As we increase the laser energy to saturate the frequency doubling crystal, the laser profile change significantly, this is indicated by the variation of the rising edge of the $Q(\phi)$ curve, and broadening the range of the $Q(\phi)$ curve. From convolution theorem [12], the variance of the convolution equal to the sum of the individual function's, so laser pulse length increase will lead to the broadening of the $Q(\phi)$ curve.

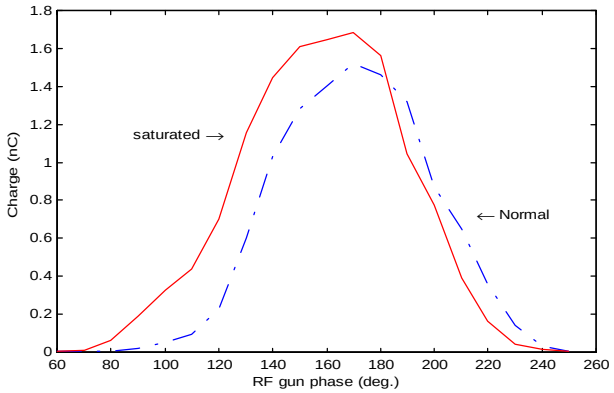

Figure 4: Photoelectron charge as function of RF gun phase for two different longitudinal laser profiles.

Fig. 5 shows variation of the $Q(\phi)$ curve FWHM from normal laser operation condition (80 deg) due to the laser pulse lengthening. We first confirmed this finding by measuring the electron beam bunch length, the laser pulse length inferred is 20 to 25 ps (FWHM). A streak camera with 2 ps resolution was employed to study the laser pulse length, and the laser pulse length obtained is 10 to 14 ps. tremendous efforts was devoted to investigate the inconsistency of those results. Since a grating was used to correct the laser intensity front tilt caused by the oblique laser incidence. We suspected that might cause the effective laser lengthening. We developed a technique of measuring the laser intensity front tilt on the cathode using $Q(\phi)$ curve. A $Q(\phi)$ curve was first obtained for normal laser spot on the cathode (2 mm diameter). Then a laser aperture was used to reduce the spot to 0.3 mm, the second $Q(\phi)$ curve for the smaller laser spot was compared with the first one. It was found that the RF gun phases corresponding to the maximum charge are different. This led us to believe that the laser arrives time varying with the position on the cathode. Further more, $Q(\phi)$ curves were measured as we move the small laser spot on the cathode. Comparing the RF phases for different positions we concluded that, the laser arrive time on the cathode vary as much as 10 ps with position.

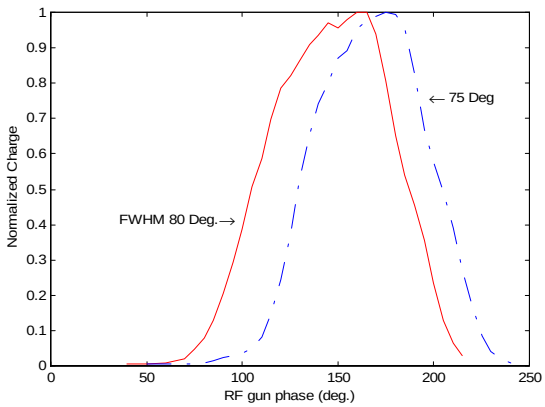

Figure 5: Q curve Width variation due to laser intensity front tilt leads to effective laser lengthening.

SUPPRESSION OF THE 1MHZ BEAM CURRENT MODULATION IN THE LEDA PROTON SOURCE

Pascal Balleyguier, CEA, Bruyeres-le-Chatel, France
Joseph Sherman, Thomas Zaugg, LANL, Los Alamos, USA

Abstract

Earlier operation of a microwave proton source exhibited an approximate 1-MHz modulation in the beam current. This oscillation could cause instabilities at higher energy in the linac, as the low-level RF control for linac operation rolls off at 200 kHz. Tests on a dummy load showed the modulation was created by the magnetron itself. Since the magnetron exhibits better behavior at higher levels, an RF power attenuator was inserted to force the magnetron to run at a higher power. This attenuator is made of two antennas plunged a quarter of guided wavelength apart in the waveguide and connected to dummy loads by a coaxial line. Magnetron operation at the higher power level gives a beam current spectrum free of the 1-MHz modulation, showing the coherent beam noise is not generated by plasma chamber phenomena.

1 MAGNETRON CHARACTERIZATION

Recent operations of the LEDA proton source [1-2] showed that the beam current was modulated in amplitude at a frequency of approximately 1 MHz. Earlier works already mention this kind of problem [3]. In the future downstream accelerator, any beam current variation would result in a varying beam-loading and could cause serious RF field instabilities. A challenge was to find out how to get rid of this modulation.

Previous measurements showed that the modulation was present in the 2.45 GHz RF power injected in the source plasma. In order to tell if the beam modulation was caused by a plasma resonance or by the RF generator itself, we connected the magnetron to a dummy load and measured the RF spectrum via a directional coupler (fig. 1). At 680 W (typical RF level for this application), its output still exhibited a strong 1 MHz modulation. Varying the RF power resulted in different spectra, and we established that the spectrum was completely free of modulation at higher powers, (see for example, the spectrum for 975 W in figure 2). The plot on figure 3 shows that the modulation strongly depends on the magnetron output power. The sideband effect is probably caused by a resonance in the tube.

Unfortunately, the useful power range for our ion source operation (500 to 800 W) is in the middle of this resonance. The good behavior of the magnetron above 800 W suggests to run it at a higher power range in order to get rid of the modulation. The magnetron can provide 750 to 1200 W of power and one third of this power can be dissipated in a power coupler.

2 POWER EXTRACTOR

The device we need is an RF attenuator that transmits 66.7% of the input power. Such an attenuator (-1.78 dB, dissipating up to 400 W on a WR284 waveguide at 2.45 GHz), is not a standard product and would have a high price and a long delay if ordered from a manufacturer. Therefore, we decided to build it within the laboratory. It is easy to extract some RF power from a waveguide by inserting an electric antenna in the high electric field region and connecting the antenna to a coaxial load. The antenna length can be adjusted to attain a given coupling value, but this generates a local mismatch and results in

a reflected wave in the guide. If the power extractor consists of two identical antennas a quarter of guided wavelength apart, the two reflected waves are out of phase and approximately cancel each other. Moreover, as each of the antennas has to extract only 1/6 of the input RF power, they can be smaller in size, and this also reduces the mismatch effects of the device.

2.1 Single antenna pick-up theory

Consider a $\lambda_g/4$ long piece of lossless waveguide. The transfer coefficient between the input and output planes is the complex number *i*. Introducing an antenna in the middle of this device can lower the transfer coefficient modulus, and also alter the phase by $\Delta\varphi$. The original $\pi/2$ phase can be restored (fig. 4) by shifting the reference planes by :

$$\Delta l = -\frac{\Delta\varphi}{2\pi}\lambda_g . \quad (1)$$

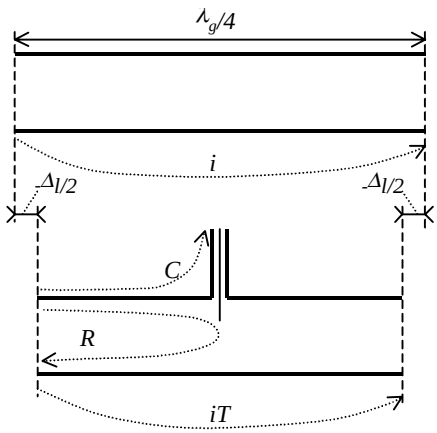

Figure 4: Single antenna pick-up. The reference planes have been displaced in order to keep the forward transfer coefficient a purely imaginary number.

The transfer coefficient of this "single antenna pick-up" is *iT, T* being a positive real number. In the coaxial line, the reference plane is chosen so the coupling coefficient *C* is also a positive real number. The antenna causes a reflected wave in the waveguide with an a priori arbitrary phase. Let *R* be the complex reflection coefficient seen from the input reference plane. Energy conservation implies:

$$|R|^2 + C^2 + T^2 = 1 . \quad (2)$$

As seen in the following section, *R* must also be a real number. That physically means that the reflection coefficient phase on the antenna is null if seen from a reference plane $\lambda_g/8$ upstream from the antenna (Δl is neglected here). In other words, the reflection phase is $\pm\pi/2$ if the reference plane is on the antenna itself.

2.2 Dual antenna pick-up theory

The dual antenna pick-up is obtained by cascading two devices identical to the single antenna pick-up described above (fig.5). We will assume that the inter antenna distance ($\lambda_g/4+\Delta l$) is large enough that the field patterns perturbation caused by one antenna is not seen by the other one. If the perturbation was non-negligible, the antennas could be separated by an additional integer number of $\lambda_g/2$.

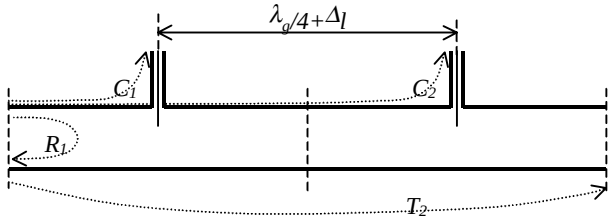

Figure 5: Dual antenna pick-up

Let T_2 be the global transfer coefficient. The incoming wave is multiplied by *iT* by the first antenna and *iT* again by the second antenna, giving $-T^2$ as the first term in T_2. The reflection on the second antenna creates a wave that is partially reflected again by the first antenna. At this point (medium reference plane), the transfer coefficient is $iT.R^2$. Going through the second antenna, this secondary waves reaches the output plane with a transfer coefficient multiplied again by *iT*, resulting in $iT.R^2.iT=-T^2R^2$. Considering now the wave doing one more round trip between the two antennas results in $iT.R^4.iT=-T^2R^4$. And so on... The summation of all these waves gives the actual transmitted wave:

$$T_2 = -T^2 + \sum_{k=1}^{\infty} -T^2R^{2k} = -\frac{T^2}{1-R^2} . \quad (3)$$

The same kind of argument gives the global reflection coefficient R_1, and the two coupling factors C_1 and C_2:

$$R_1 = R + \sum_{k=1}^{\infty} -T^2R^{2k-1} = R\left(1-\frac{T^2}{1-R^2}\right), \quad (4)$$

$$C_1 = C + \sum_{k=1}^{\infty} -iTCR^{2k-1} = C\left(1+i\frac{RT}{1-R^2}\right), \quad (5)$$

$$C_2 = iTC\sum_{k=1}^{\infty} -iTCR^{2k} = i\frac{TC}{1-R^2} . \quad (6)$$

Conservation of energy implies:

$$|R_1^2| + |C_1^2| + |C_2^2| + |T_2^2| = 1 \quad (7)$$

With equations (2) to (6), (7) can easily be proven if *R* is a pure real number. It is more difficult to prove the reciprocal proposition, but one can easily be convinced (by some numerical tests) that equation (7) can only be true if *R* is real, as mentioned in previous section.

Equation (4) shows that, as expected, the global reflection coefficient has been reduced by the second antenna, though it has not been completely cancelled because the second antenna receives a signal that has been already attenuated by the first one. For the same

reason, the two coupled output coefficients $|C_1|$ and $|C_2|$ are roughly equal to *C*.

The goal is to reach a specific transfer value $|T_2|$. From equation (3), one can see that T^2 must be chosen slightly greater than $|T_2|$, as R^2 is expected to be much smaller than unity. To be more precise, the link between *R* and *T* is needed, or equivalently because of equation (1), the link between *R* and *C*. While this link cannot easily be predicted, it can be measured experimentally.

2.3 Realization

A single antenna has been installed in the waveguide. A 9 mm hole has been drilled in the upper wall guide, and a connector socket (N type) fixed on the external side in a way that the socket pin would make an electrical antenna within the guide. As this antenna proved to be too short, a screw was placed in the socket pin (fig. 6) to increase the coupling coefficient *C*.

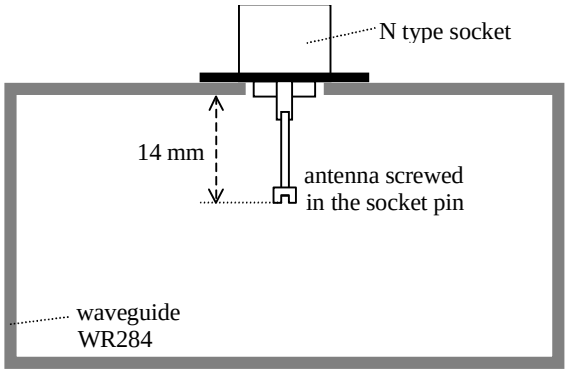

Figure 6: Mechanical design of the pick-up antenna. The two antennas are 51 mm apart.

After testing different antenna lengths, we established that the link between R and C was approximately:

$$C = 0.85 \cdot R + 0.18 . \qquad (8)$$

The goal value for C was computed numerically from equations (2)(3)(8) and from T_2^2=0.667: C=0.414. With a 14 mm antenna, we measured C≈0.399, and considered it was close enough to the goal. The phase shift introduced by a single antenna on the transmission coefficient was measured by comparing the waveguide phase transmission successively with and without the antenna: Δφ=11°. From eq.(1), the waveguide width and the operating frequency (a=72 mm, f=2.45 GHz), we computed the correct distance between the antennas:

$$\lambda_g/4+\Delta l=233/4-7\approx 51 \text{ mm}.$$

After installing the second antenna at this distance, we measured the dual antenna device characteristics:

$|R_1|$=0.028 (-30.8 dB), $|C_1|$=0.435 (-7.22 dB),
$|C_2|$=0.350 (-9.11 dB), $|T_2|$=0.822 (-1.70 dB).

The power transmission coefficient ($|T_2^2|$=0.675) is close to the design value (0.667), and the reflection coefficient is even better than predicted (SWR =1.06): the objective of power extraction without important mismatching has been reached. When operating the magnetron up to 1200 W, the loads have to dissipate up to 227 and 147 W, respectively. The loads installed can hold up to 250 W RF power, and a fan has been installed to cool them.

3 CONCLUSION

We tested the source performance with the same RF power delivered to the plasma chamber with and without the power extractor installed. With power extractor, the magnetron delivers 1010 W and the plasma chamber sees 682 W. The current source spectrum is now free of any 1 MHz modulation and cannot be distinguished from the background noise (fig. 7).

We proved that the 1 MHz modulation on the source current was entirely due to the magnetron, and was not generated by any phenomenon in the plasma chamber, and we found a simple and efficient way to get rid of this modulation.

The source current noise spectrum is now low enough to accurately identify the influence of various ion source parameters on the current spectrum.

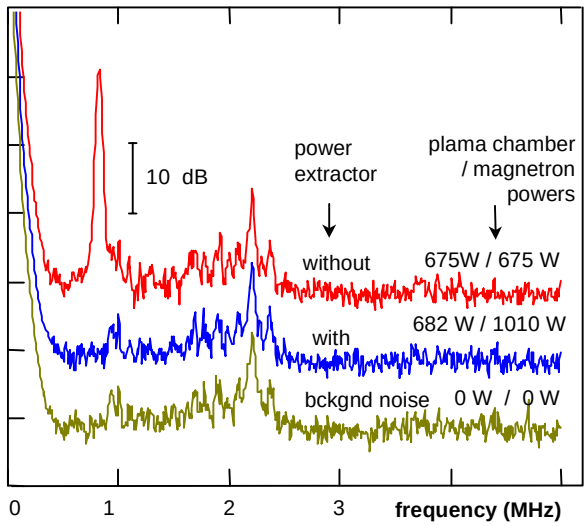

Figure 7: Current spectra comparison at constant RF power in the plasma chamber.
(For clarity, the "without" and "with" curves have been shifted up by 20 and 10 dB respectively).

PHOTO-CATHODES FOR THE CERN CLIC TEST FACILITY

E. Chevallay, J. Durand, S. Hutchins, G. Suberlucq, H. Trautner
CERN 1211 Geneva 23 Switzerland

Abstract

Since 1993 the CLIC Test Facility (CTF) has used laser-illuminated Tellurium Alkali photo-cathodes as intense electron sources (up to 50 nC in 10 ps), for the Drive Beam of a two-beam accelerator. These cathodes have been produced and tested in our photo-emission laboratory and transported under vacuum to the CTF. They are placed in a 3 GHz RF gun with a 100 MV/m electric field. This RF gun produces a train of 48 pulses, each of 13.4 nC charge and 10 ps length. The CTF Probe Beam has used air-transportable cesium iodide + germanium photo-cathodes in another RF gun, which produces a single pulse of the same duration but with only 1 nC charge. The optical damage threshold in the laser is the main limitation of energy available on the photo-cathode. From an operational point of view, the photo-cathode lifetime is defined to be the time during which the cathode is able to produce the nominal charge with the nominal laser energy. After having recalled the main characteristics of the photo-cathodes tested, this note describes in more detail the performance obtained in operation. The possibility of photo-cathode production at the RF gun in a simplified evaporation chamber will also be discussed.

1 INTRODUCTION

The CLIC Test Facility (CTF) produces and tests two different electron beams: one, with a high charge (up to 640 nC in 48 pulses), called the "Drive Beam" (DB) is used to produce 30 GHz radio frequency power. The other, called the "Probe Beam" (PB), with a lower charge of 1 nC in a single pulse, is used to sample the 30 GHz accelerating fields. A summary of results from CTF-II is reported in [1]. The electron source for each beam is a 3 GHz RF gun equipped with a laser-driven photo-cathode. The photo-cathode requirements are closely related to the electron beams and the laser characteristics.

2 PHOTOCATHODE REQUIREMENTS

2.1 Electron beam specifications

The electron beam specifications are summarized in Table 1. The repetition rate was reduced from 10 to 5 Hz to improve the vacuum in the DB RF gun and consequently to improve the photo-cathode lifetime.

Table 1 : Electron beams specifications.

		DB	PB
Charge per bunch	nC	13.4	1 - 2
Number of bunches	-	48	1
Pulse width FWHM	ps	10	10
Δt between pulses	ps	330	-
Charge stability	% rms	1	5
Jitter laser / RF	ps	$\pm$ 1	$\pm$ 1
Jitter DB / PB	ps	$\pm$ 1	$\pm$ 1
Delay PB / DB	ns	-	14
Cathode electric field	MV/m	100	70
Repetition rate	Hz	5	5

2.2 The CTF-II laser system

The laser (Fig. 1 and Ref. 2) is a "Master Oscillator-Power Amplifier" (MOPA) system in which 2 pulses are selected from a 250 MHz Nd:YLF mode-locked oscillator. The pulses are 8 ps and they have an energy of 0.5 nJ per pulse. They are amplified in a Regenerative Amplifier (RA), followed by power amplifiers to 7 mJ per pulse. The power density is 10 GW/cm^2 at the final power amplifier. This is close to the damage threshold since the beam is limited to 4.5 mm diameter due to the size of the components. The wavelength is converted from 1047 nm to 262 nm (the 4th harmonic). The 2 UV pulses are then progressively "split" with appropriate delays in a "Pulse Train Generator" (PTG) to produce the DB train of 48 pulses with 333 ps separation. The separation is exactly one 3 GHz RF period so that each light-pulse will illuminate the photo-cathode at the same RF phase and the resulting electrons will then be equally accelerated. The timing for the laser and the 3 GHz RF generator are synchronized.

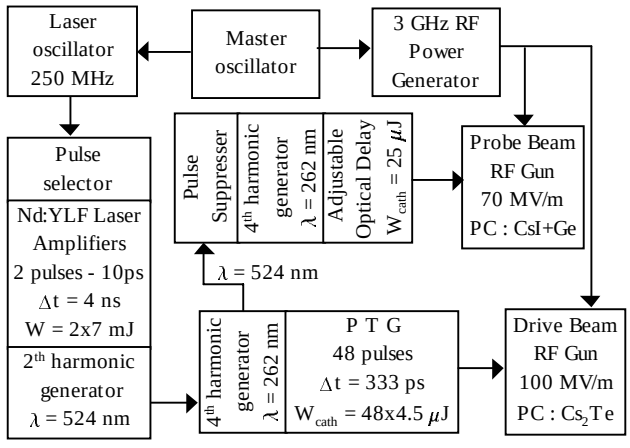

Figure 1: Laser layout for the Probe and Drive Beam

The residual green light from the initial 4th harmonic generator is used to produce a pulse for the PB. This initially passes through a Pockels cell that rotates the polarization of the second green pulse by 90°, this is then rejected by a polarizing plate. The remaining pulse is converted to UV.

The two light beams are imaged to their respective cathodes, for the DB the distance is 32 m with a magnification of 2x. The PB is delayed to arrive at the accelerating section in the linac when the 30 GHz power has been generated, making its path length equal to 36 m.

Finally, 48 pulses of 4.5 μJ at 262 nm arrive at the DB photo-cathode, and a single pulse of 25 μJ with the same wavelength on the PB photo-cathode.

2.3 Photo-cathode requirements

The photo-cathodes are characterized by their quantum efficiency (QE, the ratio of emitted electrons to incident photons) at a given wavelength and by their lifetime under operating conditions. Taking into account the available laser energy, QE must be greater than 1.5 % at 262 nm for the DB, and greater than 0.02 % for the PB at the same wavelength. The lifetime required is at least one week for an electric field in the DB RF gun of 100 MV/m. When a new cathode is installed in the PB RF gun to be operated at a field of 70 MV/m, it is necessary to bake-out the gun due to air contamination. For this reason, the lifetime must be at least one month for continuity of operation. The charges produced must be linearly related to the laser energy up to 640 nC (48 pulses of 13.4 nC) for the DB and 2 nC for the PB. In both cases, the time response must be less than a few ps.

3 PHOTO-CATHODES TESTED IN THE RF GUN

The photo-cathodes are produced and tested in a separate photo-emission laboratory. Only cathodes with properties near-nominal are installed in the CTF guns. Metallic cathodes were also tested [3], a magnesium cathode could be a candidate for the PB, but its QE is low and it has a high dark current. In the context of an informal collaboration with the Stanford Linear Accelerator Center, non-activated GaAs cathodes were tested in the DB gun with electric fields up to 87 MV/m. An activation process for GaAs is under development. The results are reported in [4,5].

Between December 1990 and October 1993 CsI photo-cathodes were used because they can be transported in air [6]. Unfortunately, their photo-emission threshold is high (6.3 eV) involving the use of the fifth harmonic of a Nd:YLF laser (λ=209 nm). This wavelength was found to be impractical, so the possibility of using photo-cathodes at the fourth harmonic (λ=262 nm) were investigated, and a system for transferring the cathodes under vacuum was developed. At this wavelength alkali photo-cathodes are able to produce high charges, and many were tried in the photo-emission lab [3]. Two kinds which matched our laser equipment and the CTF specifications were selected. The first type, for the PB, is a cesium iodide cathode with a coating of germanium. This cathode can be transported in air at the expense of a moderate QE at 262 nm. For the DB, cesium telluride was chosen because of its high QE at 262 nm and long lifetime, but it must be transported under vacuum. The complete results for these two cathode types are reported in [7,8]

3.1 CsI+Ge photo-cathodes

A thin 2 nm coating of germanium over a CsI cathode decreases the QE at 213 nm by a factor of 10, but improves it at 262 nm from $7x10^{-5}$ to 0.13 % [3]. This coating does not change the air exposure property of the CsI. To improve adhesion, a 200 nm layer of aluminum is deposited on the copper cathode plug before the 350 nm CsI layer, which is then coated with 2 nm of Ge. These photo-cathodes are stored in a desiccator. Finally they are installed, in air, in the RF gun which is then baked to 150°C to improve the vacuum. These cathodes require a delicate conditioning process using high electric fields and laser pulses to remove the oxidized surface without destroying the thin germanium layer. After 10 to 15 hours of processing, the QE reaches up to 0.2 % with an electric field of 70 MV/m. The lifetime is quite long: the time constant τ (the time to drop down to QE_{max}/e) is more than one year. In the PB gun, the same cathode has been used since October 1996.

3.2 Alkali telluride photo-cathodes

Four kinds of alkali telluride photo-cathodes were produced and tested on different substrates: Cs_2Te, K_2Te, Rb_2Te and RbCsTe. Only the first one is routinely used in the DB RF gun. All require UV light (λ < 270 nm) for operation.

Cs_2Te : about 10 nm of Te is deposited at room temperature on various substrates (Cu, Mo, Mg). The Cs is evaporated with the substrate at 110 °C until the photo-emission reaches a maximum. Typically 15 nm of Cs gives a QE of 7 %. These cathodes are very robust compared to the alkali antimonide cathodes. The working pressure is about 10^{-9} mbar. The main contamination comes from oxygen [9]. A satisfactory behavior was observed in the RF gun up to 127 MV/m. At this field level, the initial QE is close to 10 %. The QE drops during the first 50 hours with a $\tau \approx 40$ hours, followed by a slower decrease with a $\tau \approx 350$ hours. The time response is less than 2ps; the measurement is limited by the resolution of the streak camera. An electric field dependence of the QE was observed this is probably a Schottky effect [10], and seems to be independent of the Cs_2Te photo-cathode aging rate.

K_2Te : This was found to be a robust photo cathode, but with a QE between 1 to 3 % at 262 nm.

Rb_2Te and RbCsTe : About the same properties as Cs_2Te

cathodes. These cathodes seem very promising for QE rejuvenation after exposure to air. Nevertheless their performance in the RF gun must be demonstrated.

The photo-cathode substrate : Various kinds of substrates have been used : molybdenum, magnesium, and copper, the best results were obtained with Mo and Mg. Due to its higher dark current Mg was eliminated. In terms of charge availability, (QE > 2 % during a few weeks), the substrate is not so important. The second slope of the lifetime curve seems to be almost independent of the substrate.

Between November 1993 and July 1998, 50 alkali photo-cathodes were produced. Twenty eight were used in the RF gun : 26 Cs_2Te, 1 K_2Te and 1 Rb_2Te. Table 2 summarizes the statistics (mean and standard deviation values) for the produced and used alkali photo-cathodes. The cathodes were measured in the DC gun at electric fields between 6 and 9 MV/m. R is the layer thickness ratio of alkali over tellurium. T is the total time of the photo-cathode in the RF gun, and $\tau_{QE>2\%}$ is the time during which the QE is greater than 2 %. About 30 % of the time mentioned in Table 2 was with RF power and laser. The vacuum pressure was about 10^{-9} mbar.

Table 2: Alkali photo-cathodes : Production and use.

Cathode type		Cs_2Te			All	
Substrate type		Cu	Mo	Other		
Production	Numb.	31	6	8	52	-
	QE_{MOY}	4.7	8.8	7.8	5.8	%
	QE_{STDV}	1.9	3.8	2.5	3	%
	R_{MOY}	1.2	1. 5	2.6	1.6	-
	R_{STDEV}	0.5	0.2	2.5	1.3	-
Used in the CTF 70 < E < 125 MV/m	Numb.	15	6	5	28	-
	T_{TOTAL}	362	160	142	693	days
	T_{MOY}	24	27	28	25	days
	T_{STDEV}	23	23	24	22	days
	$\tau_{QE>2\%}$	20	17	14	19	days
	τ_{STDEV}	23	17	14	17	days

4 PHOTO-CATHODE PREPARATION

Three kinds of photo-cathode preparation can be identified depending on the QE and lifetime specifications. When high charge (> 10 nC per pulse), high QE and long lifetime are required (as for CTF DB), the cathode should be prepared by real time monitoring of the QE, then transported and installed in the RF gun in an ultra-high vacuum environment. For up to 1 nC per pulse, CsI+Ge photo-cathodes which can be transported in air give good performances, and lifetimes of a few months. For 1 to 10 nC per pulse it may be possible to produce photo-cathodes using more simple methods. One method would be to prepare the photo-cathode for a high QE, transport in air, then rejuvenate it in the RF gun, or in a vacuum chamber attached to the RF gun. We have tried two different rejuvenation processes: heating, and ion-bombardment etching. A Rb_2Te cathode was exposed to air during 7 minutes and its QE dropped to 10^{-5}. After heating to 200°C in vacuum, the QE improves to 0.5 %. We did not observe any further QE change during 1 week. Another RbCsTe cathode was exposed to air for 2 minutes, its QE dropped down to 0.1 %. After ion bombardment cleaning, its QE improved to 0.7 %.

The second possibility to obtain a medium charge i.e. a medium QE, is to prepare the photo-cathodes in a simplified preparation chamber linked to the RF gun. By monitoring only the layer thickness, the production of photo-cathodes with a QE between 1 and 3 % is possible. Such a cathode, with an initial QE of 2.5 %, has been used in the DB for 78 days with a QE > 2 %.

5 CONCLUSIONS

Cs_2Te and CsI+Ge cathodes fulfil the drive and probe beam CTF-II specifications. The Rb_2Te cathode, using a rejuvenation process, may be a good alternative to Cs_2Te. It is possible to produce Cs_2Te cathodes in an easier and cheaper way by monitoring only the layer thickness, this is however obtained at the expense of a lower mean QE.

A new vacuum chamber will be attached to the PB RF gun to enable laser alignment of the PB. This chamber will be equipped for a simplified cathode production and rejuvenation.

Abstract

During the winter shutdown 1997/98, the injection system of the H⁻-Linac III was upgraded. At present two different kinds of H⁻-sources are operated at DESY. The new cesium-free rf ion source is planned to operate parallel to the magnetron ion source.

In addition a new MEBT (Medium Energy Beam Transport line) between two distinct RFQ accelerators and the Alvarez accelerator of Linac III was installed to match the beam of each ion source to the Alvarez acceptance. This scheme makes it possible to operate either H⁻-source with the Alvarez linac with a miniumum of effort to switch from one to the other. The design of the transport line also facilitates the development and tests of newly proposed ion sources, for example deuterium and polarized proton sources.

After assembly of the RFQs and ion sources as well as the new components for the MEBT, a relatively easy commissioning could be demonstrated, although the ions have to be transported on a long distance from the RFQ to the Alvarez linac. First results of measurements will be presented.

1 INTRODUCTION

Linac III at DESY started operating as an H⁻-injector for the DESY III synchrotron in 1989 [1] and is part of the injector chain for the HERA collider. The negative charged ions are produced by a surface-plasma magnetron source at 18 keV and are accelerated with an RFQ to an energy of 750 keV. A conventional Alvarez linac is used to obtain the injection energy of 50 MeV into DESY III.

Further developments at the DESY cesium-free rf-volume source led to an operable and reliable design [2]. To integrate this volume source into the proton linac for standard operation it was desirable to find a technical solution to switch back to the magnetron source at any time. This improves the reliability of the proton injector chain to HERA. It was therefore decided to reconstruct the pre-accelerator of the linac to allow both ion sources to operate for the linac simultaneously.

The upgraded injection system in front of the Alvarez linac consists of the existing devices as well as of a new beamline with an additional RFQ and a rebuncher cavity. The assembly of the new MEBT beamline and the two ion sources also necessitated an extension of the accelerator tunnel. The shutdown period of the DESY accelerators

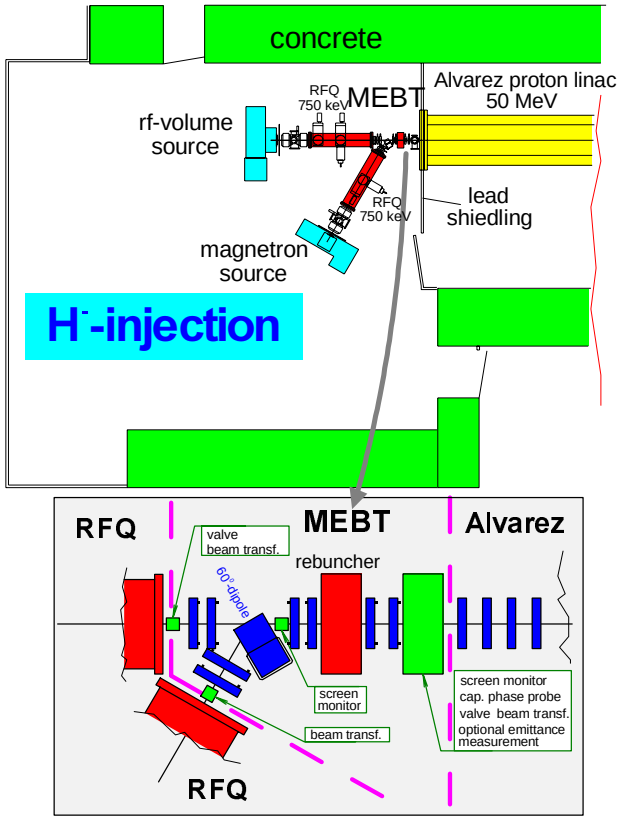

Figure 1: Floor plan of the injection system and a detailed view on the MEBT.

in winter 1997/98 was used for dismantlement of the pre-accelerator, the reconstruction of parts of the tunnel and related facilities and the assembly of the new components.

The low beam energy of 750 keV, small beam losses and a new arrangement of lead- and concrete-shielding permits access to the injection system during linac operating time.

2 CHARACTERISTICS OF THE MEBT

Beam transport of ions under space charge conditions at low energies reduces the variety of possible transport line designs. The goal was to control the longitudinal bunch shape with only one rebuncher cavity between the RFQs and the Alvarez linac. Therefore it was essential to keep the overall length of the transport line below 1 m. The mechanical components had to be composed in a very compact manner. Details of the MEBT have been given previously

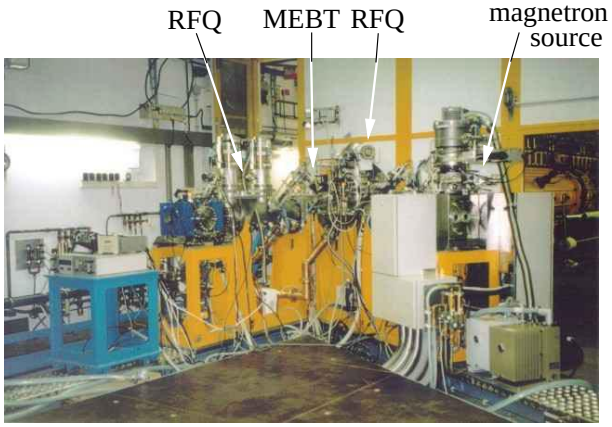

Figure 2: View of the rebuilt injection system in the Linac III tunnel.

[3], briefly the design is as follows:

The new rf-volume source is installed on the axis of the Alvarez linac, whereas the beam coming out from the magnetron source is bent by a 60°-dipole to this axis. Fig. 1 shows a survey of the injection system.

The main components including ion sources, RFQs and the MEBT are mounted independently on frames made of aluminium. These frames are put onto a rail system and are thus retracktable along the beam axis. It is therefore easy to install additional beam diagnostic elements for further investigation of beam properties at any place in one of the paths. Fig. 2 and Fig. 3 show the arrangement of the injection system and details of the MEBT transport line.

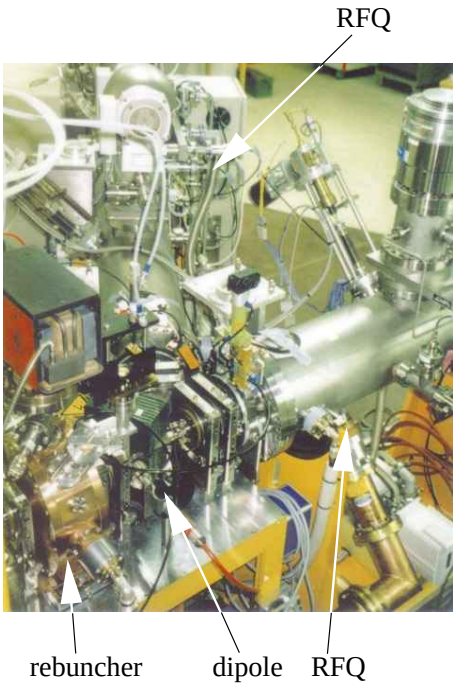

Figure 3: Side view of the MEBT beam transport line.

Table 1: Basic parameters of the new cavities for the injection system.

	RFQ	rebuncher
f_0	202 MHz	202 MHz
U_{rod} / U_{eff}	80 kV	58 kV
P	80 kW	4 kW
L	120 cm	12 cm

The 4-rod RFQ and the rebuncher cavity were delivered by the University of Frankfurt [3]. A parameter list is given in Table 1. The rf-amplifier for the rebuncher was designed and constructed at DESY. The design is based on the rf-preamplifier of the existing rf-amplifiers for Linac III.

3 FIRST OPERATION WITH THE MEBT

After the assembly and adjustment of the new injection system first acceleration tests with the magnetron source were performed. The rf-volume source is already assembled in position but not in operation yet. It is expected, that first beam tests with the new source can be performed in autumn.

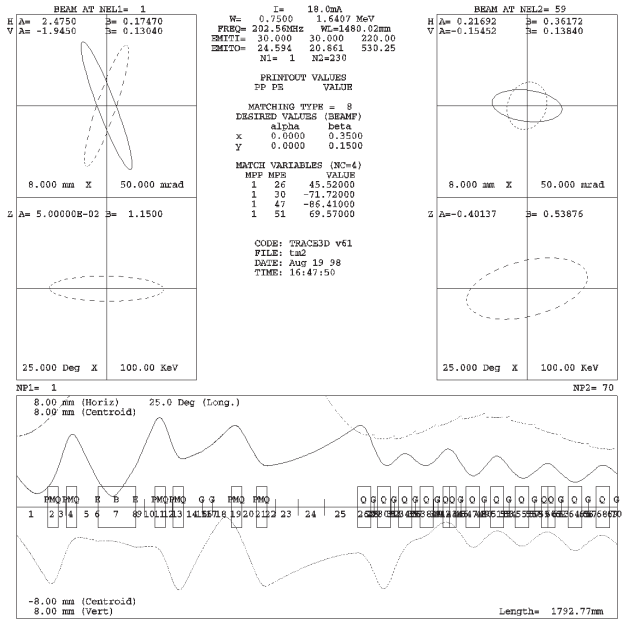

Figure 4: Matched beam envelopes (5σ) calculated by TRACE3D.

Once the beam delivered by the magnetron coasted through the MEBT line, only little empirical tuning of the MEBT quadrupole focusing strength was necessary. The numerical simulations (s. Fig. 4) led to a solution with good transmission through MEBT and the Alvarez linac. Only one quadrupole was displaced by 0.7 mm for beam steering reasons. Whereas the transmission of the solenoid focusing channel in front of the RFQ is found to be limited under space-charge conditions to 50 % [4], the transmission from the RFQ up to the end of the high energy transport line after the Alvarez linac under typical conditions

reaches 75 %. At the injection point to DESY III currents of 10 to 15 mA are obtained, depending on the current of the magnetron source of typically 30 to 65 mA.

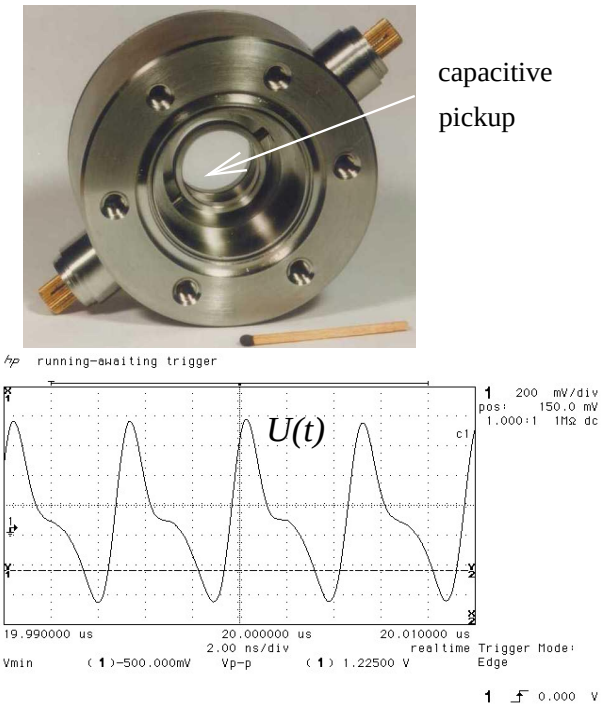

Figure 5: Signal of a bunched beam with $\Delta\varphi\,(2\sigma) = \pm 30°$ measured with the capacitive probe above.

The cavity phase and amplitude settings of the RFQ and rebuncher with respect to the Alvarez tanks was to be found more laborious. The phase settings of the cavities is based mainly on the measurements of energy and momentum spread after the Alvarez linac. A capacitive phase probe built at DESY (see Fig. 5) between rebuncher and the Alvarez was used to estimate the longitudinal bunchlength at the end of the MEBT.

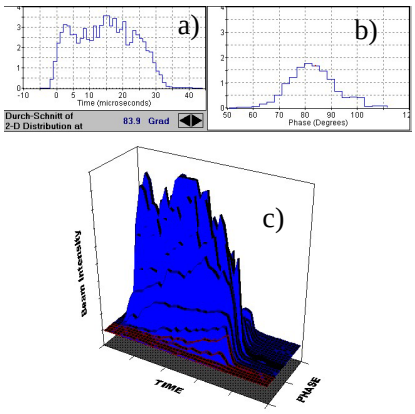

Figure 6: Current density along the bunch train **(a)**, phase spread **(b)** and a 3D-view **(c)** of the buch train measured with the bunch shape monitor at the Alvarez Tank 1.

The bunch shape monitor [5] in the Alvarez Tank 1 was used for fine tuning of the relative phase setting between the rebuncher cavity and the Tank 1 as well for the amplitude settings of these cavities. Fig. 6 shows a offline estimated 3D-view of the bunch train.

The phase tuning was to be found slightly depending on the beam current delivered by the ion source. Fig. 7 shows a typical devolution of momentum spread and energy during tuning of the cavity settings.

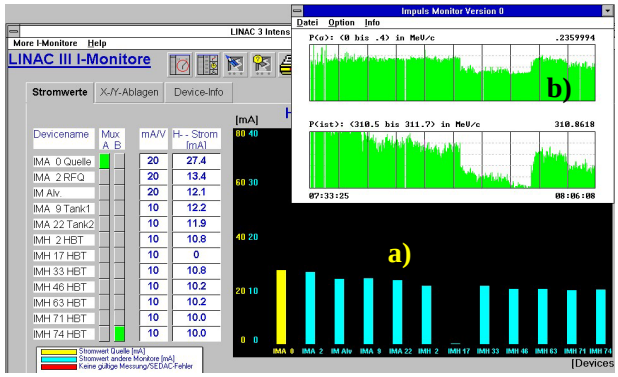

Figure 7: Transmission along the linac **(a)** and a history of evaluated beam properties **(b)** shown on a PC console station.

4 ACKNOWLEGMENT

The authors wish to thank all contributing colleagues and the collaborating institutes for their technical support and helpful discussions.

Abstract

A photoinjector is being constructed in order to produce a pulse train of up to 800 electron bunches, each with 8 nC of charge and a 3.5 ps rms bunch length. The spacing between bunches within a train is 1 μs and the train repetition rate is 1–10 Hz. The desired transverse emittance is $<20\pi$ mm $\cdot$ mrad. An rf photo-gun delivers a bunched 4–5 MeV beam which will be accelerated to 14–18 MeV by a 9-cell superconducting cavity and compressed magnetically. Measurements have been done on the beam delivered by a first prototype rf gun; installation of a new rf gun, the 9-cell cavity, and the bunch compressor is in progress.

1 INTRODUCTION

A high-brightness electron source is being constructed at Fermilab as part of an ongoing collaboration with the TeSLA Test Facility (TTF) [1], and to provide an R&D facility for advanced accelerator research at Fermilab. The facility consists of a high quantum efficiency photocathode in a 1.3 GHz normal conducting rf gun, a 9-cell superconducting cavity for acceleration, and a magnetic bunch compressor (chicane). Thus far, an initial test with an rf gun has been completed. In particular, the important operational issues of dark current production and beam transport through the rf gun were studied. In this paper, we outline the results of the gun and beam studies thus far. When completed, the facility will be used to study beam transport through the cavity and the physics of compression with the high brightness beam. In the longer term, the facility will be used to explore a number of new acceleration schemes and to provide an R & D tool for a variety of new concepts relevant to high-energy, high-intensity machines, as will be described herein.

2 DESCRIPTION OF FACILITY

The beam line consists of a normal conducting rf gun, a superconducting acceleration cavity, a magnetic chicane, a low-β section, a spectrometer, and diagnostics. In addition, there is a separate chamber for coating photo-cathodes and transferring them to the rf gun. The upstream portion of the beam line is shown in Fig. 1.

2.1 RF Gun

The rf gun consists of a 1.625-cell 1.3 GHz π mode copper cavity side-coupled to a waveguide in the full cell [2, 3]. The first prototype gun was intended for a low duty cycle ($\sim 10^{-4}$). However, it was operated with a peak surface field on the cathode of E_c = 39 MV/m with a pulse length of up to 400 μs at a 1 Hz repetition rate; a 1 ms pulse was reached with E_c = 36 MV/m at 0.1 Hz. The gun was used to produce beam at Argonne [2, 3] and Fermilab (see § 3).

A second generation gun has been designed for a high duty cycle (1%). The design parameters were (i) a beam energy of 3.9–5.5 MeV, which corresponds to E_c = 35–50 MV/m and a peak power dissipation of 2.2–4.5 MW; (ii) an rf pulse duration of 800 μs; (iii) a repetition rate of 10 Hz. The high average power (up to 36 kW) is removed by cooling channels machined into the walls of the cavity, with $\sim$4 L/s of water flow. The first of the new guns has been fabricated and is presently being conditioned. To date, it has been operated with E_c = 40 MV/m (2.7 MW peak power) with a 800 μs pulse length at 1 Hz. Dark current measurements have also been done (see § 3.2).

2.2 Nine-cell Cavity

The superconducting accelerating cavity is a 9-cell structure made from sheet Nb [1]. Sub-systems include a high-power coaxial input coupler (Q_{ext} = 10^6 to $9 \cdot 10^6$), a cold tuner (range $\approx \pm$ 400 kHz), and 2 coaxial higher-order mode couplers. The current cavity, named S12, is a prototype fabricated by industry for TTF. It was etched, rinsed, heat treated, and tested with rf at DESY. The cavity is one of a batch with a low quench field (13 MeV/m in CW), attributed to contamination in the electron beam welds at the equator. The horizontal cryostat was designed at Orsay [4] for the TTF capture cavity and built by industry. After shipment to Fermilab, the cavity and cryostat were assembled, cooled to 1.8 K, and tested (without beam). With 800 μs useful pulse length and 1 Hz repetition rate, the cryogenic load was tolerable at a gradient of $\geq$12 MeV/m. Further rf tests are needed to verify the field level calibration and measure the cryogenic losses versus field level.

2.3 Laser System

The ultra-violet (UV) laser for photo-electron production is a phase-stabilized mode-locked Nd:YLF oscillator (λ = 1054 nm) and a chain of Nd:glass amplifiers, using chirped pulse amplification [5]. Seed pulses from the oscillator are stretched and chirped in an optical fiber, then selected by a fast Pockels cell (PC). A second fast PC is

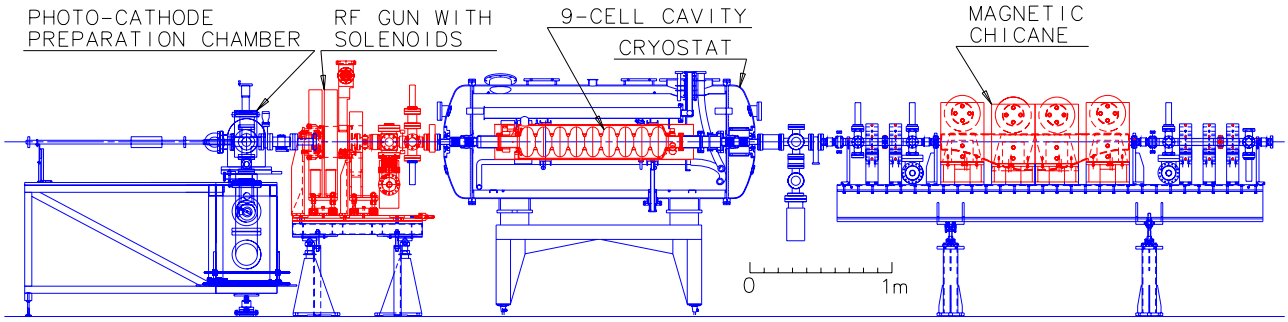

Figure 1. A0 beam line layout from the cathode preparation chamber through the chicane.

used to trap and eject the pulses into a multi-pass amplifier (see Fig. 2). After a 2-pass amplifier and spatial filtering, a grating compressor achieves a short, selectable pulse length (1–20 ps). Two stages of second harmonic generation are used to reach the UV wavelength (263 nm). The system is designed to produce 5 μJ per pulse of UV, in the following temporal pattern: pulse repetition rate of 1 MHz, pulses grouped into trains of 800, with 1 Hz repetition rate for the trains. The amplitude across the train is shaped via a third (slow) PC prior to amplification, to compensate for the time-dependent gain of the amplifiers, in order to produce a pulse train with a flat envelope.

2.4 *Photo-cathode*

The primary photo-cathode figure of merit is the quantum efficiency (QE), the ratio of the number of emitted electrons to the number of incident photons. The cathode is a Cs_2Te film on a Mo substrate. Cs_2Te can have a QE of up to 10–15%; for comparison, the QE of a metal cathode is typically 10^{-4}–10^{-6}. However, the QE of Cs_2Te is degraded by residual gases, so a Cs_2Te cathode must remain in ultra-high vacuum (UHV) for its entire useful life. A UHV system for coating cathodes and transferring them into the rf gun is hence required. So far, 2 cathodes have been coated and used with the first gun. For both, the QE was $>$10% immediately after coating, about 0.6% after being used in the gun, and $\geq$5% after rejuvenation [6].

2.5 *Diagnostics*

The beam diagnostics include integrating current transformers (ICT), Faraday cups, beam position monitors (BPM), screens, emittance slits, and a magnetic spectrometer. The BPM's employ a heterodyne scheme to avoid rf noise and enhance signal strength. The screens are YAG, Cr-doped alumina, and Al, the latter being used for optical transition radiation (OTR) measurements with an intensified camera. The emittance slits consist of a rotatable array of 10 μm slits approximately 20 mm high and 6 mm thick.

3 BEAM OPERATION

A first round of experiments was done at Argonne with the low duty cycle gun, a Cu cathode, and a Cu 9-cell cavity [2, 3]. A second round of experiments was done at Fermilab with the same gun (after retrofit for a Cs_2Te cathode), without a 9-cell cavity, as will be described in this section. The next step will be further experiments with the new high

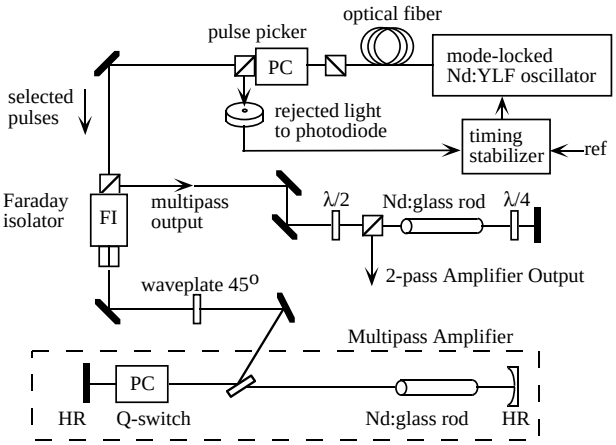

Figure 2. Block diagram of the laser system through the 2-pass amplifier.

duty cycle gun, 9-cell superconducting cavity, and chicane.

3.1 *Photo-Current Measurements*

Photo-electrons have been produced in pulse trains up to 50 μs long, as shown in Fig. 3. At present, the limit on train length is set by the laser. The maximum charge per bunch extracted from the cathode and accelerated by the gun was 30 nC, 15 nC, and $\sim$1 nC for trains of 1, 9 and 50 bunches, respectively.

The maximum beam energy measured with the spectrometer was 4.7 MeV, with a corresponding RMS energy spread of 5 to $8 \cdot 10^{-3}$. The normalized horizontal and vertical emittances were 9π and 7π mm $\cdot$ mrad, respectively, as measured via a quadrupole scan (with 10 bunches, 1.2 nC/bunch, 4.5 MeV).

A scan of rf phase shows the expected peak of transmitted current around the operating phase (Fig. 4). Direct measurements of jitter show the laser-rf jitter to be less than 10 ps, which is the limiting resolution of the measurement.

A preliminary round of measurements was done with the BPM's, ICT's, Faraday cups, and the OTR screen. Various problems were identified, e.g. amplitude modulation in the low-level rf system and inadequate alignment of the gun and focussing solenoids to the beam line.

3.2 *Dark Current Measurements*

A large amount of dark current was generated in the first rf gun after retrofit. Since field emission is strongly dependent on the rf field strength, one would expect that the dark

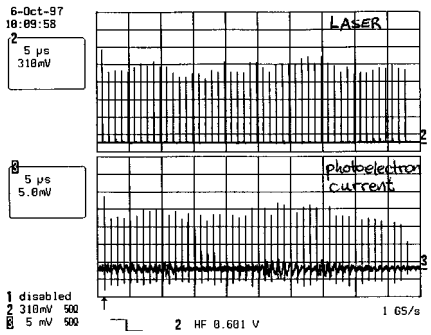

Figure 3. UV light incident on the cathode (top) and beam current (bottom) as a function of time (5 μs/division). Vertical scales are uncalibrated.

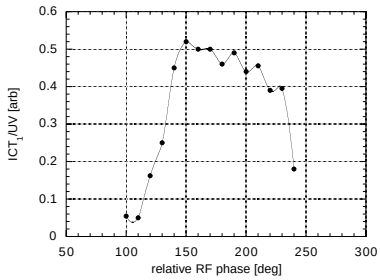

Figure 4. Normalized beam current versus rf phase.

current is generated at nearly full field, and thus emerges at full energy, but with a large energy spread. This was confirmed in spectrometric measurements. With the focussing solenoids set to image the emission on a screen downstream of the gun, it was inferred that the dark current was emitted primarily near the edge of the cathode, where a toroidal spring provides the rf contact between the cathode and the Cu wall of the gun.

In the second generation gun, the measured dark current is smaller by a factor of 20 at E_c = 38 MV/m. We attribute this to careful cleaning procedures and to the use of a slightly different geometry and a new type of spring; however, the measurements on the second gun were made 0.2 m further downstream, which may account for some of the difference. Further tests on the new gun are underway.

4 PLANNED EXPERIMENTS

In addition to those described below, experiments are planned on the measurement of the longitudinal charge distribution of short bunches and on channelling acceleration.

4.1 Chicane Operation

In order to qualify the facility for future high-brightness applications, it is necessary to further compress the bunch length using a magnetic compressor, or chicane. While this procedure is routine, there are issues that need to be studied, including the effect of strong space charge forces on the transport through the chicane [7].

4.2 Plasma Accelerator Experiments

A key test of the plasma wake field accelerator (PWFA) [8] is planned among the first applications of this facility. Since the beam is of such high brightness, it provides an excellent driver of plasma waves in the PWFA, and should be the most definitive test of the achievable gradient to date. A plasma of $1–3 \cdot 10^{13}$ cm^{-3} is created in a target chamber located in a low-β section of the beamline, shown in Fig. 5. Expectations are that gradients of 1 GeV/m should be achievable in this plasma.

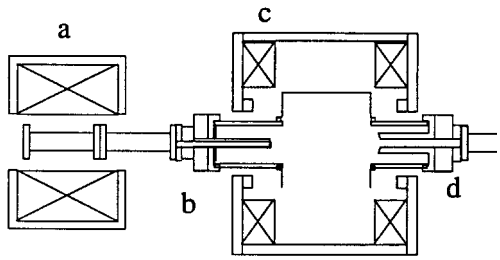

Figure 5. Plasma target chamber for PWFA, consisting of (a) matching solenoid, (b) cathode assembly, (c) plasma vessel with confinement solenoid, and (d) anode assembly. The plasma is generated between the 2 coaxial electrodes.

5 CONCLUSIONS

A flexible, high-brightness photoinjector is under construction; it will provide an intense source of electrons for a variety of experiments. Initial experiments with a prototype rf gun have shown the expected beam properties, albeit accompanied by relatively large dark current. A second-generation gun has shown a promising reduction in dark current. Further work is now in progress to commission a chicane, and to optimize performance. Experiments on such concepts as the plasma wake field accelerator will commence in the near future.

ACKNOWLEDGEMENTS

We thank our colleagues at Fermilab and in the TeSLA collaboration, especially S. Buhler, J. Crandall, R. H. Flora, T. Garvey, J. Gastebois, E. H. Hahn, M. Julliard, T. Junquera, T. W. Koeth, J. R. Le Duff, A. Matheisen, W.-D. Möller, W. Muranyi, F. A. Nezrick, J. R. Noonan, M. J. Pekeler, P. S. Prieto, D. Reschke, J. K. Santucci, S. N. Simrock, J. J. Urban, M. M. White, and D. A. Wolff, for their participation in and many contributions to this project.

ION SOURCES FOR THE NEW HIGH CURRENT INJECTOR AT GSI

P. Spädtke, H. Emig, K.D. Leible, C. Mühle, H. Reich, B.H. Wolf*
GSI Darmstadt

The new high current injector at GSI will replace the existing prestripper accelerator of Wideröe type by a RFQ and an IH structure [1]. This new accelerator will increase the possible particle currents by 2 orders of magnitude. For the design ion Uranium, the particle current will be increased from presently 20 pμA (U^{10+}) to 4 pmA (U^{4+}). As ion sources for such high currents, a multi cusp ion source (for gases) or a vacuum arc ion source (for metals) are foreseen. The existing Penning ion source, which is well experienced for all elements of the periodic table, will be used in the future as well and has to be improved in current performance for this new operating regime. For these ion sources two 320 kV high voltage terminals are presently used.

1 HIGH CURRENT TERMINAL

The high current terminal will be equipped either with a MEVVA (Metal Vapor Vacuum Arc)[1] ion source (for metals) or with a MUCIS (Multi cusp ion source)[2] ion source (for gases). Because of the high current required from this terminal, we have to replace the existing 320 kV/20 mA high voltage power supply by a new power supply 130 kV/150 mA.

The ion sources are already in use with the existing Wideröe accelerator, however not with the full ion current available from these sources. We had several beam times, mainly for accelerator experiments, with the MUCIS ion source (Ne^{+}, Ar^{2+}, H_3^+, D_3^+) and the MEVVA ion source (Ni^{3+}, Mg^{+}, Mg^{2+}). Total ion currents extracted from the sources were in the order of 100 mA for all ions mentioned above. The preparations and tests of the MUCIS and MEVVA ion sources are performed at a special test bench. Beside the ion source power supplies, the test bench consists of a 8m long beam transport line with two quadrupole triplets, a dipole analyzing magnet and a number of ion beam diagnostic elements. Typical ion beam currents, charge state distributions (CSD) and signal to noise ratios (S/N) measured at the test bench are listed in table 1. The listed values of total current (I_{tot}) depend on the extraction voltage (U_{ex}) applied, and are measured values for ion source settings with minimized beam noise. The S/N ratios listed in the tables are defined by the averaged ion current S and the intensity fluctuations N during a typical beam pulse [repetition rate: 1/s, duration: 1ms]. The listed CSD are for standard ion source settings. For both ion sources it is possible to shift the CSD to lower or higher mean charge state, adjustment parameters are: additional gases, magnetic fields, discharge power.

Table 1: Ion currents from the MUCIS (gases) and from the MEVVA (metals) measured at the test bench.

spec.	I_{tot} /mA	CSD ion : fraction	S/N	U_{ex} /kV
H	≈60	H^+:0.4,H_2^+:0.1,H_3^+:0.5	≤50	10
D	≈60	D^+:0.4,D_2^+:0.1,D_3^+:0.5	≤50	10
Ne	≈50	Ne^+:0.9,Ne^{2+}:0.1	≤50	10
Ar	≈80	Ar^+:0.6,Ar^{2+}:0.3	≤50	25
N_2	≈80	N^+:0.8,N^{2+}:0.2	≤50	25
Mg	≈160	Mg^+:0.5,Mg^{2+}:0.5	≤20	25
Cu	≈100	Cu^+:0.2,Cu^{2+}:0.5	≤10	25
Au	≈80	Au^{2+}:0.4,Au^{3+}:0.5	≈10	25
U	≈80	U^{3+}:0.3,U^{4+}:0.4	≈10	25

During accelerator experiments, we experienced some problems in the transport of the ion beam,whenever the beam was not stable enough along the pulse.Especially we encountered that problem with the MEVVA ion source, whereas the beam transport to the RF structure seemed to be less critical with quiet beams as extracted from the MUCIS. Because the same extraction system was used at both sources, we conclude that the problem is not an emittance problem, but a question of space charge compensation of the beam, which is much more effectiv for quiet beams. Therefore, to reduce the noise of the MEVVA source to the level achieved for the MUCIS is our main development goal.

The higher noise level of the ion beam extracted from the MEVVA ion source compared to the noise level of the ion beam extracted from the MUCIS is strongly connected to the very different plasma generation process. Whereas the homogenious plasma of the MUCIS has its origin in a quiet gas discharge, the plasma of the MEVVA has its origin in a number of non-stationary cathode spots[3, 4]. Moreover the charge state distribution (CSD) of the ions produced in a specific spot scatter during the life time (several μs) of the spot[5]. A number of modifications have been applied to quiet the MEVVA plasma and to influence the CSD[6]. Although the ion beam noise is a principle problem caused by the MEVVA plasma generation process its significance is for some metals (e.g. Al, Cu, U) more pronounced than for others (e.g. Mg, Cr).

* as guest from Australia

It was possible to produce high intensity Mg^+ and Mg^{2+} ion beams with high stability and low noise comparable to the quality of MUCIS ion beams, whereas Al^+ and Al^{2+} ion beams were very noisy with the same MEVVA setup. Mg and Al have similiar values of ionization energies, electric properties, chemical properties and similiar melting points (Mg: 648°C, Al: 660°C). The vapor pressure of these two metals are very different at the melting point (Mg: ≈ 2 mbar Al: $\approx 10^{-8}$ mbar). The boiling point is 1090 °C for Mg, and 2467 °C for Al.

There are indications from our experiments that for metals used as cathodes in the MEVVA ion source, a lower vapor pressure at the melting point results in more noisy ion beams. In comparison to the pure metals, metaloxides have usually a higher melting point but their vapor pressure curves do not differ too much from the pure metal ones. Experiments have been performed with these pure metal cathodes of Mg, Al and Cu and additional gas flows of O_2 and Ar into the MEVVA. A sufficient gas flow was chosen to allow the cathodes surfaces to be covered by Ar or to be oxidized by oxygen in the time between two MEVVA shots (repetition rate 1/s, pulse width 1 ms).

A preliminary evaluation of the experimental data showed a general decrease in ion beam noise and a shift in the CSD to lower charge states. The latter is well known and results from charge exchange processes in the residual gas (O_2, Ar), additionally, the increased residual gas pressure enhances the space charge compensation in the beam line. It could be shown that in the case of Mg the metal surface could be modifiedby oxygen. The ion beam produced from the oxidized Mg cathode surfaceremained low noisy for about 100 MEVVA shots after switching off theoxygen gas flow, whereas the ion beam noise with Ar auxiliary gasincreased instantly after the disconnection of the Ar gas flow.This measurement showed that a less noisy ion beam could be produced by the use of the higher vapor pressure metal compound MgO compared to pure metal Mg.Presently experiments with U and UO_2 are under preparation.The melting points of U and UO_2 differ drastically(U: 1130 °C,UO_2: $\approx$ 2500 °C), their vapor pressure as functionof temperature behaves similiar. The electrical conductivity of UO_2 should be high enough to make it usable as a cathode in a MEVVA ion source. Measurements of the ion beam noise and ion beam CSD will be performed in the near future.

2 PENNING ION SOURCE TERMINAL

To provide with the PIG source the same beam quality for the new acclerator as for the still existing Wideröe accelerator two general problems have to be solved. First the beam line has to be adapted to the new injection energy of 2.2 keV/u instead of 11.6 keV/u. Second, to make use of the capability of the new injector to accept ions with a m/q-value (m: ion mass, q: ion charge state) of up to 65 instead of 24, one has to improve the already shown capability of the source to produce lower charge states [7].

In the existing beam line there is a multi gap structure for the electrostatic acceleration. Experiments at an energy as low as 2.2 keV/u with the multi gap structure had shown that the focusing strength is too small to transport the beam through the accelerating tube with sufficient efficiency. Therefore a moveable single gap was designed, installed and first tests have been made (see figure 1). The gap width can be varied from 50 mm up to 250 mm without breaking the vacuum. In addition a screening electrode has been installed shortly behind the ground electrode to preserve the space charge compensation of the beam on ground potential.

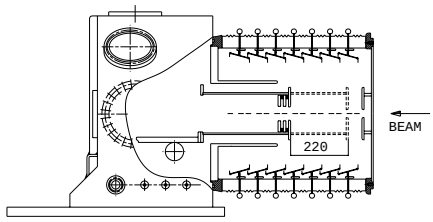

Figure 1: Sketch of the single gap structure. The most right electrode represents the high voltage potential. The moveable electrode is on ground potential. The inner diameter of the electrodes is 50 mm.

The high volatage stability of the movable single gap was tested to be very reliable. Without beam 100 % of the present available acceleration voltage (320 kV) could be applied without any breakdown. The tests with beam at the moveable single gap were carried out with Ar and Bi to have of sample of a light gas and of a heavy monoisotopic solid. For Ar^{2+} the current and emittances were measured for different gap widths. The Faraday cup (FC) and the emittance measurment device were installed about 1 m behind the single gap. The current measured in the FC behind the gap has shown a maximum value in dependence of the gap width (min. 0.9 mA max. 2.2 mA). However, it can be assumed, that this strong variation is just an optical effect (acceptance of the FC), because of the fact that losses in the order of 1 mA would create remarkable sparking in the accelerating tube. The dependence of the emittance from the gap width exhibited a not simple behaviour, created by the superposition of aberations, space charge effects and limitation by apertures. Therefore a final analysis cannot be done before a complete computer simulation is finished, which is in preparation. Furtheron Argon charge states Ar^+, Ar^{2+} and Ar^{3+} at the future injection energy (2.2 keV/u) of the new injector were compared. This showed the technical limits of the system for light ions. For Ar^{2+} the shortest possible gap width was the optimum. For Ar^{3+} the focusing was too small because of the large distance. The beam could not been focused any more. The problems for small m/q-values became obvious. Especially the splitting of extraction voltage U_{ex} and acceleration voltage U_{acc} gets difficult. On one hand one would like to increase the extraction voltage (to extract higher cur-

rents), on the other hand there is not enough voltage for the focusing any more. Further experiments were carried out with $Bi^{6+...9+}$ at optimized gap width (0.55 mA, 0.50 mA, 0.50 mA, 0.20 mA) and with Bi^{8+} with different gap widths (min. 0.25 mA, max. 0.50 mA) at the energy of 2.2 keV/u.

Almost all measured emittances of the above described experiments were within the acceptance of 140 $\pi\, mm\, mrad$ of the new RFQ-structure. Therefore, from the emittance point of view the RFQ should be accept the beam without losses. The use of the screening electrode increased the current in the FC by 5 to 10%. So we can state there is at least a partial space charge compensation. An optimization of the electrode diameters will be carried out in the beginning of the next year.

The maximum m/q-value of 65 for the new injector allows the use of lower charged ions (e.g. Bi^{4+} instead of Bi^{9+}). Therefore several experiments were carried out at the test bench. To apply high enough extraction voltages for the lower charge states the magnetic field had to be increased. The idea of changing the potential of the anti-cathode [8] (by connecting to the anode, by leaving it floating or by connecting via a resistor to cathode) to shift the CSD to lower charge states did not yield good results. With the anti-cathode on anode potential and with floating anti-cathode no ingnition at all was possible. A resistor of about 1 kΩ allowed to shift the maximum of the CSD to Bi^{4+}, but decreased the over all performance of the source. Under normal source conditions it was possible to produce a higher current of Bi^{4+}, but the maximum particle currents were observed for $Bi^{5+...7+}$ depending on the sputter gas used. Currents of about 120 pμA were measured for these ions with the standard extraction system about 1.5 m behind the source. For Au^{6+} 2 mA were measured, which corresponds to ealier measurements [9], in which 4 mA were measured with a by a factor of 2.6 enlarged extraction are. For optimized generation of charge states 5 to 7 of these ions a slightly increased source pressure was necessary. Under these conditions the source discharge was more quiet. Even at a repetition frequency as low as 1/s ignition was no problem with slightly increased heating.

To improve extractable ion currents from the source the increasing of the extraction voltage is one possibility. Because of the insulation distances in our vacuum chamber we are limited to 25 kV. Experiments with additional insulators yielded only small improvements [10]. Therefore we decided to develop an accel-decel extraction system. This gives the possibility to increase the extraction field strength without the necessity of increasing the high voltage at the source. In addition it will help to overcome the above described problem with light ions because it makes high extraction field strength at low beam energy possible. First experiments with a very simple accel-decel design were performed and showed good agreement with raytracing KOBRA3-INP [11] simulations. With +8 kV source potential and -6 kV at the accel electrode, similiar currents could be extracted as with 14 kV extraction voltage with the normal extraction system ($\approx$ 2.5 mA Ar^{2+}). Further development is focused on the cooling and the mechanical stability of the accel-decel extraction system.

K. N. Leung, M. D. Williams
Lawrence Berkeley National Laboratory

Abstract

As part of the on-going beam-current upgrade in the Proton Storage Ring (PSR) at the Los Alamos Neutron Science Center (LANSCE), the current available from the H⁻ injector will be increased from the present 16 to 18 mA to as much as 40 mA. A collaboration between the Ion Beam Technology Group at Lawrence Berkeley National Laboratory (LBNL) and the Ion Sources and Injectors Section of LANSCE-2 at Los Alamos National Laboratory (LANL) has been formed to develop and evaluate a new ion source. A new Ion Source Test Stand (ISTS) has been constructed at LANSCE to evaluate candidate ion sources . The ISTS has been constructed to duplicate as closely as possible the beam transport and ancillary systems presently in use in the LANSCE H⁻ injector, while incorporating additional beam diagnostics for source testing. The construction and commissioning of the ISTS will be described, preliminary results for the proof-of principle ion source developed by the Berkeley group will be presented, and future plans for the extension of the test stand will be presented.

1 INTRODUCTION

The surface-conversion H⁻ ion source used to supply production beam at LANSCE has been in use since 1984. References [1] and [2] describe the development of this ion source. A new collaboration between LBNL and LANL has been formed to develop an ion source [3] capable of providing 40 mA of H⁻ beam to the LANSCE linac. A new test stand has been constructed at LANL to provide a place to evaluate the new ion source before it is moved to the equipment dome of the LANSCE H⁻ Ion Injector. The test stand has been constructed to duplicate as closely as possible the low energy column and beam transport system presently installed in the equipment dome of the H⁻ Injector.

2 H⁻ ION INJECTOR BEAM TRANSPORT

The 750 keV beam produced by the H⁻ Injector is obtained from a surface-conversion H⁻ ion source on an 80 keV transport system located inside the equipment dome of a 670 kV Cockcroft-Walton. As shown in the schematic representation in Figure 1, the transport system inside the dome consists of an 80 kV accelerating column and a two-solenoid transport. A beam deflector between the two solenoids permits changing the length and repetition rate of the beam pulse delivered to ground while the ion source remains operating at a 10 to 12% duty factor (835 to 1000 μsec pulse length at 120 Hz rep rate). Beam diagnostic devices in the dome consist of four current monitoring toroids placed along the 80 keV transport and slit and collector emittance gear capable of measuring emittance in the horizontal and vertical planes. The emittance station is located mid-way between the two transport solenoids.

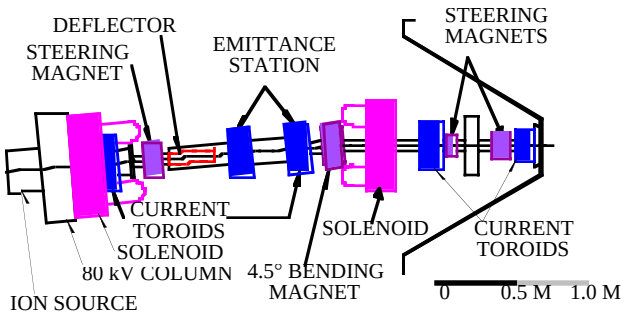

Figure 1. Schematic depiction of the major components of the 80 keV beam transport inside the LANSCE H⁻ Ion Injector.

3 ION SOURCE TEST STAND CONSTRUCTION

Constructing ISTS to duplicate the configuration of the existing H⁻ Ion Injector is highly desirable. Not only can the test stand provide an emergency supply of critical components for the injector while LANSCE is in production, but also unforeseen surprises, when a new ion source is finally moved to the injector, can be minimized by the experience gained in operating the source on a nearly identical beam transport. A test stand that closely duplicates the conditions of the H⁻ Injector dome also provides a place for off-line testing of ancillary equipment [4] that might be considered for use in the dome.

The ISTS is located in the same room that had housed an old H⁻ test stand. That stand [5] was completely removed except for its 50 KVA isolation transformer and isolated electronics racks, which were relocated in the room to provide space for the new, larger ISTS. The

* Work supported by the U. S. Department of Energy.

existing 2000 l/s turbo pump and attendant backing pumps were returned to service on the new test stand.

To begin experiments with beam early in the development of the new ion source, the construction of the initial ISTS transport was terminated at a Faraday cup installed just after the mid-transport emittance station. The remainder of the transport, including a bending magnet and second transport solenoid, will be installed later. An additional diagnostic station will also be added to measure the emittance at a distance from the transport equivalent to the entrance of the 670 kV column in the H^- Injector. The ISTS as presently constructed contains sufficient diagnostic gear to allow comparison of ISTS beam experimental results with those routinely performed during LANSCE beam production cycles in the H^- Ion Injector dome. Figure 2 shows the ISTS in its present configuration.

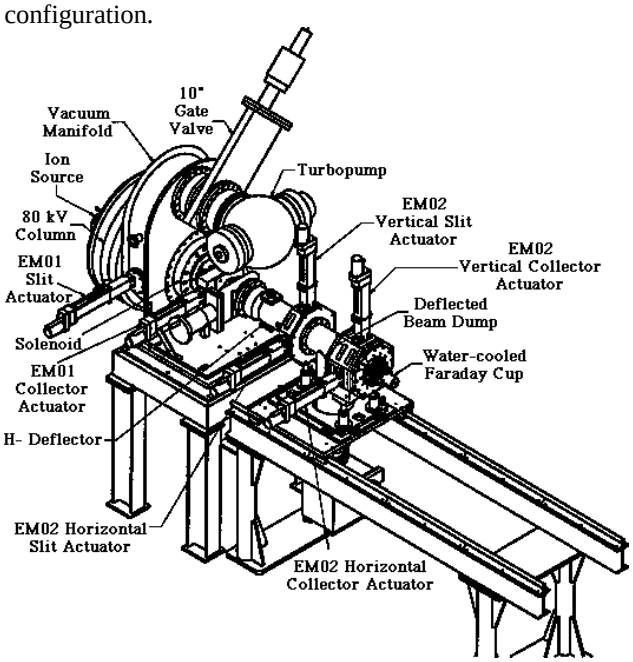

Figure 2. Isometric drawing of the beam line components assembled for the first phase of construction of the ISTS.

4 BEAM DIAGNOSTICS

4.1 Emittance Measurements

Slit and collector emittance gear identical to the gear in the H^- Injector dome was installed on the ISTS in the same relative location along the beam transport. On ISTS this gear is referred to by the acronyms EM02H for horizontal and EM02V for vertical plane. The test stand has an additional diagnostic station, not found in the H^- dome, which is used to measure the horizontal-plane beam emittance directly after the 80 kV accelerating column. This gear is referred to as the EM01H gear. There is no space available to install vertical plane actuators. A water-cooled carbon slit capable of withstanding the full duty factor of the anticipated beam (almost 400 watts) is mounted in the side of the main vacuum manifold directly after the 80 kV column. The corresponding collector is mounted just downstream of the x-y steering magnet, which follows the first focusing solenoid. Use of this diagnostic thus requires turning off the solenoid and steering magnets.

It was long thought that the 80 kV accelerating column was causing emittance growth in the dome transport, but use of this new diagnostic on the ISTS has demonstrated that the measured beam at the exit of the accelerating column is almost exactly that of the geometrical admittance of the ion source. The capability to measure emittance directly after the 80 kV accelerating column provides us with data which can be compared to ray-tracing simulations of the column dynamics. Another contribution [6] to these proceedings discusses some of these results.

4.2 Steering Magnets and Current Toroids

In the H^- Injector dome there are three sets of steering magnets located along the 80 keV transport and four current monitoring toroids. The ISTS has, at present, only one set of steering magnets, located immediately downstream of the first focusing solenoid. The primary use of the steering magnet is to sweep electron contamination out of the ion beam during emittance measurements at EM02. This same technique is used in the H^- Injector during emittance measurements.

In the H^- Injector the first two current toroids are located directly downstream of the first focusing solenoid and directly after the collectors of the emittance gear located at the mid-point of the transport. On ISTS we have exactly duplicated the second current toroid, but the inclusion of the EM01H emittance diagnostics on ISTS precluded the inclusion of a beam current toroid immediately downstream of the first solenoid. A toroid was mounted inside the vacuum manifold on ISTS and provided useful beam current information during the initial commissioning of the test stand. It did not survive the transition to a source with higher apparent electron content and has subsequently been removed.

5 COMMISSIONING

Following the cessation of LANSCE accelerator operations in mid-August of 1997, injector personnel concentrated on getting the new ISTS assembled and operational. One of the LANSCE production ion sources was mounted on the test stand for initial commissioning experiments. First beam was transported to the end of the transport on September 25, 1997 and operation of the beam current monitors and the EM02 gear was verified.

Beam current was measured at the exit of the 80 kV column and directly after the EM02 emittance gear by current toroids (1.6 m apart) with apertures of approximately 7.5 cm. The 80 keV beam is dumped into a Faraday cup with an entrance aperture of 4.4 cm. located 15 cm. after the second toroid. An additional indication of

beam current is provided by monitoring the total current drain on the 80 kV beam energy supply. Representative data of such measurements are presented in Table 1.

Table 1. Beam current measurements along the ISTS 80 kV transport. The steering magnet has been adjusted to remove the electron contamination for the data shown in the last two columns.

80 kV supply drain current, mA	80 kV column toroid, mA	Toroid after EM02 station, mA	Faraday Cup Beam Dump, mA
20	20	7.9	7
30	28	6	6
50	45	16	
40	33	16	15.6
40	32	15.2	14.8

Several hundred emittance measurements have been made to commission the operation of the ISTS emittance diagnostics and compare the results with those routinely obtained over the years in the H^- Injector dome. Agreement between H^- Injector dome data and ISTS data has generally been acceptable; emittance on ISTS is generally 5 to 10% larger than historical measurements in the dome. A sample of better agreement is presented in Table 2.

Table 2. Comparison of mid-transport emittance measurements for the ISTS and the H^- Injector dome.

Parameter	ISTS	H^- Injector
Date/Plane	5-Dec-97/H	2-May-92/H
Run Number	265	3003
E(Tot) Measured	7.305	7.627
E(Tot) Normalized	0.095	
E(RMS) Measured	1.218	1.116
E(RMS) Normalized	0.016	
Alpha	0.263	0.083
Beta	0.361	0.445

The calculated mismatch factor [7] is 0.16

Once satisfied that measurements of emittance and beam current on the test stand were in agreement with similar measurements made in the H^- Injector dome, we proceeded to test the proof-of principle (POP) ion source [3,8] that has been developed at LBNL. Further discussion of the development of this source is given elsewhere [3] at this conference.

6 INITIAL POP ION SOURCE TESTS

The Ion Beam Technology Group at LBNL developed a proof-of-principle ion source capable of producing the desired beam current of 40 mA in the Fall of 1997 [8]. The configuration of this early POP ion source evolved into the "Axial" source delivered to Los Alamos and mounted on ISTS earlier this calendar year. At LBNL at least 40 mA of 250 eV H^- current has been observed in a biased Faraday cup located directly after beam exits the ion source. In early experiments with this source we have obtained good agreement with this result in that we have observed up to 33 mA of 75 keV H^- beam through the current toroid and Faraday cup at the end of our present transport. Because the Axial source is a POP device, it does not lend itself to extensive experimentation with, for example, changes in alignment. Future measurements of its characteristics have been deferred.

7 FUTURE CONSTRUCTION

Assembly of components to complete the ISTS is underway. We will next mount a bending magnet and second solenoid to complete the duplication of the devices in the H^- Injector dome. The beam line will end with a third emittance station for studies of emittance growth and beam dynamics. Additional beam diagnostics such as current toroids will be placed along the added beam line.

8 SUMMARY

We have assembled and commissioned a test stand for H^- ion sources which closely duplicates the existing low-energy transport located in the LANSCE H^- Ion Injector equipment dome. The new test stand allows off-line measurement of ion source performance with direct comparison of results to the existing injector. The new test stand not only provides a locale to study the performance of next-generation H^- ion sources for LANSCE, but also serves as ready source of spares of critical components of our existing injector. It offers the opportunity for evaluation of H^- ion sources for others who might wish to use this new capability.

Abstract

The low-energy demonstration accelerator (LEDA) 75-keV proton injector is being developed for tests of high-current (100-mA) cw linacs. The injector comprises a microwave proton source and a space-charge neutralized magnetic low-energy beam-transport system (LEBT). The LEDA injector has been configured to provide flexible 50-keV beam matching into a cw 1.25-MeV radio-frequency quadrupole (RFQ) brought from Chalk River Laboratories (CRL). The LEBT has two solenoid focus magnets separated by 117 cm. Between the solenoids are two steering magnets and diagnostic stations for measuring the beam current, profile, and position. The ion-source extraction system was modified to a 50-keV triode to test the injector/RFQ system. Beam-matching tests showed that injector-RFQ transmission is 90% for 50-mA RFQ current. At the RFQ design current of 75 mA the beam transmission decreased to 80 - 85%. Optimized injector tuning led to 100-mA beam accelerated through the RFQ.

1 INTRODUCTION

In 1993, a 1.25-MeV cw RFQ designed for 75-mA beam current operation[1] was brought to Los Alamos from CRL for continuation of proton beam testing[2]. The final operation at CRL led to 55-mA current accelerated by the RFQ[3] using a direct-injection single-solenoid focus LEBT with no beam-steering capability[4]. Problems encountered using this LEBT for RFQ matching were discussed, but no further injector technology development was possible at CRL.

A more advanced proton injector is under development at Los Alamos for the LEDA project. This effort culminated in demonstration of a 75-keV, 130-mA proton injector[5] appropriate for the 6.7-MeV LEDA RFQ. After completion of the 75-keV injector demonstrations, the LEDA injector was modified to operate at 50-keV proton beam energy to make integration tests with the 1.25-MeV cw RFQ. This injector includes two solenoid focusing magnets, and two pairs of steering magnets for increased beam steering and matching flexibility to a RFQ. Modification of the ion extraction system from 75 to 50 keV led to a 50-keV injector whose operating parameters are shown in Table 1.

*Work supported by the US Department of Energy.

Table 1. 50-keV LEDA proton injector operation.

Parameter	Design	Measured
Beam current (mA)	100	150, max.
Proton fraction (%)	90	95, max.
Beam energy (keV)	50	50
2.45 GHz power (W)	600-800	1000-1500
Axial magnetic field (G)	875	875-960
Beam duty factor (%)	100	100
Emission radius (mm)	3.4	3.4
Extraction gap (mm)	8.1	8.1
Inj. $E_{rms,n}$ (πmm-mrad)	0.20	0.15
RFQ output current (mA)	75	100, max
RFQ acceptance (πmm-mrad)	0.5	

2 50-KEV INJECTOR DEVELOPMENT

The first 50-keV LEDA injector beam tests were completed on the prototype injector shown in a line drawing in Fig. 3 of ref.[5]. A microwave proton source[6] is used to generate a dense plasma with proton fractions in the 90 - 95% range[5,7]. Fifty-keV ion beam extraction was first attempted with the tetrode (four-element) extractor (Fig. 2 of ref.[5]) where the full acceleration voltage is held across a single gap between the first (plasma) and second (extraction) electrodes. The third electrode (electron trap) is held at -1500 V while the fourth electrode is at ground potential to terminate the electric fields from electrode 3. The beam-current requirement is transmission of 100-mA current through the LEBT solenoids. Only 50% beam transmission was observed with the tetrode, and the poor transmission was traced to higher beam divergence at 50 keV. The increased divergence arises from an increase of beam perveance, P_b, of the I_b=90-mA, V_b=50000-V injector P_{50keV}= $42.9X10^6(I_b(A)/V_b^{3/2})$=0.34 μP compared to the 130-mA, 75-keV injector where P_{75keV}=0.27 μP. A series of PBGUNS beam simulations comparing a triode (three-electrode accel-decel system) with the tetrode extractor is shown in Fig. 1, where the calculated maximum angle is plotted vs. P_b at fixed 50-keV beam energy. Four calculations for both extractors were done using a 9.2 mm

extraction gap with a r_{em} = 3.4 mm emission aperture radius. They are connected by solid lines. The letter "D" appended to a point indicates the extracted beam is divergent and the letter "C" indicates a convergent beam. The reduced triode divergence arises from an approximate 1-cm reduction of unneutralized space-charge beam transport achieved by the more compact triode extractor. The beam transmission through the LEBT solenoids on the prototype injector increases to > 90% when the triode

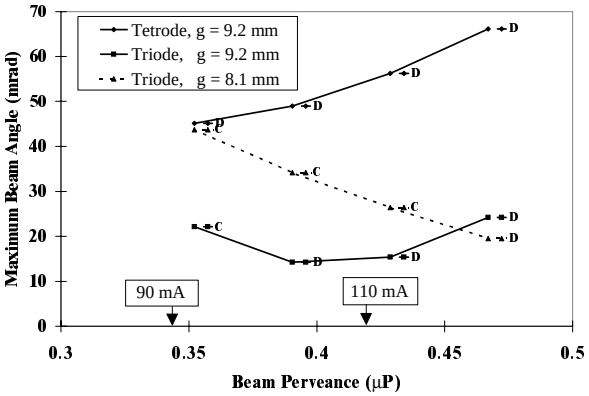

Figure 1. Maximum angle predictions from the PBGUNS code for the 50-keV ion extraction systems.

produced 90-mA beam with an extraction gap g=9.2 mm. The first focus solenoid is located 79 cm from the ion extractor, thus a beam with 45 mrad divergence (the 50-keV tetrode extractor, cf Fig. 1) at extraction position will grow to 3.5 cm radius - too large for good transmission through the 10 cm (diameter) aperture LEBT solenoids.

Baseline injector beam phase-space data using the triode extractor were accumulated on the prototype injector for use in follow-on LEBT/RFQ matching calculations[8]. These data were accumulated in dc mode, and were measured a distance of 213 cm from the ion extractor. The rms normalized emittance, $E_{rms,n}$ is 0.15 (πmm-mrad), and nearly constant over the P_b range. The data were projected back to the ion source by use of the TRACE code[9] using four times rms laboratory emittance ($4E_{rms}$). The Courant-Snyder α,β parameters extracted at the ion source are plotted vs proton beam perveance in Figs. 2 (A) and (B) respectively. The TRACE calculations used an effective transport current of $0.02I_b$ (1.8 mA) based on proton beam neutralization measurements[10]. Fig. 2(A) shows that this procedure leads to a convergent beam (α>0), which agrees with the 90 mA (0.34 μP) PBGUNS triode calculation shown in Fig. 1. The average β from Fig. 2 is 0.023 (cm/mrad) thus yielding $X_{max} = (\beta 4E_{rms})^{1/2}$ = 3.7 mm, which agrees adequately well with r_{em} = 3.4-mm.

The triode ion source was installed on a 2.54-m long version of the LEDA injector LEBT attached to the 1.25-MeV RFQ. This injector is shown in Fig. 3, and has all the ion-optical transport features of the final 2.8-m proton injector[11]. During injector operation with the g = 9.2 mm triode, it became evident that injector currents greater

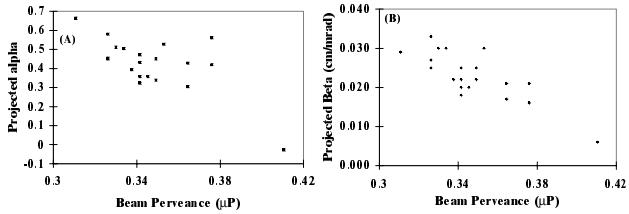

Figure 2. (A) Shows the baseline α and (B) the baseline β parameters projected to the 50-keV triode extractor installed on the prototype injector. Calculations based on these measurements are used in the 1.25 MeV cw RFQ calculations.

than 90 - 100 mA could not be efficiently transported through the LEBT, and the 75-mA RFQ design current could not be reached. As currents increased above 90 mA in DC1 the beam-profile widths in video diagnostics 1 (VD1) became unacceptably large. This has two effects: the LEBT beam transmission decreases, and the non-interceptive DC2 current monitor becomes increasingly

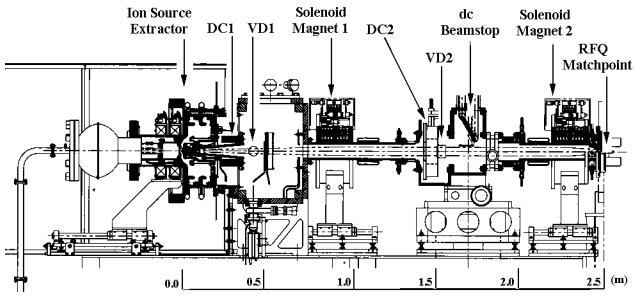

Figure 3. First version of the LEDA injector used for the 1.25 MeV cw RFQ tests.

susceptible to secondary electrons and beam plasma as the 50-keV beam approaches the vacuum wall. For these reasons, g was decreased from 9.2 to 8.1 mm. This step led to increased LEBT transmission (defined as DC2/DC1) for beam currents in the 110 - 115 mA range

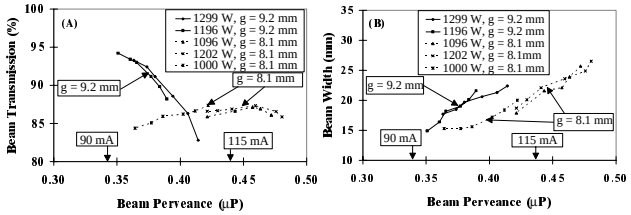

Figure 4. (A) Shows the increased beam transmission from DC1 (ion source) to DC2 (mid-LEBT), when the ion source extraction gap is decreased from 9.2 to 8.1 mm. (B) Shows the measured full-width, half maximum beam widths at VD1 for two data sets at g=8.1 and 9.2 mm extraction gaps. The lines are drawn to guide the eye.

(Fig 4(A)). The reduced extraction gap also decreased the beam size at VD1 for 110 - 115 mA beam currents (Fig. 4(B)). Plotting the beam transmissions and widths vs P_b suggests these parameters follow unique curves defined

by the extraction gap and P_b. The highest DC1 current recorded in Fig. 4 at 50 keV is 125 mA, giving P_b=0.477 μP. The improved injector optics with g=8.1 mm is also indicated in Fig. 1; the dashed curve shows that PBGUNS predicts a converging beam up to P_b=0.45 μP. The RFQ results reported below used g=8.1 mm.

3 TEST OF A 1.25 MeV cw RFQ

The basic 1.25-MeV RFQ design parameters are listed in ref. [1]. The primary diagnostic in the present measurement was to record the current transmitted through the RFQ with a third dc beam current monitor (DC3) located at the RFQ exit. See ref. [8] for a line drawing of the injector, RFQ, and CW beam dump installation. Other details on the operation of this RFQ at Los Alamos are given in ref. [12].

The RFQ transmission (%) is defined as 100(DC3/DC2). The present DC2 location tends to overestimate the RFQ input proton current which would indicate a lower-than-actual RFQ transmission. Secondary electron production and beam-plasma effects in the LEBT may also affect the accuracy of the DC2 measurement. Electrons flowing in the beam direction would produce a DC2 response lower than actual beam current, and would indicate a greater than actual RFQ transmission. An uncertainty of 5 mA in the DC2 current monitoring may be expected while the injector is operating at 75-mA RFQ design currents.

A check on the DC3 current monitor was made by doing calorimetry on the RFQ beam stop. At RFQ design current and energy there is 94-kW power in the RFQ beam. The agreement between the power measured by calorimetry and the power calculated from DC3 current assuming acceleration to full beam energy is good, varying from -6 to +2% depending on the RFQ exit quad excitation.

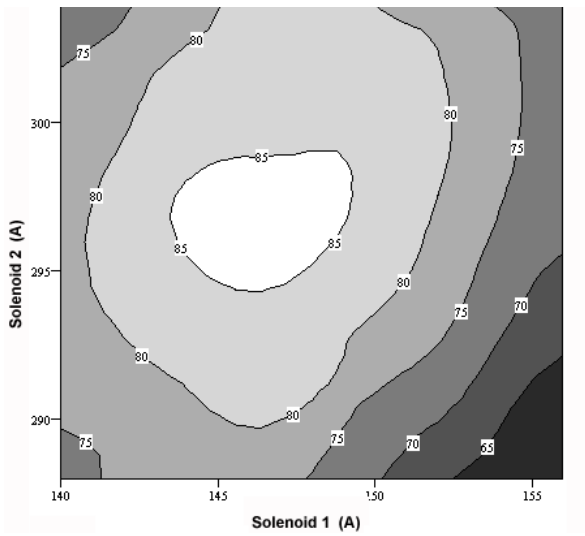

Figure 5. Contour plot of beam transmission through the 1.25 MeV RFQ as a function of the LEBT solenoid one and two currents. The RFQ is operating at 75-mA design output current for the 85% contour.

A systematic search of LEBT solenoids one and two led to the data shown in the contour plot of Fig. 5. The contour lines represent equal transmission in the solenoid tuning space. At the 75-mA RFQ design current, measured RFQ transmissions are 85%. On one occasion, while attempting to establish the maximum RFQ current, 100 mA was observed briefly in DC3. This high-current operation was limited by the injector's ability to deliver proton current to the RFQ matchpoint, and the limits of the RFQ rf power system [12]. DC1 current was 150 mA during the 100-mA RFQ current measurement. At 150-mA DC1 current, the beam is very large in the LEBT, and almost certainly the DC2 current monitor is adversely affected by secondary electron and beam plasma effects.

Abstract

Initial beam operation of the cw radio-frequency-quadrupole (RFQ) built for the Low Energy Demonstration Accelerator (LEDA) project requires the injection into the RFQ of a 75-keV, pulsed, H^+ beam with a rise and fall time less than 10 microseconds and a pulse width from 0.1 to 1 millisecond at a repetition rate up to 10 Hz. The ion source for the accelerator is a microwave proton source driven by a 2.45-GHz magnetron. Pulsed beam for the RFQ is accomplished by modulation of the magnetron tube current. The magnetron provides microwave pulses to the ion source, and a medium-bandwidth, extraction power supply produces the H^+ ion beam using a four-electrode extractor. A similar ion source with a three-element extractor operating at 50 kV has also been tested with this magnetron modulator. We report the results of modulating the ion-source microwave power and extracting a pulsed proton beam using both a triode and a tetrode extractor.

1 INTRODUCTION

The LEDA accelerator [1] is being constructed to test and verify critical accelerating components that will be part of the Accelerator Production of Tritium (APT) plant facility. A line drawing of the LEDA ion source and extraction region is shown in Figure 1. The 75-keV injector [2] for the LEDA accelerator consists of a microwave source, a tetrode extractor and a low-energy-beam-transport (LEBT) [3] that includes two solenoid magnets. A magnetron provides 500 to 700 watts of microwave power to the ion-source plasma chamber. Two solenoid magnets in the injector produce an axial magnetic field of approximately 875 gauss to create an electron-cyclotron-resonance condition in the plasma chamber. The four elements of the tetrode extractor are the ion-source aperture electrode at 75-kV, the extraction electrode at ground, the electron suppressor electrode at -1.5-kV and a second ground electrode used to quickly establish beam neutralization.

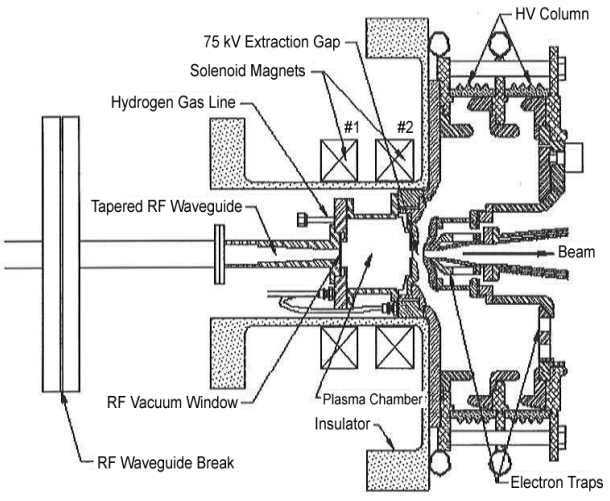

Figure 1. LEDA microwave proton source.

The current from the extraction power supply is sampled by a Pearson transformer (I_{ps}). Low-frequency components of the beam current are measured using two parametric current transformers (PCT) [4], one at the exit of the ion source (PCT1) and the second between the two solenoid magnets of the LEBT (PCT2). An ac current transformer at the exit of the ion source measures the high-frequency beam-current components. A beam stop, known as the plunging beam stop, can be inserted into the beamline between the solenoid magnets of the LEBT and also provides a means of measuring beam current (I_{pbs}).

Although dc (100% duty factor) operation is the normal operating mode, initial beam testing will be done in pulsed-mode conditions. This pulsed-mode, low-duty-factor operation is necessary to minimize equipment damage during beam impingement. The ion-source pulsing described herein is our preferred means of accomplishing this mode of operation.

2 MODULATOR DESIGN

A sketch of the magnetron modulator [5] is shown in Figure 2. A dc set point value for the desired magnetron

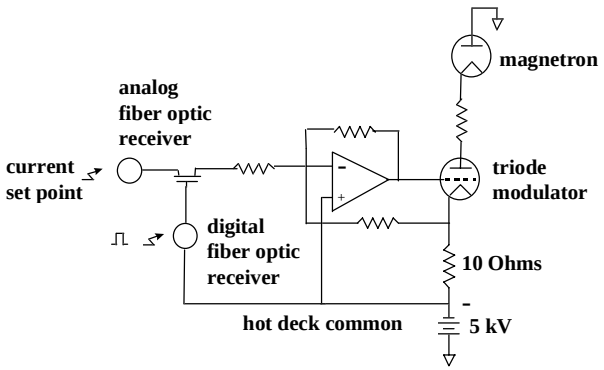

Figure 2. Magnetron current-modulator diagram.

* Work supported by the US DOE, Defense Programs.

current is compared to the voltage developed across the modulator tube's cathode resistor. The modulator acts as a current source that sets the magnetron current to zero when the digital pulse is not present and controls the magnetron current to a value determined by the set point when the digital pulse is present. The modulator tube and the feedback components are raised to the hot-deck voltage set by the -5 kV power supply. Filament supplies for the magnetron and modulator also must be isolated at this voltage level.

Our magnetron is sensitive to cathode-to-anode voltage and generates full output power variation for a few hundred volts change in voltage. Our current-controlled modulator design takes advantage of the more linear power response characteristics of the magnetron as the tube current is varied. Figure 3 shows the typical linearity of magnetron output power versus magnetron current when the magnetron is controlled by the current modulator.

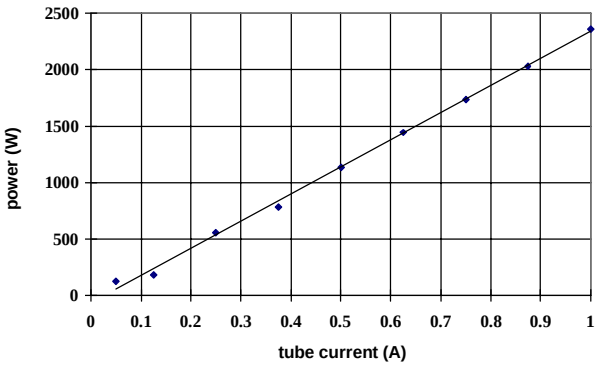

Figure 3. Microwave power versus tube current.

The output power is measured using a waveguide-directional-coupler and a calibrated diode with an error less than 0.5-db over the range of 500 W to 2500W.

3 PULSED OPERATION OF THE LEDA INJECTOR

Figure 4 shows the leading edge of the extracted beam current from the LEDA injector when the magnetron is producing a 750-W pulse. The limited bandwidths (4 kHz for PCT1 and 20 kHz for PCT2) of the two parametric current transformer devices are evident in the delayed and relatively slow risetimes seen for these two signals. Displayed difference in measured current for PCT1 and PCT2 is typical for this injector and reflects the beam-transport characteristics of the LEBT. The ac beamline transformer has a bandwidth greater than 10 MHz and droop of approximately 0.4%/μsec for a square wave of current. The plunging-beam- stop current measurement nearly equals the PCT2 measurement. (PCT2 and I_{pbs} are located close together on the beamline.)

A set of oscilloscope traces of these same five signals on the trailing edge of a 1 ms pulse is shown in Figure 5.

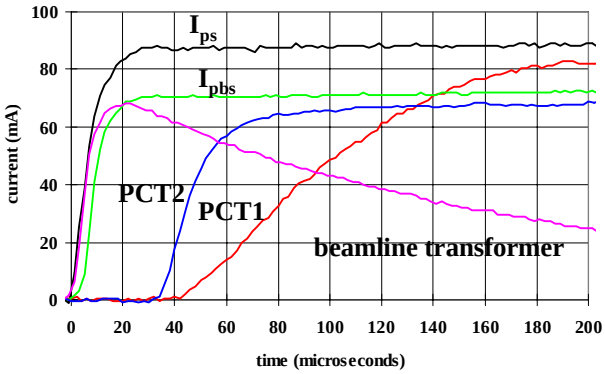

Figure 4. Leading edge of the extracted current from the LEDA injector.

The beam current response time meets the specification required for RFQ commissioning.

Longer pulse lengths show a slight rise in current as the pulse length increases. A 10 ms pulse shows a 10% increase in the current from beginning to end of the pulse. This effect is believed to be due to temperature effects in the plasma chamber that cause the source characteristics to change The flattop response of the beam current is acceptable with the modulator loop controlled around the magnetron tube current, but an improved flattop response is likely if the loop is closed around the extracted beam current

The effect of magnetron power on the extracted beam current can be seen in Figure 6. Measured values are

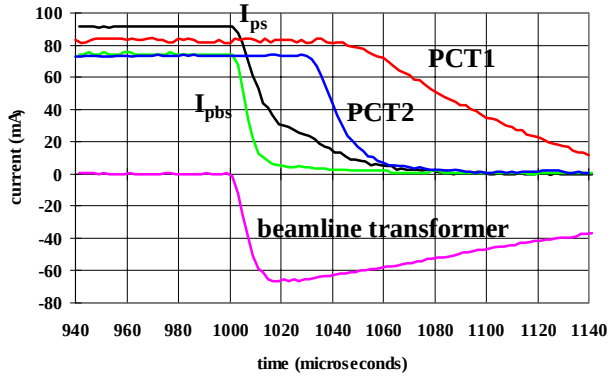

Figure 5. Trailing edge of the extracted current from the LEDA injector.

averaged over 50 samples near the end of 1 ms pulses. The solid lines are second-order polynomial fits to the data points used only to focus the eye on the trend in the data. The extractor power-supply current (I_{ps}) and PCT1 current continue to rise with increasing input power but the PCT2 and I_{pbs} currents reach a maximum value and then fall off as beam transport is affected by the beam

divergence from the source. (Standard CCD cameras are used to observe the transverse beam profile.) The measurements shown in Figure 6 were made without any

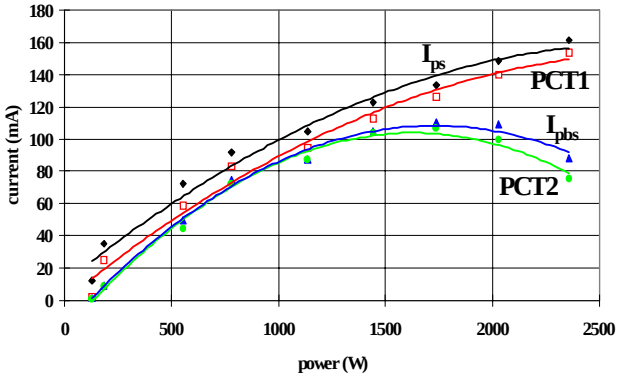

Figure 6. Beam current versus microwave power for the 75-kV tetrode extractor.

other change in the ion-source settings; the ion-source was adjusted for best operation at a microwave power of 750-W. It should be noted that a single setting is not ideal for this broad range of power.

4 PULSED OPERATION OF THE TRIODE INJECTOR

The current- modulator was also tested on a 50 kV triode injector. The LEDA microwave injector was converted from a tetrode extractor to a triode extractor. (The three elements of the triode extractor are the ion-source aperture electrode at 50-kV, an accel-decel electrode at -2.0-kV and an electrode at ground.) This injector was used to deliver a dc beam to a cw, 1.25-MeV RFQ and was conveniently available for pulsed operation into the plunging beam stop.

The time-response of the extracted beam for this injector is dramatically different from that seen for the tetrode extractor. Figure 7 is a plot of I_{ps}, PCT1, PCT2 and I_{pbs} currents with a 100 ms pulse. The extractor power supply initially supplies almost twice the current that is transported through the LEBT. Beamline current rises rapidly to about 10% of the final value and then slowly rises to its final value with a time constant of approximately 10 ms. No serious attempt has been made to discover why the extraction and transport response of the triode injector is so different from the tetrode injector. It is known that the electron suppressor voltage is not significantly affected and that electron production at the extractor electrode is not contributing to the problem.

5 SUMMARY

A linear, current-controlled magnetron modulator has been used to produce pulsed proton beams from a microwave ion source. The extracted beam from the tetrode injector produces acceptable pulsed beam for the

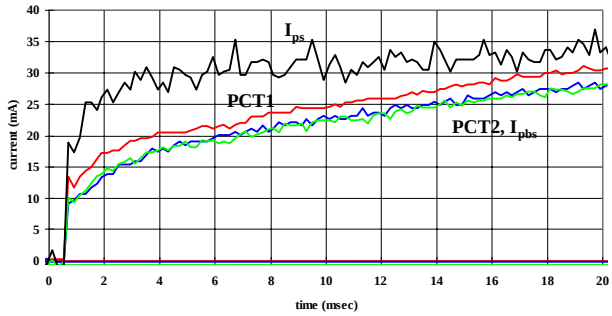

Figure 7. Leading edge of the beam current extracted from the 50-kV triode injector.

LEDA RFQ. Use of this modulator on a triode extractor is less satisfactory since extraction and transport effects cause a slowly rising beam-current pulse. Similar pulsed-beam effects from a microwave source have been observed at the Saclay laboratory [6].

THE FRANKFURT H$^-$ SOURCE FOR THE EUROPEAN SPALLATION SOURCE*

K. Volk, A. Maaser, H. Klein
Institut für Angewandte Physik, Universität Frankfurt, 60054 Frankfurt, Germany

Abstract

The **E**uropean **S**pallation **S**ource (ESS) requires two ion sources, each delivering a pulsed 70 mA H$^-$ beam with a pulse length of 1.2 ms and a repetition rate of 50 Hz. At the University of Frankfurt, an H$^-$ volume source based on the HIEFS (**Hi**gh **Ef**ficiency **S**ource) has been developed and tested. The source consists of a cesium seeded multicusp plasma generator, in which negative ions are produced via volume and surface processes. Due to improvements of the cesium injection method, the beam current density has been enhanced up to 153 mA/cm^2. Thus, an H$^-$ beam current of 120 mA has been extracted using an aperture radius of 5 mm.

This paper reports about these recent developments of the Frankfurt H$^-$ source. After a description of the experimental setup, measurements of the beam current density, the electron to H$^-$ ratio and the lifetime will be presented followed by a beam emittance estimation.

1 INTRODUCTION

For the ESS, two H$^-$ sources, each delivering a 70 mA H$^-$ beam in 1.2 ms pulses at a repetition rate of 50 Hz (duty cycle = 6 %) are foreseen [1,2]. The normalized rms beam emittance in front of the first RFQ should be 0.1π mm mrad or smaller. These requirements have to be fulfilled with great constancy and reliability. The source must operate over an acceptable period of time.

Within the ESS study, the Institut für Angewandte Physik of the Frankfurt University is concerned with the development of the accelerator part and especially with the development of H$^-$ ion source prototype. As promising candidate for this task, the so-called HIEFS was chosen. It was developed in Frankfurt [3] and belongs to the volume type family. In case of positive ion production (H^+, H_2^+, D^+, He^+, N^+, Ar^+, and Bi^+) this source has proven its capability to produce high current ion beams of a single mass to charge ratio at very low beam emittances (200 mA H^+ [4], 80 mA D^+ [5], 70 mA Bi^+ [6]).

2 EXPERIMENTAL SETUP

A schematic cross-sectional view of the experimental setup is shown in Figure 1. The plasma chamber of the ion source is made of a water-cooled copper cylinder. It is surrounded by 10 CoSm magnets in cusp field arrangement. Near the chamber axis, four tungsten filaments (1.8 mm diameter) are mounted. The front end of the chamber is enclosed by the plasma electrode. It is electrically connected with the anode. An electromagnet is installed in the flange of the plasma electrode. Its transverse magnetic field (B_f) acts as an electron filter.

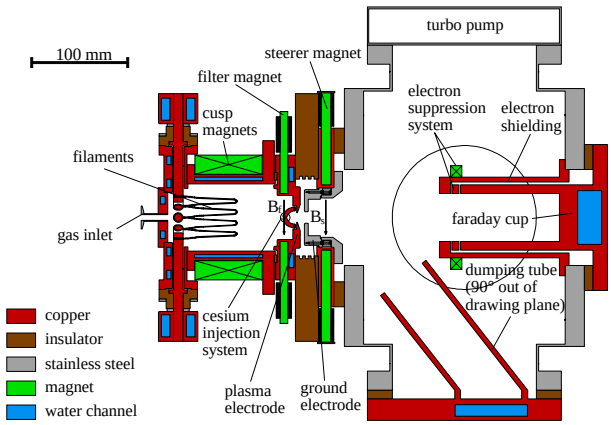

Figure 1: Schematic drawing of the experimental setup.

The arc power is provided by an array of capacitors (C_{tot} = 0.53 F) and gated by a high current switch. The used pulse generator allows arc powers up to 50 kW during 0.15 to 1.2 ms pulses and variable repetition rates from 1 to 400 Hz. Furthermore, for beam currents beyond the current limit of our extraction power supply (65 kV/300 mA), its charge also has to be accumulated in a capacitor (C = 3.5 μF). A wiring diagram of the ion source is presented in Figure 2.

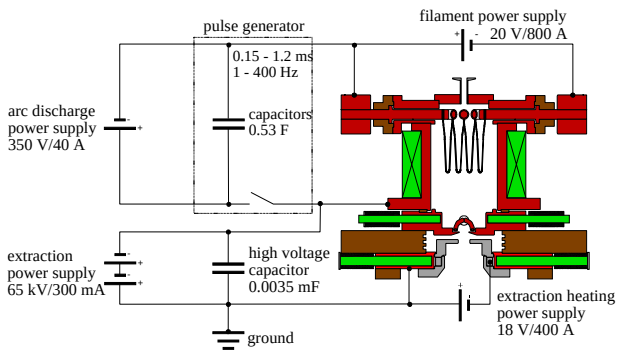

Figure 2: Wiring diagram of the H$^-$ ion source.

An external oven is mounted on the flange of the plasma electrode for introducing cesium. By means of two small pipes, the cesium vapor is deposited close to the outlet aperture. The whole system is temperature controlled.

* Work supported by BMBF under contract number 06OF841I and FZJ GmbH.

In order to extract the H^- ions, a single hole diode extraction system with an aspect ratio of 0.8 is used. A heater is integrated in the ground electrode to run the extractor at temperatures around 250 °C. That way, a cesium deposition on the ground electrode is avoided which would lead to high voltage breakdowns in the extraction gap otherwise.

As the extraction of H^- ions is always accompanied by the extraction of electrons, a device for electron beam removal is necessary. Our concept is to dump the electron beam behind the extractor at full beam energy in a water-cooled cup. Due to the extension of the filter magnet field into the gap of the extractor, the electron beam is deflected out of the beam axis. As the deflection angle of the electron beam depends on the filter field strength and the extraction energy, an additional so-called "steerer magnet" is necessary (B_s) to contrive the electron beam in the dumping tube.

The ion beam diagnostic consists of a water-cooled Faraday cup, encapsulated in a grounded screen. It is equipped with an electrostatic and magnetic electron shielding.

3 EXPERIMENTAL RESULTS

There are two dominant processes for H^- generation in this ion source: volume and surface production. Both processes can be intensified by supplying cesium to the plasma chamber [7]. In operation with cesium, the H^- emission current is up to 4.5 times higher and the e/H^- ratio is about 7 times lower compared to an operation without cesium.

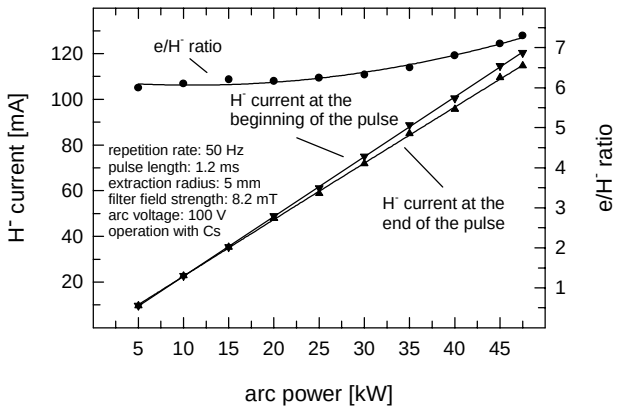

Figure 3: H^- current and e/H^- ratio vs the arc power.

Figure 3 illustrates the H^- current as function of the arc power for a cesiated source operation. The graph is split for higher arc powers: the upper graph shows the H^- current at the beginning of the pulse, the lower graph indicates the H^- current at the end of the pulse. This splitting, or current decrease during the pulse, is due to the "burn in" of the arc discharge. Especially for higher arc powers, it takes more time until the discharge achieves its balance. For an arc power of 47.5 kW, the ion source produces 120 mA H^- at the beginning of the pulse and 115 mA H^- at the end of the pulse. The former value corresponds to an emission current density of 153 mA/cm^2. In this mode of operation, the required extraction voltage for a matched beam is 33 kV (E_{gap} = 5.3 kV/mm). It is remarkable that the H^- current increases linearly as function of the arc power. Hence, a further enhancement of the H^- current is expected for arc powers beyond 50 kW. For short times 140 mA have already been achieved.

Figure 3 also shows the e/H^- ratio as function of the arc power. The plot displays a small growth rate. For full arc power the e/H^- ratio is about 7. This value corresponds to an electron current of 850 mA, equivalent to a mean electron beam power of 1.7 kW. Almost 100 % of the electron beam is captured in the dumping tube where the deposited energy of the electron beam is removed easily.

Figure 4 presents the evolution of the H^- current during a 1.2 ms pulse. After a rise time of 75 µs the curve reaches its maximum, shows a reduction of 4 %, and falls down within 35 µs.

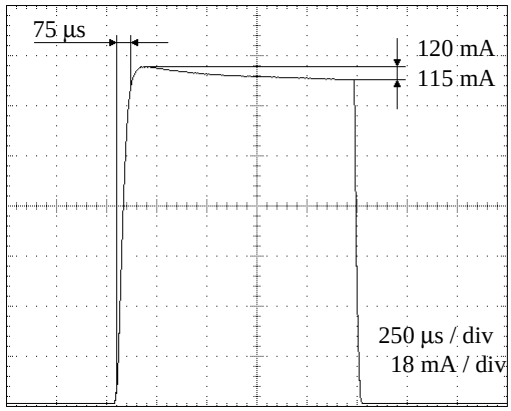

Figure 4: Oscillogram of the H^- beam.

For an arc power of 47.5 kW and a matched beam the noise level is less than 1.5 % (peak to peak). To attain such a low level, both the H^- and the electron beam must not hit any electrodes.

An ion source operation without cesium leads to a considerably faster current decrease during the pulse. Also, the beam noise level is dramatically higher.

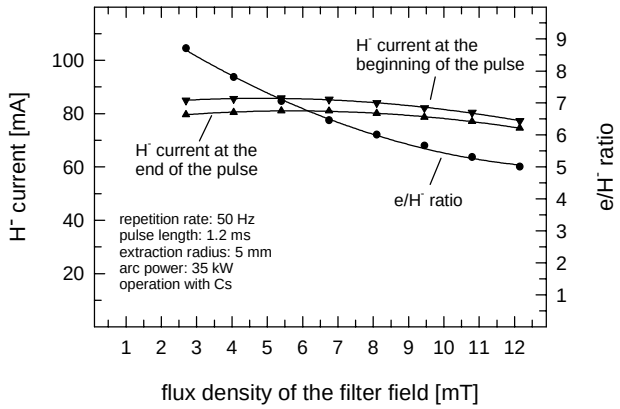

Figure 5: H^- current and e/H^- ratio vs filter field strength.

In a further experiment, the influence of the filter field strength on the H^- current and the e/H^- ratio was investigated. The measurements were made at an arc power of 35 kW. As illustrated in Figure 5, rising the filter field strength reduces the e/H^- ratio while having little influence on the H^- current. Consequently, the ion source is operated with a filter field strength of 8.2 mT.

In the course of the experiments, the dependence of the H^- current and the e/H^- ratio on the plasma electrode temperature was investigated. As depicted in Figure 6, an increase of the temperature yields higher H^- currents. For about 200 °C, the H^- current is about 1.3 times larger compared to its value at room temperature. Over the same temperature range, the e/H^- ratio drops by a factor of 2.

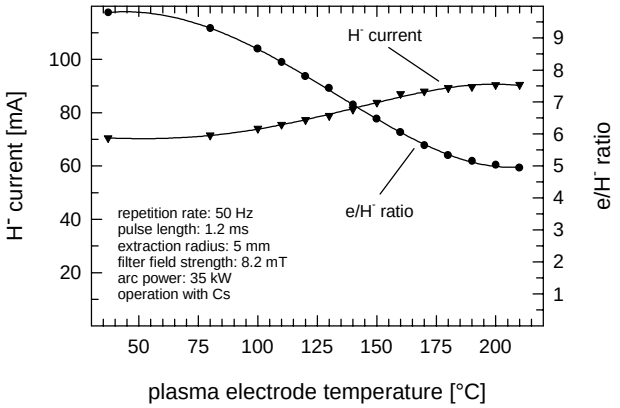

Figure 6: H^- current and e/H^- ratio vs plasma electrode temperature.

Besides a high H^- current, an appropriate ion source lifetime is another important requirement. For a given operational gas, the lifetime is limited by the wear of the filament which is approximately antiproportional to the duty cycle and the arc power. In order to obtain a long ion source lifetime, one should employ several filaments with large cross sections. This of course requires a filament power supply of the proper size. In other words, many thick filaments - which unfortunately have to be operated with a large power supply - are favorable for a long lifetime of the ion source. With the configuration described in this paper, the ion source was operated for 190 h at an arc power of 40 kW. After this time, the experiment was interrupted to check the condition of the filaments. Their diameter was reduced from 1.8 mm at the beginning to 1.5 mm. Since the filament can be used down to a thickness of about 0.9 mm, the ion source lifetime would be about 15 to 20 days.

As cesium is injected on demand only, in the normal mode of operation the injection system is off. That means, there is also a wear of the cesium layer which has to be rebuilt every 10 to 18 h. To achieve a controlled cesium deposition, a specific temperature profile of the plasma generator has to be kept. To account for this fact, the arc power has to be reduced for about 15 min. At the moment, a cesium injection system is developed, which will allow the cesium injection at high arc powers.

So far, the beam emittance has been not measured with our slit-grid emittance measurement device. Nevertheless, the H^- beam was recorded with a video camera to get a rough emittance estimation. After an optical analysis, the beam radius and the divergence angle of the 120 mA - 33 keV H^- beam could be estimated to 3 mm respectively 10 mrad. Hence, a phase space area emittance of 30π mm mrad is covered. For a KV distributed beam, the rms emittance is 7.5π mm mrad, the corresponding normalized rms emittance is 0.063π mm mrad.

4 CONCLUSIONS

In the present article, the status of the Frankfurt high duty cycle H^- ion source is described. The investigations have shown that the ion source is capable of producing a 120 mA H^- beam at an arc power of 47.5 kW (50 Hz, 1.2 ms, duty cycle = 6 %). This corresponds to an emission current density of 153 mA/cm^2. The required extraction voltage for a matched beam is 33 kV. A rough estimation indicates an excellent beam emittance of $\varepsilon_{rms,\ norm} \sim 0.06\pi$ mm mrad only. The achieved current is much lager as required for ESS, but further work has to be done to improve the lifetime of the source. A long-standing milestone is to have an ion source which satisfies simultaneously all the ion source requirements for ESS, a goal that is now within sight.

5 ACKNOWLEDGMENTS

The authors would like to thank Dr. Ka-Ngo Leung (LBNL) for the good cooperation and many fruitful discussions. We are also thank the members of the electronic lab and the mechanical workshop for their technical support as well as the ion source group members for their assistance with this work.

Abstract

An image-analysis system, based on commercially available data visualization software (IDL [1]), allows convenient interaction with image data while still providing calculated beam parameters at a rate of up to 2 Hz. Image data are transferred from the IOC to the workstation via EPICS [2] channel access. A custom EPICS record was created in order to overcome the channel access limit of 16k bytes per array. The user can conveniently calibrate optical transition radiation (OTR) and fluorescent screens, capture background images, acquire and average a series of images, and specify several other filtering and viewing options. The images can be saved in either IDL format or APS-standard format (SDDS [3]), allowing for rapid postprocessing of image data by numerous other software tools.

1 INTRODUCTION

The Advanced Photon Source [4] linear accelerator system [5] consists of a 200-MeV, 2856-MHz S-band electron linac and a 2-radiation-length-thick tungsten target followed by a 450-MeV positron linac. The linac is designed to accelerate 30-ns-long pulses containing 50 nC of electrons to an energy of 200 MeV at 48 pulses per second. The 480-W beam is focused onto a tungsten target that serves as a positron converter. Positrons [and electrons] are re-accelerated from the target to 450 MeV.

The linac was recently outfitted with a thermionic rf gun [6]. A BNL-Gun IV photocathode rf gun [7] and glass drive laser will be added in the next few months, thus allowing the linac to become a free-electron laser (FEL) driver [8]. The ability to extract accurate, on-line measurements of important beam parameters from image data has become ever more important in view of the recent upgrades, thus the imaging system has been significantly improved over the past few months. Beam emittance, profiles, spot size, and spot shape are all valuable in tuning and debugging the linac and understanding its behavior.

The APS linac's original image analysis systems were based on high-performance pipelined image processing hardware (Datacube MV20/MV200 [9]) residing in a VME crate and controlled with EPICS software. The pipeline architecture of the Datacube modules allows for pixel manipulation while the image is being digitized and routed to image memory. Additional on-board hardware provides arithmetic operations and statistical analysis. These capabilities can be used to implement many image-processing algorithms, which can function at the full 30-Hz frame rate of the incoming video.

This advanced capability has a price. In addition to a sizable investment in hardware, extensive knowledge and training are required to properly configure, program, and test the pipelined hardware. All processing must be done in the VME environment, which requires a system reboot when new features or changes are implemented. The learning curve is substantial, thus many desirable features are never actually implemented.

Since the original image analysis system was implemented five years ago, significant increases in workstation and network performance have made it feasible to accomplish limited image analysis with a workstation-based tool. The advantages are:

- Able to use high-level software, such as IDL
- Easy to modify, enhance, and debug
- User-friendly access to file systems for saving, restoring, and manipulating data
- GUI interface
- Video-capture hardware knowledge is unnecessary

The disadvantage is that speed is compromised.

Table 1 lists benchmarks of some typical image analysis operations. These statistics demonstrate that if system requirements demand frame-by-frame processing, the only solution is an image processing system designed for that task. If, however, it is sufficient to perform the analysis at a 1-Hz rate, other options can be considered.

4GL application development software package for data analysis and visualization.

2 SYSTEM OVERVIEW

The existing MaxVideo MV20 image processor is used to digitize the video image in the VME chassis. Through a new EPICS record type, an "image record," the raw image data is made available to workstation-based clients via EPICS channel access. Since there is a 16-kbyte limit for each waveform in channel access, the image record presents the data as N scanlines of M pixels, where N is the vertical resolution of the camera and M is its horizontal resolution. For a typical camera of 480×512 pixels, the entire image can be fetched by retrieving 480 arrays of 512 bytes. This retrieval takes approximately 0.4 seconds on a typical 10-Mbit Ethernet network. A "smart" client will minimize retrieval time by only fetching the scanlines within a region of interest (ROI).

All other functionality is provided in an IDL application named "imageCatcher." Standard EPICS provides a library such that channel access functions can be called directly from within the IDL code. The entire raw image can be fetched with the single IDL statement:

stat = caGet(pvNames, image, max=512, type=1)

where "pvNames" is a string array of the process variable (pv) names representing each scanline, and "image" is an IDL variable for a 2-dimensional array. The user-friendly "imageCatcher" main control screen is shown in Figure 1.

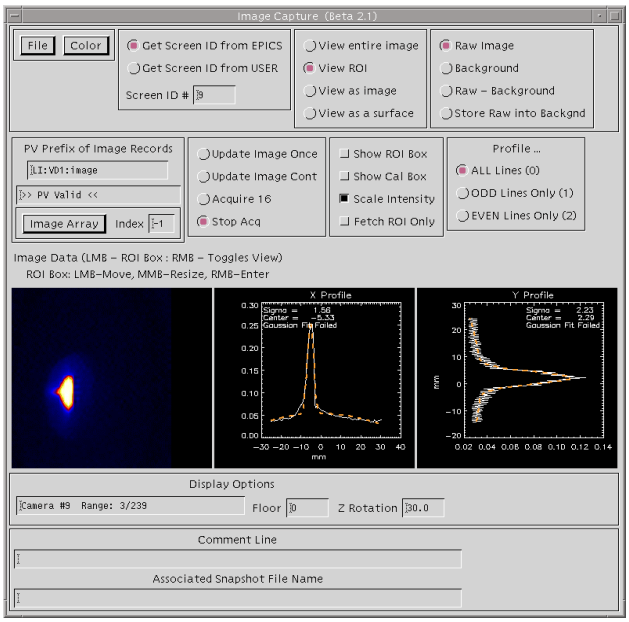

Figure 1: The "imageCatcher" main control screen. The user can easily select from several acquisition, calibration, and display options for any of the linac OTR, YAG, or Chromox screens.

The advanced IDL instruction set can easily be used to perform analysis functions on the IDL image data. Some features currently implemented in "imageCatcher" are:

- Background definition and subtraction
- Image display with pseudocolor surface view
- Surface intensity characterization with adjustable rotation and tilt
- Calculation and plotting of X and Y profiles
- Interactive screen calibration for conversion from pixels to mm
- Gaussian fit of profiles, with evaluation of fit quality
- Calculates position of peak intensity and sigma
- Performs online average of 16 consecutive images
- Saves image data in IDL or SDDS format for further analysis

The images can be saved in either IDL format or SDDS format, allowing for postprocessing of image data by other software. Figure 2 is an example of an "sddscontour" plot showing intensity versus position.

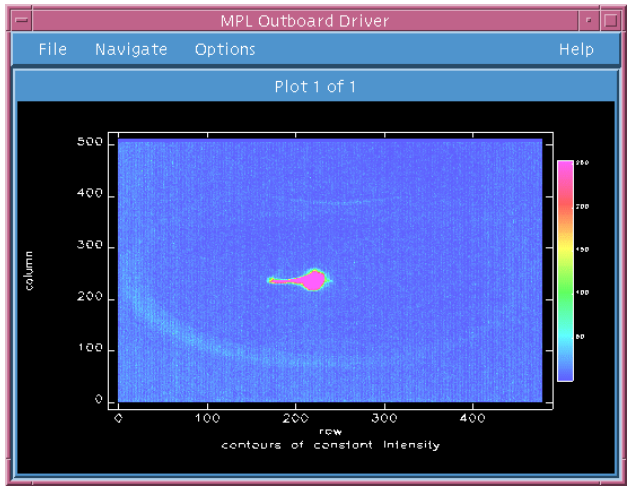

Figure 2: Contour plot of a thermionic rf gun beam spot on a Chromox screen obtained with "imageCatcher."

3 APPLICATIONS

The APS linac is equipped with 10 Chromox fluorescent screens, 2 OTR screens, and 2 YAG crystals. These screens can be viewed with any of the standard CCD or CID cameras. Bunch length data can be obtained from the OTR screens by means of a streak camera. The Chromox screens and fiducials are at 45 degrees to the beam. The calibration procedure redefines the fiducial area to compensate for any angular dependence as well as for optical alignment errors. Many of the cameras allow the user to zoom, focus, and change the iris setting; therefore, the ability to rapidly establish a calibration before capturing the image is critical. "imageCatcher" allows rapid screen calibrations to be performed and to be associated with each measurement. The screen calibration utility is shown in Fig. 3. Beam emittance, profile, spot size, and spot shape are all extremely valuable in tuning the accelerator, debugging problems, carrying out accelerator studies, and generally understanding machine behavior.

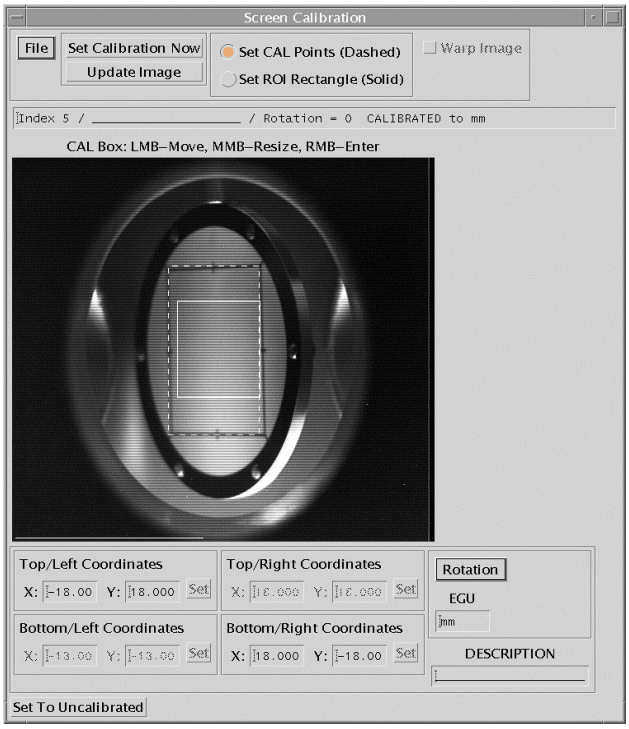

Figure 3: "imageCatcher" calibration mode is shown. The solid box is the ROI and the dashed box is the calibration box. After drawing the calibration box, known coordinates of the four corners are entered at the bottom of the screen.

Transverse profiles at each screen can be compared to beam images on the same screen or on other screens from current and previous runs.

"imageCatcher" has been used to collect data for quadrupole-scan based emittance measurements and for the characterization of Chromox (Chromium doped Al_2O_3) screens. Figure 4 shows transverse beam size data from a quadrupole-scan emittance measurement using the DC thermionic gun. Image information was saved and later processed with SDDS tools.

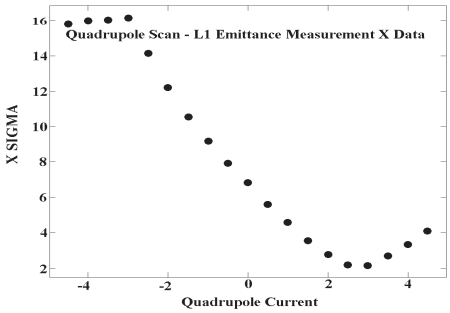

Figure 4: "imageCatcher" data; transverse beam size vs. quadrupole current, used to determine the emittance.

4 FUTURE PLANS

Future plans include upgrading the network to 100MBit, adding capability to correct the image for distortion due to the optics, and integrating "real time analysis" into the IOC so simple analysis can be done fast and more advanced analysis can be done on the workstation.

Abstract

The bunch length and velocity of a beam accelerated with the 432-MHz, 3-MeV JHP-RFQ (Japanese Hadron Project - Radio Frequency Quadrupole) linac were measured by using a Bunch Length and Velocity Detector (BLVD) developed by INR. The measured velocity (0.08002±0.00016)c showed a good agreement with the design value. The longitudinal profiles of the bunch have been measured for various setting of the RFQ. The bunch shapes of H^- beam as well as proton beam (produced by the stripping of H^- ions) have been studied. Although the BLVD has been designed for measurement of beam core (~99% of particles) the accurate study of a beam halo has been done. An almost uniformly distributed background was observed. The amount of the integrated background signal was about 1% of the beam intensity. A possible source of the background is analyzed.

1 INTRODUCTION

Well understanding of the beam characteristics output of the JHP RFQ operating at high duty cycle [1] is major step in the design of front end of the linac for future Hadron Facility [2]. For the study of longitudinal beam parameters as well as for the beam energy measurement the BLVD has been used. The design of the BLVD was based on the long-term experience of the INR group [3]. The BLVD is an extension of the Bunch Shape Monitor (BSM) to measure absolute velocity of a bunched beam [4].

2 GENERAL DESIGN OF THE DETECTOR

The technical specifications for the BLVD are shown in Table 1. The target is a tungsten wire with a diameter of 100 μm. A proton or H^- beam with energy of 3 MeV has 57.3 mg/cm^2 or 28 μm range in tungsten, therefore total beam energy will be dissipated in the target. The heating of the wire, located on the beam axis per beam pulse can be roughly estimated using the formula $\Delta T = \frac{4WI\tau}{(\pi R)^2 \rho C_p d}$, where *W[eV]* is the beam energy, *I[A]* is the beam current, *τ[s]* is the pulse duration, *R[m]* is the beam radius, *ρ[kg/m^3]* is the target density, C_p *[J/(kg·K)]* is the specific heat of the target material, *d[m]* is the target wire diameter. Assuming a beam radius to be equal to 2·rms value and using beam parameters for the most powerful beam one can get $\Delta T \approx 4700$ °K. The maximum temperature for the tungsten is restricted by thermal emission of electrons ~1500 °K. The simplest way to avoid target overheating is the use of a slit collimator upstream of the target. The 0.2 mm slit located 130 mm upstream of the target decreases the beam density at the target by a factor of 6 allowing to make safe measurements for whole beam pulse with maximum current of 40 mA and 50 Hz repetition rate, if necessary.

Table 1: BLVD specifications

1	Type of particles	H^- or H^+
2	Energy of particles	3 MeV
3	Minimum pulse current	0.1 mA
4	Maximum pulse current	40 mA
5	Pulse length	600 μs
6	Repetition rate	50 Hz
7	Accelerating frequency	432 MHz
8	Geometrical size along the beam	360 mm
9	Phase resolution at 432 MHz	2°
10	Range of phase measurements	180°
11	Accuracy of velocity measurement	0.2 %
12	Beam line aperture	32 mm

The simplified general assembly drawing of the BLVD is shown in Fig. 1. The beam to be analysed is moved perpendicularly to the plane of drawing. The BLVD consists of the following main elements: body of the detector (1), target actuator (2) with the target unit (9), rf deflector combined with electrostatic lens (3), registration unit (4), permanent magnet with adjustable field (5) to steer the electrons vertically, glider (6) with the actuator (7) to shift the longitudinal position of the detector. The extra port (8) is assigned for vacuum pump. The horizontal 0.2 mm slit is not seen in the drawing and

located 130 mm upstream of the wire. The vertical position of the slit is adjusted by a stepping motor. There is a permanent magnet located upstream of the slit. We can select one of the two positions (one is on the beam axis and the other is far from the beam axis) of the magnet remotely. By locating the magnet on the beam axis, we can bend the small amount of particles, which are not accelerated in the RFQ, far from the target. The longitudinal glider has been designed using the Linear Motion Guide Actuator manufactured by THK, the position reproducibility is ~3 μm. In order to minimise a space along the beam pipe the stepping motor of the longitudinal glider is located off-axis, parallel to the beam pipe. The glider can move the detector over the distance of $\sim\beta\lambda/2\approx 56$ mm.

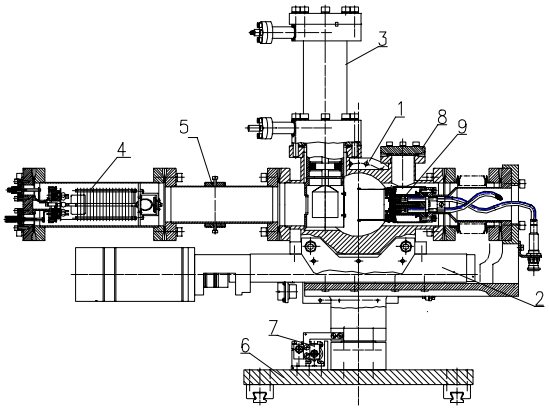

Figure1: General assembly drawing of the BLVD.

3 DATA ACQUISITION AND CONTROL SYSTEM

In order to detect secondary electrons produced on the target, a secondary electron multiplier (SEM) tube of the type of Hamamatsu R596 is used. The amplification gain of the electron multiplier can be varied within 5 orders of magnitude by changing supplied high voltage. The signal from the SEM tube is amplified by the fixed gain (0.5 V/μA) amplifier located directly on the registration unit output flange. The amplifier has an internal pulse generator to test the signal propagation. The response time of the whole signal chain is less than 1 μsec.

The control system is based on IBM PC and one CAMAC crate. Special electronic modules are housed in an additional NIM crate. There are two modes of the measurements. In the 'fast' mode the phase of the deflecting field is varied with the beam pulse and the bunch shape is measured within a beam pulse. It means that the different points of the longitudinal intensity distribution are taken along the beam pulse. In the 'slow' mode the phase is varied between the beam pulses and different points of the bunch shape are obtained for different beam pulses. In this case digitizing of the signals with 1 μsec intervals for each phase position enables to find behavior of the longitudinal distribution during the beam pulse. Obviously this procedure requires the stability from pulse-to-pulse which is perfectly provided by the accelerator.

The software for control and data acquisition system for the detector has been developed using new 32-bit version of the MOON Lab technology running under Microsoft Windows95, developed at the INR [5]. While processing the detector control and acquiring data, the software can post-process and present the data.

4 RESULTS

After the commissioning of the BLVD and optimum setting of its parameters the 3-MeV beam accelerated by the 432 MHz RFQ has been studied. The RFQ beam parameters are rather different from those in Table 1, mainly due to the performance of the ion source under development. The typical peak beam current, the maximum repetition rate and the maximum pulse length were 13 mA, 25 Hz and 300 μs respectively. In order to avoid the sputtering problem of the collimator slit, the measurements were performed with the pulse length shorter than 130 μs. Under these conditions, the wire also survives with any repetition rate less than 25 Hz. (Therefore, the collimator slit was used in order to study the relationship between the bunch shape and the vertical position.)

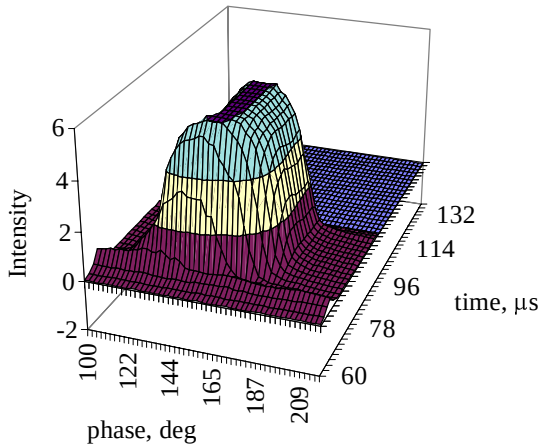

Figure 2: Bunch shape evolution along beam pulse.

In Fig. 2 the bunch shape evolution along the beam pulse is shown. Duration of the beam pulse injected to the RFQ was longer than the rf pulse length. The rf filed in the RFQ has been well stabilized on the top of beam pulse but there was some rf field parameters distortion in the transient. Therefore the bunch center at the beginning of the pulse is shifted in phase and due to the low level of the accelerating field in the beginning of pulse there is a fraction of unaccelerated particles. As for the top of the rf pulse from theory it is very unlikely to have unaccelerated particles after the long 3-MeV RFQ. However it was found that about (1÷2)% of integrated signal arises from the almost uniformly distributed in phase background. The insertion of the 1000 Gs bending

magnet upstream of the BLVD do not indicate any reduction of the background. It was supposed that the possible source of the background is the contribution of the detached electrons from H^-. In order to avoid the contribution of the detached electrons 1 μm aluminum foil has been installed upstream of the target. The passage of the H^- beam through the foil produces a proton beam without any change of the longitudinal charge distribution. In order to measure bunch shape in wide dynamic range the measurements have been done with different gains of the SEM tube using the calibration curve. The measured particle fractions as a function of phase half-width for H^- and proton beams are shown in Fig. 3. The bunch shape of the proton beam in logarithmic scale is shown in Fig. 4. These measurements show that the background noise for proton beam is smaller than that for H^- beam (see Fig. 3), however the longitudinal tail containing ~1% of particles still remains.

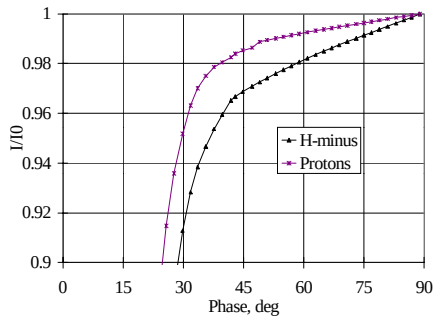

Figure 3: Particle fraction as a function of phase half-width for H^- and proton beams.

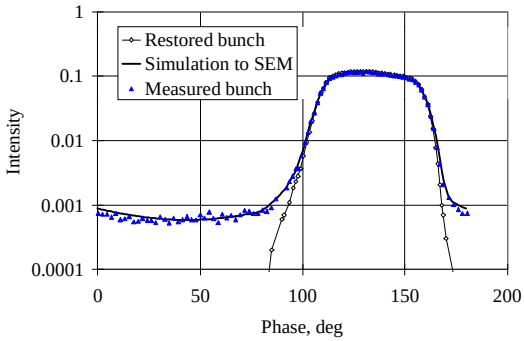

Figure 4: Bunch shape of proton beam in logarithmic scale.

Both of the H^- and proton beams have a similar longitudinal density distributions except of the halo region. The proton beam contains much less particles in the halo, but still has long tail. In order to understand the source of such signal, the secondary electron beam motion has been analyzed. A possible reason of the background formation is an interaction of the electrons with the edge of the collimator installed at the entrance of the deflector. This interaction results in increasing of energy dispersion as well as scattering of the small part of secondary electrons. In addition the beam optics can produce some aberrations. All these effects result in a diffusion of the electron beam on the detector. The secondary electron distribution $f(V_{st})$ as a function of the steering voltage V_{st} applied to the deflector plates has been measured without any rf field in the deflector. For ideally focused electron beam this function must be very narrow distribution without any background. However, in practice the very low level of background signal has been observed for whole range of steering voltage. It confirms the existence of scattered secondary electrons. The function $f(V_{st})$ has been used in order to exclude the systematic error in the measurements. Fig. 4 shows the "restored" bunch shape after excluding systematic error and the simulated bunch shape which is produced numerically using the "restored" bunch and the function $f(V_{st})$. For the restored bunch shape the bunch width on the base (see Fig. 4) is ±50° which corresponds to $3.27 \cdot \Delta\varphi_{rms}$. Where $\Delta\varphi_{rms}$ is the rms bunch width.

An ability of the target displacement across the beam provides possibility to obtain transverse parameters of the beam by processing the results of the standard measurements taken at different position of the target. The transverse profiles have been measured for different rf power levels in the RFQ. There is no change of the beam transverse position with rf power variation which means that the RFQ is well aligned and there is no transverse coherent oscillation.

The total error of energy measurement is ±12 keV (rms error is 0.13%) (including calibration of BLVD glider, statistical error due to multi bunch measurements, finding of the bunch center using longitudinal density distribution). The output energy of the RFQ is (3.02 ± 0.012) MeV which is equal to the design value.

5 CONCLUSION

A detector for the measurement of the bunch shape and average velocity for 3-MeV JHP RFQ has been developed and built. The detector has been successfully commissioned and is being used for the studies of the RFQ beam parameters.

ROLL BAR X-RAY SPOT SIZE MEASUREMENT TECHNIQUE*

R. A. Richardson, T. L. Houck
Lawrence Livermore National Laboratory, Livermore, California 94550 USA

Abstract

A time dependent x-ray spot size measurement is critical to understanding beam target physics such as target plasma generated beam instabilities. The so-called roll bar measurement uses a heavy metal material which is optically thick to X-rays, to form a 1D shadow of the x-ray origination spot. This spot is where an energetic electron beam interacts with a high Z target to produce the x-rays. The material (the "roll bar") has a slight radius to avoid alignment problems. If a beam profile is assumed (or measured by other means), the equivalent x-ray spot size can be calculated from the x-ray shadow cast by the roll bar. Typically a radiographic film is exposed over the duration of the beam pulse, and the shadow is analyzed for a time integrated measurement. This paper explores various techniques to convert the x-rays to visible photons which can be imaged using a gated camera or streak camera for time evolved x-ray spot size. Data will be presented from the measurements on the ETA II induction linac.

1 INTRODUCTION

This diagnostic is used to measure the spot size of an x-ray source. A bar that is optically thick to x-rays is used shadow the source, acting as a knife edge. This produces a shadow that is effectively the integral of the x-ray profile. We assume that the profile here is Gaussian in shape. The profiles are fitted to a erfc function, which is the integral of a Gaussian. The Gaussian assumption is verified using other diagnostics such an x-ray pinhole camera and OTR (optical transition radiation) of the focused electron beam striking the surface of an x-ray target.

The shadowed x-rays are then converted to visible photons for imaging using commercial cameras. The image is corrected for flat field using an image taken without the rollbar present. The image is averaged in the dimension orthogonal to the rollbar edge to increase photon statistics.

The full-width half maximum (FWHM) of the Gaussian (from the fitted erfc function), corrected for magnification, is reported as the spot size. The magnification of the rollbar is simply the distance from the rollbar to the x-ray image converter (scintillator) divided by the distance from the x-ray source to the rollbar (Fig. 1).

* Work performed under the auspices of the U.S. Dept. of Energy by the Lawrence Livermore National Laboratory under contract No. W-7405-ENG-48.

Limitations of this diagnostic are the blurring effects due to the finite thickness of the image converter. This can be reduced by increasing the magnification, but at a cost of reduced x-ray flux. The photon conversion efficiency is low, so that detection is marginal for short gate widths and large magnification.

2 EXPERIMENTAL SETUP

This diagnostic is used to measure the x-ray spot on the ETA II linear electron accelerator. The machine parameters are 5.5 MeV energy, 2 kA current, 50 ns pulse width. X-rays are created when the beam is focused on a (typically) 0.040" Tantalum target. The diagnostic setup (Fig. 1) consists of a heavymet (mostly Tungsten) rollbar, which is a 8x8x3 cm block with a 1 meter radius machined on one face. This bar is located a distance 108 cm from the target (x-ray source). Between the target and the rollbar is a 0.060" aluminum vacuum window. At a distance of 427 cm there is a 90x90x19 mm BC-400 scintillator. The magnification is therefore 3.95. We use a 0.010" tantalum sheet in front of the scintillator to convert the x-rays to electrons which are detectable by the scintillator. Black cloth between the tantalum and scintillator absorbs reflections.

The scintillator is imaged using a gated camera. We have used a Cohu SIT camera (10 ns gate) and a Princeton Instruments CCD camera (5 ns gate). Both cameras use a microchannel plate to intensify and gate the image.

Typically a short lead bar is placed directly in front of the scintillator-Tantalum stack orthogonal to the direction of the rollbar edge, partially blocking the x-rays. This is done to provide an edge that is representative of the blurring introduced by the scintillator and camera. The optical resolution is typically much less than the scintillator blur.

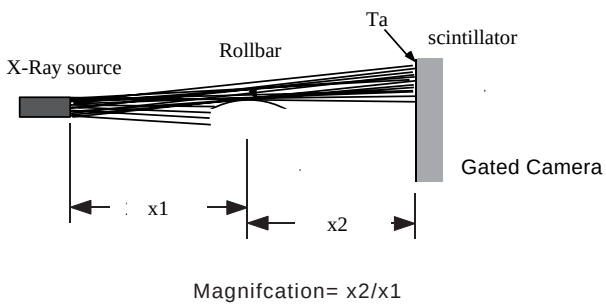

Figure 1: Sketch of rollbar diagnostic.

3 DATA

An example rollbar image is shown in Fig. 2. This is the raw scintillator image, uncorrected for flat field. The scintillator is imaged with the Princeton Instruments camera (ICCD-576). The 5 ns gate of the camera is timed to the middle of the accelerator pulse. The dark frame around the scintillator is clearly visible. The rollbar in this case is vertical, and an averaged lineout in the horizontal direction is analyzed to get the spot size of the x-ray source. The sharper horizontal shadow in the lower half of the image is due to a 0.25 inch thick lead bar placed immediately in front of the scintillator. Lineouts in the vertical direction are analyzed to approximate the blurring due to x-ray and electron scattering in the scintillator and tantalum backing, as well as optical blurring.

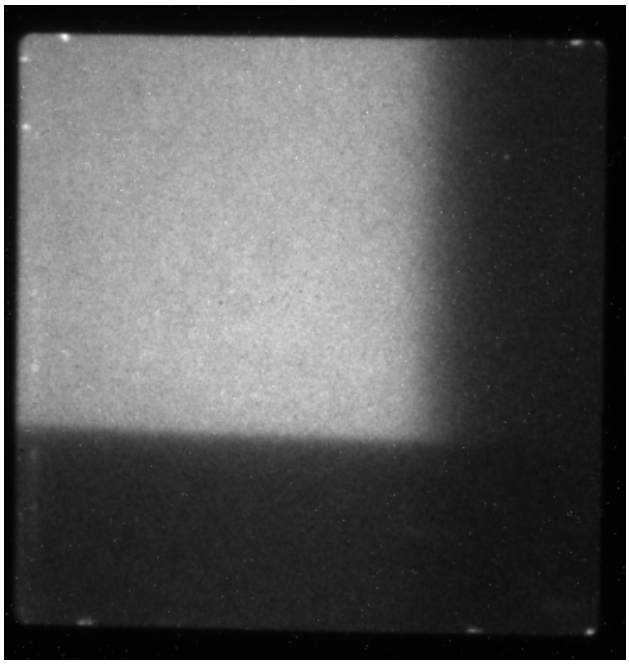

Figure 2: Scintillator image showing rollbar and edge blur x-ray shadows.

A horizontal lineout and erfc fit are shown in Fig. 3. This is the raw data, uncorrected for any blur. A lineout of the image in the vertical direction, which shows the shadow from the lead bar is shown in Fig. 4. An erfc fit is done on the data to quantify the blur produced. As expected, the fit is not perfect, but gives a representation of the spot size error, in this case around 1 mm.

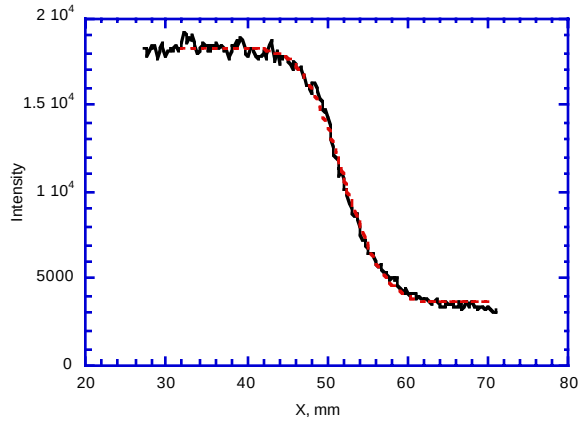

Figure 3: Rollbar data with erfc fit. Magnification=4, Gaussian FWHM = 2.4 mm.

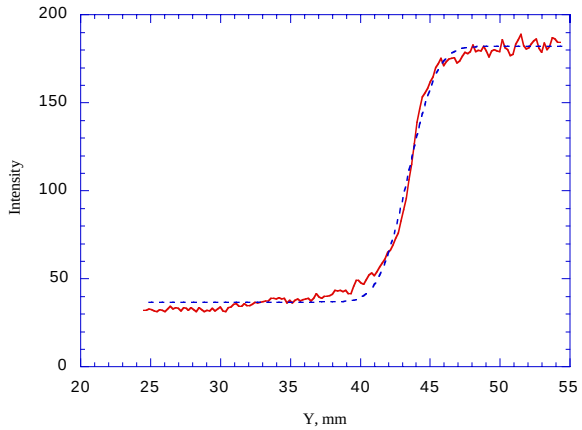

Figure 4: Scintillator blur with erfc fit. The equivalent spot size is 0.97 mm.

The scintillator blur can be corrected for by deconvolution of the data with the blur[1]. This is done using Fourier transforms of the data. First the data is smoothed and differentiated. The Fourier transform of the data is taken and normalized to give the modulation transfer function (MTF). The spot size can be obtained by finding the frequency (f_0) at which the MTF = 0.5. The equivalent Gaussian spot size is then FWHM = $0.447/f_0$. The resulting transforms are shown in Fig. 5. The spot size of 2.5 mm when corrected for scintillator blur drops to 1.9 mm. This method of spot size determination is more effected by noise. Note there is a slight difference in the uncorrected spot size when determined by FFT or erf fit to the raw data (2.5 versus 2.4 mm).

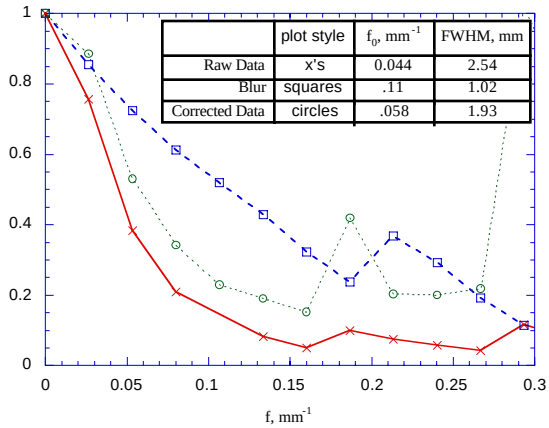

Figure 5: Fourier transforms of image lineouts, with corrected data.

4 RESULTS

The rollbar diagnostic is useful for final tuning of the accelerator. The image data is recorded real time electronically. The lineouts and fit can be done in a manner of minutes, and a tuning curve can be generated rapidly, Fig. 6.

The rollbar diagnostic can also be used to determine the time history of the x-ray spot, Fig. 7. For this data, each point represents a different shot, so some shot-to-shot stability must be assumed.

DEVELOPMENT OF NANOMETER RESOLUTION C-BAND RADIO FREQUENCY BEAM POSITION MONITORS IN THE FINAL FOCUS TEST BEAM*

Abstract

Using a 47 GeV electron beam, the Final Focus Test Beam (FFTB) produces vertical spot sizes around 70 nm [1]. These small beam sizes introduce an excellent opportunity to develop and test high resolution Radio Frequency Beam Position Monitors (RF-BPMs). These BPMs are designed to measure pulse to pulse beam motion (jitter) at a theoretical resolution of approximately 1 nm [2]. The beam induces a TM_{110} mode with an amplitude linearly proportional to its charge and displacement from the BPM's (cylindrical cavity) axis. The C-band (5712 MHz) TM_{110} signal is processed and converted into beam position for use by the Stanford Linear Collider (SLC) control system. Presented are the experimental procedures, acquisition, and analysis of data demonstrating resolution of jitter near 25 nm. With the design of future e^+e^- linear colliders requiring spot sizes close to 3 nm [3], understanding and developing RF-BPMs will be essential in resolving and controlling jitter.

1 INTRODUCTION

Because of the small vertical spot sizes in the FFTB and a horizontal to vertical aspect ratio of almost 17 to 1, the RF-BPMs were designed to measure only vertical beam motion. At the end of the SLAC linac or entrance to the FFTB, vertical jitter is typically 30% of σy [4]. Assuming contribution to jitter from the FFTB is negligible, a design βy^* of 100 μm at the Final Focal Point (FFP) and measured $\gamma\varepsilon y$ of 1.5 μm at the entrance to the FFTB would produce vertical beam jitter on the order of 20 nm. Interest in tracking and recording this jitter led to the development of these BPMs.

Although the FFTB is equipped with 34 strip-line BPMs, each with a jitter resolution of about 2 μm at a beam intensity of 6e9 [5], a direct measurement of the jitter at the FFP is very difficult. BPMs near the FFP (in the final transformer) are $n\pi/2$ out of phase measuring only angular divergence jitter. Farther away, BPMs can be found which are in phase, but are limited by their resolution and the accuracy of the transport optics model used to project the jitter to the FFP. Another concern of using BPMs which are not in the vicinity of the FFP is structural vibrations in the final transformer that could contribute to vertical jitter and would not be detected.

To make a direct measurement of the beam's motion at the FFP a single RF-BPM was installed 6.35 cm downstream of the KEK Beam Size Monitor (BSM). Because of the RF-BPM's compactness, placement close to the FFP is possible (see table 1).

Table 1. RF-BPM parameters.

PARAMETERS OF A RF-BPM	
Frequency	5712 MHz
BPM length	50 mm
cavity length	5 mm
BPM diameter	96 mm
cavity diameter	60.07 mm
beam pipe diameter	20 mm
loaded Q factor	130
signal into 50 ohms	25 μV/nC/nm

Figure 1 shows a set of three RF-BPMs which were installed at the entrance to the final transformer, an image focal point (IMFP). The final transformer has a demagnification of 7, so the jitter will be on the order of

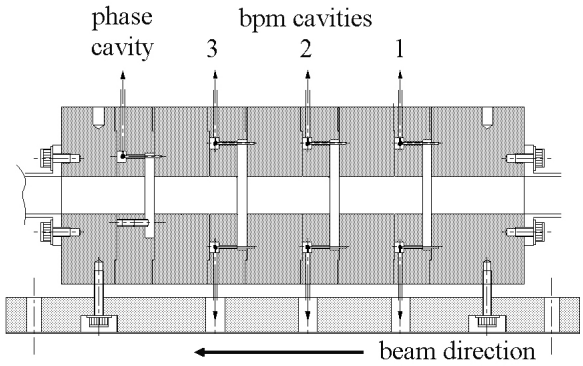

Figure 1. Mechanical drawing of the triplet RF-BPM set used for measuring the BPMs' resolutions.

* Work supported by the Department of Energy, contract DE-AC03-76SF00515.

140 nm at these BPMs. This set of BPMs is used for the resolution measurement, as well as for characterizing the beam's jitter parameters before entering the final transformer.

2 EXPERIMENT CONFIGURATION

The RF-BPMs are a typical pill box cavity design producing a signal containing four components

$$Vrf = A1qy + jA2qy' + jA3qy^{O} + Vnoise, \quad (1)$$

where q is the beam charge, y is the beam's offset with respect to the center of the cavity, y' is the beam's angle with respect to the cavity ($y'=dy/dz$), y^0 is an offset which comes from the TM_{010} signal (common mode), and j denotes the imaginary terms.

The signals from the RF-BPM are sent through a 180° hybrid that significantly reduces the second and third term in equation 1. The difference signal from the hybrid is passed into a RF receiver circuit. The RF receiver circuit is set up as a heterodyne synchronous detector that extracts the amplitude and polarity of the BPM signal. The beam induced waveform is filtered at 5712 MHz and mixed down to 500 MHz. The 500 MHz signal is then filtered, amplified, and mixed down to 50 MHz. This signal is again filtered and amplified and passed to a dual track and hold (NiTNH) module, a 16 bit digitizer with a ±2 volt limit and a 300 MHz bandwidth. The digital signal is converted into beam position and read by the SLC Control Program (SCP).

The measured dynamic range of the receiver is 51 dBm with measured noise of -82 dBm or 1 nm for a beam charge of 1 nC. The gain factor for the system is measured by moving the BPMs with respect to the beam (see section 3 below for this process).

3 DATA ACQUISITION

Before being used for data acquisition, the RF-BPMs were phased to the electron beam and a signal to position calibration constant was measured. Phasing was accomplished by using a fourth cavity which is located at the end of the triplet stack (see figure 1). Since the BPMs were phased to the beam, drifting due to timing signals were eliminated. The calibration constant was measured by moving the BPMs with respect to the beam. Calibrated linear variable differential transformers (LVDTs) measured the change in the BPM's position while the change in the BPM's signal is recorded. Within the dynamic range of the receiver, position verses signal is linear and the slope is the gain or calibration constant. This calibration constant is stored in the SCP's database for use with the BPM acquisition software. The maximum beam rate of the FFTB is 30 Hz. The signals from RF-BPMs are acquired simultaneously with the signals from standard BPMs up to the acquisition rate of 30 Hz. This allows for the comparison of the beam positions measured by the RF-BPMs to that measured by the standard BPMs.

4 DATA ANALYSIS

The top plot in figure 2 displays beam trajectories for approximately 300 machine pulses at an acquisition rate of 30 Hz. The beam's waist at the IMFP is close to the middle RF-BPM of the triplet set. With only drift spaces between the BPMs, the calculation of the slope and offset for each beam trajectory at the center BPM does not require knowledge of beam line optics. The bottom plot in figure 2 shows angles verses positions with a one sigma ellipse. This is a measurement of the jitter emittance which is equal to 1.533 μm. The equation for the emittance is

$$\varepsilon_{\text{jitter}} = \sqrt{\langle y \cdot y \rangle \langle y' \cdot y' \rangle - \langle y \cdot y' \rangle^2}, \quad (2)$$

where y is the measured position at the center BPM, y' is the measured angle using all three BPMs ($y'=dy/dz$), and <…> means an average over a series of measurements with a fixed time limit. The jitter emittance is close to one tenth of the beam emittance, which is expected for the observed beam jitter to beam size fraction of 30% in the SLC. This is an important measurement because it shows that the RF-BPMs agree with standard BPMs.

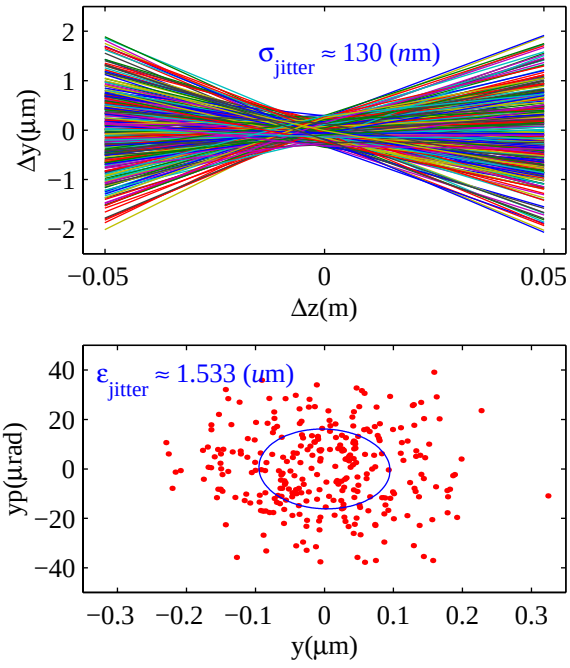

Figure 2. The top plot displays the measured beam trajectories. The bottom plot shows the calculated jitter emittance.

The resolutions of the RF-BPMs were measured using the triplet stack. With the BPMs in the triplet set being equally spaced and the beam's trajectory through them a straight line, the position from the middle BPM should equal the average of the positions from the outer BPMs. Assuming each BPM has the same resolution and uncorrelated noise, the resolution of the BPMs can be calculated from the standard deviation of the difference (residual) between the center position and the averaged positions for many beam trajectories. The equation is

$$\sigma_{bpm} = \sqrt{\frac{2}{3}}\sigma_{residual} \quad (3)$$

The first plot in figure 3 displays the distribution of the residuals with a sigma of 31 nm from a gaussian fit. This gives a BPM resolution of 25 nm for a 1 nC beam charge. The second and third plots show the time and frequency domain of the residual, respectively. It appears to be mostly white noise. The peak around 1 Hz is of some concern because it is a signature of beam motion in the SLC. The signal from the beam angle has not been completely eliminated. The fourth plot shows the integral of the residual in the frequency domain. Although the 1 Hz peak is of concern, its contribution to the overall residual is a small percentage.

If the RF-BPMs had a correlated noise source, for example a mechanical vibration or electronic noise, the resolution of the measured jitter would be understated for the rest of the beam line. To confirm the RF-BPM resolution measured by the triplet set, standard BPMs, one before and after the triplet set, were incorporated into fitting beam trajectories. All five BPMs were simultaneously fitted to the beam line model in an iterative least squares method until the resolution of each BPM converged [6]. Displayed in table 2 are the results for the triplet set and the two strip-line BPMs. The Yrslt column gives the resolutions of the RF-BPMs (The RF-BPM names are CB02 5032, 5034, and 5036).

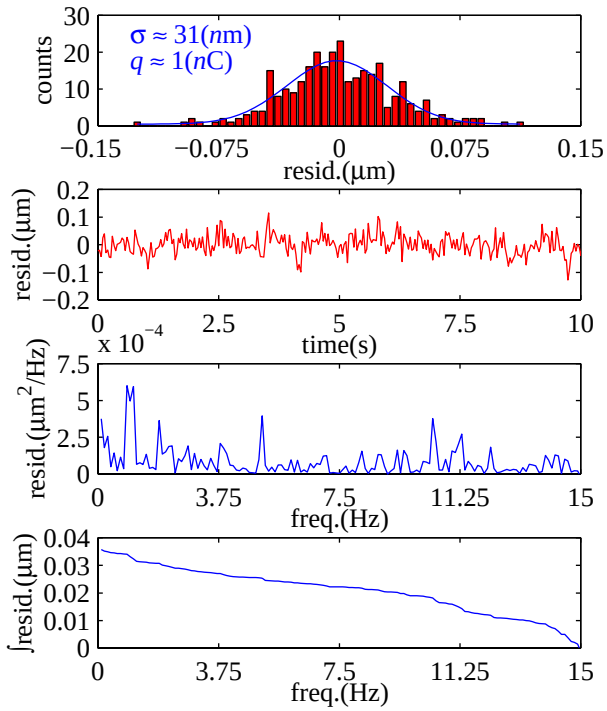

Figure 3. The histogram, time and frequency structure, and integrated amplitude of the residual from top to bottom, respectively.

Table 2. RF-BPMs resolutions.

BPMS RESOLUTIONS(μm)				
BPMS	Yest	Yrslt	Yrsdl	Yrms
CB01 5020	0.400	0.400	0.025	207.8
CB02 5032	0.045	0.045	0.040	1.8
CB02 5034	0.023	0.023	0.014	1.3
CB02 5036	0.054	0.054	0.051	1.6
CB01 5030	2.640	2.640	2.640	31.4

5 DISCUSSION AND CONCLUSION

Although the resolution of approximately 25 nm was measured for the RF-BPMs from the triplet set, the measured resolution of the RF-BPM at the FFP was around 80 nm. This is attributed to the beam's large angular divergence (460 μrad) and is not completely understood. Even though the FFP BPM was not able to measure beam motion below 80 nm, it was very efficient in minimizing beam aberrations before using the KEK BSM.

ACKNOWLEDGEMENT

The authors of this paper would like to thank Dr. David Burke for the opportunity and the beam time to develop these C-Band RF-BPMs, D. Walz for mechanical support, S. Smith, B. Traller, and K. Bouldin for electronic support, N. Spencer for control system support, and P. Raimondi for his analytical advice.

Abstract

An S-band linear accelerator is the source of particles and front end of the Advanced Photon Source [1] injector. Additionally, it will be used to support a low-energy undulator test line (LEUTL) and to drive a free-electron laser (FEL). To provide maximum linac availability for all uses, an additional modulator-klystron subsystem has been built, and a waveguide-switching and distribution subsystem is now under construction. The combined subsystems provide a hot spare for any of the five S-band transmitters that power the linac and have been given the additional function of powering an rf gun test stand whenever they are not otherwise needed. Design considerations for the waveguide-switching subsystem, topology selection, timing, control, and system protection provisions are described.

1 DESIGN CONSIDERATIONS

The APS linac [2] uses five 35-MW peak power output, pulsed klystrons, numbered in order from L1 to L5. L1 drives the first 2856-MHz accelerating structure, located just downstream of the electron gun, and L3 drives the sixth 2856-MHz accelerating structure located immediately downstream of the positron conversion target. The L2, L4, and L5 klystrons each drive a SLED cavity assembly [3] that in turn drives four 2856-MHz accelerating structures. A sixth klystron-modulator system has been installed in the linac gallery. Design work is in progress on a waveguide distribution and switching system that will allow the sixth subsystem to serve as a hot spare for any of the others.

The most critical design issues for this system are waveguide switch reliability at 35 MW of peak power and reducing losses to an acceptable operational level.

1.1 Losses and Topology

The loss issue was addressed first because of its critical effect on system topology. A loss budget was established based on maintaining operational characteristics that should allow filling of the storage ring under almost all conditions without adding unnecessary complexity and cost. A basic requirement is to be able to provide good-quality beam at the 400-MeV positron accumulator ring (PAR)/booster-synchrotron injection energy in the event of failure of any one of the klystron-modulator systems. The loss-budget allocations are: 15% power loss at L4 and L5, 25% power loss at L1 and L2, and 25% to 40% power loss at L3. The higher loss at L3 was included specifically to allow consideration of a parallel extra-low-loss path feeding L1 and L2.

There is very little unused space in the linac gallery, restricting long waveguide runs to heights sufficient to clear most other equipment. A height of 15 feet, 4 inches, was chosen in order to allow the run to be placed in front of the klystrons while allowing adequate clearance for smooth replacement of a faulty klystron. The reference design uses WR284 waveguide, which drops down to a waveguide switch located approximately at penetration height near each klystron. This results in a total length of more than 250 feet between L6 and L1 and a predicted loss of just over half the incident power. A modified topology, using an additional waveguide switch located at the height of the main waveguide run, but above each intermediate klystron, reduces the total length to 200 feet. The predicted loss in the modified topology is reduced to 41% of the incident power. With the modified topology, the predicted loss is further reduced to 28% by changing the waveguide size to WR340. This exceeds the 25% loss-budget at L1. Losses at all other klystrons, including L4 which is critical for determining positron injection energy, are within budget. Parallel, more direct waveguide runs, especially using circular waveguide can produce lower losses at L1. However, it is hard to justify the considerable extra expense, since the loss at L4 would not be improved. To verify this reasoning, tests were made of linac operation at reduced L1 power. Reductions much greater than 28% were made without unacceptable performance degradation.

Numerous configurations were evaluated over the course of this effort. When compared to alternatives, the modified daisy-chain design in WR340 either had lower losses at all klystrons or had lower cost with equal or better loss at L4. Losses at L1, L2, and L3 have been determined to be acceptable with this design, although some higher cost designs produced lower losses at one or more of these klystrons. On the basis of the above design analysis process and supporting test results, the modified daisy-chain topology, using two waveguide switches per klystron in WR340 oxygen-free high-conductivity copper waveguide, was selected for the switching system.

* Work supported by the U. S. Department of Energy, Office of Basic Energy Sciences under Contract No. W-31-109-ENG-38.

The original design concept directed power from L6 to a full-power dummy load when L6 was not needed as a hot spare for one of the other linac transmitters. This load is still included in the current design and will be used to verify operational readiness of a transmitter that has been repaired. The addition of two more waveguide switches allows for extra flexibility in the system. Various thermionic rf guns and photocathode rf guns in the linac and in the rf gun test stand can be powered whenever the hot spare function is unused.

1.2 High-Power Reliability

Waveguide switch reliability has been the subject of an ongoing investigation. Thomson CSF indicated that they preferred not to supply 35-MW klystrons for use with SF6 pressurized waveguide because breakdown and conditioning are significant issues above 30 MW [4]. Tests conducted by ANL personnel at SLAC confirmed that breakdown occurred above that level in pressurized WR284. It was also determined that the switches can be severely damaged if breakdown occurs [5].

Two approaches have been considered to increase the power level at which breakdown occurs. The use of a circulator-dehydrator to keep the SF6 both moisture-free and moving has been successfully used at the Duke University Free-Electron Laser Laboratory for trouble-free operation at 34-MW peak power [6]. The decision to build much of the distribution waveguide in WR340 suggests a second approach for which no previous experience is known. Scaling suggests that the breakdown vulnerability threshold at 30 MW in WR284 would occur above 40 MW in WR340.

A test was performed at ANL, in which a WR340 switch was successfully operated at 35 MW using WR284 windows and pressurized tapered transitions.

Additional tests will be conducted at SLAC in the near future to quantify the difference in performance between the two waveguide sizes. In the upcoming tests, all pressurized components, including windows, will be implemented in the waveguide size under test. WR340 windows will be included in the WR340 test set-up. In-house construction of WR340 windows is now underway.

We are proceeding with a design that incorporates both of the above approaches, as shown in Figure 1. WR340 had already been selected for the major portion of the switching and distribution system. Using WR340 for essentially all of it has significant standardization advantages while incurring some additional space problems that have now been solved. Use of a circulator-dehydrator is the practical approach for a relatively large, spread out system in any event.

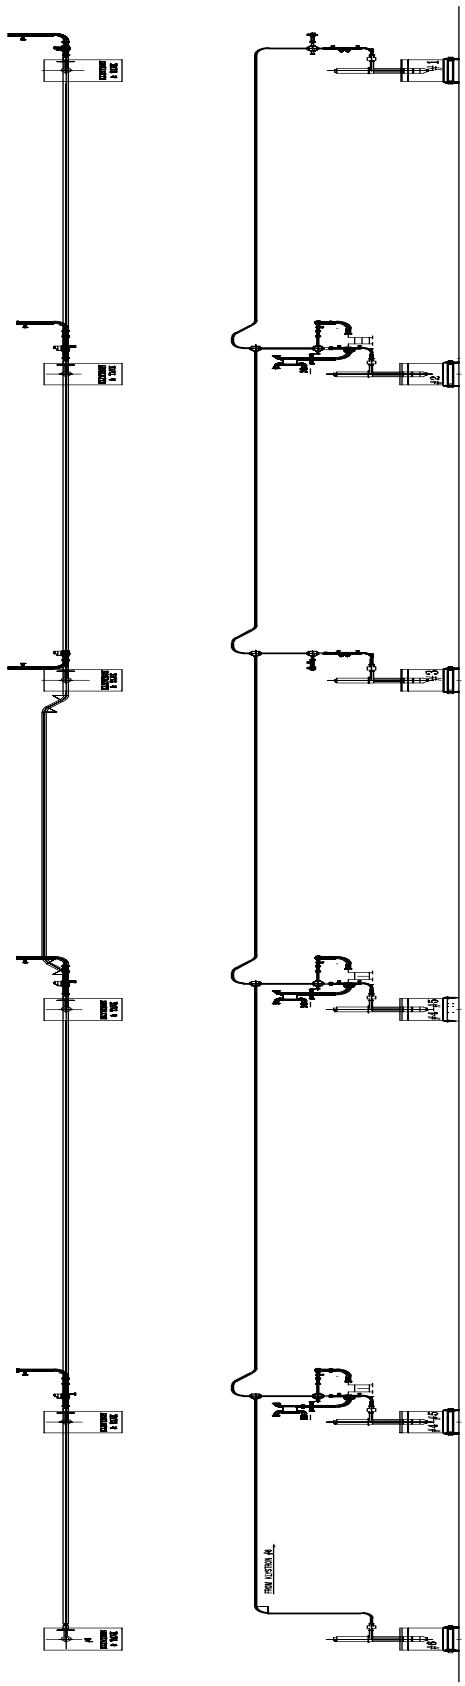

Figure 1: Mechanical layout of the klystron-switching system, by means of which the sixth klystron can be selected in place of any of the five others.

2 TIMING

Each modulator-klystron subsystem receives two modulator triggers, an rf drive gate and a SLED PSK trigger. Each trigger has unique timing requirements that are a function of trigger distribution delays, internal delays, and beam transmission time.

Therefore, a separate timing selection software window will be provided for each linac sector when driven by each allowable modulator-klystron subsystem. The switching control subsystem will provide confirmation of operational mode to EPICS [7], in order to ensure that the correct screens for the confirmed mode are active.

The linac uses two separate trigger repetition rates. The rf repetition rate is a uniform 60 Hz, or sub-multiples thereof, chosen to minimize load-regulation requirements on the modulators. The nominal rf rate is 30 Hz. The beam repetition rate and bunch pattern are completely flexible, up to a maximum of 60 Hz.

Ordinarily, each klystron is triggered synchronously at the rf repetition rate. If a klystron (L1 or L6; possibly L3 in the future) is driving an rf gun that provides beam to the linac, that klystron will be triggered at the beam rate. L6 can also drive the rf gun test stand with asynchronous, stand-alone timing.

3 CONTROL AND PROTECTION

Switching is performed under local control. The system is interlocked so that both the klystron drive and the modulator PFN voltage must be removed from all klystrons that are in the switching path. Klystron drive can be only reapplied following confirmation of successful switch transfer.

Interlocks and auxiliary reflected power protection are automatically switched in tandem with waveguide switching. SLED de-tuning needle position, water flow to the high-power rf components, and vacuum are among the categories included in the switched interlocks.

4 CURRENT STATUS

Our first priority has been the design and construction of items that support linac operation with a photocathode rf gun. Construction of a flexible rf gun test facility that can be operated without interruption, while the linac is injecting into the storage ring, is next on the priority list. Waveguide switches have been ordered. Detailed design is in progress for the main waveguide run and the L1/gun area switching. Our goal is to achieve both of these operating modes very early in 1999, and all activities are progressing well.

Switching between L1 and L6 will follow during the first half of 1999 when the initial part of the control and protection subsystem (or its prototype) can be completed and installed.

Implementation of redundancy-switching of the original five klystrons awaits detailed design and fabrication of the intermediate waveguide drops. Verification of the design and reliability of the control and protection subsystem is also a prerequisite.

Abstract

The Accelerator Production of Tritium (APT) [1] project requires a linac of nearly a kilometer in length. Accelerating potential for the 100-mA CW proton beam is provided by 350 and 700 MHz klystrons. The radio frequency (RF) power distribution for the planned 244 1MW klystrons has a wide range of design requirements and constraints. Efficient transport, control of phase, control of fault events, thermal dissipation and coupling considerations will be discussed. A description of the currently proposed configurations will be presented.

1 PLANT OVERVIEW

The primary purpose of the RF Power Distribution System is to safely and efficiently couple up to 244 MW of RF power to the APT linac in a reliable manner and to respond to fault conditions with minimum impact on beam operations. The APT linac will deliver a 1700 MeV 100mA CW proton beam to a tungsten based target that generates neutrons used in the production of tritium. 3.0 KG of tritium can be produced yearly at this power level. An alternative modular design has been conceived to allow the accelerator to be built in two stages. Stage 1 would produce 1.5 kilograms of tritium yearly, using 160 klystrons rather than 244. Stage 2 could be added while the accelerator is in operation if additional tritium is required. The design issues of this paper are applicable to either schedule, however, where absolute numbers are given, the number in parenthesis is for a 1.5 kilogram system.

APT will be located at the U.S. Government's Savannah River Site (SRS) near Aiken, South Carolina. The entire accelerating portion of the linac is about 1032 (735) meters in length. One MW klystrons provide the RF power that generates the accelerating potential in the cavities along the linac. The klystrons are located in a gallery that runs parallel to the linac tunnel.

The APT linac has three distinct sections with unique power coupling characteristics for the RF power. Power coupling to the linac under full beam (100 mA) conditions is designed to be optimum, i.e., no reflected power. Under off-normal (no beam) conditions, the coupling is inversely proportional to the Q of the cavity. Q is defined as the ratio of energy stored to energy dissipated per RF cycle. The three linac sections with distinct Q's are 1) the Radio Frequency Quadrapole (RFQ), 2) the low energy normal conducting (NC) section and 3) the medium and high-energy superconducting (SC) sections. The amount of reflected power from each section determines the size of the RF load necessary to absorb this power. Under start-up conditions, a three-stage process to bring the beam up to full current (100 mA) requires full RF fields in the cavities continuously.

1.1 RFQ

The RFQ follows the proton injector and its function is to bunch the proton beam while accelerating it to 6.7 MeV. Three 350 MHz klystrons drive the RFQ. It has an unloaded (no beam) match of approximately 2:1 which means about 1/3 of the incident power is reflected when no beam is present. Only two klystrons of the three are required to drive the RFQ. This redundancy allows three klystrons to operate at 67% of maximum power or two at 100%.

1.2 NC Section

Fifty-one 700 MHz klystrons drive the normal conducting section. The NC linac accelerates the beam from 6.7 to 211 MeV. The NC section is composed of one CCDTL (Coupled Cavity Drift Tube Linac) driven by a single klystron and ten 'supermodules' (either CCDTL's or CCL's (Coupled Cavity Linac)) each driven by multiple (up to seven) klystrons. The 'supermodule' technique provides redundancy by allowing beam operation even with a failure of one klystron per module. The phase of the RF power delivered to the cavities in any supermodule must be equal. The Low Level RF (LLRF) system [2] measures the phase at selected linac ports and controls the klystron phase to ensure phase alignment. The unloaded match for this section is approximately 4:1 resulting in reflected power of about 60% when no beam is present.

1.3 SC Section

One hundred fifty four (or seventy) 700 MHz klystrons drive cryomodules containing super conducting (SC) cavities. These boost the beam energy from 211 to 1700 (1030) MeV. The unloaded match is approximately 4000:1. Essentially all of the incident power is reflected when no beam is present. Each cryomodule has two, three, or four SC cavities with a pair of RF ports per cavity. The RF phase of each pair must be identical. As the phase relationship between pairs changes along the length of the linac with increasing beam velocity, the proportion of the reflected power going to RF loads changes. This complicates the placing and sizing of the loads.

2 RF SECTIONS

2.1 Klystron Gallery

The physical spacing of the klystrons in the gallery lines up closely with their respective coupling ports on the linac in the tunnel. Klystron garages house the klystron tubes and shield the gallery from klystron generated X-rays. The garage mechanically supports the five electric power and five water-cooling connections to the klystrons. Breaking these connections is all that is required to remove and replace a defective klystron. The water connections are at the front of the garage, the electrical connections at the rear. A trough in the concrete floor near the front of the garage contains supply and return water pipes that provide cooling water for the klystrons. This keeps the pipes short and unobtrusive.

A mezzanine running above the garages supports the control racks for the klystrons, linac magnet supplies, diagnostics and the 'transmitter' unit of the high voltage power supply (HVPS). This close proximity reduces cable length with a corresponding reduction in stored energy and enhances maintenance and troubleshooting. An HVAC duct hung under the mezzanine will connect with short spur ducts to each garage to provide cooling for the klystron solenoid coils and the garage in general. The HVPS for the klystrons sit in groups of four just across a maintenance access way and outdoors, behind the gallery building. A 95 kVDC cable from each HVPS runs through conduits in the concrete floor and up to the transmitter on the mezzanine.

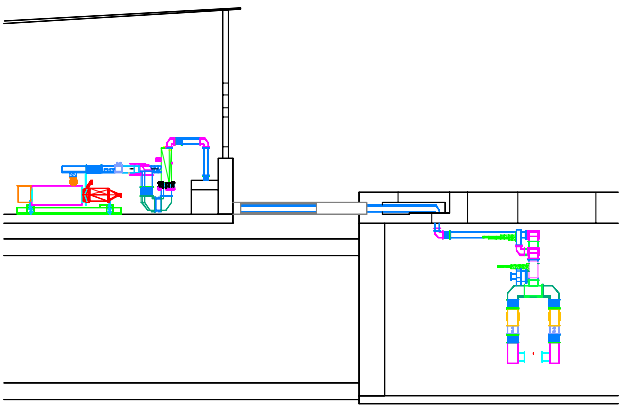

Figure1: Waveguide run between gallery and tunnel.

2.2 Waveguide System

Aluminum WR-1500 waveguide (15"x7.5") transports the 1 MW RF power from each klystron in the gallery to the linac couplers in the tunnel. A typical WG run from klystron includes the following:
1) Harmonic filter; absorbs higher order harmonics from the klystron to prevent harmful feedback. 2) Circulator; directs RF energy to the linac and routes RF energy reflected from the linac to a water load to protect the klystron. 3) Directional Couplers; detects the level of forward and reverse RF power in the waveguides, used for fault detection and phase balancing. 4) Loads: absorb incident RF power without significant reflection. 5) Magic-tees and hybrid splitters: divides RF power into two legs. 6) WG switches (remotely controlled); selects a different waveguide path. 6) Bellows; compensates for thermal expansion. 7) Linac Couplers: Air to vacuum transition between the waveguide and linac incorporates an alumina window [4]. Several waveguide components have been developed and tested [5] on the Low Energy Demonstration Accelerator (LEDA) at LANL with direct applicability for APT.

The waveguide run between the circulator and the gallery wall contains a loop which serves two functions: 1) Provide a clear walkway on the tunnel side of the gallery and 2) Provide a mechanism for equalizing the lengths of the waveguides on a supermodule by shimming. For reliability and efficiency the waveguide (WG) runs are as short, straight, and simple as feasible.

Between the klystron and the first power splitter in the tunnel, each aluminum waveguide carries 1MW with an expected loss of 250 W per foot. Waveguide temperatures of 80-100 C have been measured at English Electric Valve Ltd., in a test garage with little ventilation. In the gallery, where personnel are present, exposed waveguide should not exceed 60 C. A physical shield will envelop the guide and water-cooling is being considered. In the concrete conduit between the tunnel and gallery, the temperature may not exceed 65 C to prevent long term damage from excessive drying. An air cooling scheme forces HVAC tunnel air under and over the waveguide to keep the guide well within limits. In the tunnel, the RF power is typically divided into four equal legs before mating with the couplers. This reduces the power to the individual vacuum windows and couplers to no more than 250 KW under normal conditions. The tunnel HVAC system will be expected to handle the heat deposited such that the ambient temperature doesn't rise above 37 C. Circulating air is expected to uniformly cool individual waveguide legs such that they don't differ in temperature by more than 5 C. This last requirement ensures that differential temperatures don't contribute to significant differences in waveguide length from thermal expansion and hence RF phase differences between coupler pairs.

2.3 Phase Control

Magic-tees are four port waveguide splitters that have the characteristic of equally dividing incoming RF power between two output legs. These devices will be used to divide the RF power in the tunnel. The RF phase at each coupler pair should be equal within $\pm$ 0.5 degree. To minimize phase discrepancy, the legs to the couplers will be as short as feasible and the length of each leg uniform within $\pm$ 0.015" (standard EIA tolerance).

3 OFF-NORMAL CONDITIONS

The linac is designed such that if any klystron in a NC supermodule goes off-line, the remaining klystrons can be boosted in power to compensate. The SC linac also compensates for an RF system failure by adjustment of the RF phase and amplitude. This function is performed by the LLRF system.

The three most likely RF system faults are klystron or HVPS failure, waveguide arcs and window failure.

3.1 Klystron or HVPS failure

The klystron or HVPS is taken off line. The beam is shut off for approximately six seconds while a waveguide switch is thrown which presents the proper impedance to the cavity. If the failed klystron drives a supermodule, then the power on remaining klystrons on the supermodule is raised. If the failure is in a cryomodule, the offending cryomodule's cavity is de-tuned (no beam interaction) and the power on the remaining downstream klystrons is raised and rephased.

3.2 Waveguide arcs

An arc in the waveguide is effectively a short that will cause 100% reflection in that particular leg. This usually occurs near a window or discontinuity. The fiber optic arc detector system (part of the Low-Level RF system) shuts down the klystron and beam momentarily (<150 ms) then brings them back on. If the arc persists, the associated klystron is shut down and the waveguide switch thrown. During the arc, the klystron power is reflected into the local magic-tee load.

3.3 Window failure

Impending window failure can usually be detected by a temperature excursion at the thermal sensors. RF power to the window is shut down. If the window can be isolated and power can still be sent to other couplers driven by the same klystron, then only a coupler pair (rather than a klystron) will be taken out of service. In the event of an actual vacuum window leak, the RF and beam will be shut down. If the window is in the NC section, a vacuum gate valve may be incorporated to separate the window from the linac, and operations would resume. If the window is in the SC section, a double window is employed. The volume between the windows is evacuated, the RF is removed from the defective window, and the associated cavity is detuned (no RF from the beam will couple to the window). Beam operation can then begin with that cryomodule cavity off line.

4 SAFETY

Safety is a main driving force in the APT design. All systems must pass a rigorous safety review. A concerted effort is being made to incorporate safety by design rather than add on. Physical access, for both safety and maintenance, thermal surfaces, electrical procedures, RF and radiation, noise and ambient temperature are all factors in the overall plant safety design.

For radiation shielding purposes, the gallery is broken into three sections along its length. At the low energy (injector) section of the linac, up to 211 MeV, the distance between the gallery and the tunnel is 7' of soil. Between 211 and 471 MeV, the gallery is 12' from the tunnel. And above 471 MeV to the end of the accelerator at 1700 (1030) MeV, the separation is 17' of soil. The waveguide run is imbedded in the four-foot thick tunnel ceiling resulting in a tenfold reduction of neutron streaming. Borel lined shield blocks form an igloo around the aperture where the waveguide enters the gallery from the tunnel. This attenuates neutrons streaming through the waveguide into the gallery [6] to a level below requirements. An air block between gallery and tunnel prevents potentially activated tunnel air from permeating the gallery. The waveguides and klystrons are shielded physically and electrically. Dual redundant RF and radiation detection systems are planned.

ACKNOWLEDGEMENTS

Many thanks to Karen Cummings, William Roybal, Amy Regan and Dale Schrage, of LANL for generous sharing of their time and experience on the LEDA accelerator from which much of the RF design of APT is based. And to Harry Yip for klystron support in the gallery layout and Mark Pippenger for his many practical suggestions.

Abstract

We have performed a conceptual design work of an RF system for a superconducting (SC) linac proposed for Neutron Science Project (NSP) at JAERI. An accelerating structure of the SC linac is divided into 8 different β-sections. The linac has 284-cavities and the length of 690-m. The 8 sections system suppresses the beam emittance growth and reduces the linac length. In the steady state, beam loading for three operation modes is calculated. For a pulse operation with a peak beam current of 30mA (chopping factor of 0.6), the peak RF power of 138kW is required at the high-β cavity. The power of 41kW is required for CW operation at a beam current of 5.33mA. Tuning errors on coupling and cavity resonant frequency are evaluated. In the conceptual design in which an RF power of klystron is distributed to 4-cavities, supply power is estimated. The supply power of about 20 MW is required for both operation modes.

1 INTRODUCTION

The NSP accelerator will consist of RFQ, DTL, Separated-type DTL and SC linac [1]. The SC linac accelerates hydrogen ions from 0.1 to 1.5GeV. It should be operated both in pulse and CW for demands in the applications. This requirement is the essential feature for the RF system. Table 1 shows a preliminary specification for the SC linac. Beam dynamics study has been carried out to determine the SC linac structure. RF system design work is performed under those parameters.

2 SC LINAC STRUCTURE DESIGN

The relative particle velocity (β) gradually increases from 0.43 to 0.92 along the SC linac. Therefore, accelerating cavities are divided into several sections with different β values to match to the particle velocity. The β-section is determined in the view of the bunch phase slip. The SC linac divided by many β-sections has the advantage of accelerating efficiency and less emittance growth because of the less phase slip. For the capital and maintenance cost, number of sections should not be increased so much.

Table 1: Preliminary specification of the SC linac

Energy	0.1 to 1.5GeV
Final beam power	8 MW
Accelerating particle	H^- , H^+
Frequency	600 MHz
Synchronous phase	-30 degree
Beam operation	1st stage pulse
	2nd stage pulse/CW
Peak current	16 mA at 1st stage
	30 mA at 2nd pulse mode
	5.33 mA at CW mode
Repetition rate	50 Hz
Macro pulse width	2 to 5.9 ms, CW
Intermediate pulse width	400 ns (interval 270 ns)

Prior to the β-section decision, basic parameters were prepared [2]. The number of cells per cavity is 5. The peak surface electrical field (Epeak) is limited to be 16 MV/m. The cavity surface resistance is estimated to be 15 nΩ. The number of cavities excited by an amplifier is set to be 4. It is indicated that the 4 cavities are fed with the same RF power.

The number of β-sections is decided by considering the RMS emittance growth and the linac length [3]. As the result of the study, the length and the emittance growth can be saturated over 8 β-sections. In the conceptual design, we chose the linac structure with 8 β-sections. The diagram is shown in Fig. 1 and its RF parameters are listed in Table 2. The linac has 284-cavities and the 690-m length.

3 STEADY-STATE BEAM LOADING

We calculated the required peak RF power in the steady state for each operation modes. The required power (P_f) is given by [4]

$$P_f = \frac{(1+\beta_c)^2 V_{acc}^2}{4\beta_c R} \times \left\{ (1-\tan\psi_b/\tan\phi)^2 + (\tan\psi_c - \tan\psi_b)^2 \right\}, \quad (1)$$

where β_c is the coupling factor to the cavity, ϕ is the synchronous phase and R is the cavity shunt impedance defined by $R=V_{acc}^2/$(cavity wall loss). Beam-loading detune angle (ψ_b) and cavity detuning angle (ψ_c) are defined by following equations, respectively.

$$\tan\psi_b = -\frac{R \cdot I_b}{(1+\beta_c)V_{acc}}\sin\phi \ , \quad (2)$$

$$\tan\psi_c = \frac{\omega_c - \omega_{rf}}{\omega_c}\frac{2Q_0}{1+\beta_c} \ , \quad (3)$$

where I_b is beam current, ω_c is cavity resonant frequency, ω_{rf} is driven frequency and Q_0 is unloaded Q value. To minimize the P_f , those angles have to be set to $\psi_b = \psi_c = -\phi$. Therefore, the optimum β_c and ω_c are obtained by

* Cavity accelerating voltage = Average electric field x Cavity length x TTF (Transit Time Factor)

$$\beta_{copt} = 1 + \frac{RI_b \cos\phi}{V_{acc}}, \qquad (4)$$

$$\omega_{copt} = \omega_{rf}\left\{1 - \frac{I_b}{2V_{acc}}(R/Q_0)\sin\phi\right\}. \qquad (5)$$

Under the optimum condition, the required power is given by $P_{fopt}=(1+\beta_c)^2 V_{acc}{}^2/(\beta_c R)$.

In the SC cavity, the required RF power is almost the same as beam loading under the optimum condition. The required power is shown in Fig. 2. The power is gradually increasing with the cavity number and the power at the high-β end is 6.6 times as large as that at the low-β end. For the pulse operation, the maximum power of 138 kW/cav. is needed at the high β-section. On the other hand, the power of 41 kW/cav. is required for the CW operation. There is difference of 3.4 times in the power between CW and pulse operations. The RF system including tuner, coupler, amplifier and so on have to manage this difference.

Tuning errors on β_c and ω_c cause the increase of the required RF power. Those tuning errors are evaluated for the SC linac. Figure 3 shows the dependence of the power enhancement on the coupling error (normalized by the optimum power P_{fopt} and the coupling factor β_{copt}). For the coupling error of +/-30 %, the power to keep the V_{acc} in the cavity increases 1.7% at over coupling and 3.2 % at under coupling. The coupling error does not seriously affect the power enhancement.

The cavity tuning error is evaluated for the cavity detuning angle (ψ_c). Figure 4 shows the dependence of the power on the ψ_c. The power is minimized at ψ_c =30 degree (=ψ_b). Over the 30 degree, the power is rapidly increased. For the shift of +/-30 degree from the optimum detuning angle, the power increases 8 % at –30 degree shift and 33 % at +30 degree. Using the parameters seen in Table 2 and the described equations, resonant frequency error of the cavity #1 at the 2nd stage CW mode is calculated. The tuning error of +/-30 degree corresponds to the resonant frequency error of -24 Hz and +47 Hz, respectively. The precise tuning is needed for the cavity pre-detuning.

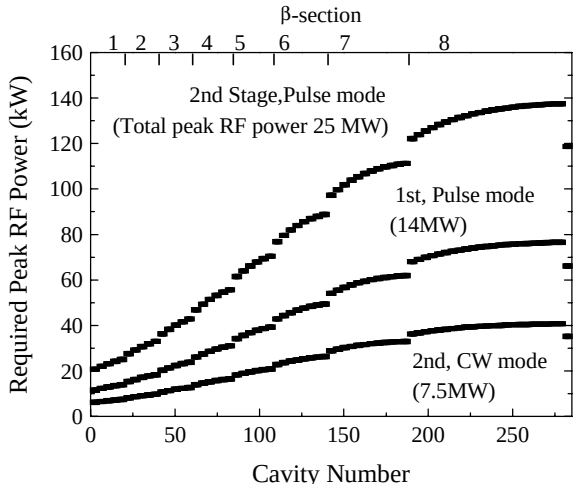

Fig. 2: Peak RF Power Requirement for the SC Linac

4 RF SYSTEM OF SC LINAC

4.1 Klystron

The design study of the RF system has been performed on the basis on klystrons, which are well suited to accelerator use. In the SC linac RF system, the klystron has to operate in the high power pulse mode and low power CW mode. In addition, the klystron also has to cover wide power range because of varying the required power along the SC linac. We have selected the klystron with modulating anode. Klystrons with property of UHF-band (508 MHz), high power (1MW) and CW operation have been already operated in TRISTAN and SPring-8. The maximum power satisfies our request (138kWx 4cavites + α).

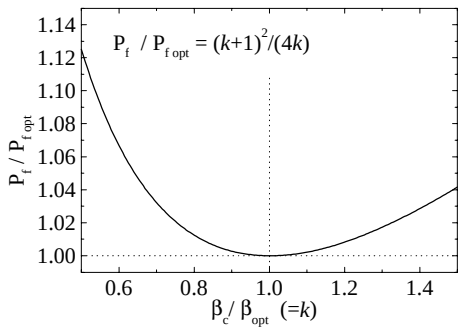

Fig 3: Required Power Enhancement for Coupling Error

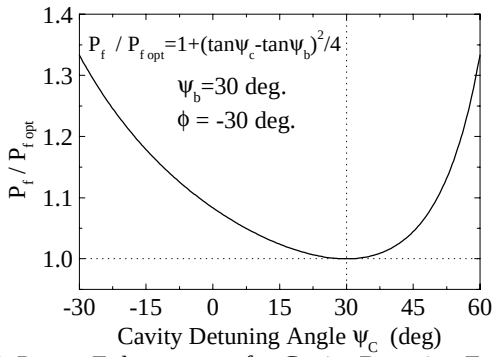

Fig 4: Power Enhancement for Cavity Detuning Error

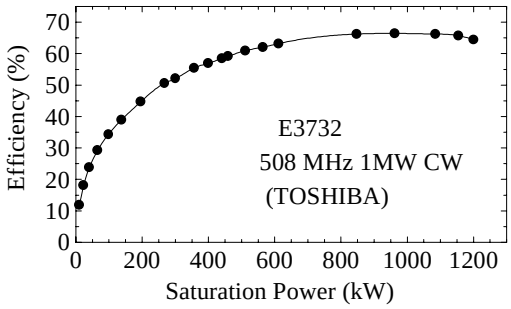

Fig.5: Efficiency Characteristic of the Klystron

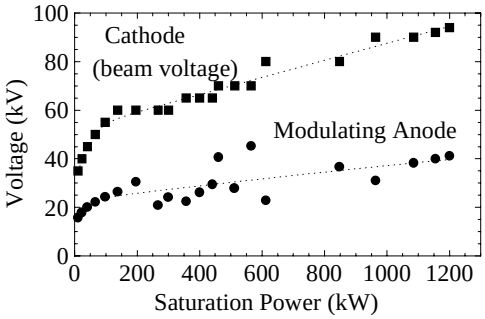

Fig.6: Cathode and Anode Voltage for Saturation Power

Klystron is manufactured such that its maximum efficiency becomes at the full saturation power. When the klystron operates below the saturation, the efficiency falls if the klystron beam power is not reduced. To keep higher efficiency in the low power range, the beam voltage is reduced. We have measured the efficiency characteristics using a 508 MHz klystron (E3732, TOSHIBA). Figure 5 shows dependence of the efficiency on the saturation power. Figure 6 shows the cathode and anode voltage where the power is saturated, respectively. The efficiency below 50% is measured at the power of 250 kW or less.

4.2 System efficiency and supply power

The RF system efficiency and supply power are estimated on the basis of the characteristic seen in Fig 5[5]. The result is given in Table 3. Since the klystron drives the 4-cavities, klystrons of 71 unit are needed in the RF system. High power tubes (44 units) with 1MW output and low power tubes (27units) with 400 kW are arranged in the linac to cope with the varying RF power requirement along the linac. To control the cavity field, some amount of RF margins are necessary. In this design, the margin of 15% is assumed. Considering power loss of 5 % in the transmission line, the klystrons are operated at 80% for the saturation power. Therefore operation efficiency becomes 0.8 times of saturation efficiency.

In the 2nd stage pulse operation, maximum output power of 690 kW (138 kW x 4 cavities x 1/0.8) is required at high β-end klystron. Since the efficiency at the saturation power is 64 % (see in Fig. 5), operating efficiency is estimated to be 51 % (64 % x 0.8). The supply power to the klystron is calculated to be 1082 kW (138kW x 4 cavities / 0.51 %).

The estimation is carried out for the klystrons of 71 units at each operation mode. At CW operation, averaged klystron efficiency is 33% due to operate the klystrons at low power. Averaged supply power is calculated to take into account the duty including time to rise field in the cavity. The averaged supply power to the RF system needs of about 20 MW for both of CW and pulse mode at the 2nd stage.

4.3 IOT system

Another choice of the SC linac RF system is a scheme that one-cavity is driven by one-IOT (Inductive Output Tube). This system is regarded as a suitable system for an RF control. In addition, the IOT is compact and is kept with high efficiency at low output power. In a rough estimation, the supply power at CW operation is reduced to 14 MW. However, high power IOT (more then 120kW) does not exist at present. In the case that the IOT is applied as all amplifiers, 568 tubes including pre-amplifiers are needed. Using many tubes may cause decrease of accelerator reliability. At present, we have done the preparation to evaluate the performance of a CW-35 kW IOT.

5 CONCLUSION

The SC linac with 8 β-sections is determined in the view of the bunch phase slip with respect to the RF phase in the cavity. This linac is an effective option for its shorter length and lower emittance growth. In steady state, the beam loadings under the optimum conditions were calculated. The maximum RF power requirements of 138kW at pulse operation and 41kW at CW operation are estimated. As a result of consideration on the tuning error, the precise tuning is needed for the cavity pre-detuning. In the conceptual design there the output power of a klystron is distributed to 4-cavities, the averaged supply power is estimated. The powers of about 20 MW are needed for both operation modes at 2nd stage.

Table 3: Efficiency and Supply Power in the RF System

Operation Mode	1st	2nd stage	
	Pulse	Pulse	CW
Beam pulse width (ms)	2	5.9	cw
Peak RF power (MW)	14	25	7.5
Klystron efficiency (%)	41	48	33
Peak supply power (MW)	34	53	23
Averaged duty *	0.18	0.38	1
Averaged supply power (MW)	5.8	20	23

A NEW RF SYSTEM FOR THE DEBUNCHER AT THE KEK 40-MEV PROTON LINAC

Z. Igarashi, E. Takasaki, T. Takenaka and K. Nanmo
High Energy Accelerator Research Organization, KEK
1-1 Oho Tsukuba-shi Ibaraki-ken, 305-0801, Japan

Abstract

The rf system for the debuncher at the KEK 40-MeV proton linac was renewed to an all solid-state one during the long shut down last summer. Since the amplifier of this system, containing one hundred and eight power transistors on its' final stage, can deliver a stable 20kW at 201MHz, the momentum spread of the linac beam can be decreased to less than 1%. This new rf system for the debuncher and its operational results are described.

1 INTRODUCTION

Although the debuncher cavity was replaced by the reentrant type with a single gap when the linac was upgraded from 20MeV to 40MeV in 1980 [1], the vacuum tube amplifier had been used since the linac construction as the rf source for the debuncher. This vacuum-tube amplifier had caused problems due to the short-lived vacuum-tube; furthermore production of the vacuum-tube for the final stage of the amplifier was discontinued. It was thus decided to replace it by a new amplifier which is the same as those of the predrivers of the rf systems for the DTLs [2] and the prebuncher [3].

2 NEW RF SYSTEM

The new rf system consists of nine transistor amplifier modules, rf power divider/combiners, dc power supplies and a control system. Figs. 1 and 2 show this system and a block diagram [4].

The transistor amplifier module, which was originally developed for cw operation of a TV transmitter, was refined for pulse operation, and can deliver more than 2kW.

Figure 1: New rf system.

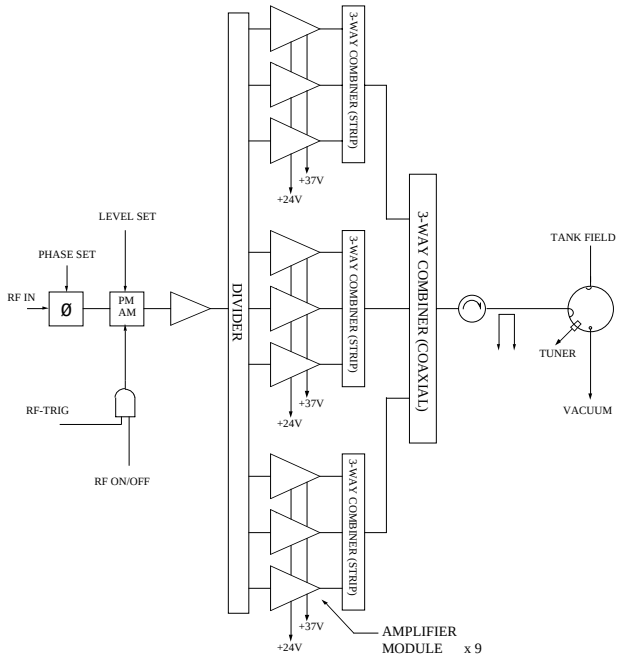

Figure 2: Block diagram of the new rf system.

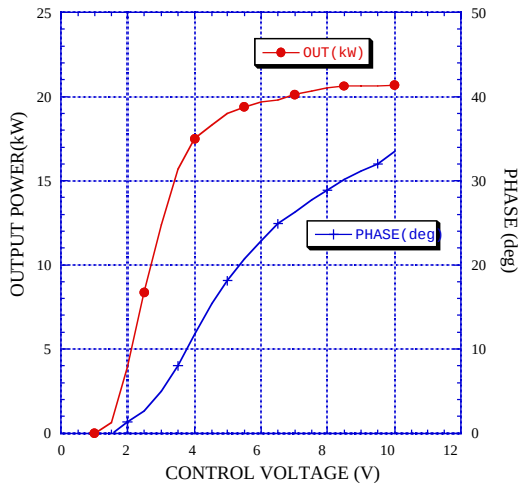

Figure 3: Output characteristics of the new rf system.

The rf power transistor used in the final stage of the module is the 2SC3286-M, which adops the so-called Gemini package, in which two transistor chips are mounted for push-pull operation, and generates about 200W.

The outputs of the nine modules are first summed up by three stripline 3-way combiners, and then by a coaxial 3-way combiner.

The output power and phase of the system are shown in Fig. 3. Control of this new rf source is achieved using a programmable logic controller [5]. The screen for control and status display of the system is shown in Fig. 4.

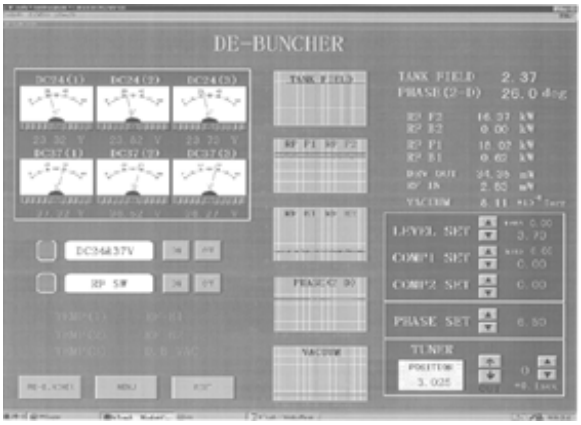

Figure 4: The screen for control and status display.

3 OPERATIONAL RESULTS

The field waveform of the debuncher and the beam-energy variations by the debuncher phase are shown in Figs. 5 and 6.

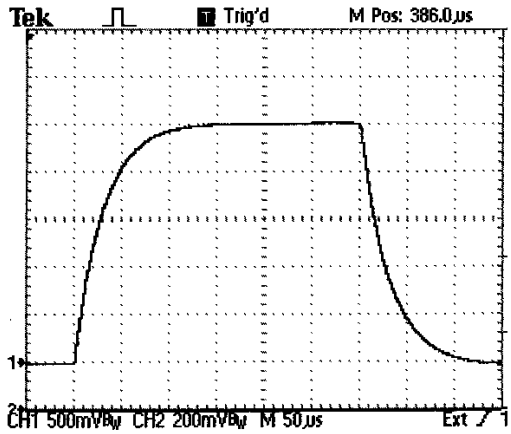

Figure 5: Waveform of the tank field.

The energy variations shown in Fig. 6, which were measured by the velocity monitor [6], are in good agreement with the calculated values. The upper part of the momentum-analyzer output in Fig. 7 is for the debuncher being off, and the lower one is for the input power being 19kW.

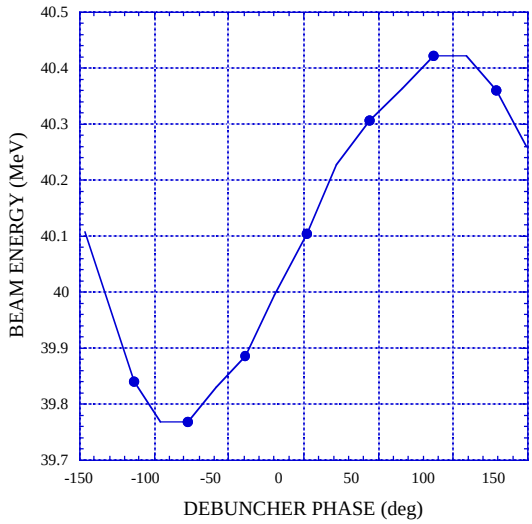

Figure 6: Beam energy versus debuncher phase.

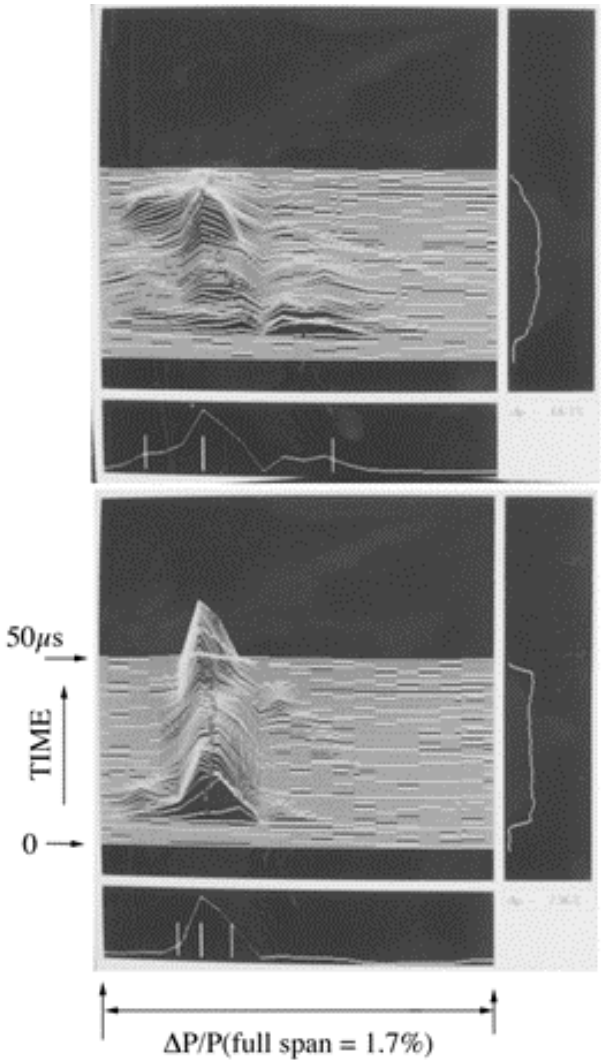

Figure 7: Momentum-analyzer outputs.
Upper : debuncher off
Lower : Pin=19kW

The momentum spread of the linac beam(ΔP/P) versus the debuncher field and the bunch length of the 500MeV booster synchrotron before extraction versus ΔP/P varied by the debuncher are given in Figs. 8 and 9. These results show that the debuncher is effetive to decrease ΔP/P of the linac and the booster synchrotron.

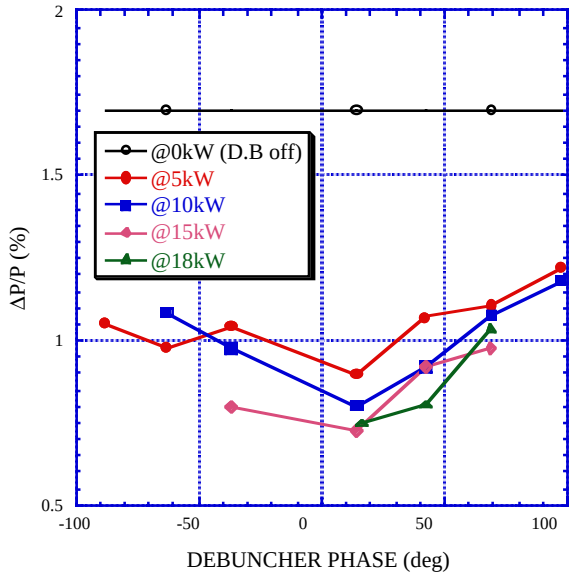

Figure 8: ΔP/P versus debuncher field.

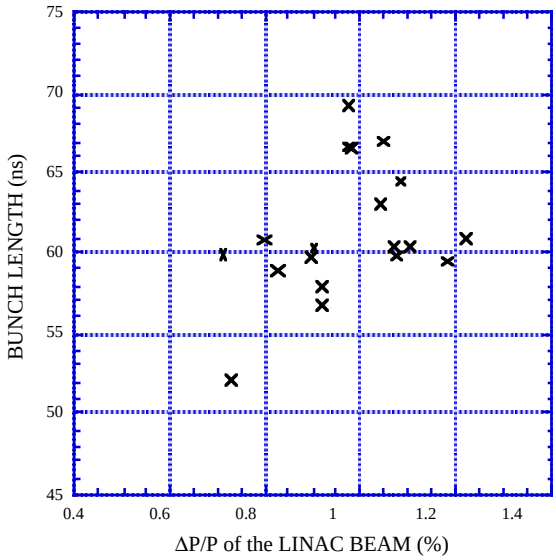

Figure 9: Booster bunch length versus linac ΔP/P.

4 CONCLUSION

The momentum spread of the linac beam has been decreased from 1.4% to 0.7% by the renewing of the rf system for the debuncher. Throughout the operations for about one year, it was proved that the new system is very stable and reliable without any problems; furthermore, the debuncher is much more useful for the tuning the linac and the booster synchrotron, consequentry all of the 12-GeV proton synchrotron, than before.

THE C-BAND 50MW KLYSTRON USING TRAVELING-WAVE OUTPUT STRUCTURE

Y. Ohkubo, H. Yonezawa, TOSHIBA Co., 1385, Shimoishigami, Ohtawara, Tochigi, 324, Japan
T. Shintake, H. Matsumoto and N. Akasaka, High Energy Accelerator Research Organization (KEK), 1-1 Oho, Tsukuba, Ibaraki, 305, Japan

Abstract

The second tube of the C-band 50 MW klystron (model TOSHIBA E3746 series) has been developed in the course of the C-band rf-system R&D [1]. It uses the half-π mode traveling-wave structure in the output circuit in order to enhance the power-conversion efficiency and reduce the electric field gradient in the output circuit.

The three-cell traveling-wave structure was analyzed by the coupled-resonator model, and parameterized in a 3-by-3 impedance matrix form. The electrical performance at a hot condition was evaluated by a particle-in-cell simulation code: FCI, which predicted a power efficiency of 44%. The agreement of the simulation of FCI-code and test result was within 1%.

1 INTRODUCTION

In the future accelerators such as e+e- linear colliders, the system has to be highly reliable and efficient. The R&D of C-band accelerator system has been carried out at KEK since 1996.

Among the R&D work, two 50 MW C-band klystrons (TOSHIBA E3746 series) have been developed. The first tube using a conventional single gap in the output circuit was tested in August 1997, and generated a 50 MW peak power in 1 μs pulse duration at 20 pps pulse repetition rate, and also in a long pulse mode it generated 46 MW in 2.5 μs at 50 pps [2,3].

In the second tube, the output circuit was replaced to a traveling-wave structure to achieve over 50 MW peak power in 2.5 μs pulse width. The drift tube diameter at the output structure was enlarged to reduce the beam loss. The second tube was tested in April 1998, and generated a stable output power of 54 MW with 2.5 μs pulse duration, and 44% power efficiency at 50 pps repetition rate. The performance of the developed klystron agreed well with the predictions by the FCI-code.

2 DESIGN

The target performance of the E3746 klystron is shown in Table 1. The target value of peak power was chosen by scaling from the existing S-band klystrons to the C-band frequency.

The cross-sectional view of the E3746 klystron is shown in Fig.1. The left half in Fig.1 shows the first tube and the right half shows the second tube.

The output circuits consists of two output waveguides and two output windows, and they are recombined to one output port at the external circuits after the ceramic windows.

Table1:Main target parameters

Parameter		Unit
Output Power	50	MW
Operating Frequency	5712	MHz
Beam Voltage	350	kV
Beam Perveance	1.53	$\mu A/V^{3/2}$
RF Pulse Width	2.5	μs
Pulse Repetition Rate	50	pps
Drive Power	< 500	W
Power Efficiency	45	%
Gain	> 50	dB

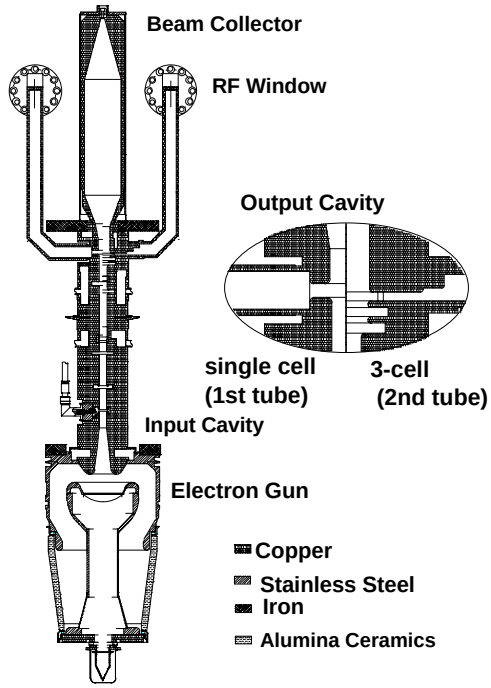

Figure 1: Cross sectional view of E3746 Klystron.

At the high power test of the first tube, the electron gun operated stably without diode-oscillation or high-voltage breakdown, and also rf windows showed nice high power performance. A stable 50 MW output power was generated in 1 μs pulse width. However the measured power efficiency was slightly lower than the target value.

The second tube uses a half-π mode traveling-wave output structure, which has advantages described below.

(1) Electric field gradient in the output cavity is reduced.

(2) The drift tube-diameter at downstream side of the output cavity can be enlarged without deteriorating the power efficiency, thus a high-voltage breakdown associated with the beam loss can be eliminated.

(3) Since the traveling-wave smoothly decelerates the electron beam in synchronous with the beam velocity, the power conversion efficiency is enhanced.

The multi-cell coupled cavity type output structure has been recently used for high power pulse klystrons, such as X-band klystrons at SLAC [4], where successful results were obtained. However there are still some problems in design described below.

(a) Optimum design procedure of the multi-cell cavity is not fully established.

(b) Countermeasure to prevent the parasitic oscillation phenomena is not fully established.

Thus, we decided to develop advanced design procedure for a traveling-wave structure. To do this, we laid the following basic guidelines.

(1) An equivalent circuit model is used for analyzing the multi-cell output cavity.

(2) To prevent the parasitic oscillation, the three-cell structure was chosen, which is the minimum number of cells to realize a traveling-wave.

(3) The half-π mode was chosen, since the impedance matrix becomes a simple form, also it makes frequency tuning simple.

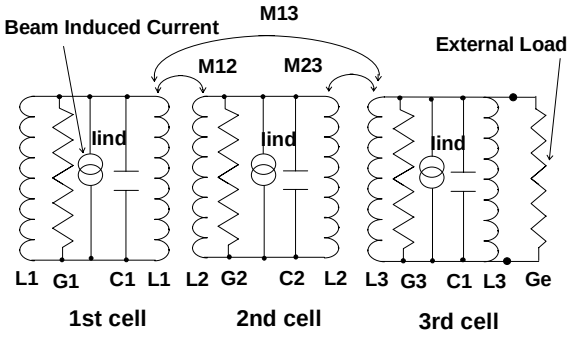

Figure 2: The equivalent circuit model.

The equivalent circuit for the three-cell structure is shown in Fig.2. Three resonator circuits are coupled each other through the mutual inductances M12, M23, M13. The current source in each circuit represents induced current by the beam. The conductance at the 3rd cell shows the output waveguide and external load. This equivalent circuit is identical to the coupled resonator model which has been widely used to analyze various kinds of accelerator structures. A special situation in klystron analysis is that the next neighbor coupling M13 plays an important role. Klystron output structure requires so large coupling coefficients between neighbor cells that the next neighbor coupling becomes non negligible.

The design procedure is,

(1) The beam rf current and beam energy at cavity center location of each cell are estimated by the beam simulation (FCI-code), mounting a single cell output cavity.

(2) The shunt impedance R/Q and the beam coupling coefficient of each cell are estimated from numerical simulation code, such as SUPER FISH, etc.

(3) Assume the same amount of the deceleration voltage in each cell. Compute the cell-voltage from the beam coupling coefficient.

(4) The mutual inductances M12, M23, M13, the external-Q and the cell resonance frequencies at half-π mode are computed by the impedance matrix using the estimated induced currents and the cell voltages.

(5) The physical dimensions of each cell are determined by numerical simulations. We repeat process (4) to (5) using the estimated R/Q and the beam coupling coefficient by the code.

(6) We run the FCI-code using the circuit parameters obtained above, and check the output power with the target value.

(7) The 3rd cell is connected to the output waveguides, thus we use 3D-simulation code HFSS, by which we decide the optimum iris size and cavity diameter.

At the actual design, almost all the cavity parameters were determined by the method described above in one process. We did not use FCI-code for a try-and-error parameter search.

The simulation result of the second tube is shown in Table 2. FCI said that the output power of 49 MW and the power efficiency as high as 44% can be obtained at the beam voltage of 350 kV.

Table 2: Design parameters (Values in parenthesis show the design parameter of the first tube.)

Parameter		Unit
Output Power	49	MW
Operating Frequency	5712	MHz
Beam Voltage	350	kV
Beam Current	317	A
Drive Power	300	W
Power Efficiency	44	%
Electric Field Gradient in Output Cavity	29.2 (45)	kV/mm
Drift Diameter of Collector Side	14 (9.5)	mm

In the second tube, the drift tube-diameter at the output structure was enlarged by 1.4 times than the first tube, and the electric field gradient in the output structure was reduced to 0.7 times lower than the first tube. Thus the second tube has more safety margin against rf-breakdown and beam-loss damage around the output structure.

3 TEST RESULT

The second tube was tested at KEK in April 1998. In this test, the output power was measured by the absolute calorimetric method. In this method, the output power is measured from the water temperature rise at the rf dummy load. In order to calibrate the temperature rise, an electrical heater was loaded in the water cooling system after the rf dummy load. The heat dissipation can be simply determined by the product of the terminal voltage and the current. This method is independent from the

error in the flow rate of water measurement, thus it is very reliable.

Table 3 shows the experimental result, and Fig.3 shows the rf output power and the beam voltage waveforms. This klystron achieved 54 MW output power at the beam voltage of 369 kV, 2.5 μs pulse width and 50 pps repetition rate. The output waveform was always steady and stable for wide range of operating conditions. We tested the effect of reducing the focusing field, where no oscillation nor beam loss was observed.

Fig.4 shows the saturated output power as a function of the beam voltage and Fig.5 shows the input-output characteristic at the beam voltage of 362 kV. No unstable phenomena was observed in the input-output characteristic.

The test result of saturated output characteristics agreed well with the FCI simulation result. The difference between the measured output power and the simulation was within 1%.

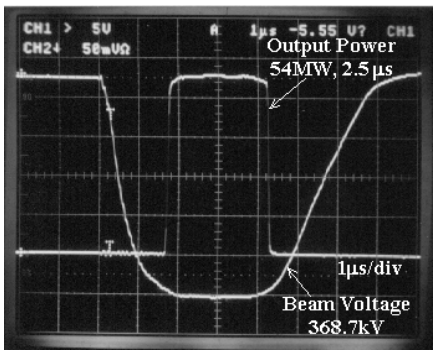

Figure 3: Output power and Beam voltage waveform.

Table 3: Test result

Parameter	1st tube	2nd tube	Unit
Operating Frequency	5712	5712	MHz
Beam Voltage	360.4	368.7	kV
Beam Current	326.4	333.0	A
Output Power	50.1	53.9	MW
RF Pulse Width	1.0	2.5	μs
Pulse Repetition Rate	20	50	pps
Drive Power	259	323	W
Power Efficiency	42.6	43.9	%
Power Gain	52.9	52.2	dB
Beam Perveance	1.51	1.49	$\mu A/V^{3/2}$
Solenoid Coil Power	6.38	4.55	kW

4 CONCLUSION

The second C-band klystron which uses the three-cell traveling-wave output structure successfully generated a stable 54 MW output power at 369 kV beam voltage, 2.5 μs pulse width, 50 pps repetition rate.

The test result showed a good agreement with the FCI-code simulation. It demonstrated that the design procedure established here is powerful and reliable for the design of multi-cell output structure.

As the next step, in order to improve the system efficiency, we will start development of a periodic permanent magnet (PPM) focused klystron from 1998, which eliminates the focussing magnet power.

EFFICIENCY AND GAIN ENHANCEMENT OF RF-PULSE COMPRESSOR FOR C-BAND RF SYSTEM

M.Yoshida,
International Center for Elementary Particle Physics, University of Tokyo, Tokyo 113, Japan

High Energy Accelerator Research Organization (KEK), 1-1 Oho, Tsukuba, Ibaraki, 305, Japan

Abstract

In order to make use of the additional energy in the front part of the modulator output pulse, the phase modulation system was proposed for the efficiency enhancement in various RF system. The phase modulation system compensates the undesirable phase rotaion associated with the rising power of the klystron to store the additional energy in the RF-Pulse Compressor. This idea leads the enhancement of the RF-Pulse Compressor in both respect of the power efficiency and gain which are keys of the e^+e^-linear collier.

To demonstrate the efficiency and gain enhancement of the RF-Pulse Compressor, we confirmed the complete phase compensation of the klystron and observed the gain enhancement of 125% using the cold model of the RF-Pulse Compressor in the C-band RF system.

1 INTRODUCTION

In the oridinary RF system with the RF-Pulse Compressor in the electon linear accelerator, only the flat top of the modulator pulse is used. The conventional modulator using the line-type PFN(pulse forming network circuit) with the thyratron switch usually generates a pulse with the considerable settling time(Fig. 1), and it is technically difficult to reduce this time. The front part of the pulse contains a large amount of energy. However this useful energy cannot be used due to the undesirable phase rotation associated with the rising voltage of the modulator output pulse.

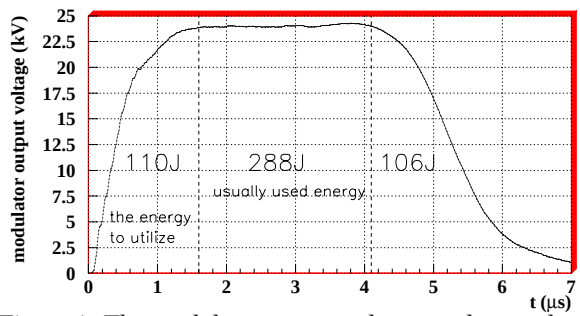

Figure 1: The modulator output voltage on dummy load

If we can utilize the energy in the front part of the modulator output pulse, the gain enhancement factor of $1.38(=(110+280)/280)$ will be roughly estimated in the ideal case. Considering the klystron efficiency, this factor becomes to $1.32(=(40+126)/126)$. If we assume 30% of the energy loss in the RF-Pulse Compressor, the gain enhancement factor of $1.22(=(40\times 0.7+126)/126)$ is finally expected.

To do this, we employ the phase modulation system to compensate the phase rotation in the klystron. Then the integrated energy of the front part can be stored in the pulse compression cavity, which contributes to increase the power gain of the compressed output pulse.

Furthermore this phase modulation system with the adaptive feedback may be used as a multipurpose apparatus as follows.

- A compensation of the ringing response of the RF-Pulse Compressor associated with the coupled-resonator circuit.
- A beam-to-rf phase adjustment.
- An energy gain adjustment.
- A frequency locking by rotating the phase: $\Delta f = \frac{1}{2\pi}\frac{d\phi}{dt}$ where Δf is the frequency shift and ϕ is the phase.

2 PHASE MODULATION SYSTEM

The schematic diagram of the phase modulation system for the C-band RF system [1, 2] is shown in Fig. 2.

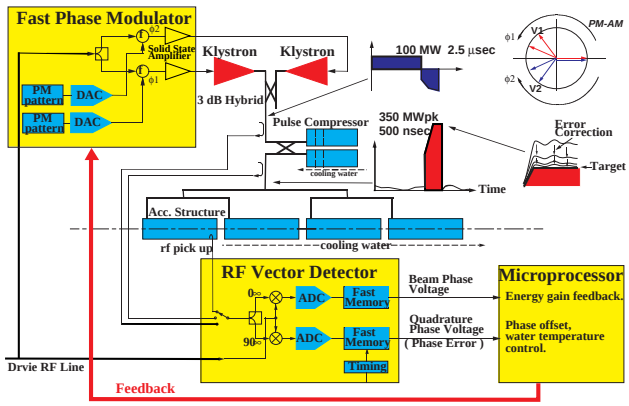

Figure 2: The schematic diagram of the phase modulation system.

It consists of the fast phase modulator, the vector rf voltage detector, the solid-state driver amplifier and the feedback control computer.

In this system, the vector-rf-voltage detector monitor the power flow at the several points; klystron output, pulse compressor output and the output coupler of the acceler-

ating structure. The software computes errors from the target value and stores the phase modulation pattern to the memory in the fast phase modulator. This feedback loop is repeatedly applied on the successive pulses to maintain a constant energy gain. The feedback is automatically controlled corresponding to the various situation: some system failures, temparature change and timing drift etc.

In the two klystrons system as shown in Fig. 2, the Phase-to-Amplitude conversion is performed to flip the input voltage of the RF-Pulse Compressor. The single klystron configuration is also possible, but it is more difficult than the two klystron system because the klystron is usually operated in the saturated region for the high effiency and the stability, and furtheremode the nonlinearity must be compensated.

3 SIMULATION

To find the optimized parameters of the RF-Pulse Compressor, the computer simulation was performed using the measured data of the C-band modulator [3] pulse and the klystron characteristics. The C-band RF-Pulse Compressor was designed for the multi-bunch operation in the future e^+e^- linear collider. The concept is: (1) the multi-cell coupled cavity is used to delay the energy output, (2) the input pulse is controlled to obtain a flat-pulse output.

In the simulation, we used a 3-cell non-uniform coupled cavity pulse compressor whose characteristics had been measured in 1997 using the cold model [4].

Fig. 3 shows the simulated output from the RF-Pulse Compressor. The dashed line shows the normalized input voltage, the light solid line shows the gain for the square input pulse, and the dark solid line shows the gain for the extended input pulse with the phase compensation. The phase compensation started at the period of 50% peak power.

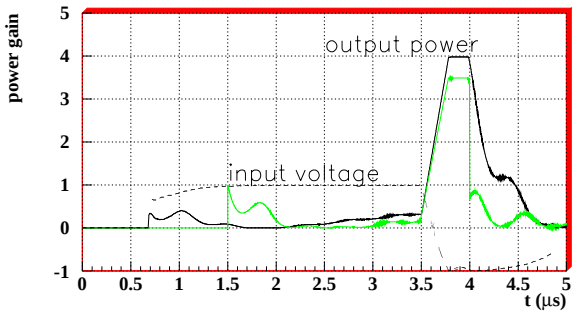

Figure 3: The simulated RF-Pulse Compressor output. Vertical axis is the normalized power gain.

The rf energy from 0.7 to $1.5\mu sec$ in Fig. 3 was stored additionally in the RF-Pulse Compressor. Futhermore we found that the lower side band through the smooth input contributes to reduce the reflection power so that the power gain reached to 4.0.

As described in Section. 1, the gain enhancement factor of 1.32 and the the maximum gain of 4.6 is expected in the ideal case. The optimization will enhance the gain.

4 EXPERIMENTAL TESTS

To demonstrate the efficiency and gain enhancement of the RF-Pulse Compressor, we performed the experimental test with the single klystron configuration using the cold model of the C-band RF-Pulse Compressor, the 50MW klystron(Toshiba, E3746) and the pulse modulator(Nihon Koshuha, KLY-M-104). The phase modulation system mainly consists of double balanced mixer(Stellex, M14A), CAMAC 100MHz 8bit Flush-ADC, VME 250MHz Programable Pattern Generator, VME 12bit DAC, VME board computer(force CPU 5V), and the feedback software which was written in Perl with SWIG, Perl/Tk, Perl/MesaGL and C++. Fig. 4 shows an experimental setup.

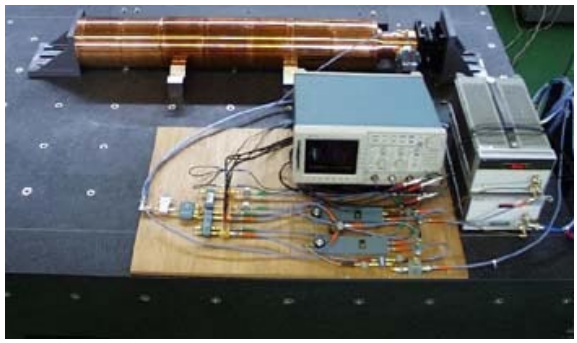

Figure 4: An experimental setup.

4.1 Phase Compensation of Klystron

At the first step, the undesirable phase rotation in the klystron associated with the rising cathode voltage was compensated by the feedback loop. The procedure of the phase compensation is as follows.

- Timing Adustment: It is important to adjust the timing of the fast phase modulator and the vector-rf-detector because it seriously affects the accuracy of the adaptive feedback. To correct the timing, we used a step pulse modulation and detecteted the timing of the rising edge.
- Calibration: The vector modulator invariably has the in-phase and quadrature (called I-Q) errros and the amplitude error. The I-Q errors affect only the settling time of the feedback, but the amplitude error causes the error in controlling the klystron output voltage. A few times of measurement was enough to determine the vector errors by setting the manual phase shifter at various phase points.
- Feedback: The vector rf voltage detector monitors the I-Q components and the amplitude of the klystron output. In the software, the I-Q sampled data is used to compute the phase correction data. Considering the characteristics and errors of the system, the software generates the I-Q modulation pattern from the phase correction data. The AM modulation pattern for the RF-Pulse Compressor must be also considered in this time. Then the I-Q pattern is stored to the memory of

DACs. When the next pulse is triggered, DACs generates the I-Q modulation waveforms.
This feedback loop is repeatedly applied on the successive pulses to maintain a constant energy gain.
In this experiment, the quadrature component of the klystron output was reduced to the noise level after 4 times feedback processes.

The Fig. 5 shows the the I-Q components of the vector demodulator versus time for the klystron output, and their X-Y(I-Q) display is shown in Fig. 6. We can interpret the I-Q display by $A(t)e^{j\phi(t)}$ where $A(t)$ and $\phi(t)$ is the amplitude and phase of the klystron output respectively, so we find that the phase rotates to the positive direction associating with the rising amplitude.

The Fig. 7 and 8 show the temporal display and I-Q display of the klystron output with the phase compensation.

It was found that the phase rotation of both the rising and falling part was completely compensated.

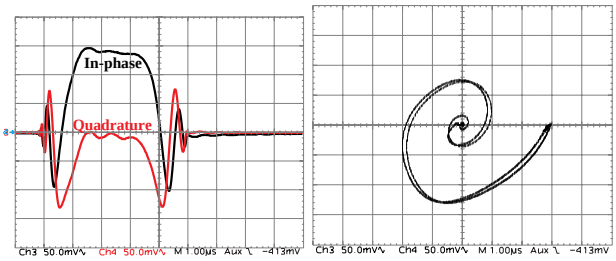

Figure 5: I-Q demodulator pulse without the phase compensation

Figure 6: I-Q display without the phase compensation

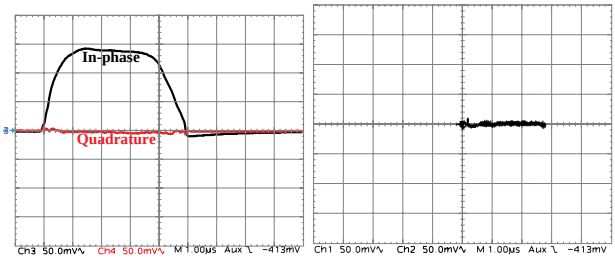

Figure 7: I-Q demodulator pulse with the phase compensation

Figure 8: I-Q display with the phase compensation

4.2 *Gain Enhancement of RF-Pulse Compressor*

Using the monitor signal from a Bethe-hole coupler at the klystron output, the pulse compression was demonstrated with the phase compensation of the klystron. The RF-Pulse Compressor in this measurement was the cold model of the C-Band RF-Pulse Compressor with a 3-cell non-uniform coupled cavity and we used the single klystron configuration. As the pulsed klystron modulator had been already tuned up to generate the $2\mu s$ flat pulse, the expected gain with the phase compensation was 3.5.

For the AM modulation to control the RF-Pulse Compressor output, we must consider the non-linear characteristic of klystron, not only for phase but also for amplitude.

Fig. 9 shows the power gain of the RF-Pulse Compressor output. The light line shows the gain for the square input pulse, and the dark line shows the gain for the extended input pulse with the phase compensation. We observed the gain enhancement factor of 1.25 and obtained the power gain of 3.5. It should be noted that the $2.5\mu s$ flat pulse was required for this power gain without the phase compensation.

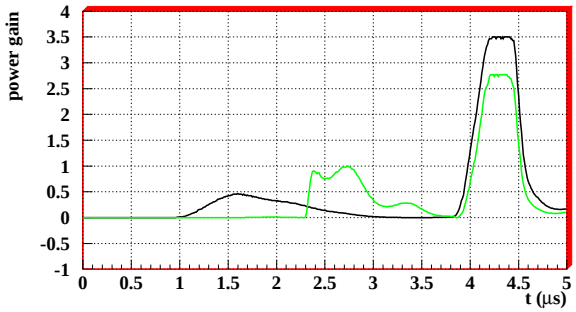

Figure 9: The power gain of the RF-Pulse Compressor.

5 DISCUSSION

We successfully demonstrated the phase modulation system. We confirmed that this phase modulation system provides a important gain enhancement with no hardware modification in high-power components.

For the further R&D, it is neccessary to optimize the parameters of the C-band RF-Pulse Compressor for a higher gain and to develop the phase modulation module for common uses. Especially, the solid-state RF amplifier is an important R&D task to drive each klystron at 500W level. It must be compact, minimum phase walk and low cost. A pulsed-class-A amplifier will be suitable for this purpose.

RESULTS AND LESSONS LEARNED FROM CONDITIONING 1 MW CW 350 MHZ COAXIAL VACUUM WINDOWS*

K. Cummings, R. Cordova, D. Rees, W. Roybal, Los Alamos National Laboratory, Los Alamos, NM 87545 and
S. Risbud, University of California, Davis, CA 95616 and
D. Wilcox, EEV, Ltd. Chelmsford, England

Abstract

The reliability of the radio frequency (RF) windows on the Low Energy Demonstration Accelerator (LEDA) is critical to the success of the Accelerator Production of Tritium Program (APT). On the APT accelerator there will be over 1000 windows, each passing on the order of 250 kW of CW RF power. This power level is well above power levels historically used in RF windows. Based on the high-power RF test results of the RF window prototypes from vendors, the coaxial windows made by EEV Ltd. of Chelmsford, England, were selected for LEDA. This paper describes the high-power RF testing of the 16 EEV coaxial windows. The RF window diagnostic equipment, data acquisition system and test stand are described. The results of the high power RF testing of the windows are presented. The successes and failures in the conditioning, manufacturing and testing techniques of the windows are presented. The conditioning timeline, power profile and the conditioning waveform are also discussed.

1 INRODUCTION

To select a reliable RF window for the radio frequency quadrapole (RFQ), prototype windows were tested from three different vendors. Based on the prototype test results EEV, Ltd. of Chelmsford, England was selected as the vendor for the 350 MHz RF windows. This paper describes the high power acceptance testing of the windows ordered for the RFQ. Under normal operating conditions these windows are required to transmit up to 250 kW of continuous wave (CW) RF power. Prior to acceptance from the vendor each window was conditioned to 1 MW of CW RF power and run at 1 MW for four hours to obtain steady state results. The power was generated by a EEV klystron capable of producing 1.2 MW CW RF power at 350 MHz.

2 EXPERIMENTAL SETUP

2.1 Window Geometry

The cross section of the EEV window is shown in Fig. 1. The window is a coaxial AL300 alumina ceramic. The air and vacuum side flanges are half height WR2300 and T-bars are used on the air and vacuum sides of the window to transition to the coaxial line. The waveguide transition on the vacuum side is copper plated stainless steel waveguide, and on the air side it is aluminum.

2.2 Test Stand

The experimental test stand is capable of testing four windows at a time. The four windows are in two pairs in a back to back configuration. The test stand is capable of passing 1 MW CW RF power through the windows. The windows are both air and water cooled. The water cooling is circulated through the vacuum side T-Bar. The air cooling goes through the air side T-bar,down the inner conductor, exits the inner conductor through a series of

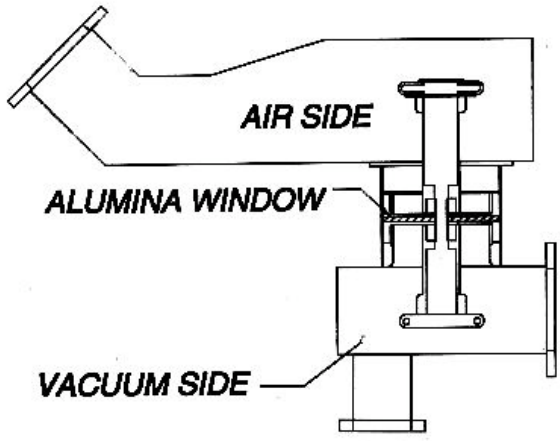

Figure 1: Sketch of the EEV Window

Figure 2: RF Window Pair on the Test Stand

*Work supported by U.S. Department of Energy.

holes and is directed over the ceramic. Then the air exits the outer conductor through a series of holes. A RF window pair in a back to back configuration is shown in Figure 2.

2.3 Diagnostic Equipment

The RF window test stand includes many diagnostics. The vacuum pressure is measured at three places in each window pair. It is interlocked to the RF power. The pressure setting for the RF interlock is adjusted during the conditioning routine. Each RF window has two fiber optic arc detectors, one on the air side and one on the vacuum side. The arc detectors are also interlocked with the RF power and will shut down the RF drive for 1.6 seconds upon detection of an arc. The water and air inlet and exit temperatures are monitored and interlocked with the RF power. In addition, the temperature of the outer coaxial surface in the region of the alumina ceramic is also monitored and recorded. An infrared camera was used to obtain the temperature distribution across the ceramic.

2.4 Data Acquisition System

The data acquisition system is used to record data from the RF window test stand and the klystron. The coaxial RTD and vacuum and arc detector data is read by a LabView program and archived. The air and water temperatures are recorded by the klystron transmitter PLC. The RGA data are read from a second LabView program. A master processor has access to all the data and allows for a common display.

3 EXPERIMENTAL RESULTS

3.1 Processing Results

The ceramic on the prototype windows was coated with copper black to prevent multipacting. During the high temperature bakeout, the coating was discolored and redistributed over the ceramic and metal surfaces. These surfaces were grit blasted to remove the coating. The prototype windows conditioned to 1 MW in 26 hours and no excessive heating or arcing were observed. The first two windows after the prototypes were not grit blasted. Excessive heating and arcing were seen as shown in Figure 3, and one of these windows failed at 500 kW. From then on, all the windows were grit blasted.

All the grit blasted windows achieved the expected power level of 1 MW and conditioned in a timely manner. Windows that were originally grit blasted at EEV had to be grit blasted again at LANL. The difference in the grit blasting is assumed to be due to differences in nozzle size and geometry. At LANL a small nozzle with a 90° bend was used allowing easy access to the corners and back sides. EEV has now adapted the same nozzle as at LANL. The windows were grit blasted with 220 alumina grit at 55 psi.

3.2 RF Conditioning Results

A low vacuum pressure is essential during RF conditioning. At higher pressures, more arcing and heating occurred. The vacuum interlocks were set at 1 x 10^{-5} Torr for power levels less than 100 kW, 5 x 10^{-6} Torr for power levels between 100 kW and 500 kW, and 2 x 10^{-6} Torr for power levels above 500 kW.

During conditioning it is important to monitor the rate of temperature increase as a function of RF power. By conditioning 4 windows at a time, nonlinear temperature increases are easier to detect. An example of the nonlinear temperature increase is illustrated by the windows that were not grit blasted as shown in Figure 3. If a large temperature increase is detected, the power level is immediately reduced until the temperatures are more typical.

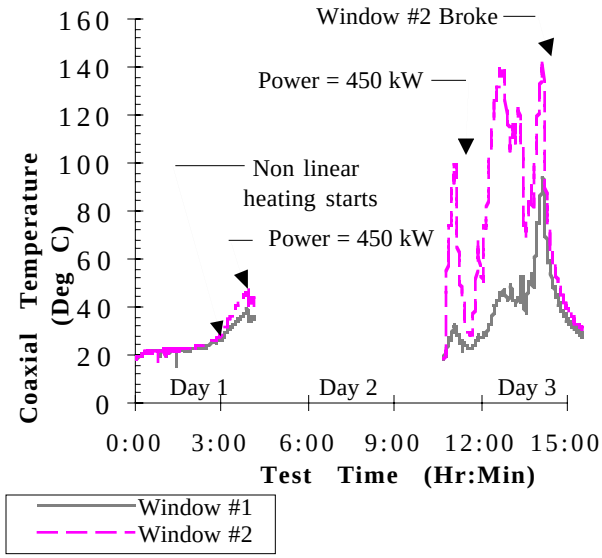

Figure 3: Window Temperature vs. Test Time of Two Windows that were not Grit Blasted.

3.2 High Power Test Results

The time to condition the windows to 1 MW is shown in Figure 4. The average conditioning time is approximately 19 hours and the average outer coaxial temperature near the ceramic at 1 MW is approximately 75 degrees C.

Different RF waveforms used in conditioning included CW, pulsed, and amplitude modulation. In CW conditioning the power could only be increased in discrete steps. The power is increased in decibels, thus, the steps are quite large at high RF power levels. At times, large gas loads were seen due to the large power increase. Pulsed conditioning helps decrease the average power and the heating in the window; however, it does not eliminate or reverse the nonlinear heating which leads to the failure of the window. Amplitude modulation was used as a conditioning method to pass a power region of high outgassing. CW conditioning is easily compared to amplitude modulation in Figure 5. In this particular case, CW conditioning was used during the first four hours and amplitude modulation was used the remainder of the test time. The increased speed of conditioning the windows with amplitude modulation is easily observed.

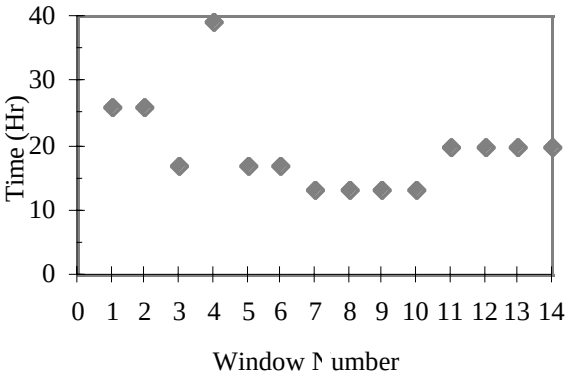

Figure 4: Comparision of Conditioning Times to 1 MW.

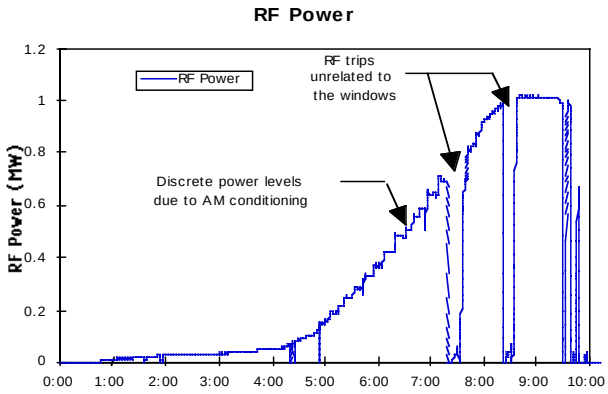

Figure 5: RF Power vs. Test Time with CW Conditioning until 4 hrs. and Amplitude Modulation after 4 hrs.

4 DISCUSSION

Grit blasting is believed to reduce cause of the nonlinear temperature increase by cleaning the surface and changing the surface topography[1]. Changes in the surface topography dull the potential field enhancement sites which reduces multipacting. Surface characterization work showed the grit blasted samples to have a higher carbon content on the surface than non-grit blasted samples[2].

In amplitude modulation a continuous range of power levels are conditioned. As previously discussed, in CW conditioning discrete power levels are conditioned, and when returning to a previously conditioned power level, multipacting may still be seen. With amplitude modulation there are no discrete power levels and multipacting does not reoccur at specific power levels.

During conditioning, two separate phenomena, multipacting and ion bombardment, are thought to be occurring[1]. The signs of multipacting are rapid fluctuations in the vacuum pressure and nonlinear temperature increases with power[3,4]. Multipacting tends to occur at specific power levels for a given window geometry. The second phenomenon is believed to be due to ion bombardment. As electrons are freed from the surface, they are colliding with molecules in the vacuum chamber which produces ions. The ions collide with the surfaces on the vacuum chamber, which causes heating and additional electrons to be freed due to the high kinetic energy of the ions at the time of the collision. As more electrons are freed, more ions are made. Ions may also form when molecules are exposed to small electric fields at less than very good vacuum conditions and the electric fields pull the molecule apart. These ions are then accelerated by the Lorenz forces into a surface where they cause heating and liberate more gas that further drives the process. The ion bombardment can be observed by a slow steady increase in the vacuum pressure. Following the slow steady pressure increase, nonlinear heating can be observed.

5 CONCLUSIONS

Sixteen windows passed 1 MW of power and stabilized to steady state conditions. Grit blasting was found to be a critical processing step to avoid excessive heating and arcing at higher power levels. Amplitude modulation is the recommended method of RF conditioning because it conditions a continuous range of power levels while minimizing the gas load.

SOLID STATE POWER AMPLIFIER AS 805 MHZ MASTER SOURCE FOR THE LANSCE COUPLED-CAVITY LINAC*

J. T. M. Lyles, J. L. Davis
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

From 100 to 800 MeV, the Los Alamos Neutron Science Center (LANSCE) proton linac receives RF power from forty-four 1.25 MW klystrons at 805 Megahertz (MHz). A single master RF source provides a continuous high level phase reference signal which drives the klystrons along the 731 meter-long linac through a coaxial transmission line. A single point failure of this system can deenergize the entire coupled-cavity linac (CCL) RF plant. The authors replaced a physically large air-cooled tetrode amplifier with a compact water-cooled unit based on modular amplifier pallets developed at LANSCE. Each 600 Watt pallet utilizes eight push-pull bipolar power transistor pairs operated in class AB. Four of these can easily provide the 2000 watt reference carrier from the stable master RF source. A radial splitter and combiner parallels the modules. This amplifier has proven to be completely reliable after two years of operation without failure. A second unit was constructed and installed for redundancy, and the old tetrode system was removed in 1998. The compact packaging for cooling, DC power, impedance matching, RF interconnection, and power combining met the electrical and mechanical requirements. CRT display of individual collector currents and RF levels is made possible with built-in samplers and a VXI data acquisition unit.

1 INTRODUCTION

The LANSCE linac is an 800 MeV proton machine capable of accelerating high average current, up to 1 mA of H^+. In addition, a 70 uA H^- beam is accelerated for the proton storage ring; the accumulated charge is extracted and directed to a spallation target for neutron production.

The CCL accelerates the two proton beams from 100 to 800 MeV. It is supplied with pulsed radio frequency power at 805 MHz from forty-four klystrons capable of producing up to 1.25 MW. These are driven by the RF reference source, which is located near the 100 MeV end of the structure. The RF source used a Burle Industries 8501 Cermolox® tetrode. The source generates 2000 watts of continuous RF. It is distributed to each klystron via directional coupler taps along a single temperature-stabilized drive line, located adjacent to the linac structure. This series-feed technique is simple and reliable, as long as the coaxial drive line is not compromised. In over twenty-five years of operation, this has not been a problem. For redundancy, the RF source itself is duplicated in a main/backup switched configuration. In 1993, the 8501 tetrode became obsolete. With an immediate purchase of enough tubes to supply operations for five years, we began searching for an alternative amplifier.

2 NEW POWER AMPLIFIER

2.1 Existing Transmitters

We considered developing a new cavity amplifier around another available UHF television transmitting tetrode. This idea was eliminated when we observed that fewer transmitters were being designed around medium power tetrodes, as all solid-state (transistorized) amplifiers were coming to market. LANSCE is situated at an elevation of 2120 meters above sea level, so the air density is reduced by 22% from sea level. We prefer water cooling where it is practical to remove the heat load from RF equipment. It is cooled in plant cooling towers, so that the water is continuously recycled though the RF system. There were no commercial water-cooled solid-state TV transmitters in this power range when this work began.

2.2 Solid-State Amplifier Concept

We developed a water-cooled amplifier module, using bipolar power transistors developed for cellular telephone stations. This began in 1992, and by 1993 the basic RF amplifier board was operating as designed. A multiple amplifier module was designed with four printed circuit boards mounted on two sides of an aluminum block with water passages drilled through the central core for heat removal.

2.3 RF Amplifier Module

The transistors used are Motorola part number MRF899, which are actually two bipolar transistors on a single flange. They contain gold-metallized NPN silicon transistors rated for 230 Watts of dissipation and are characterized for 150 Watts of output at 900 MHz. These transistors are factory-tested with a 5:1 load voltage standing wave ratio (VSWR) at all phases, while operating at 150 Watts at 26 Volts DC. We only operate with 22 Volts for an additional safety factor. The two devices are operated in class AB push-pull and are in common-emitter (CE) configuration, advantageous for high gain at UHF frequencies. Push-pull operation with

* Work supported by the US Department of Energy

the MRF899 minimizes the emitter-to-emitter inductance to the bonds between the devices on the flange, instead of the higher emitter to ground inductance of separate CE transistors [1]. Only the DC current flows to ground in the MRF899.

Push-pull operation of the device uses coaxial line baluns on the input and output sides. Matching to raise the transistor impedance to the coaxial line impedance is accomplished with microstrip over the PTFE/glass (ε_r'= 2.55) board and discrete chip capacitors to ground. Each push-pull amplifier is combined with an adjacent one on the same printed circuit board using Wireline® 3 dB quadrature hybrids, made by Sage Laboratories, Inc. Thick film resistors mounted on the pallet terminate the forth port of these hybrids. In figure 1, the "U"-shaped baluns are seen, along with the straight sections of Wireline® used for power dividing and combining. Two MRF899 devices are on each printed circuit board, which is mounted in a machined recess in the aluminum block. There are four boards and eight push-pull transistors per pallet. A total of 32 of these bipolar transistors are used in this amplifier on four pallets.

2.4 Cooling

The water cooling passages are drilled with three long passages along the length of the block, and short intersecting passages drilled at right angles to make the crossovers. Pipe plugs are used to block the drill holes after the passages are joined. Water enters the fitting at the bottom (see figure 1) and circulates along a serpentine path shown by the dotted line. In worst-case testing, we operated one push-pull transistor with 130 Watts of RF, and the semiconductor junction temperature was 135 degrees Celsius. Good engineering practice suggests limiting this to no more than 150 degrees [2]. In actual operation, each device operates at 80 Watts, with a generous safety margin which should ensure transistor lifetimes above 50,000 hours.

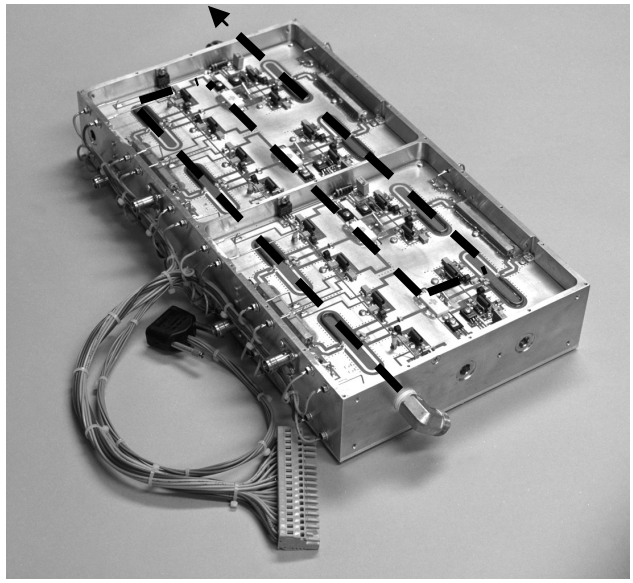

Figure 1. Basic pallet, one of four used in amplifier

2.5 Combined Amplifier

After the basic module and pallet concept was developed and tested, we completed the design of the splitting/combining networks, the overall packaging, cooling, monitoring, and control circuitry. Four of the pallets are arranged in a compact 48.3 cm-wide enclosure, with cooling paths in series. Sixteen amplifier boards are available, but only fourteen are combined

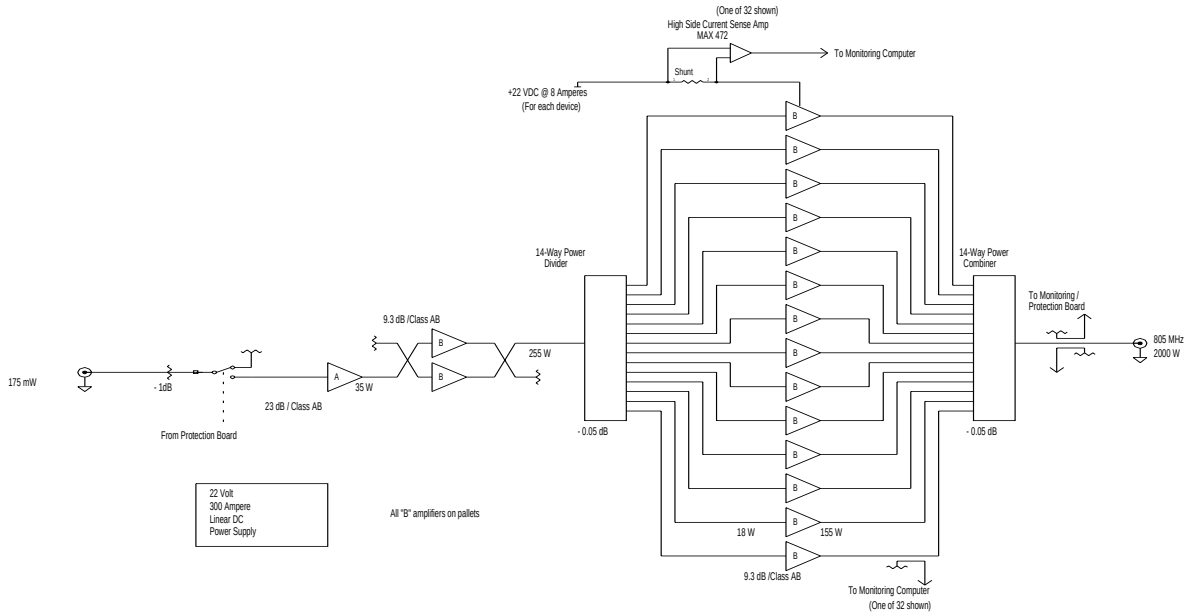

Figure 2. Block diagram of solid-state power amplifier

for the final stage, each supplying 155 Watts. Two are used as an intermediate stage, to drive the 14-way splitter with 255 Watts of power. These two boards (one half pallet) are driven and combined with 3 dB quadrature hybrids with isolation loads. In the block diagram the driver stage (marked "A") uses a commercial 35 Watt amplifier, also operated in class AB.

A 14-way radial "Tee" divider and combiner was supplied by Werlatone, Inc. Radial combiners have a good active match at each port, as long as each port is being driven by an equal source. The effects of complete failure of one amplifier in the 14-way device would theoretically create only a 1.15:1 VSWR at the remaining ports. RF power transistors typically do not fail in a shorted mode, at least not for very long. The worst case failure mode would most likely be if several transistor failures (open collector to emitter) or open terminations on the Wireline® hybrids reflected a short into the center of the output combiner. Our transmission line lengths transform an open circuit on any board to an open at the center of the combiner. This has worked well, as evident when we operated at full power for many days while one collector tab was disconnected on a board. No long term damage was sustained by the amplifier.

The amplifier load is a very long transmission line terminated in a fifty Ohm dummy load. There is no isolator needed since a fast-acting reflectometer/detector commands the protective logic to remove drive and power from the amplifier if the output reflected power becomes excessive.

2.6 Control System

For control, protection and monitoring, two separate schemes are used. An internal logic board handles the RF-on command, and monitors pallet temperatures, water flow, power supply voltage, and output reflected power. It protects the amplifier by switching off the 22 Volt DC power, and muting the RF drive.

A second system scans the DC bus voltage, the water temperature rise across the amplifier, the individual input and ouput RF levels from each amplifier board, and the collector currents from each transistor. This monitoring system uses a VXI-based data acquisition system from Hewlett-Packard, using a workstation/controller. A CRT screen provides all the amplifier parameters, along with a printer for hardcopy. We examine and track individual transistor and board performance; no major variations have been noted in over a year of operation of two amplifiers. Thirty-two surface mounted high-side current-sensing integrated circuits were incorporated to measure the collector currents from a shunt resistor on each connection to the DC bus bar. They provide ground-referenced zero to five volt analog levels to the multiplexer, without the common-mode DC bus voltage.

2.7 Power Supply

The RF reference must have low sideband noise as it could be amplified by the klystrons and be within the modulation bandwidth of the RF controls. We designed the amplifier for low phase noise and low modulation sidebands with respect to carrier. Massive linear power supplies were obtained from Kikusui Electronics, instead of lighter switchmode or SCR-type supplies, to eliminate the possibility of power supply noise sidebands. 250 Amperes DC is the normal operating current for 2000 Watts.

3 RESULTS AND CONCLUSION

The new amplifiers can provide as much as 2800 Watts of CW power at 805 MHz, with 40 dB of power gain. The DC-to-RF efficiency is 36%. The first amplifier was installed in 1996 and has operated continuously without failure. A second amplifier was installed in 1997, along with an RF switchover system and controls. Each amplifier in a single equipment rack (see figure 3) is much more compact than the four racks containing each original tetrode system.

ACKNOWLEDGEMENTS

The authors wish to thank Irene DeBaca, Mark Doub, Andrew Espinoza, Diane Johnson and Roger Johnson of LANSCE for their skillful work and dedication.

Abstract

The Low Energy Demonstration Accelerator (LEDA) for the Accelerator for the Production of Tritium (APT) project will be built at Los Alamos National Laboratory. The low-level RF (LLRF) control system portion of this accelerator must perform many functions, of which the primary one is controlling the RF fields in the accelerating cavities. Plans have been made to provide for on-line characterization of the LLRF control system and the complete RF system through use of stimulus and response buffers, and a digital signal processor built into the field control system electronics. The purpose of this circuitry is to characterize the behavior of the entire RF system (klystron, waveguides, high power splitters, accelerator cavity, etc.). This characterization feature can be used to measure the performance of the closed loop system with respect to the open loop system, to provide an automated way to set loop parameters, to determine the cavity Q-curve, and to detect any abnormal behavior in the RF chain. The types of measurements include frequency and time-domain responses to given perturbations, amplitude modulations, etc. This paper will discuss types of algorithms that can be implemented and present a description and block diagram of the electronics to be used.

1 BACKGROUND MOTIVATION

Initially LEDA will be operated "manually" as we bring systems on-line individually. However, in planning for the APT plant, it is realized that we will be operating an accelerator with upwards of fifty control systems. Automatic calibration and test sequences will enable the operators to quickly diagnose a system and anticipate possible failures. In addition, performing a dynamic frequency response measurement of the RF chain around its normal working point, will provide for characterization of individual control systems throughout their "lifetime."

Here the RF chain refers to part of the LLRF control system hardware, the preamplifier, the klystron, waveguide, high power splitters, couplers, cavity, pickup loop, downconverter, and return signal cable. This measurement will be a special mode of operation, incompatible with the normal control algorithm. The aim is to measure how a known perturbation at a given frequency is transmitted along the RF chain.

Uses of such measurements include:

- Optimizing performances of the control system, by predicting ultimate loop gain possibilities
- Checking performance of closed loop operation with respect to open loop
- Setting the correct loop phase shift
- Detecting any abnormal behavior in the RF chain

2 DISCUSSION

One of the primary functions of the low-level RF control system is to maintain the field levels inside the accelerating cavities. The basic VXIbus module architecture for the LEDA LLRF control system has been described previously[1] as well as some preliminary low-level RF modeling for the APT[2]. By implementing a LLRF control system that provides easy software/hardware interaction, other functions can be implemented besides simple real-time setup by the accelerator operators. Software can also be used to perform RF system analysis.

A fundamental component of the LLRF control system is the Field Control Module (FCM). This module is a feedback/feedforward controller used to regulate the RF field parameters of the accelerator cavity. The FCM performs cavity field feedback and beam feedforward control algorithms in both digital and analog circuitry. The digital processing on the FCM is centered around a Texas Instruments TMS320C50 fixed point digital signal processor (DSP). The DSP processor provides powerful control algorithms and flexible operational scenarios. The digital processing provides precision detection and flexible control signals to bandwidths around 10 kHz. In order to extend the bandwidth beyond this, analog circuitry is used to process the field and beam signals in parallel with the DSP. The analog circuitry is more susceptible to errors and noise, and is less flexible, but provides control signal bandwidths to around 1 MHz. A block diagram of the FCM is depicted in figure 1.

The flexibility of the digital processing on the FCM is demonstrated by its ability to function in significantly different operating modes. The operating modes encompass many different operational scenarios including continuous operation, pulsed operation, amplitude modulation, phase modulation, frequency modulation, amplitude and phase control, amplitude-only control, open-loop operation, and closed-loop operation. Also, setpoints, gains, bandwidths, and algorithms can be adjusted by the operator through the VXIbus interface. In

addition to the control circuitry, the FCM includes circuitry that performs self-calibration and system characterization. The calibration and characterization functions are accomplished with either frequency modulation or arbitrary waveform modulation.

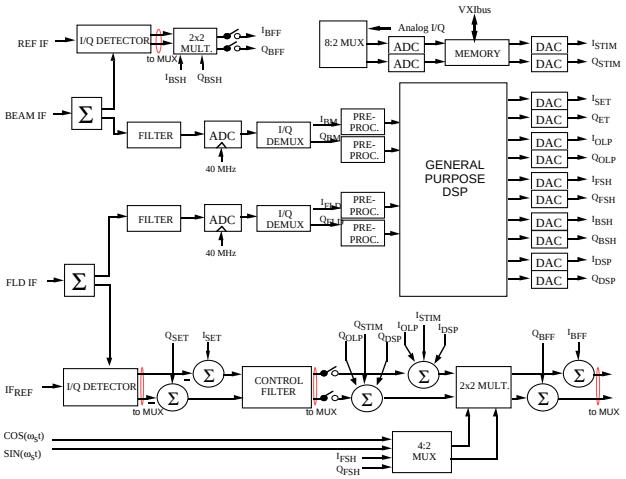

Figure 1. Block Diagram of Field Control Module

The frequency modulation functionality can be used for self-calibration of the in-phase/quadrature (I/Q) detectors on the FCM and other modules in the system. The FCM can be placed into an operating mode where it generates a control output that applies a frequency shift to the master oscillator frequency. The original purpose of this shift is to provide a means of resonance tracking to rapidly heat the accelerating structure after a RF fault.[3] It has the additional feature though, of providing us with a means of inputting a test frequency for measurement of the offsets, quadrature errors, and gain imbalances in the I/Q detectors. This frequency modulation functionality will also allow us to modulate the klystron drive with a swept FM signal, something SLAC has found quite useful for processing cavities.

The arbitrary waveform modulation functionality can be used to characterize the RF system response and configure the RF system control parameters. The arbitrary waveform functionality is provided by stimulus and response waveform buffers on the FCM. The stimulus waveform buffer allows loop excitation with arbitrary modulation signals stored in memory and converted to analog signals in DACs operating at 10 MHz. The response waveform buffer captures the response of the RF system to the stimulus. Various points along the signal path in the FCM can be multiplexed and their data stored for later analysis. The cavity field feedback signal can be examined to characterize and configure the total RF system. In effect, this can be thought of as a baseband arbitrary waveform generator, with the ability to perform baseband network analysis.

The first step to system characterization is to set the DSP outputs to a constant value such that the normal field level is measured in the cavity (without beam). A generated perturbation (test signal) is then added to the normal output values to generate the perturbed input signal (I_{STIM} and Q_{STIM}). We will operate the klystrons some percentage below saturation, in order to allow operating room for the disturbance input. The modulation we place on the drive will be simply some small noise on top of a baseband level. One type of test signal consists of a succession of pre-calculated samples at a certain frequency rate and during a certain period of time. While this test signal is being injected into the system, the cavity field perturbed inputs to the DSP are measured and stored for future analysis. Therefore, the only real-time process would be to read a pre-calculated complex signal, add it to a constant value, output this signal at a certain frequency rate, acquire the perturbed signal at the same frequency rate, subtract the constant value, and store it in memory. All other analysis could be done after this sequence, in a non-real time mode by the supervisory system software, EPICS.

Some of the input test signals will be time domain versions of single frequency tones at known system-problem frequencies. Other possible input test signals include chirp pulse-compression waveforms. This methodology will also allow us to modulate the RF drive with a swept frequency signal for frequency-domain analysis of the RF system. In another test scenario, a small amount of white noise can be injected. Such a technique has been used with success on the ELSA linac at Bruyeres le Chatel.[4] The test signal was actually a special kind of noise: constant in amplitude and random in phase in the frequency domain. We anticipate bandwidth-limiting the noise for better measurements, and more realistic inputs.

Off-line processes include generating the desired input test signals and performing data analysis. One nice feature about EPICS is its ability to incorporate MATLAB functions. MATLAB, a control system design and analysis software package, has a very useful function known as TFE. The Transfer Function Estimate simply requires a set of system inputs and outputs, for which it returns the system's transfer function. The complex frequency response can then be plotted in the complex plane with frequency as a parameter, or as a Bode diagram. Once transfer functions are calculated, they can be compared to models for determining desirable operating parameters

3 HARDWARE SPECIFICS

A photograph of the Field Control VXIbus Module is shown in figure 2. The analog electronics are along the bottom of the module, while the digital hardware is located in the upper two thirds. The analog circuitry consists of two intermediate frequency I/Q detectors, baseband analog PID control circuitry, analog switches and multipliers for adjustments, and the analog control

output drivers. The digital circuitry consists of quadrature-sampling ADCs, decimating digital filters, the DSP, the control output DACs, the DSP memory resources, and the VXIbus interface. In addition, The FCM contains the stimulus waveform memory banks and DACs and response waveform memory banks and ADCs.

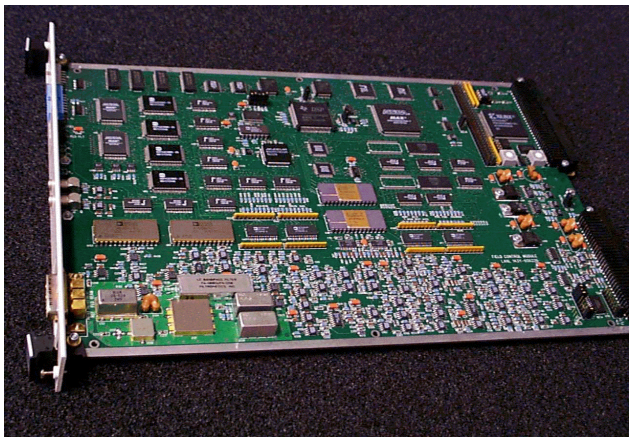

Figure 2. Field Control VXIbus Module

The EPICS interface to the stimulus/response functionality is accomplished with two sets of read/write registers that have been designated as the Stimulus I (or Q) Memory Register and the Response I (or Q) Memory Register. These registers provide access to the First-In, Last-Out (FILO) memory buffers for the stimulus DACs and response ADCs. Each FILO memory is 256 kwords in length, providing a time duration of approximately 26 ms at the 10 MHz DAC and ADC rate. In order to measure the response of the system, the FILO memory buffers are placed in their record mode, thus capturing response waveforms from the control system. There are two possibilities for the time-duration of the stimulus/response signals. The continuous duration causes the stimulus waveforms to be generated repeatedly and the response waveforms to be captured repeatedly. The single duration causes the stimulus DACs and response ADCs to generate and capture data only once until the waveform buffers are full. After the response waveform buffers are full, the FILO memory buffers stop and the VXIbus host processor is notified.

4 CONCLUSION

The FCM is one of five fundamental modules in the APT LEDA LLRF control system. It not only performs analog and digital field control, but has some features built in to allow us to perform on-line RF system characterization. This will be useful in determining various operational parameters, as well as provide a means for conditioning cavities. We expect to integrate the first LLRF control system with the rest of LEDA later this year. Once commissioning commences, one of the first LLRF tests we will perform is RF system characterization.

LEDA RF DISTRIBUTION SYSTEM DESIGN AND COMPONENT TEST RESULTS*

William T. Roybal, Daniel E. Rees, Heather L. Borchert
Los Alamos National Laboratory
Michael McCarthy, General Atomics, Loren Toole, Savannah River Site

Abstract

The 350 MHz and 700 MHz RF distribution systems for the Low Energy Demonstration Accelerator (LEDA) have been designed and are currently being installed at Los Alamos National Laboratory. Since 350 MHz is a familiar frequency used at other accelerator facilities, most of the major high-power components were available. The 700 MHz, 1.0 MW, CW RF delivery system designed for LEDA is a new development. Therefore, high-power circulators, waterloads, phase shifters, switches, and harmonic filters had to be designed and built for this application. The final Accelerator Production of Tritium (APT) RF distribution systems design will be based on much of the same technology as the LEDA systems and will have many of the RF components tested for LEDA incorporated into the design. Low power and high-power tests performed on various components of these LEDA systems and their results are presented here.

1 WAVEGUIDE SYSTEMS

The first accelerating section of LEDA is the radio frequency quadrupole (RFQ). Three 350 MHz 1.3 MW CW klystrons can deliver RF power to the RFQ.[1] Each of the waveguide runs from the klystron contain several important components that will be described in the next section

The RFQ is followed by the Coupled Cavity Drift Tube Linac (CCDTL). This section of the accelerator is driven by a single 700 1.0 MW CW klystron.[2] Many of the components used in the 350 MHz system are also used in the 700 MHz systems. The 700 MHz RF systems will comprise most of the RF systems used on the APT accelerator. [3]

WR2300 full-hcight waveguide is used for delivering up to 1.2 MW of CW RF power at 350 MHz to the RFQ. In order to minimize the RF power passed through the vacuum windows to the RFQ the power is divided into equal parts. Hybrid couplers (3 dB) are used to split the power. After the power division, the waveguide size transitions to half-height and the power from one klystron is delivered to the RFQ through four waveguide feeds. Since the RFQ serves as the power combiner, the effective electrical length of the waveguide runs must be controlled. High-power phase shifters are introduced to the waveguide runs to set the phase at the proper value and to make adjustments when needed. A typical waveguide configuration from the klystron to the RFQ is shown in Figure 1.

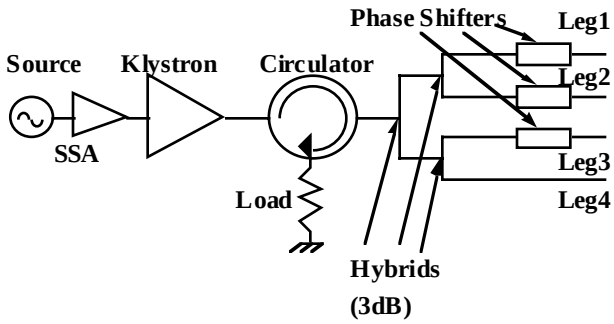

Figure 1: Schematic of LEDA RFQ RF power delivery system.

2 RF COMPONENTS

2.1 Circulators

Both the 350 and 700 MHz RF delivery systems use a high-power circulator to protect the klystron from excessive reflected power. The circulators used on LEDA are manufactured by Advanced Ferrite Technology (AFT). The circulators have a measured insertion loss of less than 0.05 dB at the center frequency. The isolation for the three ports of each circulator is greater than 30 dB.

2.2 Phase Shifters

Phase shifters supplied by Mega Industries are used to correct any phase differences introduced to the waveguide runs that lead to the accelerator. The phase shifters adjust the phase in the waveguide up to 45 °. The phase shifters move three posts in and out of a section of waveguide (0.0 to 2.5") to introduce the required phase shift. They are adjusted manually with a knob or electronically with a motor. A photograph of a 350 MHz WR2300 phase shifter is shown in Figure 2.

The WR2300 half-height phase shifters were tested on the test stand for 4 hours at 200 kW CW. The 45 ° of phase shift was demonstrated at this power level. A WR2300 full height phase shifter was tested on the up to 1.0 MW CW over the 45° range at 350 MHz for several hours. The external temperature near the base of one of

* Work supported by the US Department of Energy.

the posts (with the posts fully inserted into the waveguide) reached a constant temperature of 154 °F at this power level. The posts were extracted with the power held constant and the temperature at that location reduced to 135 °F.

Figure 2: Photograph of 350 MHz WR2300 half-height Phase Shifter.

2.3 Waveguide Switches

A three port waveguide switch, also manufactured by Mega Industries, is used to isolate a klystron from the accelerating structure. The APT accelerator has installed redundancy on each copper structure and the waveguide switch is used to isolate a failed RF station from the cavity. A phase shifter and a shorting plate on the third port of the waveguide switch is used to present a short at the proper phase to the accelerating cavity iris to allow operation with one system removed.

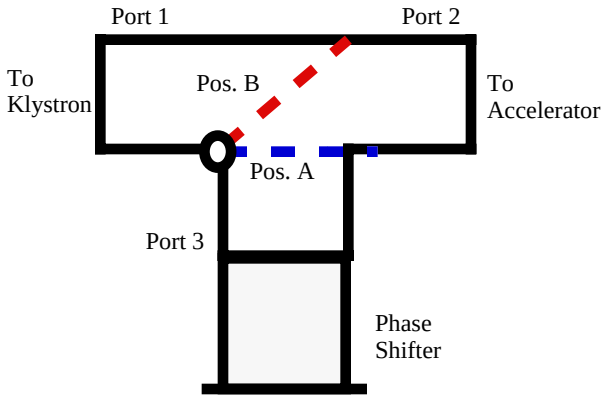

Figure 3: Schematic of a Waveguide Switch in its typical configuration.

As shown in Figure 3, with the waveguide switch in position A the power is directed to the accelerating structure. In position B a short circuit at the correct phase is presented to the coupling iris of the accelerator and any power from the klystron is reflected back to the circulator load.

2.4 Harmonic Filters

Harmonic filters are used between each klystron and circulator to de-Q any potential resonant circuits at the harmonic frequencies. The harmonic filter occupies a 46" section of waveguide. It has 6 antennas protruding into the narrow wall of the waveguide which are terminated in 200 W, 50 Ohm, air cooled loads. A photograph of a 350 MHz harmonic filter is shown in Figure 4.

Figure 4: Photograph of LEDA 350 MHz Harmonic Filter.

Since the fundamental frequency is carried in the TE_{10} mode with the electric fields orthogonal to the broad wall, the antennas are inserted through the narrow wall of the waveguide to couple out harmonic power in the TE_{11} and TM_{11} modes. [4] If the antenna is too thick, it can couple a significant amount of power at the fundamental frequency. An optimal length and thickness for the antennas were chosen.

The diameter of all antennas is 0.0787" (2 mm). The length of antennas for the harmonic filter for the 350 MHz system is 3.88" (9.85 cm) and 1.75" (4.44 cm) for the 700 MHz. The measured insertion loss for the harmonic filters are 0.04 dB and 0.01 dB for the 350 and 700 MHz filters, respectively. The measured antenna coupling value for either fundamental frequency is -60 to -70 dB. For the first through the third harmonic, the coupling value varied between -20 to -30 dB. Currently, several harmonic filters at 350 MHz are installed and have been in use for hundreds of hours without a failure. As much as 20 Watts of harmonic power have been measured on some antennas during operation of the klystrons at full power.

2.5 RF Loads

RF loads are used on the all high-power RF systems. Except for the test stand, 200 kW loads are placed on the return leg of the 3 dB hybrids and circulators. For testing

RF components, the test stands use RF loads that are capable of taking the full power out of the klystron.

The 350 MHz full power loads were developed by Titan Beta. They are used on the test stand for testing components up to 1.2 MW CW. To reduce the length of these water loads, they operate using a 70% water and 30% propylene glycol mixture. At this mixture, the VSWR for the loads according to factory low power testing is 1.05:1, however the best achieved under high power conditions is 1.07:1.

Similar loads are used for the test stand at 700 MHz. Premier Microwave (now Atlantic Microwave) provided the 1.0 MW CW RF water loads. Deionized water is used in these loads. The body of the load is stainless steel. The VSWR for these loads is also 1.05:1. This load has been operated at 1.1 MW for 24 hours of continuous operation for a klystron test.

Altronics Research supplies a coaxial mounted 50 Ohm film resistor rated at 200 kW. Five resistors of this type are used on each RF transmitter. It is based on a shell-and-tube design and is cooled with deionized water.

The resistor's transient rating is about 22 joules. It can accept 6 times the average rated power for 100 microseconds. Coolant flow results in a rated pressure drop of 50 psi at 20 gpm. All resistors are continuously monitored for flow and temperature. The flow rate is monitored using a Rosemount flowmeter coupled to a Oripac orifice plate. Omega RTD probes are used for all temperature measurements in the cooling systems. An Allen-Bradley system is used to monitor these sensors and software interlocks will recognize the effect of transients and the associated time constant of the piping system and instrumentation.

The robustness of this design has been an ongoing concern in relation to offnormal conditions expected during acceleration operation. At outlet temperatures above 90 °C, localized boiling has been observed to occur in the cooling channel, reducing the film's heat transfer coefficient and potentially creating conditions for failure. However, the rate of failure has yet to be determined. Preliminary acceptance tests of 21 resistors have accumulated nearly 100 hours of test stand time at rated power. Of the 21 loads, 18 passed the 4 hour full power test, 2 required rebuilding and passed the 4 hour test on the second attempt, and 1 was rebuilt twice before finally passing the 4 hour acceptance test.

2.6 Flexible Waveguide

Sections of flexible waveguide are located in every leg of every waveguide run to accommodate thermal expansion between fixed points. Ultraflexible pieces are used to connect critical components such as the klystron and RF windows [5] to the rest of the system.

Ultraflexible WR2300 half-height guide with a 90° E-plane bend incorporated into it is used as the last sections of waveguide that connects the RF windows to the RFQ. These sections allow for the expansion of the RFQ due to heating. The manufacturer of these flexible sections is Mega Industries. These sections have been tested and installed on the waveguide runs. The results of the mechanical testing is given in Table 1. The measured results for the compression and expansion displacement and the horizontal offset were not compliant with the original requirement. The results of all the mechanical tests were reevaluated and later determined to be sufficient.

	Measured	Expected
Çompression with 12.5 lbs force	0.109"	0.125" min.
Expansion with 12.5 lbs force	0.045"	0.125" min.
Vertical Tilt force to get 1° tilt	18 ft-lbs	25 ft-lbs max.
Horizontal Tilt force to get 1° tilt	14 ft-lbs	25 ft-lbs max.
Vertical Offset force to achieve 0.0625" offset	+7 lbs & -5 lbs	15.7 lbs max.
Horizontal Offset force to achieve 0.0625" offset	+18 lbs & -21.5 lbs	15.7 lbs max.
Clockwise Twist with 20 ft-lbs of torque	0.165"	0.10" min.
CounterClockwise Twist with 20 ft-lbs of torque	0.165"	0.10" min.

Table 1: Mechanical test results of the 90° E-bend flexible half-height WR2300 waveguide.

High-power electrical tests were performed on one WR2300 half-height flexible 90° E-bend. It was tested for 4 hours at 900 kW CW without failure.

A THERMAL ANALYSIS AND OPTIMIZATION OF THE APT 210 kW POWER COUPLER*

J.A. Waynert, F.C. Prenger
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

This paper presents the thermal analysis and heat load optimization of the continuous power 210 kW, 700 MHz RF power coupler (PC) for the Accelerator Production of Tritium (APT). The PC is a co-axial design with RF power transmitted in the annular region between two concentric cylinders. Thermally, the PC represents a link from room temperature to the superconducting niobium cavities operating at 2 K. The analysis includes all the major heat transfer mechanisms: conduction, RF joule heating in normal and superconducting materials, infra-red radiation, and, forced and natural convection cooling of the inner and outer conductors. A performance comparison is given for one and two single point thermal intercepts, versus a counter-flow heat exchanger on the outer conductor. The benefits of reducing the operating temperature of the center conductor are discussed. The variation in thermal performance of the inner and outer conductors for several operating modes is also presented.

1 INTRODUCTION

The APT utilizes a linear accelerator to produce energetic protons, which strike a metal target of tungsten and lead, producing neutrons through spallation. The neutrons are captured in ^{3}He, producing tritium. The low energy portion of the accelerator uses conventional normal-conducting components, after which, the protons enter the superconducting accelerator section. The superconducting portion of the APT has cryomodules containing superconducting RF accelerating cavities separated by resistive focusing quadrupole magnets. The RF cavities are cooled by saturated superfluid helium at 2.15 K. Although there are two and possibly three variations of cryomodule, depending on the location of the module within the linac relative to the proton energy, this paper will focus on only the β=0.82 cryomodule.

Within a cryomodule, the PCs represent the second largest thermal load on the 2 K system, only the cavities generate a larger heat load. There are several objectives of the PC thermal analysis:

- Develop a model which accounts for the major heat loads and can be used to explore a wide range of geometries, material properties, and operating conditions;
- Ensure viable thermal operation of the PC; and
- Optimize total system refrigeration input power.

This paper will discuss each of the objectives in detail. Section 2 provides a description of the PC and the thermal model that has been developed. Section 3 presents the results for the inner and outer conductors and considers the implications of various cooling schemes on the cryomodule system total refrigeration input power. Section 4 gives a summary and discussion of the work.

2 DESCRIPTION OF THERMAL MODEL

Figure 1 shows a cut-away view of the PC as modeled, with a simple illustration of a counterflow heat exchanger for cooling of the outer conductor. The total length of the PC is about 1006 mm. Not shown are the two RF windows which couple the microwave power from the wave guide to the PC, mating at a 90^o angle to the coupler at the 300 K end.

The outer conductor is 152.4 mm ID at the 300 K end and tapers to 100 mm ID at the 2.15 K end where it attaches to the beam tube. The co-axial inner conductor has a similar taper, going from 66.7 mm OD to 43.5 mm OD at the beam tube end. The outer conductor is 2.4 mm thick stainless steel plated with a 15 μm copper film on the inside. About 120 mm from the beam tube end, the outer conductor mates with a niobium nipple with RRR=40 and a wall thickness of 3.2 mm. The inner conductor is solid copper with RRR=50 and wall thickness of 1.5 mm. There is a concentric stainless steel tube within the copper tube (see Fig. 1) which provides coolant for the inner conductor. Helium gas enters the ID of the stainless tube from the left of Fig. 1, passes to the right end of the PC, and returns through a 3.2 mm radial gap between the stainless and copper tubes.

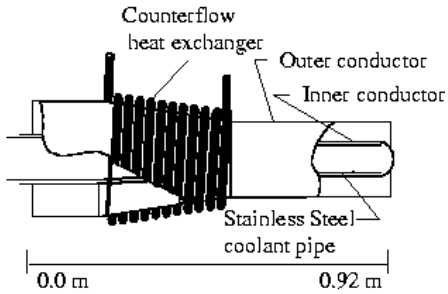

Figure 1: Schematic of the PC with a simple illustration of a counterflow heat exchanger on the outer conductor.

* Work supported through U.S. Department of Energy

The thermal model is axisymmetric, one-dimensional, and uses a finite difference approximation. There are over 200 nodes. Temperature dependent properties are used for the thermal conductivity, RF resistivity (RRR = 2, for 750 MHz), and specific heat and enthalpy of the helium gas coolant. Infra-red radiation heating is calculated assuming gray body, diffuse scattering through a CAD based program called RadCAD [1]. SINDA [2] is used for the thermal analyzer.

The heat transfer mechanisms considered for the inner conductor are:

- Conduction through copper (RRR=50)
- Radiation (gray body, diffuse, emissivity=0.3);
- RF heating (distributed or constant current); and
- Internal forced convection (supercritical helium in annular region).

The outer conductor heat transfer mechanisms considered are:

- Conduction through stainless steel (304L) and copper plating (thermal conductivity ratio=50);
- Radiation (gray body, diffuse, emissivity=0.3);
- RF heating (distributed or constant current); and
- Cooling - through localized single point thermal intercepts or distributed through forced convection counterflow cooling.

The emissivity value for copper has been chosen as 0.3. Typical values range from about 0.05 to 0.9 depending on the condition of the surface. We believe our selection of 0.3 represents a conservative choice for copper. How the emissivity will change over the 40 year life of the accelerator is unknown. The emissivity for niobium was also chosen as 0.3.

The inner and outer conductors are joined by a 1.27 mm thick copper plate at the furthest most position to the left of Fig. 1. This plate is the electrical shorting plate of the RF quarter-wave stub.

3 RESULTS

The analysis naturally divides into separate consideration of the inner and outer conductors. The temperature distribution on the inner conductor is only marginally coupled, via radiation, to the temperature distribution on the outer conductor, and hence, may be considered independent of the cooling scheme for the outer conductor.

3.1 Inner Conductor Results

The temperature distribution on the inner conductor was calculated for 210 kW traveling and standing wave (TW, and SW respectively) conditions, and for the special test condition of 500 kW TW. Figure 2 shows the RF-induced power distributions on the inner conductor for the 210 kW, 750 MHz TW and SW as calculated from MAFIA [3]. In Fig. 2, 0.0 represents the leftmost end of the PC shown in Fig. 1, and the beam tube interface is roughly at 0.92 m. Although the RF analysis shows an azimuthal power variation in addition to the axial dependence, the maximum circumferencial value of power dissipation at each axial position was chosen as a conservative and simplifying assumption. The data points show the power values as used at the individual nodal coordinates.

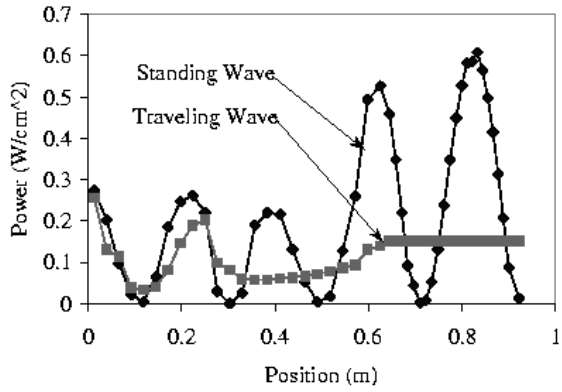

Figure 2. RF-induced heating distribution on the inner conductor for both the 210 kW standing wave and traveling wave.

Figures 3 and 4 show the resulting temperature distributions on the inner conductor and the coolant fluid, assumed to be 3 g/s, 300 K helium at 3 atmospheres at the inlet, in all cases. The temperature distributions from using a constant current with the same total power dissipation in the inner conductor are also shown.

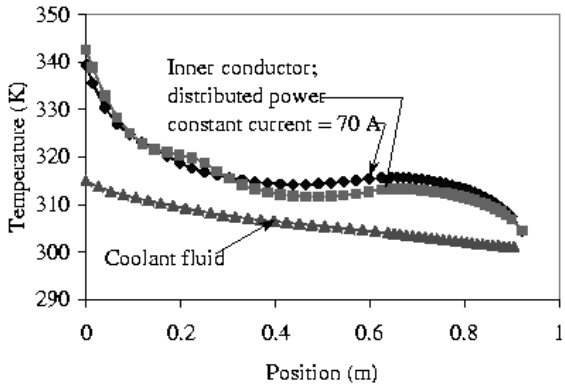

Figure 3. Temperature distribution in inner conductor (upper two curves) and cooling fluid (lower curve) for 210 kW TW. (235 W dissipated on inner conductor).

As seen in Fig. 3, the difference in temperature distribution between distributed power and constant current, is less than 5 K. The difference in the fluid temperatures for constant current vs distributed power is even less, so only one is shown in Fig. 3. The same small difference in temperature between distributed power and constant current is seen in the 210 kW SW results, Fig.4.

The results for the 500 kW TW are not plotted due to space limitations in this article. The highest temperature in the inner conductor is 365 K (at the leftmost end of Fig. 1) and the coolant fluid outlet temperature is 330 K. The results of the analysis of the inner conductor

demonstrate that, for the operating conditions considered, the inner conductor is adequately cooled.

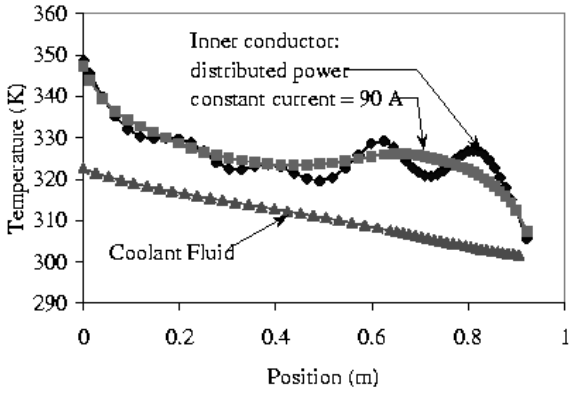

Figure 4. Temperature distribution in the inner conductor (upper two curves) and cooling fluid (lower curve) for 210 kW SW. (310 kW dissipated on inner conductor).

3.2 Outer Conductor Results

The outer conductor analysis focuses on the total room temperature refrigeration input power as a function of two different cooling approaches:

- The distributed cooling of the counterflow vs
- The localized cooling of single point intercepts.

Regardless of which cooling approach is chosen, the heat load to 2.15 K is largely determined in the niobium nipple. This may be understood by reference to the solution of the one-dimensional heat diffusion equation with constant thermal conductivity, k, and uniformly generated heat load, Q_{gen}. Equation 1 shows the solution for a Nb nipple of length, L and heat conduction cross-sectional area, A. The hot end is assumed to be at T_h, while the cold end is at T_c = 2.15 K. If the Nb is kept below its superconducting transition temperature of 9.2 K, the heat load generated in the Nb is mainly due to IR radiation = Q_{gen}. Q_c is the heat load at 2.15 K.

$$Q_c = \frac{kA}{L}(T_h - T_c) + \frac{Q_{gen}}{2} \qquad (1)$$

There is an optimum length, L, since Q_{gen} will vary linearly with L, but, generally, L is chosen for mechanical or manufacturing reasons. To minimize Q_c, A should be made as small as practical, and k should also be small, i.e. RRR should be low. Q_{gen} can be reduced by lowering the emissivity of the materials (this has been discussed in an earlier section), or the inner conductor temperature can be reduced (this will be discussed later). In a typical situation, with geometry, emissivities and inner conductor temperature fixed, T_h, and hence, Q_c, are determined by the temperature developed by the cooling configuration at the stainless steel, Nb interface. Table 1 presents the heat loads at 2 K and at the various intercept temperatures, plus the resulting room temperature refrigeration input power. For example, the third configuration, with two single point intercepts, one at 7.8 K at the stainless steel niobium interface, and the other at 56 K at the location for minimum refrigeration input power, has respective heat loads of 7 W and 23 W, and a total 310 K refrigeration input power of 3550 W. Refrigeration input power is based on real refrigerator efficiencies of 0.13 and 0.18 (0.25 and 0.27) for 2.1 K (4.6 K) liquefaction and refrigeration loads respectively. When the lowest temperature intercept is above 9.2 K, a copper strap was used to connect the stainless steel/Nb boundary to the 2.15K helium vessel, which increases the 2 K heat loads.

Table 1. Calculated heat loads at 2 K, intercept 1 at T1, and intercept 2 at T2 for point intercepts, with T2 at optimal location. Calculated 2 K load for counterflow heat exchanger for coolant inlet temperatures of 2.6 K or 4.6 K. Wtot = total refrigeration input power.

Thermal intercept configuration	**Q at 2K (W)**	**Q at T1 (W:K)**	**Q at T2 (W:K)**	**W total (W)**
1 single point	1.8	15:4.6	-	5525
1 single point	4.3	53:15	-	7570
2 single points	2.4	7:7.8	23:56	3550
2 single points	4.1	6.2:15	24:56	4400
Counterflow 2.6 K, 0.07 g/s	1.9	-	-	3070
Counterflow 4.6 K, 0.07 g/s	2.0	-	-	3371

Lowering the inner conductor temperature can reduce the 2 K radiation load, Q_{gen}, but the work required to remove the inner conductor heat load at the reduced temperature increases. Using the double point intercept at 7.8 K and 56 K as an example, the total refrigeration input power can be reduced by as much as 26% by lowering the inner conductor coolant temperature to 200 K.

4 SUMMARY

A thermal model has been built which accounts for the major heat loads in the 210 kW PC. Inner conductor results indicate adequate cooling under TW and SW conditions. There is a 14% reduction in refrigeration input power by using 2.6 K counterflow cooling on the outer conductor over the best double point cooling approach. Further trade-off studies on the outer conductor cooling scheme are required. Lowering the inner conductor temperature adds complexity to the system, but offers a 26% reduction in PC refrigeration input power.

Abstract

Millimeter-wave (mmWave) accelerating cavity structures have been manufactured using the deep x-ray lithography (DXRL) technique. These cavity structures have potential applications as parts of linear accelerators, microwave undulators, and mm-wave amplifiers. The microfabrication process includes manufacturing of precision x-ray masks, exposure of positive resist by x-rays through the mask, resist development, and electroforming of the final microstructure. Prototypes of a 32-cell, 108-GHz constant-impedance cavity and a 66-cell, 94-GHz constant-gradient cavity were fabricated at APS. Using an HP8510C 26-GHz vector network analyzer, rf measurements are being prepared with a frequency up- and down-converter before and after a test cavity structure. Preliminary design parameters for a 91-GHz multi-module klystron along with an overview of the DXRL technology are also discussed.

1 INTRODUCTION

A potential advantage of mmWave accelerators for particle physics is a higher accelerating gradient. It is known from experience with S- or X-band accelerating structures that gradients are limited by dark current capture, which is the acceleration of field-emitted electrons to relativistic energies, and by rf breakdown. The maximum gradient from these phenomena scales approximately inversely with wavelength; scaling accelerating structures to significantly higher frequencies could provide a higher field gradient as proposed by P.B. Wilson [1].

The new micromachining technology, known as LIGA, consists of deep-etched x-ray lithography (DXRL), electroplating, and micromolding. The microfabrication processes have been developed by W. Ehrfeld and co-workers to the degree that submillimeter actuators, motors, and gears can be built with great accuracy and a high aspect ratio. Electric field levels as high as 50 MV/m and magnetic field levels of 1 T have been achieved with these components [2]. Specifically, this technology could offer significant advantages over conventional manufacturing methods in such areas as precision fabrication and mass production.

The concept of applying these techniques to develop rf cavities for mm-wave linacs [3], undulators [4], free-electron lasers [5], and mm-wave amplifiers originated at Argonne National Laboratory. A meter-long structure with similar accuracy that also provides channels for vacuum pumping, adequate cooling, and focusing elements is feasible. Major challenges of the DXRL techniques are: fabrication of the wafers into three-dimensional rf structures, alignment and overlay accuracy of the structures, adhesion of the poly-methylmethacrylate (PMMA) on the copper substrate, and selection of a developer to obtain high resolution.

2 FABRICATION

The simplified version of the DXRL process is shown in Fig. 1. It consists of making an x-ray mask, preparing a sample and x-ray exposure, developing, and electroplating the structure. The process is related to the fabrication of semiconductor integrated circuits and requires similar tooling, in addition to a high-energy light source and electroplating equipment. In DXRL, no dissolution of unexposed positive thick resist is allowed during development, and good adhesion of the high-aspect ratio resist structure to the copper substrate is essential. In addition, the microstructures must have high mechanical stability and low internal stresses to prevent stress corrosion during exposure and development. Also, the resist material must be compatible with the electroplating process.

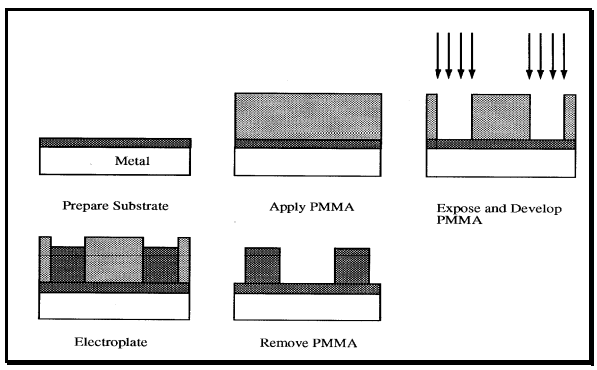

Figure 1: Simplified DXRL process.

DXRL with high-energy synchrotron radiation allows resists up to 1 mm thick to be fabricated with submicron accuracy. A high-accuracy DXRL mask was made by means of an intermediate mask--that is in two steps. The first step was the photolithography. A plating base of Ti/Au 75/300 Å was used for the e-beam writer and then a

*This work was supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Contract No W-31-109-ENG-38.

3-μm-thick layer of Au was plated on the intermediate mask. The second step used soft x-ray lithography at the Center for X-ray Lithography in Stoughton, Wisconsin (1-GeV Aladdin). For the DXRL mask, a 45-μm-thick layer of Au was plated over a 300-μm-thick Si wafer where the x-ray was exposed and the resist removed. To observe the high depth-to-width aspect ratio in the final product, micron-range structures were patterned on the DXRL mask. To avoid alignment problems and x-ray diffraction, these two steps were done on the same sample substrate without a physical gap.

PMMA up to 1 mm thick was used as a positive resist. The copper substrate was diamond-finished to have a flatness of 1 μm over 4 inches. Then either an oxide film was grown to one micron thick or an equally thick Ti coating was deposited in order to promote better adhesion to the copper substrate. Through these processes, the flatness of the copper surface is maintained, but is still rough enough to give good adhesion to the PMMA sheet, which has a roughness of less than 0.1 μm [6].

When the PMMA film was cast onto the copper substrate, it was annealed at various temperatures from 110 to 170° C for one to three hours [7]. The APS 2-BM-A beamline was used to expose the sample. The transmitted x-ray intensity was calculated based on the APS bending magnet parameters and is plotted in Fig. 2. The ratio of the top dose to the bottom dose for the 1-mm-thick PMMA is about 1.1. During the exposure, the sample was enclosed in a He-purged housing with a Kapton window, and the sample holder baseplate was water cooled. The first platinum (Pt) mirror with a grazing angle of 0.15° was used to cut off all the high-energy x-rays above 40 keV as shown in Fig. 2. More information on the APS 2-BM beamline for the DXRL can be found in Ref. 8.

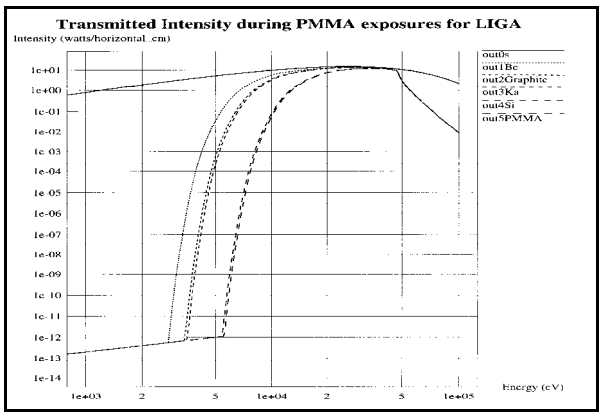

Figure 2: Transmitted x-ray intensity during PMMA exposures for DXRL at APS, energy vs. intensity.

Two different developers were used in the developing process. The first developer, so-called GG, was a mixture of 60% vol 2-(2-butoxy-ethoxy) ethanol, 20% tetrahydro-1, 4-oxazine, 5% 2-aminoethanol-1, and 15% deionized water. The allowed dose range was from 3 to about 10 kJ/cm^3. Below that threshold the crosslinked resist could not be dissolved, and above that range damage to the resist can occur from production of gases in the PMMA. The second developer was methyl-iso-butyl ketone (MIBK) diluted with 2-propanol. After developing the microstructure, copper can be electroplated to the positive resist and the surface can be diamond-finished.

3 MM-WAVE STRUCTURES

Due to DXRL's ability to maintain precise tolerances, it is ideally suited for the manufacture of rf components operating at frequencies above 30 GHz. The first two structures fabricated were a 32-cell, 108-GHz constant-impedance cavity and a 66-cell, 94-GHz constant-gradient cavity. A 32-cell, 108-GHz constant-impedance cavity is a planar accelerating structure with parameters as shown in Table 1. The change from a typical cylindrical symmetrical disk-like structure to a planar accelerating structure results in a loss in shunt impedance and Q value of less than 5%. An accelerating gradient of 50 MV/m is chosen for a practical 50-MeV microlinac application, but it is not limited to 50 MV/m when the rf system is operational in the pulse mode with less repetition rate.

Table 1: The Design rf Parameters of a 32-Cell, 108-GHz Constant-Impedance Cavity

Frequency	f	108 GHz
Shunt impedance	R	312 MΩ/m
Quality factor	Q	2160
Operating mode	TW	2π/3
Group velocity	v_g	0.043c
Attenuation factor	α	13.5 m^{-1}
Accelerating gradient	E	50 MV/m
Peak power	P	750 kW

For a constant-impedance planar structure, the double-periodic structures with confluence in the p-mode design were considered. The 2π/3-mode operation in these structures can give high shunt impedance, group velocity, and low sensitivity on dimensional errors. More detailed descriptions, such as rf simulation using the MAFIA computer code and the thermal analysis related to this structure, can be found in Ref. 9.

Constant-gradient accelerating structures are used in many present-day accelerators because of their higher energy gain and better frequency characteristics, such as higher shunt impedance, more uniform power dissipation, and lower sensitive to frequency deviations, when compared to the constant-impedance structure. Tapering the cells along the structure while keeping the gap and cell depth constant is difficult. Since the structure needs to be manufactured on a planar wafer, adjusting the cell width and length while maintaining a constant depth within the structure is necessary. Figure 3 shows the constant-gradient structure with cuts in the irises; its rf parameters can be found in Ref. 10.

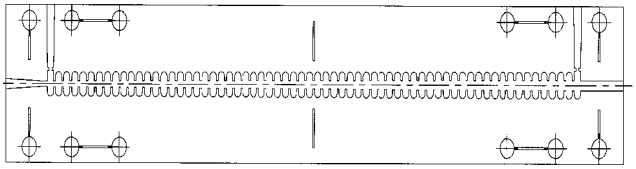

Figure 3: The 66-cell, 94-GHz constant-gradient cavity: side-coupling for mm-wave transmission and circled hole for the alignment.

4 KLYSTRON DESIGN

The mm-wave amplifier is designed to meet a pulsed klystron operating at a high voltage, high current, by combing multi-cells and multi-modules as shown Figure 4 [11]. Beam optics become easier and permanent periodic magnet (PPM) focusing is possible. A higher efficiency also results, because of the low beam perveance. A number of klystrons can then be fabricated on a single substrate, using a deep-etch lithography technique. They can be water-cooled individually and operated in parallel. Several such modules can be stacked to form a klystron "brick," requiring a relatively low voltage for the peak and average power produced. The brick can be provided with a single output, or with individual, spatially combined radiators. The klystron consists of a 4×10×l.5-inch module producing 500 kW peak, 500 W average at 91 GHz, operating at 120 kV, 10 A in total. Its main parameters are summarized in Table 2.

Table 2: Detailed Klystron Design Parameters

Frequency	9l GHz
Voltage	120 kV
Current	2.5 A
Perveance	0.06×10^{-6}
Output power	125 kW
Pulse length	1 μs
Drift tube diameter	0.8 mm
Beam diameter	0.5 mm
Cavity gap length	0.4 mm
Brillouin field	2.7 kG
Cathode current density	15 A/cm^2
Magnetic period	6 mm
Duty cycle	0.1%
Beam area convergence	85:1

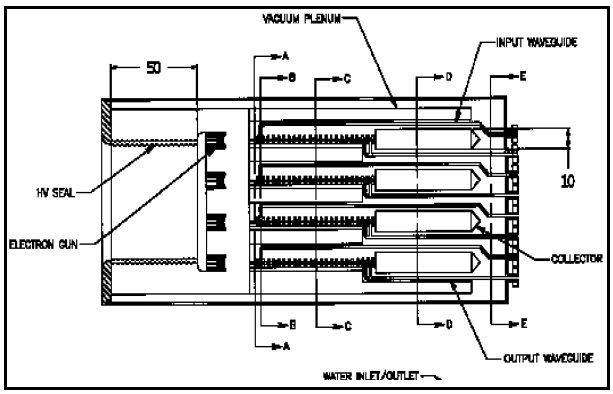

Figure 4: Four-klystron module layout.

The cathode loading and beam convergence parameters are quite conservative, except for the low perveance and PPM focusing. The beam voltage is very high for the power produced by a single klystron due to the low perveance required for PPM focusing (and for good efficiency). However, it is the PPM-focusing feature that makes the module design and tube paralleling possible.

5 SUMMARY AND FURTHER WORK

The final electroplated structure for the prototype of the 108-GHz constant-impedance cavity is shown in Fig. 5. The size of the cavity cell appears to be a few microns off from the design, but the size is controllable by adjusting the x-ray mask to meet the specification. The roughness and flatness of the sidewall of the cavity cell were measured to be 0.05 μm and 2 μm, respectively.

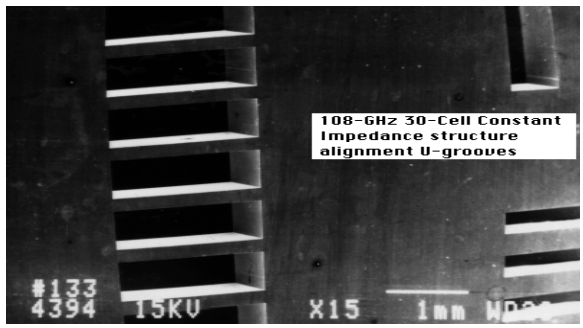

Figure 5: Scanning electron microscopy picture of the 108-GHz constant-impedance cavity structure.

Two mirror-imaged fabricated structures were aligned and measured on a network analyzer. The initial measurement of the quality factor is about 800, which is only 40% of the calculated value. The main contribution to the low value of Q is the MIBK chemical processing used to make the sample above. When the GG chemical was applied to develop the sample, the contrast between the exposed area and unexposed area was at least one order of magnitude higher than MIBK. The metallurgical study of the copper-electroplated sample shows that the level of oxygen in the sample appears to be too high. The electroplating process must be improved so that the structure can sustain against the vacuum and high-power rf.

Abstract

This paper reports the development of 350 MHz niobium superconducting cavities for the velocity range $0.2 < v/c < 0.6$. Such cavities could be used to form a linac of exceptional flexibility, capable of efficiently accelerating beams of either protons, deuterons, or any of a wide range of light ions, at intensities sufficient for a production beam for a radioactive beam facility. Results of numerical modeling for several resonator geometries are presented. The design and construction status of prototype niobium cavities is discussed.

1 INTRODUCTION

For more than a decade, various concepts for an ISOL-type (isotope separator on-line) radioactive ion beam facility have been developed and discussed within the nuclear physics community [1,2]. The Argonne Physics Division several years ago put forward a concept requiring a linac for protons and light ions as a driver for spallation sources [3]. As initially proposed, the driver linac would be a fixed velocity profile, 220 MV, normally-conducting linac which could provide various beams of protons or light ions at a output energy of 100 MeV per nucleon with a total beam power of 100 kW. The different beams would be used in a variety of different production mechanisms.

To be cost-effective, however, a normal-conducting linac would have several limitations. To maximize shunt impedance, the velocity profile would need to be fixed. Consequently, for the lighter ions, particularly protons, the linac would have to be operated at substantially less than its maximum gradient. Also, operation would be pulsed, at 120 Hz, with a duty factor of at most a few percent. This mode of operation would aggravate heating problems in the spallation source and might also make voltage stability of the radioactive ion source problematic.

These limitations could be overcome by making the driver linac superconducting [4]. In this case, shunt impedance would not be a strong consideration, and the linac could be formed of short independently-phased cavities. The resulting broadly variable velocity profile would enhance performance, for example roughly doubling the maximum proton energy.

A superconducting linac would provide for cw operation, which would be advantageous in several respects beyond that of reducing target heating transients. Requirements for the injecting ion sources would be simplified. The reduction of space charge effects could provide for increased beam currents, opening, for example, the possibility of driving several targets simultaneously.

However, to date little development work has been done on superconducting cavities with the characteristics required for such a machine, most particularly in the upper part of the required velocity range . Before such a machine can be designed in detail, suitable cavities need to be fully developed and characterized.

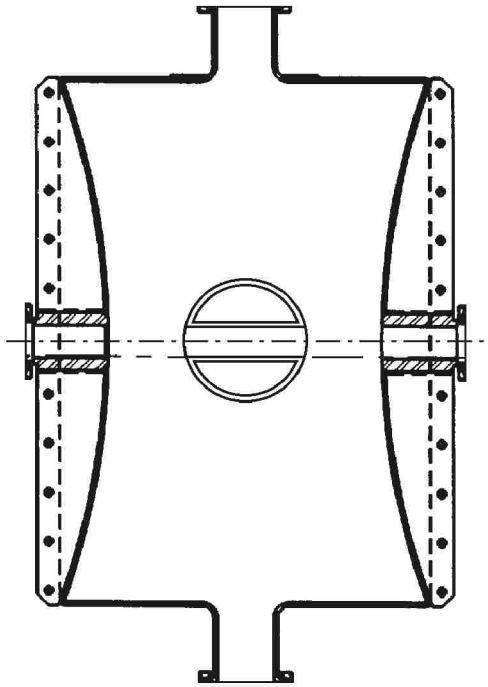

Figure 1: Section for a 44 cm diameter, 350 MHz spoke cavity

Medium-beta cavities are currently being developed for protons of 200 MeV and higher energies, in the form of foreshortened versions of the multi-cell elliptical cavities long used for electron acceleration [5]. The present application, however, is aimed at energies below 200 MeV, and the cavities required would be excessively foreshortened, with several adverse consequences. To obtain a reasonable accelerating voltage, particularly in single or double cell structures, cavities of adequate length would require large diameters, approaching a meter. Construction, handling, and cryostat design would all be rendered more difficult. Also, the mechanical stability of such large, highly foreshortened cavities would be marginal.

For the present application, a more promising geometry is the spoke resonator, which has been successfully prototyped in the form of an 855 MHz, single-cell superconducting niobium cavity [6, 7]. For the linac contemplated here, a substantially lower frequency is desirable. As will be shown below, a frequency choice in the range 300-400 MHz can provide for increased voltage, larger beam aperture, and enable higher operating temperatures. This frequency range differs nearly a factor of three from the single spoke cavity tested to date. Further prototyping is required to establish reliable estimates of the performance of the needed structures.

We have evaluated several possible configurations. In what follows, we discuss parameter choices for several prototype cavities, describe the resulting designs, and report the status of construction and tests.

2 PROTOTYPE CAVITY DESIGN AND CONSTRUCTION

The spoke resonator, in either single or double cell configuration, has a broad enough velocity acceptance

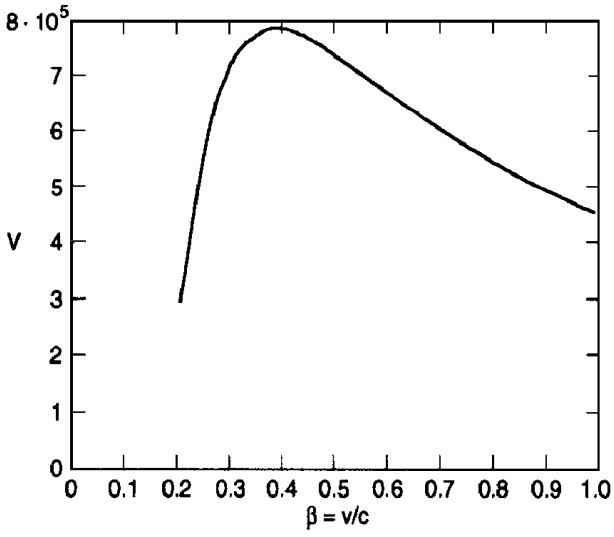

Figure 2: Velocity acceptance characteristic for the two-gap, $\beta = 0.4$ spoke cavity. The voltage gain is given in volts for an rf energy content of 1 joule, corresponding to an accelerating field of 3.4 MV/m in the 22.9 cm long structure.

Table I: Calculated and measured parameters for the $\beta = 0.4$ prototype niobium spoke cavity

Parameter	Calculated	Measured
Frequency	351.89 MHz	348.56 MHz
Active Length	-	22.9 cm
Q (niobium)	5491	5223
U_0*	80.4 mJ	85.3
Peak Electric Field*	4.0 MV/m	-
Peak Magnetic field*	107 Gauss	-
Optimum β (v/c)	0.40	0.39

* At an accelerating field of 1 MV/m

that for the linac contemplated here only two different types of structure are required to cover efficiently the velocity range $0.2 < \beta = v/c < 0.7$ [4]. We need consider only the velocity range above 0.2c, since many resonator types have been successfully developed for the velocity range below 0.2c [8].

The prototype design, shown in Figure 1, was chosen to minimize the number of sheet-metal forming dies required. To further minimize time and cost, we form spoke cavities for two different velocities by changing only the cavity length and spoke diameter.

The cavity housing is formed from 1/8 inch sheet, and the central spoke of 1/16 inch sheet niobium. The 17 inch diameter bulkheads at either end are dished inwards by 1.2 inches to reduce cavity deformation under external pressure. However, numerical finite element analysis indicated that to obtain adequate mechanical stability, a series of support ribs should be welded to the bulkhead exterior, as shown in Fig. 1.

The 2.5 cm diameter beam aperture could be increased with little effect on either energy gain or peak surface electric field. The two coupling ports provide access for vacuum and rf coupling, and also for chemical processing.

2.1 Prototype Cavity for $\beta \geq 0.4$

The first of the two prototype cavities is sized for an optimum particle velocity $\beta = 0.4$ and is shown in Figure 1. The active length of the structure, *i.e.* the interior distance between beam ports, is 22.9 cm. The diameter of the central spoke is 10 cm.

The electromagnetic properties of the prototype cavities have been calculated by numerical modeling using MAFIA. In Table 1 the calculated values are compared with values measured for the recently completed prototype $\beta = 0.4$ niobium cavity.

Figure 2 shows the voltage gain as a function of particle velocity through the two-gap cavity, for an rf field level corresponding to an energy content of one joule. The broad velocity acceptance of the structure makes it particularly suitable for the present application.

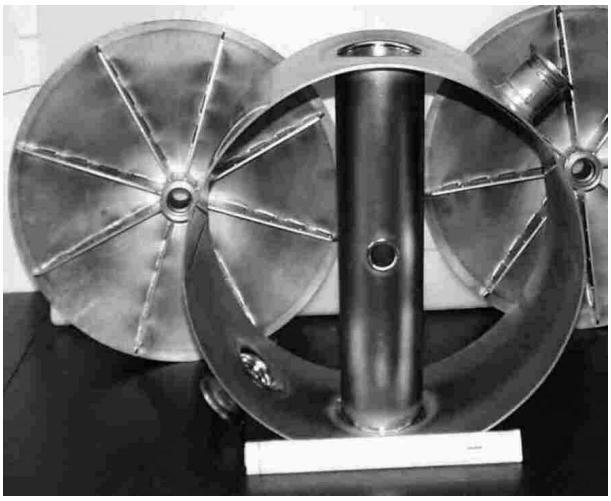

Figure 3: Elements of the prototype niobium cavity just before closure welds attached end sections to the spoke mid-section. A twelve-inch scale is shown.

2.2 Prototype Cavity for $\beta \geq 0.29$

Also under construction is a prototype cavity sized for an optimum particle velocity β = .29. The cavity differs from that shown in Fig. 1 in that the active length is shortened to 18 cm, and the diameter of the central spoke is reduced to 6.25 cm. For use in a linac, the cavity diameter would need to be reduced slightly to bring the frequency to 350 MHz to match the β = .4 cavity. But for purposes of evaluating resonator performance, the slightly lower frequency that results from using the same tooling as for the higher velocity cavity is of no consequence. Table II details the main parameters of the cavity. As in the section above, the electromagnetic properties shown are the results of numerical modeling (MAFIA).

3 RESULTS AND CONCLUSIONS

Designs for spoke cavities operating at 350 MHz have been developed which have low rf losses and low peak surface fields. Room temperature measurements have been made on the recently completed β = .4 cavity, and are compared in Table I with the design values. The measured Q agrees well with the calculated value, confirming that the rf losses for these structures are quite low. With niobium surfaces of good, currently attainable quality, i.e. residual resistivity of 10 nΩ or less, economic operation of the 350 MHz structures at 4.2 K should be feasible. Also, preliminary indication that the mechanical stability of the β = .4 structure is very good.

Plans for further work include finishing the β = .29 prototype, which is nearly complete, and performing low temperature tests of both prototypes. The major remaining question for these cavity designs is the nature of multipacting and other electron loading properties, which can be resolved only by cold tests.

Table II: Parameters for the β = 0.29 Prototype Niobium Spoke Cavity

Parameter	Design Value
Frequency	338.05 MHz
Active Length	18.0 cm
Q (niobium)	5384

A TAPERED DAMPED ACCELERATING STRUCTURE FOR CLIC

M. Dehler, I. Wilson, W. Wuensch
CERN, Geneva, Switzerland

Abstract

A new 30 GHz multibunch accelerating structure incorporating both damping and detuning has been designed for the Compact LInear Collider (CLIC). Each cell of the 150-cell structure is damped by its own set of four radial waveguides resulting in a *Q* of 16 for the lowest dipole mode. A simple linear taper of the beam-pipe dimension provides a detuning frequency spread of 2 GHz (5.4%). Predictions of the transverse wakefield levels in this structure have been made using both uncoupled, and two-band coupled equivalent circuit models with non-perfect loads. The short-range wakefield has been calculated to be about 1000 V/(pC.mm.m) decreasing to less than 1% at the second bunch (0.67 ns) and with a long time level below 0.1%.

1 INTRODUCTION

The CLIC study of a 0.5 to 5 TeV $e^{\pm}$ linear collider [1] proposes the use of 30 GHz normal-conducting structures operating at high accelerating fields (100 to 200 MV/m) to reduce the length and, in consequence, the cost of the main linacs. In order to reach the required luminosities (10^{34}-10^{35} cm^{-2} sec^{-1}) it is necessary to accelerate and collide multiple bunches per RF pulse. The present CLIC parameter list has 150 bunches each with 4.10^{9} particles spaced at 0.67 ns.

The luminosity that can be achieved depends strongly on the vertical emittance at the interaction point. The main source of emittance dilution in CLIC comes from the strong transverse wakefields produced by the accelerating structures. Beam dynamics simulations show that transverse wakefield levels of about 1000 V/(pC.mm.m) decreasing to less than 1% at the second bunch and continuing to decrease thereafter, are required to limit the vertical emittance blow-up along the linac to reasonable values [2]. These wakefield levels cannot be obtained by detuning only, because of a limited bandwidth and recoherence effects [3] nor by a combination of detuning and light damping as proposed for NLC [4]. The required levels were obtained using a structure with four T-cross-sectioned damping waveguides per cell terminated by perfect loads [5]. This structure was considered too difficult to fabricate. It became evident that the problematic stem of the T-shape waveguide could be eliminated if the beneficial detuning effects of a quasi-constant gradient structure were included in the analysis. This has finally resulted in a multi-bunch structure design suitable for CLIC.

2 THE TAPERED DAMPED STRUCTURE

The new structure geometry is shown in Fig. 1. It incorporates both damping and detuning, but does not rely on a high degree of optimization of either. Each cell of the 150-cell structure is damped by its own set of four radial waveguides. The damping waveguides have a rectangular cross-section (4.5 mm x 1.39 mm) with a cut-off frequency above the 30 GHz fundamental but below all higher-order modes. Higher-order mode energy propagates out via the waveguides to small individual RF loads. A taper of the iris dimension from 3.5 mm to 4.5 mm provides a detuning frequency spread of 2 GHz (5.4%) for the lowest dipole mode which helps to decrease the roll-off time. The detuning also plays an important role in reducing the levels of all higher longitudinal and transverse modes.

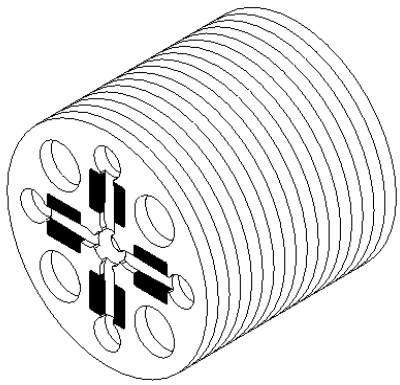

Figure 1: 30 GHz Tapered Damped Structure.

The transverse wakefield of the standard CLIC structure without damping or detuning is dominated by the lowest transverse passband with the higher bands contributing at the 5-10% level. The damping waveguides produce a $Q < 20$ for the lowest dipole band and a $Q \approx 100$ for the next transverse band. The synchronous mode of the lowest band propagates with a velocity of 3% of the speed of light and is attenuated by 5×10^{-3} per cell. The energy does not propagate very far along the structure so the behaviour of this mode can be estimated very well using an uncoupled model.

2.1 Uncoupled-cell analysis

A good estimate of the transverse wake behaviour can be obtained from a simple RLC lumped-element single-cell circuit analysis of the lower band. The values of *L* and *C* were chosen to make the circuit resonant at the

synchronous frequency of the equivalent undamped constant impedance (CI) structure with $2a$ = 4mm. From [5] it is known that a Q of 16 is obtained for this mode for the chosen waveguide dimensions. Below cut-off the Q is assumed to be 4000 (the Q of an undamped cell). These effects were simulated in the circuit by an abrupt change of R at cut-off. The Fourier transform of the frequency response of this circuit gives the wakefield time response (Fig. 2). It can be seen that the wakefield does not always decrease exponentially-the long range wakefield is affected by the waveguide cut-off.

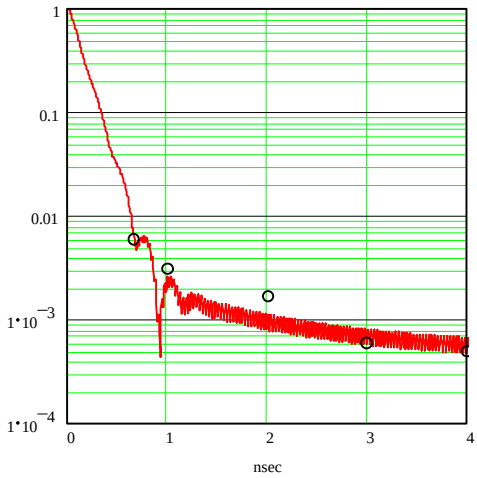

Figure 2: Normalised wakefield using only damping for single-band uncoupled model with perfect loads.
(o MAFIA analysis).

Results from a complete MAFIA time-domain multi-cell analysis of the T-waveguide damped CI structure with perfect loads [5] are given in Fig. 2 for comparison. The stem part of the T-waveguide takes out the contribution to the wake of the upper band. The simple model predicts the basic behaviour very well.

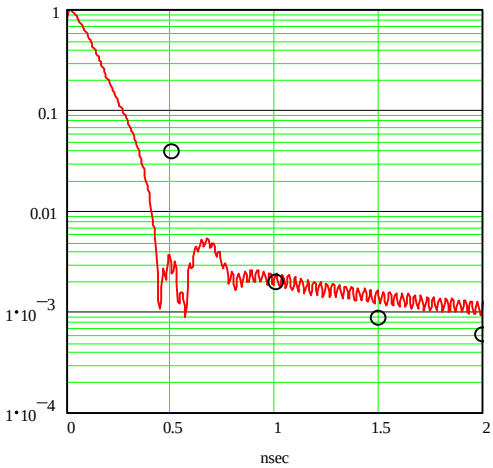

Figure 3: Normalised wakefield with damping and detuning for single-band uncoupled model with perfect loads. (o Two-band coupled-cell results)

The effects of detuning were included by adding the responses of 150 different circuits covering the detuning range ($2a$ = 3.5 mm to 4.5 mm). The wakefield for these damped-detuned uncoupled cells is given in Fig. 3 together with results obtained from a complete two-band coupled-cell analysis (see Section 2.2). To improve the overall model, the upper band of the first pass band which contributes at the 5-10% level to the undiluted wake was treated in the same way as the lower band. The waveguides damp this primarily TE-like mode to a $Q \approx 100$ which alone results in a wakefield level at the second bunch which would be too high. The level is however further reduced by the detuning. As done previously, the responses of 150 different circuits covering the detuning range ($2a$ = 3.5 mm to 4.5 mm) were added to produce the wakefield shown in Fig. 4.

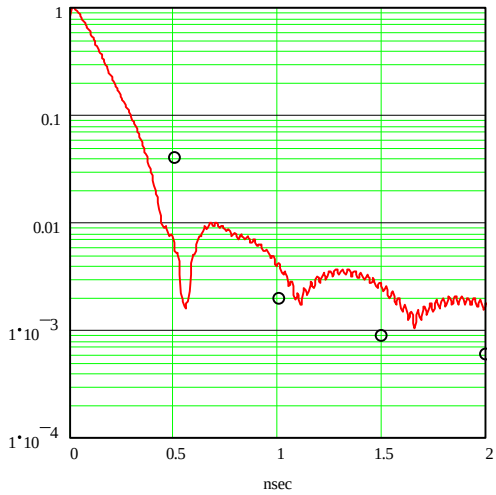

Figure 4: The normalised wakefield with damping and detuning for the double-band uncoupled model with perfect loads. (o Two-band coupled-cell results)

2.2 Coupled-cell double-band analysis

A complete double-band coupled-cell analysis of this new structure has been made using a more complete equivalent circuit model [6]. The damping waveguide, which couples only to the TM part of the circuit, is modeled by a resistor in parallel with the TM inductance. The waveguide load is incorporated into the circuit directly in the form of a table of scattering parameters calculated by MAFIA. The determination of the damped circuit parameters follows the procedures of Bane and Gluckstern [7] for the detuning, and Kroll and Yu [8] for the damping. Circuit voltages are determined as a function of frequency and phase advance by the spectral function method [9]. Calculation of the transverse wakefield from the results of this circuit analysis is not straightforward. For high-Q structures the beam sees a real transverse impedance only at discrete frequencies which are synchronous with the velocity of

light. For low-*Q* structures the resonances spread out such that there is interaction with the beam over a continuous range of phases and frequencies. In this case, the usual Brillouin diagram has to be replaced by a two-dimensional broad-band impedance function depending on frequency and phase advance.

For this particular analysis, the detuning distribution used was not quite linear - it had slight rounding at the ends to improve the long time response, and a conservative value $Q = 200$ was used for the upper-band damping (MAFIA results gave 80 to 130). The load consists of two SiC slabs which sit in the side walls of the waveguide (see Fig. 1) giving a good absorption behaviour close to cut-off. The reflection coefficient data obtained from a MAFIA analysis of this load assuming a dielectric constant of 30 and a loss tangent of 0.5 for all frequencies is given in Fig. 5. The calculated transverse wakefield is given in Fig. 6. The levels obtained are below those determined by beam dynamics simulations for beam stability and good emittance preservation in the CLIC main linac.

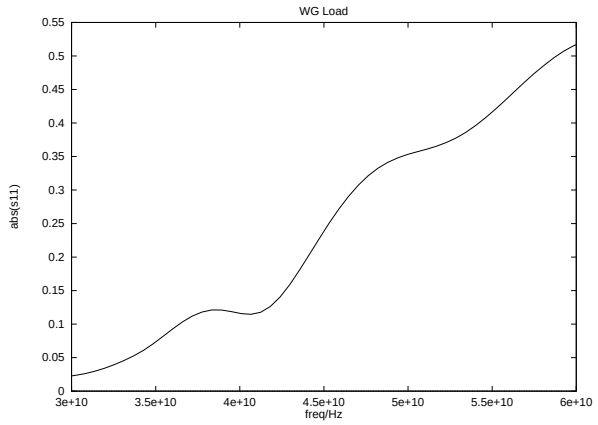

Figure 5: Reflection coefficient versus frequency.

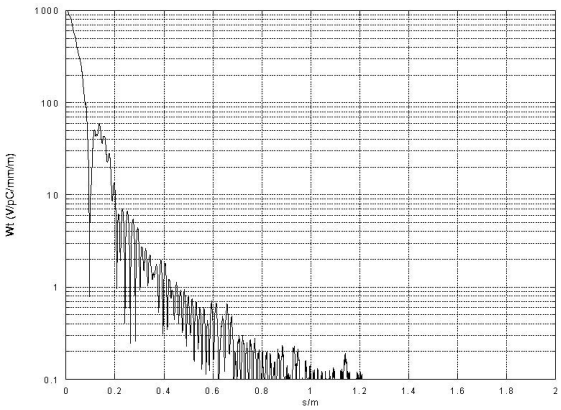

Figure 6: The wakefield obtained for the double-band coupled model plus RF load.

3 CONCLUSIONS

A 30 GHz tapered damped accelerating structure has been designed for CLIC which gives very low transverse wakefields. The wakefield behaviour has been analysed by simple single-cell equivalent circuits assuming perfect loads, and by a very complete two-band coupled-cell analysis with a real load. The single-cell analysis provides a quick and simple way to calculate the wakefield envelope with sufficient accuracy to establish, and study the influence of changing basic design parameters such as the damped *Q*, detuning range, waveguide cut-off frequency and number of cells. The full analysis is however essential for a detailed design. Cold model tests are presently underway to confirm the calculated values, and prototype structures are foreseen. In particular, it is planned to build an X-band scale model for tests in the ASSET facility at SLAC.

Π/2 INTERLEAVED CAVITY DEVELOPMENTS FOR THE MUON COLLIDER COOLING EXPERIMENT

A. Moretti, FNAL, Batavia, IL USA
J.N. Corlett, D. Li, W.C. Turner, LBNL, Berkeley, CA, USA
H. G. Kirk, R.B. Palmer, Y. Zhao, BNL, Upton, NY USA

Abstract

In this paper we discuss the development of a π/2 interleaved standing wave linac for the proposed muon cooling experiment. The nominal beam momentum is 186 MeV/c (beta=0.87). Each muon cooling channel section contains a 1.3m rf accelerating linac separated by 0.64m of liquid hydrogen absorbers immersed in a alternating superconducting solenoidal magnetic transport line. Instead of conventional open cavity beam apertures, the 805 MHz linacs have thin Be windows covering the iris apertures. The accelerating cavities closely resemble pillbox cavities and have little or no field enhancement due to iris aperture corners. Further, since the peak field is on the axis, the shunt impedance is about a factor 2 larger than conventional designs. It is also proposed to cool the cavity to liquid nitrogen temperature to reduce the losses and increase the shunt impedance. Our π/2 interleaved cavity design is essentially two chains of side coupled π/2 cavities interleaved to form a continuous chain of accelerating cells on the beam axis. Each accelerating cell has a phase advance of π/2 and, therefore, a favorable transit time factor. This paper will discuss the design of the cavity, MAFIA calculations, low-power rf model cavity measurements, low-temperature effects with Be windows, design of high-power rf test models and a proposed high-power rf test facility.

1 INTRODUCTION

Studies of muon colliders have been going on for about five years and more recently a international collaboration has been formed to study the feasibility of muon colliders for high energy physics research. The collaboration is focused at BNL, Fermilab, and LBL [1,2]. For a practical high-luminosity collider, large numbers of muons must be produced and transported through the collider complex. Because of the short lifetime of the muon, this must be accomplished very quickly to minimize loss of muons and to preserve the machine luminosity. The muons are generated from the decay of pions produced in proton-nucleus interaction in a high-Z target and collected in a solenoidal decay channel. This produces muons with a large initial phase volume which must be reduced (cooled) quickly by several orders of magnitude. The technique of ionization cooling has been adopted to reduce the phase-space volume of the muons. In this technique, muons lose both transverse and longitudinal momentum while passing through low-Z material and the longitudinal momentum is then restored by acceleration in rf cavities. This process is repeated numerous times to reduce the phase-space volume sufficiently for acceptance by the acceleration system of the collider complex.

After studying a number of cavity designs, the interleaved π/2 side coupled cavity, Fig. 1, with thin (125 μm) beryllium windows over the cavity apertures was selected [3,4,5]. This design resembles a pillbox cavity and achieves a high shunt impedance over the required large beam aperture (16 cm). The peak accelerating electric field and maximum surface field are identical. This gives a maximum possible accelerating field limited only by electrical breakdown. In addition, the π/2 interleaved pillbox design gives a transit time factor of 0.90. This design has the highest group velocity (being in the center of the passband) and is more tolerant of dimensional errors, beam and mechanical perturbations. The pillbox design is made possible because of the low scattering rate of muons in matter, especially low-Z beryllium. Further, the cavity is to be cooled to liquid nitrogen temperature to increase the shunt impedance by about a factor two and reduce the large peak power requirements of the muon cooling channel. This feature requires the design of bi-metallic transitions between the copper cavity walls and Be window foils to compensate for differences in the material thermal expansions and keep the window flat during cool-down and operation. Also, the high group velocity of the π/2 mode will make it more tolerant of thermal distortions during cool-down and operation.

2 RF CAVITY DETAILS

The cooling channel rf cavity details are shown in Fig. 1. It is a 805 MHz interleaved side-coupled π/2 cavity. (The same frequency as the Fermilab Upgrade Linac commissioned in 1993.) The interleaved design was chosen over the more conventional side-coupled cavity design because of its larger shunt impedance (ZTT=38MOhm/m and Q=19,600 from MAFIA calculations). The conventional design, because of the required large beam aperture of 16 cm, had a ZTT about a factor two smaller. The operating principle can be understood with reference to Figs. 1 and 2.

The upper part of figure 1 shows cells labeled C coupled together to form a side-coupled cavity while the cells labeled D form another independent side-coupled cavity. Structures C and D have been designed with the computer program MAFIA to resonate in the π/2 mode and are excited with high fields in the on-axis accelerating cells

*Supported by the US DOE under contract numbers DE-AC03-76-SF00098, DE-AC02-76-CH00016 and DE-AC02-76-CH03000.

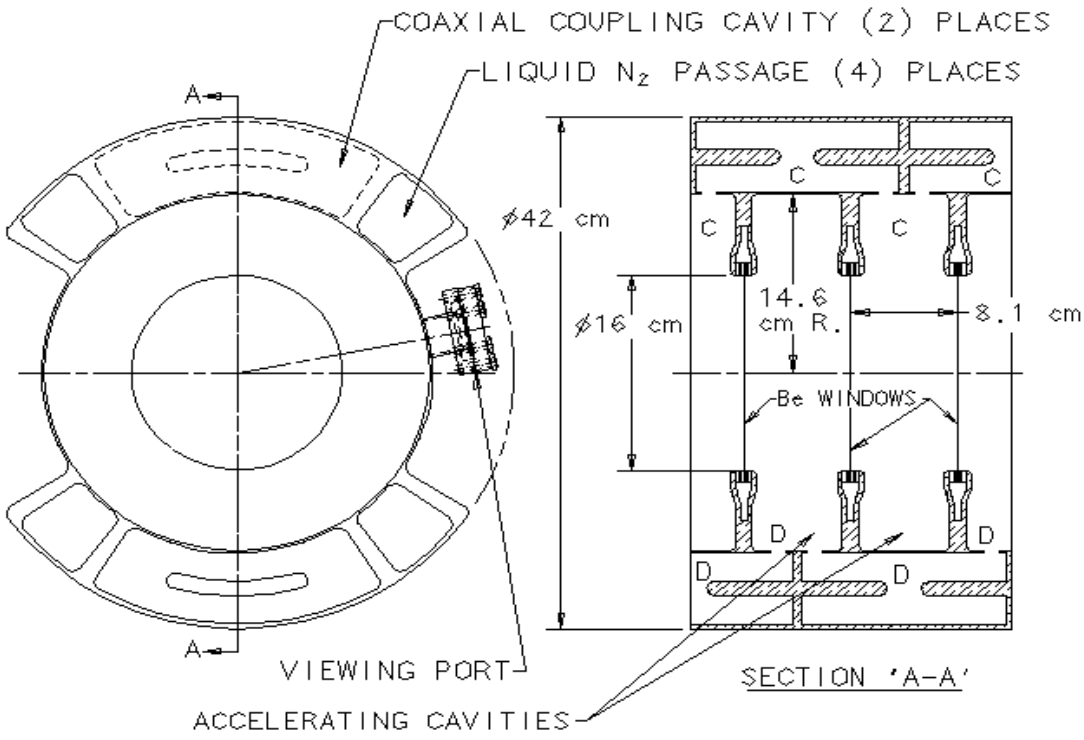

Figure 1: $\pi/2$ Interleaved Cavity Cross Section

and near zero fields in the off-axis coupling cells. The on-axis cells of the C structure and the D structure each have a phase advance of π per cell, but together have the transit time factor of 0.90 of a $\pi/2$ mode cell rather than 0.637 of a conventional side-coupled structure. Fig. 2 shows the method of excitation. Two independent waveguides are slot coupled to adjacent accelerating cells and are driven $\pi/2$ apart in phase through a 90 degree waveguide hybrid.

Figure 1 gives some details of the bi-metallic transition between the outside cavity iris walls and the central 125 μm Be foil. Because of the large difference in thermal expansion between copper and beryllium from room temperature to liquid nitrogen temperature, a buffer material must be used to bridge this difference. Large distortions will otherwise occur resulting in detuning of the cavity and distortions in the required fields. Molybdenum has been chosen as the buffer material. Its Young's modulus is about the same as Be and three times that of copper at room temperature. Its thermal expansion coefficient is about 30% less than Be. With proper design (ANSYS calculations are under way) this should result in slight tension on the Be foil and keep it flat at liquid nitrogen temperatures. Keeping the foil flat will preserve the cavity tune and field flatness. This is illustrated by the rings of different material surrounding the Be window foils in Fig. 1.

3 EXPERIMENTAL STATUS

The design of a low-power three cell test cavity has been completed at LBL using MAFIA. Copper for the cavity has been ordered by the University of Mississippi where the final machining will be done. Testing of this cavity to liquid nitrogen temperature will take place at LBL in the next few months. Studies of the electrical properties of Be at liquid nitrogen temperature are underway at BNL and Mississippi. A high-power three cell cavity is currently being designed at LBL. This cavity will also be machined at Mississippi and then tested at low power at LBL. A high-power 805 MHz test facility is now being planned at Fermilab. It will use a high-power Litton klystron and a Fermilab built modulator to produce up to 15 MW of rf power for 50 μs at 15 Hz. Testing will take place to determine the upper power limit of the klystron. The cavity will be put in a pair of 5.5T superconducting solenoids to simulate the alternating solenoid environment of the cooling channel. The solenoids are being designed and built at LBL and will be shipped to Fermilab as part of the test facility.

Abstract

The new injector PIAVE (Positive Ion Accelerator for Very low Energy) will use two bulk niobium (Nb) superconducting RFQs (SRFQ1 and SRFQ2), which will be operated at 80 MHz. The electrode length of SRFQ1 is about twice as long as the being built SRFQ2 thus requiring an EBW vacuum chamber larger than the previously available one. A principal decision was hence taken to split the electrodes and the tank into two parts. A half-scale room temperature model was built at LNL in order to test RF characteristics of the structure and to determine its exact dimensions. Results of the model measurements and M.A.F.I.A. code simulations are presented.

1 INTRODUCTION

PIAVE injector is now under construction at LNL for the superconducting (SC) linac ALPI. The beam, generated by an ECR source, will be bunched by a three harmonic buncher and accelerated by two SC RFQs, followed by eight SC QWRs, for an equivalent voltage of 8 MV (U^{+28} beam) [1]. The cavity design of both SRFQ1 and SRFQ2 is based on the 4-rod structure with 90°-apart-stem arrangement [2]. The components of the cavities will be manufactured from 3 mm thick niobium (Nb) sheet and will be assembled by electron beam welding (EBW). SRFQ2 is being already manufactured in LNL [3]. A design of SRFQ1 was done based on the M.A.F.I.A. code simulation for the case of unmodulated electrodes [4]. Since SRFQ1 electrodes are about twice as long as those of SRFQ2, it is impossible to weld them in the EBW vacuum chamber used for SRFQ2. We decided to split the vanes and the tank into two parts. Finally the two tanks will be welded by EBW into a single cavity. The cutting point of the unmodulated electrodes should be at the center between the stems (the point of zero longitudinal current) in order to minimize the field disturbance of the gaps. However, for modulated electrodes, the point should be slightly shifted to the position of electric field minimum closest to the position of zero longitudinal current. Since the welding of the electrode tips is technically impossible, a 1 mm gap between electrode parts is foreseen. RF contact between them will be provided by welding only proper Nb strips to avoid mode disturbance.

A half scale aluminum model of SRFQ1 with modulated electrodes was constructed having the goal:

1) to determine the tank diameter for the required resonant frequency;

2) to optimize the stem position in order to obtain proper field distribution;

3) to test the effect of the vane cutting and the strip connecting the gap;

4) to determine alignment error tolerance.

2 ALUMINUM MODEL DESIGN

The model (Fig.1) allowed easy access to the central part of the structure and hence proper alignment of the electrodes.

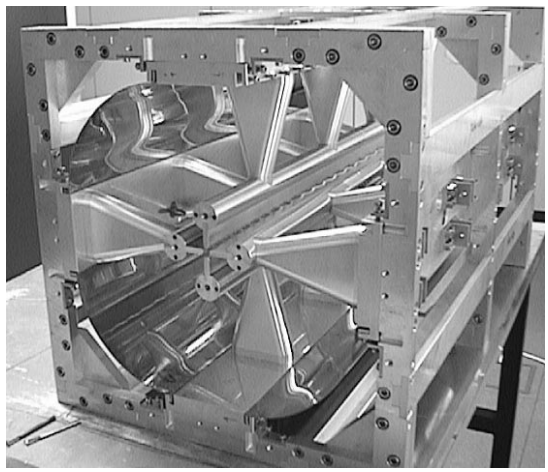

Figure 1: View of the half scale model of SRFQ1 (end flanges and one of the shells are not installed)

It is first assembled in 4 parts by means of longitudinal and transverse aluminum bars. The assembling procedure of the structure was the following.

At first each 1/4 structure was assembled independently: four stems, supporting the split (with 0.5 mm gap) electrode were installed onto the longitudinal bar and fixed. Then four such parts were assembled with respect to an external frame and aligned. After that four copper cavity shells were slided into proper slits with good RF contact. Finally two end flanges closed the structure. The first alignment procedure was the longitudinal positioning of the electrodes. Transverse positioning of the electrodes was obtained with respect to reference planes manufactured on each electrode.

Positioning of the electrodes was provided with an accuracy of $\pm$ 25 μm.

3 RESULTS OF MEASUREMENTS

3.1 Resonant frequency, Q-factor and mode separation

A comparison between M.A.F.I.A. simulations, performed using unmodulated electrode because of mesh number constraints, and measurements (modulated electrodes) is shown in Table 1.

Table 1 : RF parameters of the model

	M.A.F.I.A. simulations	Measurements
Frequency of quadrupole mode [MHz]	158.038	158.546
Q-factor	7400	3700
Frequencies of dipole modes [MHz]	181.169	178.197 179.440
Capacitance [pF/m]	141	_

As it can be seen from Table 1 simulated value of the quadrupole mode frequency for unmodulated electrodes is slightly lower than measured one with modulated electrodes, but it should be higher since the modulation results in lowering resonant frequency. It means that the simulation underestimated the frequency value mainly because of the unavoidable roughness of the mesh size in the simulation, especially around the vane tips. The modulation of the electrodes can result also in tilt of the longitudinal inter-electrode voltage distribution due to a change of inter-electrode capacitance, since modulation factor changes from 1.2 to 2.8. Instead of direct simulation of the version with modulated electrodes we calculate the capacitance variation along the regular channel of the structure for several cells by means of M.A.F.I.A. static solver. The input geometry used for calculation included one cell with vane tip and cilindrical part of the electrode. Figure 2 shows results of the calculations.

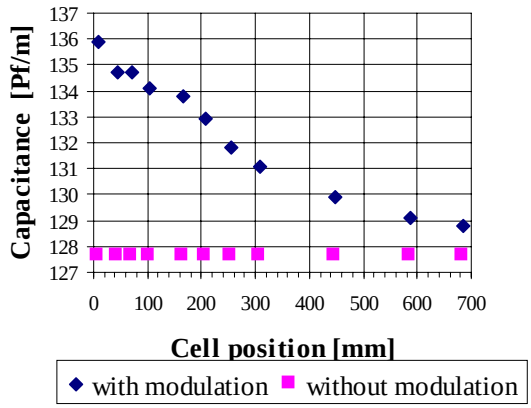

Figure 2. Inter-electrode capacitance variation

The effect of frequency shift due to the modulation was estimated to be 2.7 MHz ($\delta f = (f*\delta C)/(2*C_t)$, where C_t - total capacitance of the RFQ, and δC is change of it.

Measured frequencies of the dipole modes are split owing both to electrode modulation and to not ideal alignment. The frequency separation between the qudrupole mode and dipole ones is about 20 MHz. For 80 MHz Nb SRFQ1 it will be 10MHz, but it is enough to prevent the mode mixing. Measured Q value is also lower than simulated one due to not ideal RF joints.

3.2 Field distribution measurements

Measurements of the fields were carried out by means of standard bead-pull technique. We used for transverse field measurements a plexiglas bead (6 mm in diameter) and for longitudinal ones an aluminium cylindrical rod (1 mm in diameter and 3 mm in length). The inter-electrode voltage distribution (transverse E) along the structure was measured for each pair of neighbouring electrodes. To reduce effects of the modulation, the bead was pulled between electrode cylindrical parts at a distance of 30 mm from the beam axis. The results of field measurements were obtained after averaging 8 runs for each position. Standard deviation was 0.5%.

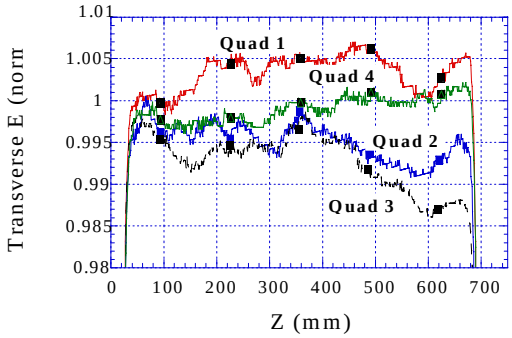

Figure 3: Close view of normalized transverse electric field distribution for 4 quadrants

As can be seen from figure 3 electric field unbalance among four qudrants is within ± 1%. Upper curves correspond to quadrants in which the distance between electrodes at the exit of the structure. is slightly smaller (~0.02 mm) than in the other two. The tilt of electric field distribution less 1% and no correction of the stems position is hence required. Electric field distribution at the beam axis is shown in figure 4.

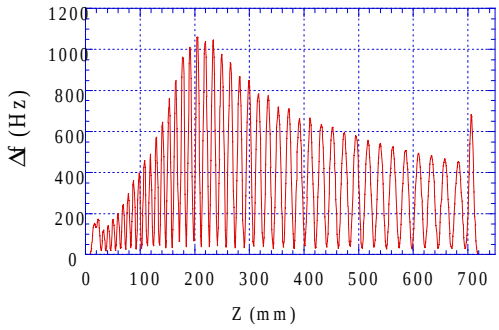

Figure 4: $\Delta f (\propto E_z^2)$ distribution at beam axis

The increase of E_z^2 in the initial part (0-200 mm) of the structure is due to the change of the modulation factor

(m) from 1.2 to 2.8 The behaviour of the rest of the curve is explained by the constant value of m. More detailed distribution (E_z^2) in the 8 mm long gaps between the end flanges and the electrodes are shown in figure 5 (a, b). Like all 4-rod structures a voltage difference exists in the gap between end flanges and ends of the electrodes. The effect of the exit gap voltage is used here in order to create an additional accelerating cell [5]. The different shapes of the electric field distribution in the input and output gaps are due to the termination of the electrodes (SRFQ1 adopts a half cell termination at the end) and the positioning of the stems.

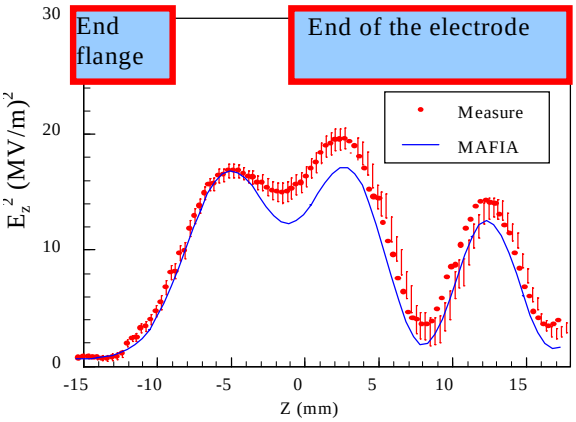

Figure 5 a): E_z^2 distribution at the entrance of the RFQ

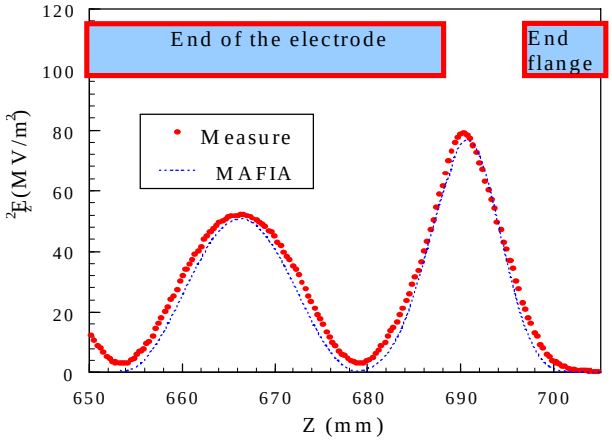

Figure 5 b) E_z^2 distribution at the exit of the RFQ

Field measurement were carried out along the beam axis near the electrode spliting points to observe effect of the split electrodes when RF strips were installed. M.A.F.I.A. static solver simulation predicted very small (~0.2%) field drop. No effect was consistently observed on the 0.5 mm gap with measurement accuracy. In order to estimate sensitivity to alignment errors the upper electrode was moved downwards by 0.1 mm. The resonant frequency of quadrupole mode was decreased by 257 kHz as a consequence. The measured transverse electric field distribution for the 4 quadrants is shown in figure 6.

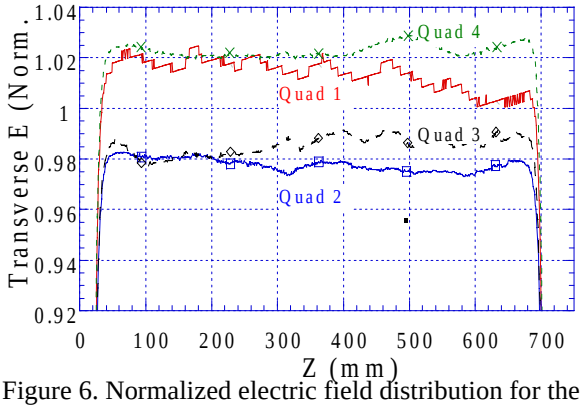

Figure 6. Normalized electric field distribution for the 4 quadrants after 0.1 mm misalignment of one of them

As it is shown by figure 6, transverse electric field in the upper quadrants (1 and 4) were increased and in lower ones (2 and 3) reduced. Total unbalance between the quadrants of the RFQ does not exceed ± 2% (i.e . ± 1% in the full-scale 80 MHz Nb structure).

4 CONCLUSION

Cold model measurements allowed to answer all the questions and to get results which will be a guideline in the construction of the full scale Nb SRFQ1.

Tank diameter for required resonant frequency was determined. Tolerance for the electrode misalignment should not exceed ± 0.1 mm in the 80 MHz SRFQ1.

A 1 mm gap between split electrodes parts will not affect the field distribution appreciably.

M.A.F.I.A. static solver simulations and experimental results obtained for E_z^2 distribution on the beam axis are in very good agreement.

EQUIVALENT LUMPED CIRCUIT STUDY FOR THE FIELD STABILIZATION OF A LONG FOUR-VANES RFQ

A. Pisent, R. Celentano* and R. Zennaro#
INFN-Laboratori Nazionali di Legnaro, Padova (Italy)

Abstract

The possibility to design an RFQ long respect to the RF wavelength is very important for the feasibility of linacs with different applications, from the high power CW linacs for neutron production to the low power high frequency linacs proposed for hadrotherapy. In particular INFN has been funded for the study of the critical parts of a waste transmutation linac. In this framework the field stabilization of a 352 MHz RFQ has been studied, using the LANL resonant coupling technique; an equivalent lumped circuit approach has been used, and compared with MAFIA simulations. Based on the results of these studies an aluminum model (1:1 scale, 0.04 mm tolerances) has been built and we are now ready for the test of the tuning procedure.

1 CIRCUIT MODEL

A four vanes RFQ resonator is based on a transfer line quadrupolar mode, with dispersion relation:

$$\omega^2 = \omega_o^{\ 2} + k^2 c^2 \qquad (1)$$

where ω_0 is the cut-off frequency, k is the wave number and c is the asymptotic phase velocity. In an RFQ the boundary conditions are such that the eigen modes are given by $k\ell = \pi n$, with ℓ cavity length and n (integer) mode number. The same dispersion relation (1) is valid for the circuit in Fig. 1, governed by the equation:

$$\frac{d^2V}{dz^2} = -Z_L Y_0 V \qquad (2)$$

with V intervane voltage, $Z_L dz = i\omega L_1\, dz$ coupling impedance, L_1 coupling inductance per unit length, and

$$Y_0 dz = \left(\frac{1}{i\omega L} + i\omega C\right)dz = \frac{1}{i\omega L}\left(1 - \frac{\omega^2}{\omega_0^2}\right)dz$$

with L inductance length, C capacitance per unit length. The solution of (2) can be written as:

$$V = V_0 e^{ikz} \qquad k^2 = -\frac{L_1}{L}\left(1 - \frac{\omega^2}{\omega_0^2}\right)$$

All these parameters have for a RFQ a straightforward meaning; $\omega_0 = 1/\sqrt{LC}$ is the frequency of operation, C is mainly the capacitance per unit length of the quadrupolar vane tips, (of the order of 120pF/m), that can be evaluated with the help of SUPERFISH. Moreover $L_1 / L = \omega_0^2 / c^2$, so as to have the asymptotic phase velocity equal to c. This model can be discretized, keeping the same meaning of the parameters involved, as long as we are only interested in the first modes and the upper cut-off in frequency can be neglected. The resulting dispersion relation is:

$$\left(\frac{\omega_n}{\omega_0}\right)^2 = 1 + \frac{L}{L_1 dz^2} 2(1 - \cos\alpha n)$$

with dz (finite) discretization step and $\alpha = \pi\, dz/\ell$. In the limit of dz→0 this relation reduces to (1), but if one is only interested in the first two modes (n=0,1), one can take $dz = \ell/2$, and the two frequencies correspond to the α=0 and α=π modes by imposing $L_1 / L = 32/\lambda^2$, with $\lambda = 2\pi c/\omega_0$; we shall use this result in the following.

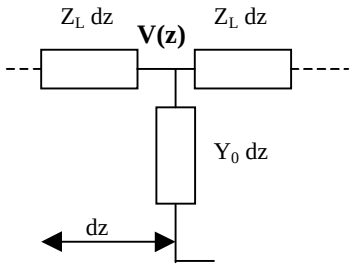

Figure 1: Equivalent circuit for the longitudinal dependence of the quadrupole modes a four vanes RFQ.

In a four vanes RFQ the operating frequency is ω_0, and therefore the field cannot be stabilized as foreseen by the resonant coupling theory, since ω_0 is never between an upper and lower symmetrical frequency[1]. As a consequence some drop of the voltage along the RFQ can be expected in presence of mechanical errors for a long RFQ, since the distance of the operating frequency respect to the first mode frequency is function of λ/ℓ.

A possible way to stabilize the RFQ is suggested by our circuit; we introduce a capacitance every two cells. In other words we cut the transmission line into segments of

* from University of Naples, Italy
# from University of Ferrara, Italy

length 2dz, for each segment we consider only the n=0 and 1 modes, and we couple the segments with an impedance $Z_{Ca} = 1/i\omega C_a$. The result is a biperiodic system governed by the equations

$$\begin{cases} (1 - x - \beta\gamma x + \gamma)u_n + \beta\gamma x u_{n-1} - \gamma u_{n+1} = 0 \\ (1 - x - \beta\gamma x + \gamma)u_m - \gamma u_{m-1} + \beta u_m = 0 \end{cases}$$

with m=2j+1, n=2j, j integer,

$$\omega_c \equiv \frac{1}{\sqrt{L_1 2dz C_a}}, \quad \beta \equiv \frac{\omega_c^2}{\omega_0^2}, \quad \gamma \equiv \frac{2C_a}{Cdz}, \quad x \equiv \frac{\omega_0^2}{\omega^2}.$$

It is interesting to observe that the unknown x appears in the non-diagonal terms and this is therefore a so-called extended eigen value problem. Nevertheless, since we have a lossless chain, one can look for a solution of the form: $u_n = e^{i\alpha} u_{n-2}$. This condition leaves two independent voltages, for example u_n and u_{n+1}, and therefore the recursive relations determine a couple of linear equations that have solution different from zero if:

$$x = \frac{[\beta\gamma^2(1-\cos\alpha)+1+\beta\gamma+\gamma] \pm \sqrt{[\beta\gamma^2(1-\cos\alpha)+1+\beta\gamma+\gamma]^2 - (1+2\beta\gamma)(1+2\gamma)}}{(1+2\beta\gamma)} \quad (3)$$

This is the new dispersion relation. The two bands, corresponding to the two sign determination of the square root, have even dependence on α, and the fundamental frequency $x=1$, corresponding to $\alpha=0$, is not any more the lowest. Moreover we have the coalescence of the two bands at $\alpha=0$ when the square root vanishes, i.e. for $\beta=1$. Therefore the stabilization of the fundamental mode is realized when $\omega_0=\omega_C$, condition that resembles the coalescence condition for the coupled pillbox biperiodic chains.

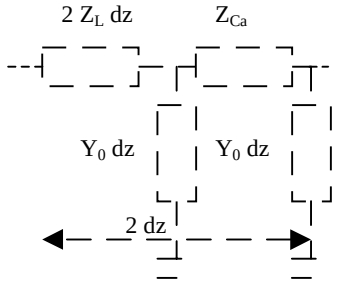

Figure 2: Biperiodic equivalent circuit.

In Fig. 3 we show the numerical solution a chain of 10 resonators (γ=.024, β=1). In the upper part we plot the normalized frequency of the modes, together with the dispersion relation (3) for an infinite chain of resonators; the agreement is good, meaning that in this case the termination conditions do not play an important role. The fundamental mode and the two neighbor modes are plotted in the lower part of Fig 3. These two modes have the same long range dependence, but the oscillation between next cells is in opposite phase. As a consequence, for a small (1%) perturbation in the eigen-frequency of the first resonator, the long range drop of the field is compensated, but the short range oscillation (first mode for each wave-guide segment) is enhanced. In this sense the stabilization is not complete.

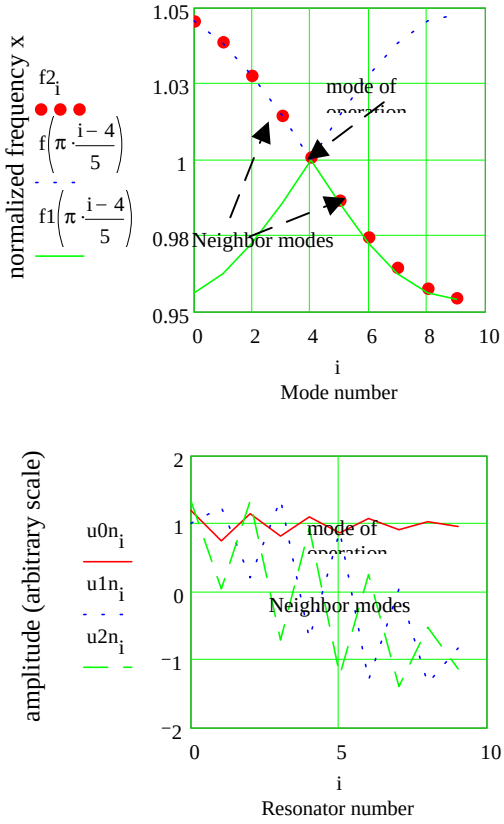

Figure 3: Numerical solution of the equivalent circuit (γ =.024, β =1, 1% perturbation in the frequency of the first resonator) and dispersion relation for an infinite chain of resonators.

2 SCALING FOR A SEGMENTED RFQ

The lumped circuit model of the previous section has been developed so to dimension a 352 MHz RFQ (about 6 m long) using the LANL technique for field stabilization[2]. We just remind that the RFQ is split in segments (of length 2 dz) coupled throw a coupling cell with the geometry shown in the MAFIA plot of fig. 4.

The impedance of this coupling-cell has in general an inductive (L_A) and a capacitive component (C_A), determined by the cross talk of the magnetic fields of the neighbor RFQ throw the opening, and by the capacitance of the facing electrode terminations respectively. Nevertheless for practical range of parameters the capacitive term is the dominating one:

$$Z_a = \frac{1}{i\omega C_A}\left(1 - \omega^2 L_A C_A\right) \approx \frac{1}{i\omega C_A}\left(1 - \omega_0^2 L_A C_A\right) = \frac{1}{i\omega C_a}$$

With these assumptions we can get very practical scaling relations. From the resonant coupling condition β=1 we calculate the desired coupling capacitance:

$$C_a = \frac{C}{dz}\frac{\lambda^2}{64} \quad (4)$$

that determines the gap between electrode terminations. Moreover the coupling strength is:

$$\gamma = \frac{1}{64}\frac{\lambda^2}{dz^2} \qquad (5)$$

The relative strength of the geometrical errors that can be corrected (for example the relative error of the local frequency) scales like γ; therefore short RFQ segments give a better correction but a higher coupling capacitance and a shorter gap. A short gap can be a problem because of the construction tolerances even if in the lumped circuit model we saw that the tolerances in β are rather loose, and for example for the case in Fig. 3 β=1.2 still gives significant field stabilization.

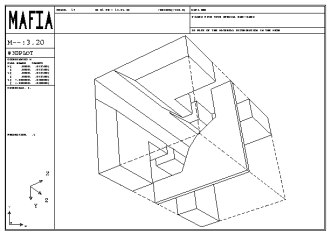

Figure 4: MAFIA simulation geometry in the coupling cell.

3 SIMULATIONS WITH MAFIA

One quarter of the structure has been simulated with MAFIA. Moreover, to reduce the number of mesh points we employed a simplified geometry, six times shorter, that resonates at 5.9 times higher frequency, but preserving the 352 MHz electrode geometry as much as possible (Fig. 4). In this way the "ratio limit", that is substantially the ratio between the smallest mesh size required (in the gap) and the total structure length, is kept reasonable, and the CPU time required for simulations is affordable.

In Fig. 5 and Fig 6 we show some typical. In Fig 5 the frequencies of the fundamental and of the two neighbor modes are plotted as a function of the gap length. The fundamental mode frequency is of course untouched by the change of capacitance. The equidistance of the spurious modes is reached for a gap of 3.3 mm. With the rough approximation of a planar condenser we get C_a=0.27 pF.

From equation (4), taking into account that for our simplified transverse C=80 pF/m, the capacitance for the coalescence of modes is C_a=0.32 pF. If we consider that the magnetic effects in the coupling cell and the edge electric field due to the finite dimensions of the electrode cross section have been neglected, the 16% agreement achieved is fair.

To test the compensation we have compared the longitudinal behavior of the voltage between the segmented and the uncoupled RFQ in thee presence of a perturbing piston tuner (fig 6).

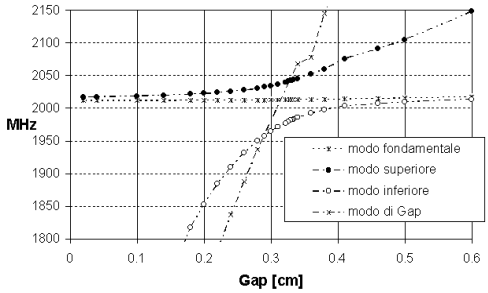

Figure 5: Frequencies of the most relevant modes as a function of gap length.

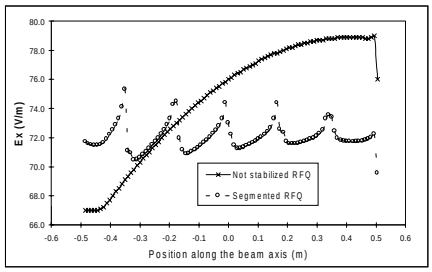

Figure 6: Effect of a perturbation on the RFQ with and without coupling cells. .

4 CONCLUSIONS

We have introduced an equivalent circuit to model an RFQ stabilized with the LANL technique. We think that this rough model catches the essence of the problem, giving the coalescence condition and the pass band amplitude (related to the error correction capability) as a function of few RFQ parameters, namely the operating frequency, the length, the quadrupole capacitance per unit length and the capacitance of the coupling cell. The comparison with MAFIA confirms our scaling laws; however we are not able to test the entire tuning procedure (including the influence of dipole modes) with MAFIA. For these reasons we have built an aluminum model, 3 m long, 352 MHz. The RF measurements are in progress.

THE POSSIBILITY OF MULTIPACTOR DISCHARGE IN COUPLING CELLS OF COUPLED CELLS ACCELERATING STRUCTURES

V.V. Paramonov, S.G. Tarasov
Institute for Nuclear Research, 117312, Moscow, Russia

Abstract

The Multipactor Discharge (MD) takes place at low values of electric rf field. Operating values of the field in accelerating cells are usually match more higher than the upper threshold of the discharge and this phenomenon take place during structure conditioning. In operating regime, during rf pulse, weak electric field, linearly decreasing from the point of the rf drive to the end of the cavity, exists in coupling cells to provide rf power flux along the cavity. Depending on cavity operating regime and coupling cells parameters, the value of this field can be in limits of the discharge. In this paper parameters of coupling cells for Side Coupled (SCS), On-axis Coupled (OCS) and Annular Coupled (ACS) structures are considered and estimations for electric field are given. Results of numerical simulations of the discharge in coupling cells are presented.

1 INTRODUCTION

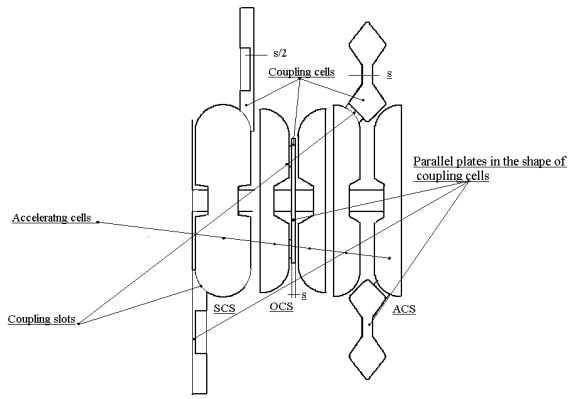

Figure 1: A sketch of SCS, OCS and ACS structures

The effect of the MD in accelerating cells of Coupled Cells (CCL) structures is straightforward, because parameters of accelerating cells directly define parameters of the cavity and the discharge is equivalent to additional parasitic conductivity. In operating regime coupling cells in first order do not excite, the MD in coupling cells may be simulated as additional rf losses, leading to reduction of quality factor for coupling cell and has not such evident sequences on operating parameters. To decrease dimensions of coupling cells, one need provide capacitive load by providing 'noses' in the region of strong electric field of the coupling mode. As the result, coupling cells have parallel plates, like capacitor (Fig.1). Such shape is favourable for MD excitation.

The MD in coupling cells of CCL structures was not described in papers directly, just indications that OCS was rejected for application in TRISPAL project due to MD possibility [1] or private communications [2]. The purpose of this paper is to discuss the possibility of most popular first order two-surface MD in coupling cells, to compare different types of coupling cells and specify operating parameters of the structure, which can provide conditions for MD in coupling cells.

2 STEADY-STATE CONDITIONS

2.1 The energy stored in coupling cells

If the steady-state operating regime of the CCL structure is specified, one can easy find the energy W_a of electric field stored in accelerating cell:

$$W_a = \frac{c\beta_p Q_a (E_0 T)^2}{4\pi f_0^2 Z_e}, \qquad (1)$$

where Q_a is quality factor for accelerating cells, Z_e - effective shunt impedance, f_0 - operating frequency, β_p - relative velocity of particles, c - velocity of light, E_0 - average electric field along axis, T -transit time factor. To find stored energy in coupling cells, one can use conclusions both lumped circuit [3] and electrodynamical [4] approaches, which coincide for coupling cells. The energy stored in coupling cells W_c is

$$W_c = W_a \alpha^2 (n - N)^2, \qquad (2)$$

where α is attenuation constant per period, n - number of the coupling cell from the point of rf input, N - number of the structure periods from the point of rf input to the end of the cavity. If the beam loading is not strong $I_b Z_e cos^2\varphi_s \leq E_0 T$, attenuation constant α may be estimated as:

$$\alpha \approx (1 + \frac{I_b Z_e cos\varphi_s}{E_0 T}) \frac{2}{k_c Q_a} \qquad (3)$$

where k_c is the coupling coefficient of the CCL structure, φ_s - synhronous phase. For strong beam loading attenuation should be founded as the result of solution for the power balance equation [4]. Combining (1-3), one can define W_c for any operating regime given. For proton linacs at typical values f_0=805 MHz, β_p=0.5, Q_a=20000, k_c=5%, Z_e=35 MOhm/m, supposing I_b=0 and N=40 (total tank has 80 accelerating cells and rf input is in the middle of the tank) dependencies of W_c on the accelerating gradient $E_0 T$ and n are plotted in Fig.2. As one see, W_c may varies in wide range, depending on $E_0 T$ and N values.

2.2 Estimations for MD threshold

In typical shape of coupling cells there are parallel plates (Fig.1) with electric field of coupling mode between them. Because the gap length s between plates is small, we can suppose uniform electric field between plates, considering this region as a capacitor. Simple estimations for the MD range may be obtained by using the model of single electron sheet ([5],[6] and relates references). The resonant condition for electric field strength E_r in coupling cells for two electrode MD is:

$$E_r = \frac{4\pi^2 f_0^2 sG}{(e/m)}, \tag{4}$$

$$G = [(\frac{k_v+1}{k_v-1})(2n_p-1)\pi cos\phi_e + 2sin\phi_e]^{-1}, \tag{5}$$

where e/m is the ratio of electron charge and mass, n_p - order of MD (number of rf halfperiods needed for electron to pass distance s, k_v is assumed constant ratio of electron emission to impact velocities and ϕ_e is secondary emission electron starting phase. Below we consider mostly first order $n_p = 1$ MD. For phase stable MD the phase of electron impact with second plate ϕ_i should be $\phi_i \approx \phi_e + n_p\pi$ with the condition of stability $-1 \geq d\phi_i/ \geq 1$ [6]. The minimum value of E_r depends on $G(k_v, \phi_e)$ and G_{min}= 0.27 (k_v=0), G_{min}=0.23 (k_v=0.1), G_{min}=0.21 (k_v=0.25). The assumption $k_v = const$ has no physical basement, but due to week dependence, results obtained are in good agreement with experiments [7] and direct numerical MD simulation [6] and assumption k_v=0 is a good approximation.
From (4) one can see, that rf resonant rf voltage for MD excitation $V_r = E_r s$ does not depend on frequency f_0 if scaling is applied for dimensions of coupling cell.
Another important value for MD exitation is the energy of impact electrons W_i (supposing nonrelativistic electrons):

$$W_i = 8\pi^2 m(\frac{f_0 sGcos\phi_e}{1-k_v})^2 \tag{6}$$

For high order (n_p=2,3,4..) MD estimations for resonant rf voltage V_{rn_p} and impact energy W_{in_p} may be obtained using G-factor, if equivalent values for n_p=1 discharge are known ($V_{rn_p} \approx V_{r1}/n_p$, $W_{in_p} \approx W_{i1}/n_p^2$).

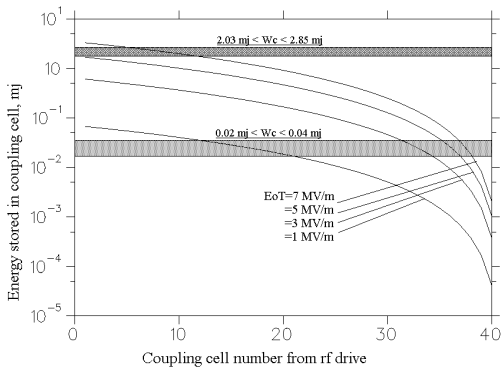

Figure 2: The energy stored in coupling cells, mj

2.3 Coupling cells parameters

To compare parameters of different cells, three types of structures - SCS, ACS and OCS (Fig.1) were calculated at the same frequency 805 MHz for $0.45 \leq \beta_p \leq 0.8$. By using powerful 3D code Mafia, one can calculate field distribution for coupling mode and define simply, what value of electric field E_c or rf voltage V_c between plates in coupling cell corresponds to stored energy W_c. To describe the this parameters for coupling cell, the best way is to introduce "equivalent capacitance" C_e:

$$C_e = \frac{2W_c}{V_c^2} \tag{7}$$

If this C_e value is known at the given frequency, for another value it can be estimated from scaling relation $C_e \sim f^{-1}$. For SCS geometry is the same as for [8], ACS geometry was scaled from [9]. For OCS structure the length of coupling cells was 0.1 from the length of accelerating one. Last OCS example for β_p=1, f_0=2797 MHz is from reference [10]. For OCS structure V_c is calculated at radius of beam aperture. If dimensions of coupling are specified, one can estimate $f_0 s$ value, which is of main importance for calculation of V_r (4) and estimate energy stored in coupling cell $W_{c1} = C_e V_r^2/2$ and impact energy W_{i1} (6) which correspond to condition of n_p=1 stable ($0 \leq \phi_e \leq 33^o$ [6]) discharge. Results are summarised in Table 1, W_c and W_i are estimated for n_p=1 MD.

Table 1: Parameters of coupling cells

CCL	β_p	$f_0 s$	C_e	W_{c1}	W_{i1}
			pF	mj	keV
SCS	0.45	705	4.42	0.02÷0.03	1.1÷2.3

3 DISCUSSION

3.1 Conditions of discharge

To have stable discharge, one need fulfil three conditions:
a) - space stability;
b) - phase stability;
c) - impact electron energy should be in range where secondary emission coefficient $\sigma_e \geq$1.0. For copper this range is from $\approx$ 200 eV to $\approx$ 2 keV, depending on surface quality. As one see from Table 1, conditions b) and c) are valid for

low β_p SCS and OCS structures. Not so big energy 0.02 mj $\leq W_{c1} \leq$ 0.04 mj should be stored in coupling cells to provide conditions for n_p=1 discharge. This range is shadowed at Fig.2 and one can see these values realistic for proton linacs. In accelerating cavity several coupling cells may be in range of possible discharge. For ACS structure impact electron energy is too big even for low β_p (due to big $f_0 s$ value) to provide conditions for n_p=1 discharge. Only high order MD n_p=2,3,4 are possible in ACS structure at low β_p.

3.2 Numerical simulations

Special code was written for direct tracking of electrons in calculated fields of coupling cells. Main purpose of this tracking was to check space stability of discharge. Results of simulations confirm good analytical estimations for n_p=1,2 MD at low β_p for all structures. For SCS and ACS structures at low β_p electric field is practically constant both in longitudinal and in transverse directions in the space between noses. It means, that MD (if exists) takes practically all space between noses, but MD range in respect of W_c is limited. With increasing of β_p distance s rises, becomes comparable with transversal dimensions of noses. For ACS and SCS structures the approximation of plane capacitor becomes not acceptable. Direct numerical simulation shows no stable electron trajectories in the space $\approx 1.5s$ from outer side of the nose. It is sequence of nonuniform electric field in this region. It is especially important for ACS structure because nose is open both from top and bottom sides. For $\beta_p \geq$0.7 results show no stable trajectories for ACS coupling cells and reduced region (near centre of nose) of space stability n_p=1 MD in SCS coupling cells. Condition of the space stability for high order MD with respect field homogeneity are more rigid than for n_p=1 MD.

For OCS coupling cell is narrow cylindrical cavity. Electric field varies as Bessel J_0 function along radius. Nonuniform fields are only near beam aperture and coupling slots. Results of simulation show, that if MD exists at W_{c1} given, it takes a part of coupling cell and for $W_{c11} \geq W_{c1}$ it may displays to another part of the cell with lower electric field. All time there are regions with space stability of discharge. If for β_p =1 the impact energy W_i for n_p=1 MD is too big, conditions for high order MD may be fulfilled.

3.3 Effect of MD in coupling cells

It is known [6], [11], that the discharge current is limited by space charge effect and for maximum value of current density for n_p=1 MD is:

$$j_{1\ max} \simeq \frac{\epsilon_0 m f_0^3 s}{e}. \qquad (8)$$

For typical values f_0=805 MHz, s=1 cm, $j_{1\ max}$=2500A/m^2. For high order discharge n_p=2,3,4.. $j_{n_p\ max}$ value is 3(n_p+3) times less. Suppose n_p=1 discharge exists in one SCS coupling cell (nose radius is r_n=3.0437 cm [8]). The total MD current I_{MD} is estimated as $I_{MD} = \pi r_n^2 j_{1\ max} \sim 7$ A. With impact energy $W_{i1} \approx 1$ keV it leads to additional rf power dissipation $P_{rf} = I_{MD} W_{i1}/e \sim 7$ kW (upper estimation). It is not so big value to see drastic disappearance of rf power from rf generator with total power in several MW. But quality factor Q_l for this cells decreases to value $Q_l = 2\pi f_0 W_{c1}/P_{rf} \sim 20$. Such low Q cell do not keep amplitude and phase stability for operating $\pi/2$ mode so good as high Q one.

4 SUMMARY

Results of analytic estimations and numerical simulations show that first order multipactor discharge of is possible in SCS and OCS coupling cells for low $\beta_p \approx 0.4$. In ACS only high order discharge is possible. for low $\beta_p \approx 0.4$. With β_p increasing the gap between cell noses increases too, leading to nonuniform field between noses, reducing possible space for stable MD in SCS and eliminating it in ACS structure.

The best way to decrease MD possibility is trancformation of parallel plates into conical surface.

For coupling cells of OCS structure at β_p=1 condition for higher modes of discharge may be fulfilled.

Abstract

A 27 MHz heavy ion RFQ is now under construction at ITEP. It based on new ring-connected resonant structure. This structure is low frequency version of previously described "four – ladder" structure. The RFQ has been designed for acceleration of heavy ions with charge to mass ratio of 1/60 (U^{4+}) to energy 100 keV/u. At present the manufacture of the structure is completed, RFQ is assembled and installed into a vacuum tank. The RF measurements confirm the expected parameters calculated by MAFIA and SOPRANO codes – resonant frequency, very reliable mode separation and perfect electrical field distribution.

The carried out numerical simulations and experimental results show that given RFQ type is considerably promising candidate for use as initial part of high current heavy ion linac for HIF.

1 INTRODUCTION

The RFQ for acceleration of intense pulse beam of ions with charge to mass ratio 1/60 up to energy 100 keV/u is under construction in ITEP during last years. The main goal of this work is a maintenance of experimental base for reaserches of interaction of the heavy ion beam with dense plasma. At the time the accelerator was considered as a prototype of an initial part of the linac driver for heavy ion fusion. This work allow to test experimentally the results of investigations and developments for heavy ion high-power accelerator made during last years in ITEP. The main requirements produced to driver are effective acceleration of an intense beam with minimum particles losses and emittance growth. The design of the RFQ is completely based on new ITEP approach to the construction of initial part of high intensity heavy ion linac. A version of "90^0 - apart stem structure" named "ring - connected structure" has been chosen for the RFQ. The structure is the best choice to reach perfect field distributions in low frequency RFQ. Beam dynamics has been designed to minimize emittance growth for intense pulsed beam current.

The important factor influenced the design of the RFQ was very limited financial resources. It means, that from economy purposes some deterioration of radiotechnical, mechanical and operational parameters were allowed. At present the accelerator has been assembled and RF tuning is being carried out.

2 RFQ DESIGN

The described RFQ is the version of "90^0 - apart stem" structure proposed in ITEP for initial part of intense heavy ion linac. The detailed description of the structure and data of both computer simulations and results of RF measurements at the cold models are given in the earlier published works [1,2].

The basic advantages of described structure in comparison with known are:

- rather small transversal dimension;
- high RF parameters;
- reliable mode separation that provides proper field distribution;
- simplicity of mechanical design and low cost of manufacturing;
- low sensitivity to mechanical tolerances.

The mechanical construction of the RFQ is presented in Figure 1, where the RFQ is shown at assembling place before its installation into vacuum tank. The resonant structure consists of octangular shape "rings" produced together with stems. Rings are connected by longitudinal bars. Rings, bars and basements of the electrodes are manufactured of copperplated aluminum alloy. OFHC copper is used for tips of the electrodes. The stem pairs at adjacent rings are perpendicular to each other and to the beam direction. The stems in horizontal and vertical planes are connected by cylindrical electrode basements. The assembled structure represents a rigid 3-D construction allowed to reach required accuracy of electrode positioning. The thickness of the copper layer is not less

Figure 1: RFQ view at assembling place

* The work is supported by GSI, Germany

than 60 microns. The accuracy of machining of the structure parts was not worse than 20 microns.

The basic parameters of the RFQ construction are given in Table 1.

Table 1: Basic RFQ geometry.

Maximum outer ring size, mm	880
Maximum inner ring size, mm	780
Ring thickness, mm	50
Distance between adjacent rings, mm	580
Ring number	22
Cross-section of bars, mm x mm	50x25
Height of stems, mm	280
Height of electrode tips, mm	26
Thickness of electrodes, mm	10
RFQ length, m	12

As mentioned above the mechanical design of the RFQ was largely defined by the limited financial opportunities. In particular the cooling required for high average currents operation has been not provided. Not all of the structure elements connections design have been optimized for highest Q - factor. The expected Q factor is approximately 2 times lower then calculated one. However, it is enough to provide RFQ operation with acceptable RF losses. The improvement of RF contacts does not represent a basic problem, but would result in increasing the total cost of the RFQ.

3 BEAM DYNAMICS

Beam dynamics in the RFQ has been calculated using developed in ITEP procedure for high current linac design. The main goal of the procedure is to achieve maximum value of accelerated beam current with at least 95% transmission and minimum emittance growth.

The modulation parameter along part of initial bunch formation in early RFQ designs was chosen to keep geometrical length of separatrix approximately constant. If particle distribution in separatrix is uniform this method allow to keep constant space charge forces along RFQ. It should minimize beam emittance growth [3]. However, using of monochromatic beam for injection to RFQ leads to considerable variations of space charge density along formation part. The result is noticeable emittance growth for high intense beam at this part. It is also troublesome to propose in advance optimal synchronous phase and modulation along RFQ.

The described RFQ has been designed using some modification of the above mentioned approach. Cell geometry is calculated taking into account real particle distribution in phase space, obtaining from beam dynamics simulations in preceding cells. The simulation takes into account as space charge forces as real external field distribution.

In the procedure the geometry of cell is chosen to fulfill some requirements and limitations for RFQ parameters:

- space charge forces do not exceed some prescribed value;
- longitudinal stability has to be obtained not less than for 95% of particles;
- phase advance doesn't change more than on ±10 % of its chosen value;
- maximum strength of electric field on electrodes surface doesn't differ more than on 1% of its chosen value.

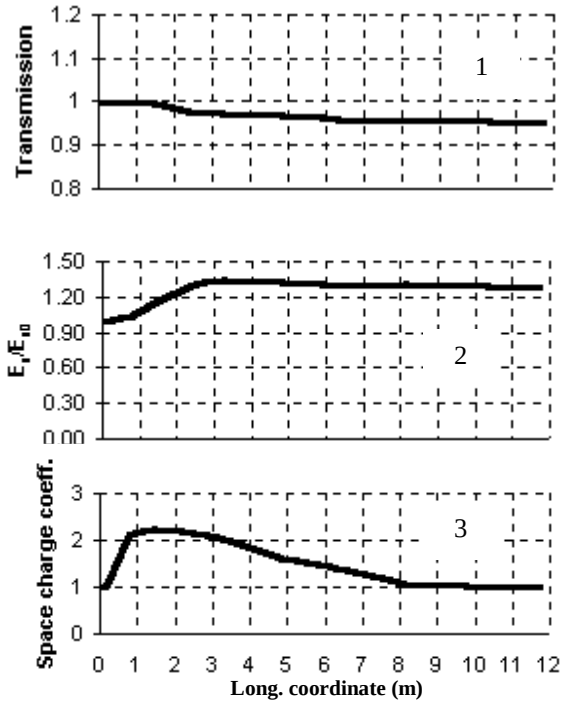

Figure 2: Calculated beam transmission (curve 1), relative transverse emittance growth (2) and Coulomb parameters (3) *h* relatively to its initial value along RFQ

These requirements has to minimize emittance growth due to space charge effects and mismatching of the beam in channel with changing phase advance.

The RFQ generating procedure controls space charge effects using Coulomb parameter *h*, introduced in [3]:

$$h = \frac{\lambda}{\mu_0 \beta \gamma^2 I_0} \frac{I}{V_p},$$

where I - peak current of the beam, V_p - normalized transversal emittance, λ - wave length, β - relative velocity of particles, γ - relativistic factor, μ_0 - phase advance, I_o - characteristic current, equal $3.13 \cdot 10^7$ *A/Z*, *A/Z* - mass to charge ratio. Peak current and emittance are calculated by simulations in preceding cells.

As a rule, the monochromatic beam is injected to RFQ. It means that at bunching of the beam in initial part of structure peak current can change in width enough range with formal maintenance of separatrix length. In this case *h* in bunch formation part is always higher than

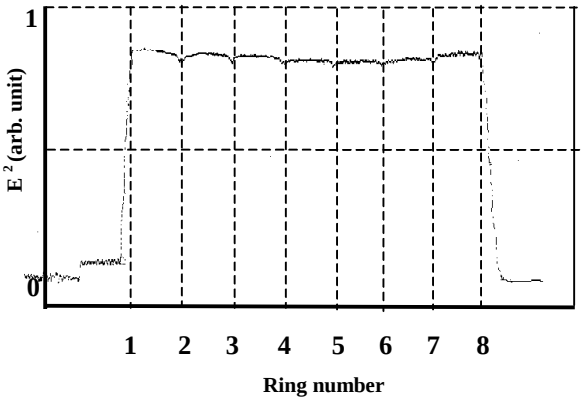

Figure 3: Measured field distribution along 8 ring assembly

in injected beam. The procedure of RFQ generating should to keep *h* lower than some prescribed upper limit.

Some results of RFQ design using described procedure are presented on Fig. 2. The simulations were carried out using written in ITEP code DYNAMION for beam current 12 mA and initial emittance 0.3 mm*mrad. Curve 3 shows Coulomb parameter along RFQ. At pre-bunching part (0 -1 m) Coulomb parameter smoothly increases to its prescribed value h_{max}. At formation part (1 - 3 m) *h* is kept under h_{max}. At gentle buncher *h* decreases because phase advance is dominated factor at this part. At main accelerating part the geometrical length of separatrix is constant and *h* is practically equal to its value in injected beam.

Curve 2 on Figure 2 shows relative growth of normalized rms emittance along RFQ. It can be seen from picture that rms emittance increases on ≈25% and main growth happens in the part of RFQ corresponding to the maximum value of Coulomb parameter. It has to be noticed that high enougth value of h_{max} = 0.34 was chosen only due to necessity of accelerating of particles up to 100 keV/u on the length limited by existing vacuum tank. Curve 1 shows that some particle losses are appeared at beam current 12 mA in spite of the fact that ratio acceptance to emittance is approximately factor 2.5. The explanation is that at given h_{max} the process of halo formation plays significant role [4].

4 FIRST RF MEASURMENTS

Measurements of the fields were carried out by means of standard bead-pull technique. Inter-electrode voltage distribution along the structure was measured for each pair of neighboring electrodes. On Figure 3 the distribution of the normalized inter-electrode voltage along structure for one pair adjacent electrodes is shown. The measurements have been carried out for the part of RFQ - 8 rings assembly. The measured non-uniformity of the field along the section is 1.5 %. It is mainly due to the measurements have been carried outside of the tank and end regions of the structure were tuned for lower frequency. The field distributions for other pairs of the electrodes have the same character. The average fields for different pairs electrodes differ within the limits of 3 %, that can be explained by the fact that the a preliminary alignment had more pure accuracy then it is foreseen for final one. Since this first measurements were made on a part of the structure, for whole structure it is possible to expect the aspiring of the frequency to design value 27.14 MHz and increasing of Q-factor. However even the given results of measurements completely confirm advantages of this variant RFQ for low working frequencies.

Table 2: Calculated and measured RF parameters

	Calculated	Measured
Frequency of quadrupole mode, MHz	27.14	27.66
Q-factor	13000	5650
Frequency of dipole mode, MHz	37.2	36
Shunt-impedance, MOhm ∗ m	1.1	0.48

5 CONCLUSION

The 27 MHz heavy ion RFQ has been designed in ITEP using new resonant structure and original procedure of RFQ generating. The computer simulations as well as RF measurements show that new resonant structure allow:

- to improve the linearity of focusing field due to significant shift of the dipole mode of oscillations;
- to have uniform field distribution along axis;
- to minimize the emittance growth due to improvement of field distribution and minimization of space charge effects;
- to decrease essentially the total cost of the RFQ due to using compact and simple construction.

Final adjustment of structure nowadays is close to completion. The first beam experiments are scheduled for the end of the 1998. In case of experimental confirmation of calculated parameters of the RFQ it will be possible to assert, that RFQ of the given type is a good option for an initial part of HIF driver.

CALCULATIONS OF EXTERNAL COUPLING TO A SINGLE CELL RF CAVITY*

Derun Li, Robert Rimmer, Shakti Kosta, LBNL, One Cyclotron Road, Berkeley, CA 94720, USA

Abstract

A method is proposed to calculate the intrinsic and external Q values of a cavity coupled to a waveguide using MAFIA code in time domain. Typical methods used for the Q calculation in time domain are also reviewed. The method works efficiently for high Q cavities with coupling strengths close to critical coupling case. Applications of the method to a single cell RF cavity coupled to a waveguide are presented. The comparisons between simulation and experimental results are given for a set of different coupling iris apertures.

1 INTRODUCTION

Calculations of external coupling to a resonant RF structure is important in many accelerator applications. There have been a few methods available for specific systems. The methods range from analytical approximations based on the equivalent circuit theory or analytical field solutions to numerical simulations. With the development of powerful computer codes such as MAFIA, SUPERFISH etc., numerical methods are favored for their versatility. Among the numerical methods, two types of the simulation techniques are often used: frequency domain and time domain. In the frequency domain, The Kroll-Yu method [1] has been used widely and proven to be efficient in the external Q calculations for systems having low Q values and strong coupling. The Kroll-Yu method uses the resonance frequencies computed from the MAFIA for different lengths of the waveguides and fits the induced phase variations with a theoretical formula. Both the loaded resonant frequency and the external Q are then obtained from the fitting. When the coupling becomes weak and Q gets higher, to fit the phase variation curve requires very high accuracy of the resonant frequency. This is difficult for many simulation codes. An improved version of this method is Kroll-Lin method, but we do not have enough data and experience to comment about it. We developed a method using the MAFIA time domain simulation results. Unlike the conventional decay method in the time domain, which calculates the natural decay time constant, we calculate the Q_0, $Q_{\rm ext}$ using an energy method [2]. The method involves the use of waveguide boundary condition which is available in the MAFIA time domain module. Application of this method to a single cell RF cavity coupled to a rectangular waveguide, shown in Figure 1 will be presented. Comparisons between simulations and experimental measurement will be given for a set of different coupling iris apertures.

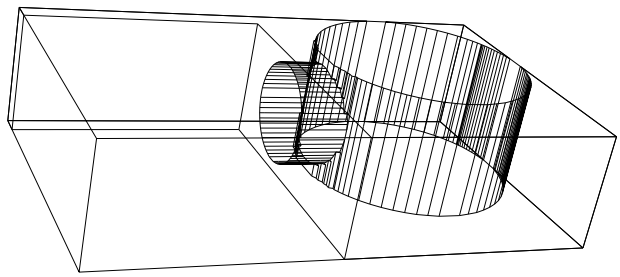

Figure 1: A 3D MAFIA model of a single cell pill-box cavity coupled to a rectangular waveguide through an open iris. The design resonant frequency for the cavity is 1.5 GHz.

2 THE METHOD

We define a cavity (or a chain of coupled cavities) coupled to an external RF component such as a waveguide or a coaxial line, through an open iris or a probe as a cavity-coupler system. The system, in a narrow band around its natural resonant frequency, can be very well presented by an equivalent RCL circuit coupled to a transmission line through a transformer. Due to the presence of the coupling between the cavity and the coupler, the electro-magnetic fields become quite complicated in the iris region. Numerical simulation codes are often used to model this region. The resonant frequency of the system will depend on how the coupler is terminated as well. In analogy to the definition of the unloaded quality factor Q_0, an external quality factor $Q_{\rm ext}$ is defined in such a way that makes the coupling and the resonant frequency of the system unique by terminating the coupler with a matched load. It is difficult to numerically simulate a matched load in the frequency domain. We instead take the advantage of the built-in waveguide boundary condition in the MAFIA time domain, calculate the instantaneous stored energy and power loss over one RF period based on the time domain simulation results. We assume the following relations hold at any instant,

$$Q_0 = \omega_0 \frac{U(t)}{P_w(t)}, \quad Q_{\rm ext} = \omega_0 \frac{U(t)}{P_{\rm out}(t)} \tag{1}$$

where ω_0 is the natural angular resonant frequency; $U(t)$ and $P_w(t)$ are respectively the stored energy and power loss on the cavity averaged over one RF period at time t; $P_{\rm out}(t)$ is the RF power flowing out from the waveguide port over one RF cycle at time t. Two time domain runs are needed to determine both the resonant frequency and the $Q_{\rm ext}$ of the system: one for the resonant frequency and the other

* This Research Work is supported by the Director, Office of Energy Research, Office of High Energy and Nuclear Physics, High Energy Physics Division, of the U.S. Department of Energy, under Contract No. DE-AC03-76SF00098

for the $Q_{\rm L}$ which is given by,

$$\frac{1}{Q_{\rm L}} = \frac{1}{Q_0} + \frac{1}{Q_{\rm ext}}. \qquad (2)$$

As the MAFIA time domain module can handle lossy dielectric materials, system involving coupling with ceramic windows and lossy materials can also be simulated correctly.

2.1 Resonant Frequency of the System

We first drive the cavity-coupler system with a broad band dipole pulse with its center frequency approximately around the natural resonant frequency of the system. A Gaussin pulse built-in in MAFIA is often used with its bandwidth wide enough to cover the natural resonant frequency, but not to excite high order modes. The location and the polarization direction of the dipole should be at the place where the mode of interest has a strong electric field component in the same direction. Waveguide boundary condition at the waveguide port must be used. The bandwidth of the waveguide should be wide enough so that there are no reflected fields coming back from the port. The induced time varying electro-magnetic fields in the cavity are also monitored at a place where the mode of interest has a strong component, but not too close to the driving point. The electro-magnetic field whose frequency is equal to the natural resonant frequency of the system will be coherently excited, and be built up. If the driving source is removed, the field decays with its natural time constant. For high Q cavities, the decay time, therefore the CPU time is so long that makes it in-efficient to calculate Q in this way. Nevertheless this field does provide enough information to determine the resonant frequency. Having carefully chosen the driving bandwidth, the only field left after the driving source will be the field with the natural resonant frequency. A Fast Fourier Transform (FFT) of the field then can be used to find the frequency. However better accuracy of the frequency can be determined by measuring the oscillation period of the time varying field signal using the last 5 to 10 RF cycles. Based on our experiences, typically less than 30 RF cycles are long enough to get a good measurement. Figure 2 shows an example of the time varying electric field signal excited by a pulse. The field is calculated by the MAFIA time domain module, T3.

2.2 The Energy Method

The same procedure used to measure the resonant frequency is repeated except the dipole excitation will be at a single frequency equal to the resonant frequency obtained from the 1st time domain simulation. In addition to monitoring the time varying electro-magnetic fields at the same location, 3D electro-magnetic fields in the system are recorded as well at time $t_0 \pm \Delta t$. The t_0 is chosen at a time when the relative energy contribution from the excitation source to the total stored energy in the cavity is negligible. In order to calculate the average stored energy and the

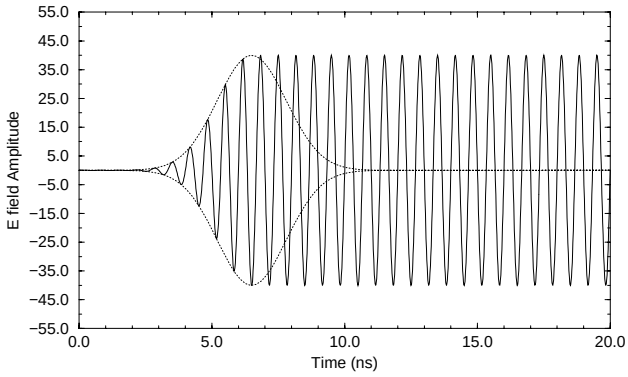

Figure 2: An electric field component is plotted as a function of time (solid line). The envelop of the driving pulse is plotted at the same time with dotted line. Only the last 5 to 10 RF cycles are used to calculate the resonant frequency of the system.

power loss at t_0, we take,

$$\Delta t = \frac{1}{4 f_{\rm drv}}, \qquad (3)$$

with $f_{\rm drv} = \omega_0/2\pi$ as the driving frequency and ω_0 as the angular resonant frequency. With this driving source, the electro-magnetic fields will be building up coherently with time, e.g.,

$$\Phi(t) = \Phi_\infty \left(1 - e^{\frac{t}{\tau}}\right) \sin(\omega_0 t + \theta_0), \qquad (4)$$

where $\Phi(t)$ may denote any field component of $\vec{E}(\vec{r},t)$ or $\vec{B}(\vec{r},t)$, and Φ_∞ is the field amplitude at steady state. $\tau = \frac{2Q_{\rm L}}{\omega_0}$ is the time constant of the system. θ_0 is an initial phase. For a high $Q_{\rm L}$ system it is impractical to run MAFIA in time domain to obtain either an accurate value for the decay time or until the steady-state field amplitude Φ_∞ is reached. We find that it is convenient to record the 3D fields at t_0 and $t_0 \pm + \Delta t$ during the time while the fields build-up and use the fields to re-construct a quasi-time harmonic field (mode). Taking the advantage of many built-in features in the MAFIA post-processor (P code), the quasi-time harmonic field can be used readily for the calculation of Q_0 and $Q_{\rm ext}$.

As indicated in Equation (4), the field build-up is approximately linear when $\frac{t}{\tau} << 1$. Figure 3 shows an electric field component as a function of time calculated by MAFIA during the field build-up. A linear build-up pattern of the field is exhibited. The same cavity-coupler system shown in Figure 1 is used for the simulation. The system is driven at its resonant frequency, obtained from the first time domain simulation discussed in Section 2.1.

As we pointed out earlier, the excitation dipole will inevitably contribute its energy to the total stored energy in the cavity, but its relative contribution decreases with time. Therefore it is preferable to record the fields at several times until we are sure that approximately the same Q values are obtained. Usually about 30 RF cycles are needed. To calculate $U(t), P_w(t)$ and $P_{\rm out}(t)$, the MAFIA P code

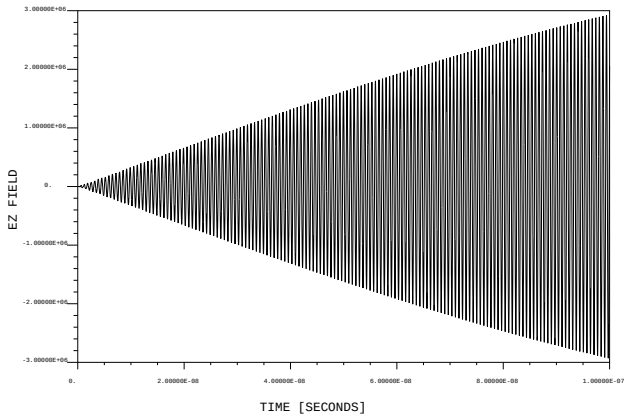

Figure 3: An electric field component is built up linearly as a function of time for a high Q cavity-coupler system driven at its resonant frequency.

is needed. In fact, the P code treats the electro-magnetic fields at time t_0 and $t_0 \pm \Delta t$ as time harmonic fields. Both the energy and power loss calculations from the P code have phase dependent terms. However, the phase dependent terms are cancelled out automatically by the careful choice of Δt in Equation (3). The stored energy at t_0 is then given by,

$$U_\Phi(t_0) \approx \frac{\alpha}{2} \oint_V \left\{ \Phi^2(t_0) + \Phi^2(t_0 \pm \Delta t) \right\} dv \qquad (5)$$

with

$$\alpha = \begin{cases} \epsilon_0 & \text{electric energy, } \Phi = \vec{E} \\ \frac{1}{\mu_0} & \text{magnetic energy, } \Phi = \vec{B} \end{cases}$$

Similarly the power loss is calculated by,

$$P_w \approx \frac{R_s}{2} \oint_S \left\{ H(t_0)^2 + H(t_0 \pm \Delta t)^2 \right\} ds \qquad (6)$$

The unloaded Q_0 is then computed by,

$$Q_0 \approx \omega_0 \frac{U_E(t_0) + U_B(t_0)}{P_w(t_0)}. \qquad (7)$$

2.3 Poynting Vector Calculations

To calculate $Q_{\rm ext}$, $P_{\rm out}$ has to be calculated using the Poynting vector $\vec{S} = \vec{E} \times \vec{H}$, which is constructed by the MAFIA P code using the recorded fields at t_0 and $t_0 \pm \Delta t$,

$$P_{\rm out}(t_0) \approx \frac{1}{2} \int_s \{ S_\perp(t_0) + S_\perp(t_0 \pm \Delta t) \} ds \qquad (8)$$

$S_\perp$ is the transverse component of the Poynting vector in the waveguide. The integral in Equation (8) may be conducted at any cross section s in the waveguide away from the iris. It is also worthy to point out that $E_\perp$ and $H_\perp$ are in phase in the waveguide, therefore the phase dependent terms are cancelled out in Equation (8) for the same reason stated earlier.

Considering the simple geometry of the rectangular waveguide, $P_{\rm out}(t_0)$ may be computed by an analytical formula combining with an energy density $W_{\rm wg}$ obtained from MAFIA by,

$$\begin{aligned} P_{\rm out}(t_0) &= c\sqrt{1 - \left(\frac{f_c}{f_{\rm drv}}\right)^2}\, W_{\rm wg}(t_0) \\ W_{\rm wg}(t_0) &= \frac{1}{d} \left[U_E(t_0) + U_B(t_0) \right]_d , \end{aligned} \qquad (9)$$

where $v_g = c\sqrt{1 - \left(\frac{f_c}{f_{\rm drv}}\right)^2}$ is the group velocity; f_c is cut-off frequency determined by the geometry of the waveguide; $W_{\rm wg}(t_0)$ is stored energy per unit length in the propagation direction with d as the length used for the stored energy calculation. The same $P_{\rm out}$ values are achieved from either Equation (8) or Equation (9). $Q_{\rm ext}$ is then directly calculated from Equation (1).

3 NUMERICAL RESULTS

Numerical simulations of the system have been performed for a set of different iris apertures, and compared with experimental measurements on a simple cold-test model. The results are shown in Figure 4.

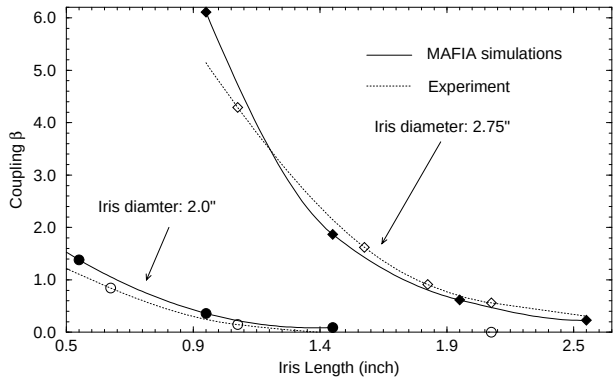

Figure 4: Coupling coefficient $\beta = \frac{Q_0}{Q_{\rm ext}}$ is plotted as a function of iris length for two different iris diameters.

4 CONCLUSION

The time domain method works efficiently for the cavity-coupler system with high Qs and weak coupling. Good agreements are achieved between the MAFIA simulations and the experimental measurements. The method can be easily applied to other systems as well.

Abstract

The ISAC RFQ is an 8 meter long, 4-rod split-ring structure operating at 35 MHz in cw mode. The rods are vane-shaped and supported by 19 rings spaced 40 cm apart. The stringent, $\pm$ 0.08 mm, quadrature positioning tolerance of the four rod electrodes over the 8 m length was met by adopting a design philosophy based on manufacturing 19 identical rings and mounting them on precision ground plates which are accurately aligned in the vacuum tank prior to ring installation. The vacuum tank is also unique in that it is square in cross-section and split diagonally to obtain full unobstructed side access to the RFQ modules. A seven ring section of the RFQ has been successfully tested with beam at full power.

1 INTRODUCTION

The accelerating system of the ISAC radioactive ion beams facility consists of an RFQ and a post - stripper DTL. Ion beams with A/q $\leq$ 30, from the on line mass separator will be accelerated from 2 keV/u to 150 keV/u through the RFQ and then to an energy up to 1.5 MeV/u through the DTL structure. The reference design[1] for the RFQ is a four rod split ring structure operating cw at 35 MHz. The RFQ accelerator section is 8 meters long and is designed in 40 cm long modules with a peak potential between the electrodes of 74 kV. Full power tests on a single module[2] and on a three module assembly[3] enabled us to complete the basic electrical and mechanical design for the RFQ accelerator. The alignment philosophy was based on manufacturing 19 identical rings and mounting them on precision ground platens which are accurately aligned in the vacuum tank prior to ring installation. The theodolite intersection method was used to align two platen bases in the tank to allow 7 of the 19 rings to be installed in the first section of the vacuum tank. The alignment of the ring assemblies on the platens was accomplished by the same method. Because of the manufacturing procedures and alignment philosophy adopted, when the electrodes were installed on their mounting surfaces they were aligned by definition, assuming that the fabrication tolerances were met.

2 VACUUM TANK

The vacuum tank for the RFQ accelerator is square in cross section (approx. 1 m x 1 m) and 8 m long. It is welded in mild steel and made in two pieces, a base and a lid, with a diagonal split line (Fig. 1) sealed with an 'O' ring. The intent is to provide a very rigid base and heavy back wall on which to mount the turbo pumps, diagnostics, gauges and rf coupling loop; leaving the lid a lighter structure easily removable for access. The diagonal split line provides exceptional accessibility. Cooling water manifolds run along the front floor of the tank fed by penetrations in the tank floor. The inside of the tank is completely cyanide bath copper plated. This was accomplished by using each half of the tank as its own bath vessel – tipped 45°. All the mounting pads on the floor are machined in one pass to ensure they are co-planar. The tank base is mounted on a 9 m x 1.5 m x 0.5 m concrete pad with 22 imbedded studs to match the 7 mounting flanges on the tank base. In order to avoid distortion, the tank is set down on epoxy grout which is allowed to set before the nuts are torqued. After final adjustment no movement of the tank base was observed when the lid was bolted down or when the tank was evacuated. Each half of the tank has forty-two 500 W heaters uniformly installed, covered with a glass fiber blanket, for bake out. A tank temperature of 60°C is reached in less than 2 hours creating a longitu-

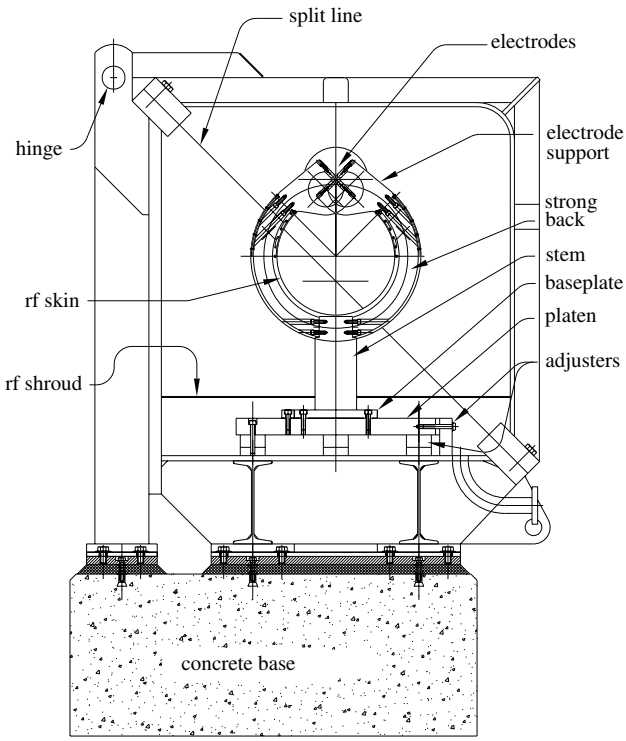

Figure 1: End view of RFQ tank assembly.

dinal growth of $\sim$ 2.0 mm. The elasticity of the mounting system copes with this and growth returns to zero at operating temperature.

3 ACCELERATOR COMPONENTS

3.1 Design Considerations

Each ring is identical and consists of a base, a stem, a split strong back, two electrode supports and an rf skin (Fig. 1). To achieve thermal stability all rf surfaces are water cooled (except for the outer rf skin). This is done by using two separate water circuits. Circuit 1 supplies cooling water from the inlet manifold to a tube array soldered on the inside of the inner rf skin; from there the water enters a circuit drilled into the electrode support (Fig. 2) and then returns to the outer manifold. Circuit 2 transports water from the inlet manifold to the electrode supports through the electrodes to the adjacent ring. Hence, with a 3-ring platen, number 2-ring supplies water to the 4 electrodes, and number 1 and 3 rings receive and return the water. The rf skin encloses the strong back but is attached only where it meets the electrode supports, thus allowing for thermal growth of the skin without loading the structure and causing electrode misalignment. Prototype tests indicate a very small movement during voltage ramp-up but this returns to zero at steady state. Tests on the seven rings showed no movement at all.

As mentioned the philosophy of mechanical positioning, or alignment of the rings, in order to control the accuracy of the electrodes around a true datum line in space (i.e., beam centerline), is to make each ring identical such that when sitting in a jig on its baseplate the electrode mounting pads are within 25 μm, of true position. In the tank there are 6 platens – the first supports 4 rings, and the remaining five 3 rings each. Each platen consists of a special steel 63.5 mm thick with an offset longitudinal rail bolted and doweled in place. The platen and rail are accurately ground in one set up, thus providing accurate datums for mounting and locating the ring bases (the flatness tolerances, i.e., < 12 μm). The platens have 5 adjustable mounting points - 3 vertical and 2 lateral. Each platen is adjusted in the tank using special targets for each platen and aligned by the theodolite intersection procedure which is covered in a later section. Once the platens are aligned they are locked in position and are ready for installation of the rings.

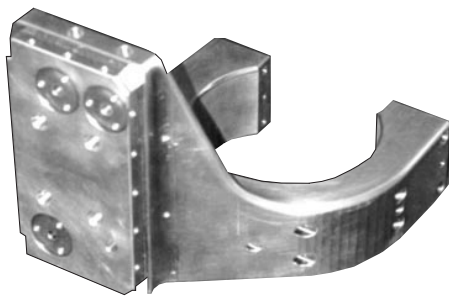

Figure 2: Electrode support showing holes drilled for water cooling circuits.

3.2 Fabrication Considerations

In order to achieve the manufacture of identical rings a philosophy of fabrication and assembly had to be decided upon. The key to this is that the mounting surface on which the vane shaped electrodes are mounted are machined as the last major operation. In order to achieve this with such an awkward shape it was decided to use Electrical Discharge Machining (EDM) and employ a master fixture that would engage datum features on the ring base (the same features that would eventually engage the datums on the platen) and accurately hold the ring in the EDM machine for final machining, thus ensuring that all rings are machined in an identical set up. This master fixture also had provision for addition of inspection tooling to check the result. The same fixture was also used to manufacture special targets previously mentioned which are used to align the platens. Finally, each ring is inspected by an independent organization using a coordinate measuring system. This method of ring manufacture means that individual components can be held to reasonable tolerances with enough machine allowance on the electrode platform to accommodate the accumulated assembly tolerances. Prior to EDM machining at final assembly, all components are doweled together and cleaned.

The electrode support is also of some complexity due to the cooling circuits drilled within the shape of this component (see Fig. 2). This is a fully NC machined component produced to a better than 0.80 μm surface finish in chromium copper (tellurium copper was chosen due to a higher machinability and conductivity rating but pieces of this size are unavailable).

The only other components that require special mention are the electrodes and the rf skin. The electrodes are $\sim$ 13 mm x 38 mm x 120 cm long (except the first two sets which are 80 cm long) and made from tellurium copper for improved machinability and good conductivity. The rods are rough machined, gun drilled for water cooling channels and straightened by the supplier. The cooling holes are plugged at either end with silver soldered plugs. They are then finally machined and profile cut on an NC machine to an overall tolerance of $\sim$ 25 μm. Both the electrode and electrode support quality and accuracy met or exceeded our expectations.

The rf skin is made from 2.2 mm thick C110 copper and the u-shaped ring was created by spinning over a mandrel in two pieces that were later brazed together. Mounting frames and flanges are soldered and finished machined and the cooling array is then soldered in position.

3.3 *Assembly*

Rings were assembled in a semi-clean room environment. The base, stem and strong back and electrode supports were bolted together and aligned in a fixture. These components were then drilled and reamed to allow repeatability during the cleaning and subsequent disassembly in order to fit the rf skin. Once the ring was completely assembled it was shipped to the EDM shop in a special protective container. Handling was a major issue due to the awkward shape, high centre of gravity, and fragility of the rings, hence several handling devices were employed to avoid accidents.

After final EDM machining and inspection the rings were cleaned and installed onto the previously aligned platens and the accuracy of their placement in situ was measured, the results of which are discussed in the next section.

4 ALIGNMENT OF PLATENS AND RINGS

Alignment of the first 2 platens was done as a two step process involving a direct on beam axis sighting with an alignment telescope to position the platens, and confirmation of the position using a three dimensional theodolite intersection technique. Four alignment monuments with targets on the beam axis for direct position and off the beam axis to eliminate rotation about the beam axis were manufactured in the ring assembly jig using EDM. These monuments which simulated the rings were placed on the upstream and downstream ends of both platens. The platens were then adjusted so that the monument targets were on beam axis defined by a line of sight telescope with a resolving power of 3.4 arc sec (0.08 mm) and offset micrometer resolution of 0.001".

The three dimensional theodolite technique involves locating two theodolites within a known grid then measuring the angles to monument targets to compute their coordinates. Two 1 sec electronic theodolites (KERN E2) and their in-house software, SIMS (SLAC industrial measurements system), were used to process the data. Simulations using a grid of five fixed points and two independent measurements of the targets with both theodolites indicated measurement accuracy of 0.04 mm in the vertical off axis and on beam axis directions and 0.075 mm in the horizontal off axis direction. Physical constraints that required the theodolites and the grid to be only along one side of the RFQ meant that the horizontal off axis measurement are less accurate because they are along the theodolite sight line.

The grid was established by measuring angles to 17 points with both theodolites and the distance between two of the points which was defined by an invar scale with a tolerance of ± 0.013 mm. All measurements were done twice to improve the accuracy. Five points in the concrete base beneath the RFQ were used to establish the fixed points for the grid. The alignment of the platens was then confirmed by theodolite intersection of the alignment monuments to be on a straight line within 0.010 ± 0.025 mm vertically and within 0.080 ± 0.100 mm horizontally. Following this measurement the seven rings were installed on the platens and a datum face on one side of each ring was measured with the theodolites. The relative aligment of the rings shown in Fig. 3 shows that the rings were aligned to a straight line within 0.060 ± 0.045 mm horizontally and 0.040 ± 0.010 mm vertically which is well within the strident alignment requirement of ± 0.080 mm. The remaining 12 rings will be aligned by extending the grid to the adjacent platen to be aligned and then aligning the platen to the line defined by the previously aligned platens. This process will be repeated as the grid is extended to the next platen to be aligned. Each platen will be aligned to the new straight line.

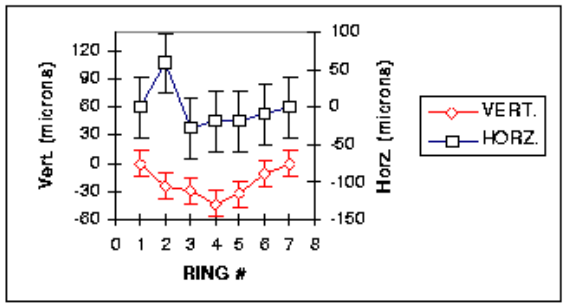

Figure 3: Relative alignment of RFQ rings.

5 CONCLUSION

The outstanding results obtained with beam at full power[4] is a positive indication that the mechanical design, construction and alignment philosophy adopted was a success.

6 ACKNOWLEDGEMENT

A special thanks to Bhalwinder Warich, Peter Harmer and Tim Emmens for the assembly and installation of the RFQ components, and the beam line/alignment group for their help in the alignment of the tank, platens and rings. TRIUMF would also like to thank the alignment group at SLAC for the loan of the two theodilites and their in-house software.

ENGINEERING DESIGN OF THE APT CRYOMODULES*

B.M. Campbell, M.J. Fagan, J.P. Kelley, A.D. Puckett, R. Valicenti, J.A. Waynert
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

The high energy section of the Accelerator Production of Tritium (APT) linac uses Superconducting Radio Frequency (SRF) cavities to accelerate a 100 mA proton beam from 211 MeV to 1700 MeV. Since these SRF cavities can accept protons over a wide velocity range, only 2 different β designs are required. However, 3 different length cryostats, or cryomodules, are required primarily to accommodate the changing magnet focussing lattice. The comparatively short development time span for these cryomodules has inclined us to adopt many design features from proven operating cryomodules. What sets the APT cryomodules apart is the comparatively high RF power; making design to minimize refrigerator work a high priority.

1 INTRODUCTION

A cryomodule containing 2 β=0.64 cavities (β=particle-velocity/speed-of-light) is under design at Los Alamos as part of the Engineering Development and Demostration (ED&D) program. The other types of cryomodules will be designed by General Atomics, one type for 3 β=0.64 cavities and another type for 4 β=0.82 cavities. A modular approach has been adopted that will reduce the total engineering and design effort required to produce these cryomodules.

2 THE β=0.64 ED&D CRYOMODULE

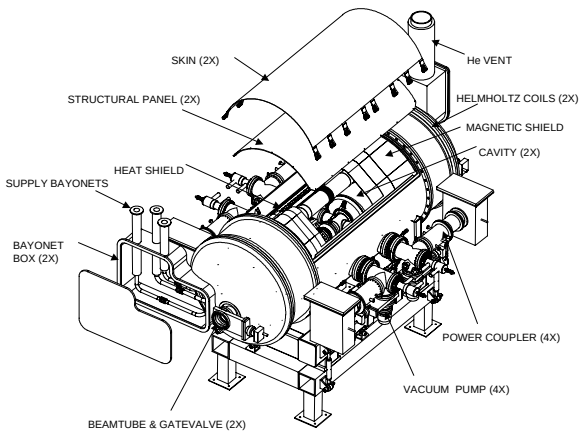

Figure 1: The β=0.64, 2 cavity, ED&D Cryomodule.

The β=0.64 ED&D cryomodule is pictured in Figure 1. The length is 4.9 m, width is 2.7 m, diameter is 1 m, and it weighs 3100 kg .

The extension sections, domed ends, and bayonet boxes are identical modules for all 3 types of cryomodules. Only the length of the RF Section, pictured in Figure 2, varies for the other types of cryomodules.

2.1 Vacuum Tank

The 120° [angle] top opening in the vacuum tank can be seen in Figure 1 with the structural panel and vacuum skin popped up. This design was adopted from the CERN-LEP cryomodule. A similarly large lower opening provides excellent access for assembly and laminar air flow in the clean room.

The center section of the vacuum tank is designed to be easily cleaned before going into the clean room. The side walls are formed from 310 stainless steel plate with a ground finish. No tapped or blind holes are used.

2.2 Heat Shield

The heat shield installed in the complete RF Section is pictured in Figure 2. The heat shield is assembled from top and bottom parts and two end parts. The parts are made from aluminum sheet with a tube trace attached by welding. Slots in the sheet relieve stresses during cool down as in the Tesla Test Facility (TTF) cryomodule.

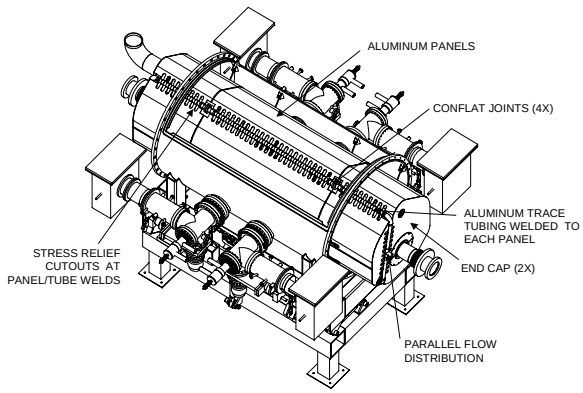

Figure 2: Complete RF Section with heat shield installed.

* Work supported by US Department of Energy

2.3 Magnetic Shield

The magnetic shielding is designed to attenuate the earth's magnetic field reaching the cavity to about 10 mGauss. Two passive shields will be used to attenuate the radial fields and Helmholtz coils used for the axial fields.

2.4 Helium Venting for Fault Conditions

With a loss of vacuum, the liquid helium in the helium vessels will boil and rapidly evolve helium vapor that is vented to prevent over pressurizing the helium vessels and cavities. Four separate vent systems are required to handle the various fault conditions. The worst case is a breach in the beam tube outside the cryomodule that allows air to rush into the 2-K cavity. The air condenses on the cavity wall and deposits a heat flux of 3.8 W/cm^2 into the helium bath. The helium vessels vent through the 15-cm duct to pressure relief devices that discharge the helium directly into the tunnel.

2.5 Vacuum System

Separate vacuum systems provide the insulating vacuum and the power coupler and cavity vacuum. Turbo molecular pumps were selected over ion pumps because design advances have improved reliability and there is less risk of contamination from back streaming.

2.6 Cryomodule Heat Loads

Table 1: β = 0.82 Component Heat Loads

	β = 0.82 Cryomodule	
	2-K (W)	45-K (W)
Cavity (each)	24.1	0
Power Coupler (each)	5	22
HOMs (per cavity)	1.7	0
End Beam Tubes (2)	1.84	24
Radiation - MLI	2.2	19.4
Other	4	47.5

Table2: β = 0.64 Component Heat Loads

	β = 0.64 Cryomodule	
	2-K (W)	45-K (W)
Cavity (each)	15.4	0
Power Coupler (each)	3.5	15
HOMs (per cavity)	1.2	0
End Beam Tubes (2)	1.64	24
Radiation - MLI	0.92	9.1
Other	3	47.5

Tables 1 & 2 summarize the various heat loads, both static and dynamic, that the cryomodule components place on the refrigeration.

2.7 Cryomodule Assembly

The couplers and cavities are assembled and hermetically sealed in a class 100 clean room. The center section of the vacuum vessel goes into the clean room for assembly because the power coupler windows are located outside the vacuum vessel. This approach follows the procedure at CERN. The thermal intercept, cryogenic plumbing, and remaining components are installed outside the clean room with the cryomodule rotated 90°.

3 CAVITIES

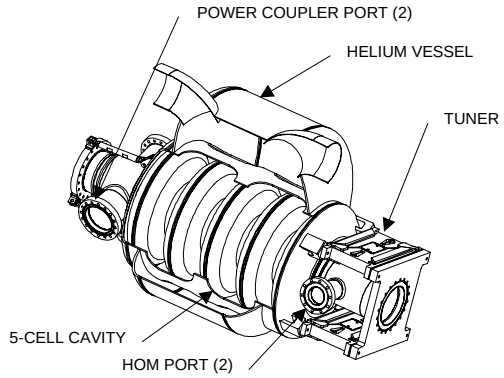

Figure 3: A β=0.64 Cavity and Helium Vessel

3.1 Cavity Design

A cavity and helium vessel, with ¼ of the wall cut away, is pictured in Figure 3. Table 1 gives a summary of the cavity design. The cavities are made from RRR 250 niobium that is formed and e-beam welded following well established cavity fabrication methods. The thickness of the niobium sheet is 3-mm for the β=0.82 cavity and 4-mm for the β=0.64 cavity.

Table 1: Cavity Design Summary

	β=0.64	**β=0.82**
Aperture Radius	65 mm	80 mm
Cavity Radius	194 mm	200 mm
Wall slope	10°	10°
Number of cells	5	5
Length	685 mm	878 mm
Frequency	700 MHz	700 MHz
Peak surface field	15 to 17 MV/m	14 to 17 MV/m
Accelerating gradient	4.7 to 5.0 MV/m	Constant 5.5 MV/m
RF losses @ $Q_0 = 5 \times 10^9$	15.4 W	24.1 W

After fabrication the cavities are chemically etched and high pressure water rinsed using state-of-the art procedures.

3.2 Helium Vessel Design

The helium vessels are made from grade 2 titanium that nearly matches the expansion rate of niobium and avoids possible residual magnetic fields inside the shielding. In the cryomodule the helium vessels are connected by an upper 15-cm vapor return duct and a lower 2-cm liquid transfer line. The liquid helium level at 2.15-K is 7-cm above the cavity. Sufficient ullage is provided in the helium vessel to allow the helium to expand in the event sub-atmospheric pumping is interrupted causing the helium to warm to 4.5-K. The purpose is to keep the return duct free of liquid to reduce recovery time after pumping resumes.

3.3 Cavity Frequency Tuner

Each cavity can be tuned to its 700 MHz resonant frequency by a magnetostrictive linear actuator that either compresses or lengthens the 5 cells. The actuator acts through a flexure device that provides parallel action and 4:1 leverage. The tuning range is ±324 KHz and the resolution is 10 Hz. The actuator travel of 2-cm is obtained by alternately clamping each end of the magnetostrictive rod. The tuner can also be used to de-tune the cavity 20 KHz to take it off line so that proton bunches do not excite cavity fields.

3.4 Cavity Microphonics

Cavity vibration and its effect on the RF frequency will be measured on the prototype 5-cell β=0.64 cavity that is currently being fabricated. The cavity will be installed in its inner perforated shell, shown in Figure 3, but without the outer helium vessel. This permits access to the cavity for installing accelerometers and also for adding cavity supports if needed. The RF control system has been extensively modeled [1] and this measured data will be used with the model to assess microphonic instability.

The next phase will be testing the cavity in the ED&D cryomodule at 2-K. A wire position monitor will be used to measure helium vessel vibration.

4 POWER COUPLERS

Each cavity is powered by 2 coaxial couplers [2], each rated at 210 kW for the β=0.82 and 140 kW for the β=0.64 cavities. A power coupler is pictured in Figure 4. Dual RF windows are warm and located outside the vacuum tank.

The losses from the high RF power transmitted by the couplers can result in large heat loads on the refrigeration plant. The power coupler cooling must be carefully designed to minimize these loads.

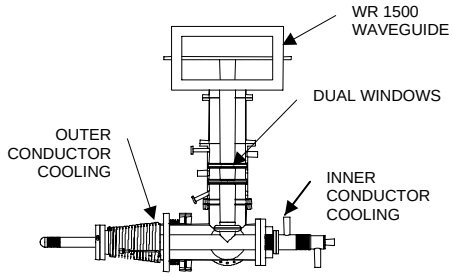

Figure 4: Coaxial Power Coupler

The power coupler cooling naturally divides into two separate considerations: maintaining thermal stability of the inner conductor under various operating scenarios, such as traveling and standing wave RF; and, outer conductor cooling to reduce the heat conducted to the low temperature superconducting cavities. Analysis has shown that the inner conductor is adequately cooled with 3 g/s of helium gas at 3 atm and 300 K. The maximum temperature rise of the inner conductor is limited to 50 K under 210 kW standing wave condition.

Two basic approaches have been considered for cooling the outer conductor: one or two localized thermal intercepts, and distributed cooling from counterflow heat exchange [3]. Independent of the cooling approach, the 2 K heat load is about 2 W, if the niobium is maintained in the superconducting state. The total room temperature refrigeration input power will depend on the details of the cooling approach, but a trade-off study considering additional factors such as manufacturability, reliability, and controllability will ultimately determine which cooling approach is used.

5 STATUS

We are currently in the final design phase and planning a design review for November. Testing is scheduled to begin in April of year 2000.

ANALYSIS OF PERFORMANCE LIMITATIONS FOR SUPERCONDUCTING CAVITIES *

J. R. Delayen, L. R. Doolittle, and C. E. Reece
Thomas Jefferson National Accelerator Facility, Newport News, Virginia 23606 USA

Abstract

The performance of superconducting cavities in accelerators can be limited by several factors, such as: field emission, quenches, arcing, rf power; and the maximum gradient at which a cavity can operate will be determined by the lowest of these limitations for that particular cavity. The CEBAF accelerator operates with over 300 cavities and, for each of them, we have determined the maximum operating gradient and its limiting factor. We have developed a model that allows us to determine the distribution of gradients that could be achieved for each of these limitations independently of the others. The result of this analysis can guide an R&D program to achieve the best overall performance improvement. The same model can be used to relate the performance of single-cell and multi-cell cavities.

1 MODEL AND ANALYSIS

We assume n independent random variables X_i, each with probability density $f_i(x)$ and probability distribution $F_i(x) = \int_{-\infty}^{x} f_i(t)dt$.

We define a new random variable X as $X = \min(X_i)$. Its probability density $f(x)$ and distribution $F(x)$ are related to those of the X_i by:

$$1 - F(x) = \prod_i [1 - F_i(x)]$$

$$f(x) = (1 - F(x)) \sum_i \frac{f_i(x)}{1 - F_i(x)}$$

While $f(x)$ and $F(x)$ are directly observable, the above relations are not sufficient to determine the $f_i(x)$ and $F_i(x)$. This can be done, however, if for each realization of X we can identify for which variable X_i we had $x = x_i$.

In the application to superconducting cavities this means that for each cavity, not only do we know the maximum gradient at which it will operate but also which limitation prevents it from operating at a higher field. This is shown in figure 1. For each variable X_i, we can then define the function $g_i(x)$ as:

$$g_i(x)dx = \text{Prob}\{x < X_i \leq x + dx,\ X_j > x \text{ for } j \neq i\}$$

$$= f_i(x)dx \prod_{j \neq i} [1 - F_j(x)]$$

* Work supported by the U.S. DOE Contract # DE-AC05-84ER40150

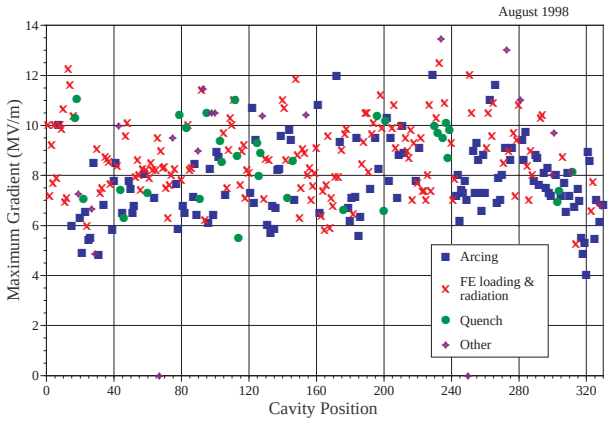

Figure 1: Maximum useful gradient and type of limitation for CEBAF cavities.

$$g_i(x) = \frac{f_i(x)}{1 - F_i(x)} \prod_j [1 - F_j(x)] \qquad (1)$$

The functions $g_i(x)$ are directly observable and the corresponding histograms are shown in figure 2 for our application. Note that the functions $g_i(x)$ are not true probability densities but represent how often a particular variable will be the minimum for a particular value x. Their primitives, G_i which are shown in figure 3, are the cumulative rate of occurrence for each limitation. The functions $g_i(x)$ also satisfy

$$\sum_i g_i(x) = f(x)$$

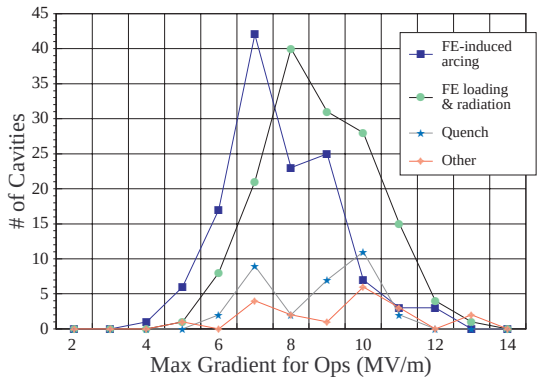

Figure 2: Histograms of the cavity gradients for the different limitations.

Equation (1) can be rewritten as:

$$\frac{f_i(x)}{1 - F_i(x)} = \frac{g_i(x)}{1 - F(x)}$$

Since $f_i(x)$ is the derivative of $F_i(x)$ the above equation can be simply integrated to yield:

$$F_i(x) = 1 - \exp\left(-\int_{-\infty}^{x} \frac{g_i(t)dt}{1-F(t)}\right) \qquad (2)$$

$$f_i(x) = \frac{g_i(x)}{1-F(x)} \exp\left(-\int_{-\infty}^{x} \frac{g_i(t)dt}{1-F(t)}\right)$$

For a finite number of cavities, the measured probability densities $f_i(x)$ are constructed from delta functions. For n cavities, each with a limit of type l_k at energy E_k,

$$g_i(x) = \frac{1}{n}\sum_k \delta(x - E_k)\delta_{i,l_k},$$

where l_k ranges over the same set of integers as i (arcs, radiation, etc.). The distribution F and the individual G_i are easily computed by integration of g_i. As shown in figure 3, they are summations of step-functions.

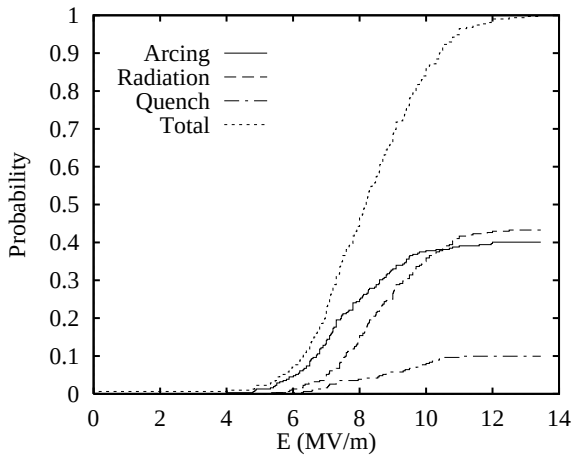

Figure 3: Measured distributions F and G_i vs. energy.

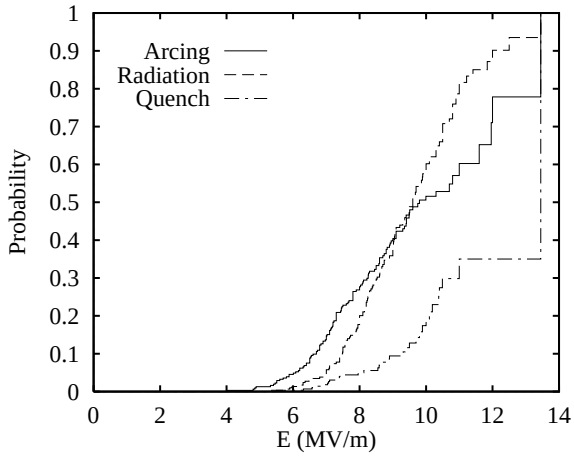

Figure 4: Calculated distributions F_i vs. energy.

Equation (2) also integrates sums of delta functions into sums of step-functions. The resulting derived probabilities F_i are shown in figure 4, and the corresponding density functions f_i are again sums of delta functions. To be shown in a useful form one could sort them into bins; instead, we assumed they have an approximate log-normal form, and chose coefficients for that distribution based on the calculated F_i.

The smoothed probability densities $f_i(E)$ for the 3 main limitations are shown in figure 5, along with the overall density $f(E)$. The same analysis was performed in 1995 on data collected at that time, and is shown in figure 6.

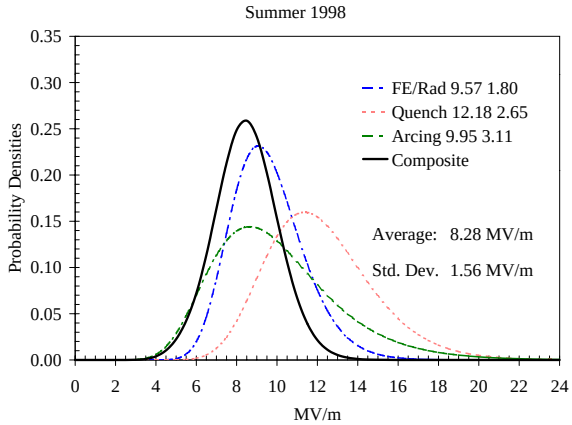

Figure 5: Probability densities for 1998 limitations.

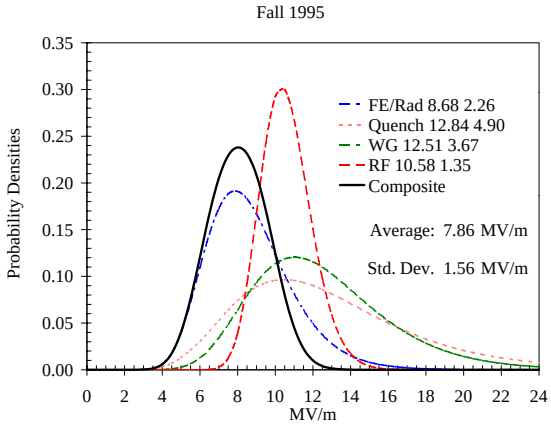

Figure 6: Probability densities for 1995 limitations.

2 DISCUSSION

Two of the important limitations which were present in 1995 have been eliminated. At that time, the beam current required of the machine was modest, so to reduce power consumption, the output power of the klystrons was limited to 2 kW. This imposed a limit on the gradient that some cavities, whose external Q was not optimal, could achieve. In 1998, with the klystrons operating at 5 kW output power, rf is not a limitation anymore.

Another limitation which was present in 1995 (labelled WG in the figure) was due to pressure fluctuations in the

waveguide section between the cold and warm windows leading to an rf trip. Since then a program to improve *in situ* the performance of the cavities has been implemented. This program includes a cryocycle of the cryomodules to about 40 K to outgas the waveguide section, followed by rf conditioning of the same section. As a result, waveguide pressure fluctuations and their associated rf trips have been eliminated as an important performance limitation [1].

The main limitation, as can be seen from figure 6, was field emission in the cavities. This was the main target of the *in situ* processing of the cavities and, although not yet completed, has resulted in raising the field-emission-limited performance by 1 MV/m. When this improvement program is completed in February 1999 it is expected to have raised the operational energy of CEBAF from 5 to 6 GeV.

As indicated in figure 5 a new limitation has appeared which was not included in the 1995 data. It is due to occasional arcing or flashover on the cold window, which is located close to the beam line, and is probably caused by slow charging from field-emitted electrons. This limitation is different from the others in that it is operational in nature, and not as hard a limitation as the others. Although arcing is infrequent (which is why is was not identified in the 1995 commissioning data), with more that 300 cavities in operation it can have a significant impact on accelerator up-time. We have set a limit of less than one arc-related trip every eight hours for each of the cavities which display this behavior, and some of these cavities have had their operating gradient reduced as a result.

A new configuration for the cold window, which places it further from the beam line and shields it from field-emitted electrons, has been developed and tested, and has led to a virtual elimination of arcing in laboratory tests. While this modification cannot be done on cryomodules while they are installed in the accelerator, it is being implemented on new cryomodules which are under construction for the FEL, and will be incorporated in the CEBAF cryomodules when the opportunity presents itself.

3 PERFORMANCE OF MULTI-CELL CAVITIES

The same model can be used to predict or compare the performance of cavities composed of different numbers of cells under the same set of assumptions: each individual cell's performance is independent of other's and governed by the same variables, and the performance of a multi-cell cavity is limited by its weaker cell.

If f_1, resp. F_1 are the probability density, resp. distribution for the operating gradient of single-cell cavities and f_n and F_n the same functions for n-cell cavities, then:

$$F_n(E) = 1 - [1 - F_1(E)]^n$$

$$f_n(E) = n f_1(E) [1 - F_1(E)]^{n-1}$$

In particular, if $\langle E_1 \rangle = \int_0^\infty E f_1(E) dE$ and $\langle E_n \rangle = \int_0^\infty E f_n(E) dE$, under reasonable assumptions on $F_1(E)$ one can estimate the reduction in performance $\langle E_n \rangle / \langle E_1 \rangle$ from 1 to n cells. It is found that $\langle E_n \rangle / \langle E_1 \rangle$ is relatively insensitive to the actual shape of $f_1(E)$ but depends strongly, as should be expected, on its normalized standard deviation $\sigma / \langle E_1 \rangle$.

An example is shown in figure 7 where we assumed a log-normal distribution for $f_1(E)$. Figure 8 shows the decrease in average gradient as a function of the number of cells for normalized standard distributions between 0.1 and 0.4. This shows that the expected gradient in multi-cell cavities has a negative power-law dependence on the number of cells. This is similar to the apparent negative power-law dependence on the cavity surface area [2].

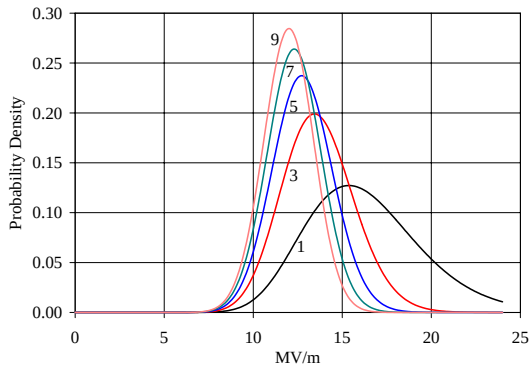

Figure 7: Probability densities for the gradient of single and multi-cell cavities.

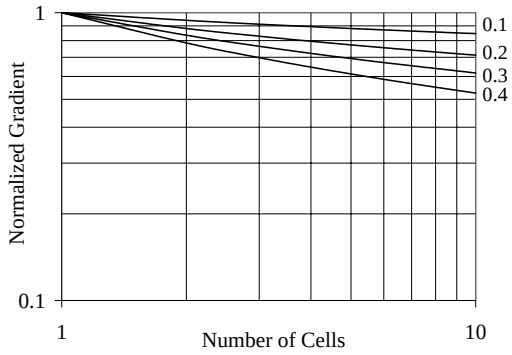

Figure 8: Normalized gradient of multi-cell cavities as a function of the number of cells. The parameter is the normalized standard deviation for gradient of a single-cell cavity.

RESONANCE CONTROL COOLING SYSTEM FOR THE APT/LEDA RFQ*

R. Floersch, G. Domer
AlliedSignal Federal Manufacturing & Technologies**, Kansas City, Missouri 64141 USA

Abstract

The Radio Frequency Quadrupole (RFQ) [1] resonance control cooling system (RCCS) for the Low Energy Demonstration Accelerator (LEDA) [2] in support of the Accelerator Production of Tritium (APT) [3] is described. Constant flow regulating valves to distribute the required flow to the 424 channels and to permit use of centrifugal pumps is discussed. Control system schema are described to regulate resonance frequency during steady state operation.

1 CONTROL OF RESONANCE FREQUENCY

Resonance frequency in the RFQ is manipulated by changing the gap between opposing vane tips in each of the four Segments. The quadrupole vanes are cooled with constant temperature 50 degree Fahrenheit water to hold their geometry constant. The RFQ cavity wall and all of the systems interfacing through the cavity wall are cooled with temperature controlled water. By manipulating the cavity wall water temperature, the vane tip gap will either increase or decrease based on whether the cavity wall diameter grows or shrinks, thus manipulating the rf resonant frequency.

2 COOLING SYSTEM

The resonance control cooling system is comprised of two subsystems, one open loop and one closed loop.

2.1 Open Loop Subsystem

The open loop subsystem supplies constant temperature coolant to the vane and coupling plate channel passages. The open loop subsystem dissipates approximately 350 kilowatts of heat. To dissipate that heat, 360 gallons per minute of constant temperature 50 °F water is supplied to 84 individual channels. The 84 channels are subdivided into 4 channel types that are common to each of the four 2-meter RFQ Segments. Four sets of supply and return pipes connected directly to the chilled water system distribute approximately 90 gallons per minute of the coolant to/from each of the four Segments.

Parallel piped constant flow regulating valves are used to assure the correct total flow is supplied to each of the channel types within each Segment. Each constant flow-regulating valve supplies a manifold which distributes the coolant among the individual channels.

2.2 Closed Loop Subsystem

The closed loop system supplies temperature controlled water to five different channel types in the cavity wall to dissipate approximately 910 kilowatts of heat. To dissipate that heat, a total of 1160 gallons per minute is supplied to 340 individual channels.

The closed loop subsystem is comprised of four pump loops which circulate coolant through the cavity wall channels of the four RFQ Segments. Connecting the four pump loops is an outer piping loop whose purpose is to control the water temperature being supplied to the four pump loops.

Due to the different amounts of heat dissipated in each RFQ Segment, the inlet water temperature to the cavity wall channels of each Segment must be adjustable and no two will be the same. Figure 1 illustrates a single pump loop. The inlet temperature to the cavity wall channels of each Segment is established by fixing the ratio of the mass flow of the RFQ heated returning coolant that is diverted to mix with the entering mass flow from the outer loop. Setting the stem position of each pumping loop's diverting valve controls that mass flow ratio. The final stem position will be a function of desired inlet temperature and the heat dissipated by the loop and, once established, is not changed during steady state operation.

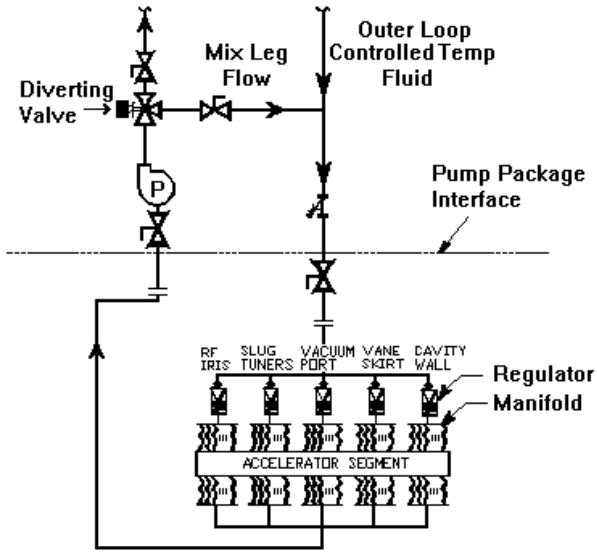

Figure 1: One of four Pump Loops

* Work supported by the US Department of Energy.
** Operated for the United States Department of Energy under Contract No. DE-ACO4-76-DP00613.

To force the cavity to the desired resonant frequency, the rf frequency controller manipulates an outer loop control valve to allow more or less constant temperature chilled water to enter the outer loop and mix with the water from the Segments which is not diverted down the mix leg. The amount of mass flow entering either lowers or raises the outer loop temperature. When the outer loop temperature changes incrementally, the inlet temperatures of all four of the RFQ Segments will increase or decrease by the same incremental amount as long as the rf power is at steady state.

2.3 Constant Flow Regulating Valves

Parallel piped constant flow regulating valves are employed to assure the correct proportion of the total pump flow is supplied to each of the closed loop channel types within each Segment. Each constant flow regulating valve supplies a manifold that distributes the coolant among the individual channels within a channel type.

Flow through the regulating valve is described by the following equation.

$$Q = Cv*SQRT(dP)$$

The flow coefficient (Cv) of the constant flow regulating valves, changes as the differential pressure (dP) across the valve changes. Figure 2 depicts the internals of the AutoFlow regulating valve manufactured by Flow Design Inc. [4].

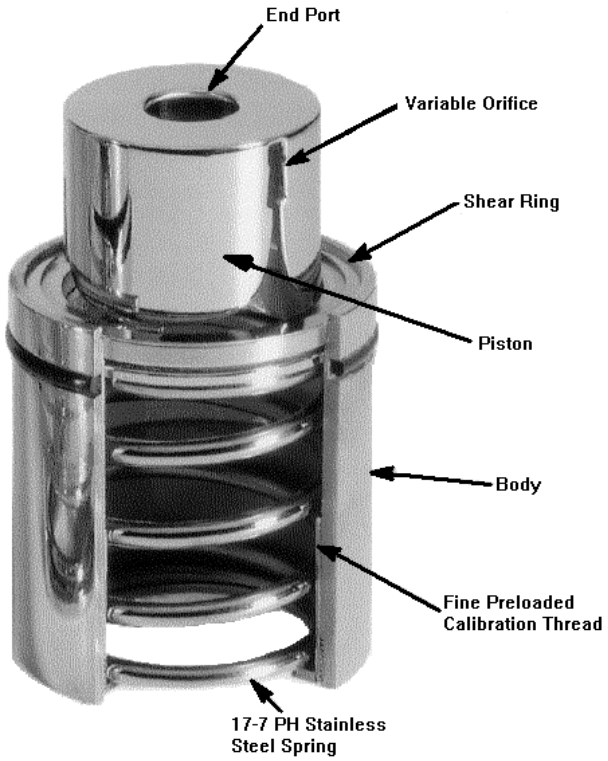

Figure 2: Internals of Constant Flow Regulating Valve

As the pressure drop increases, the piston depresses, reducing the exposed orifice area, thus reducing the Cv. The opposite is true when the pressure drop decreases. The valve's Cv increases/decreases in proportion to the square root of the differential pressure. The net effect is that the flow (Q) through the valve will remain at the designed flow rate (within +/- 5%) as long as the spring is not fully compressed or extended. Spring ranges can be purchased for two pressure drop ranges, 2-30 psi and 5-60 psi.

These flow-regulating valves are used to regulate the flow to each different channel type within a one meter RFQ Section. Since all flow paths utilize a regulating valve, the total volumetric flow of the pump is clamped to the sum of the designed regulating valve flows as long as the pressure drop variance among the channels doesn't exceed the valves spring range. Figure 3 shows the effect that the constant flow-regulating valves have on each loop's loss curve. The discontinuity in the loop loss curve begins when all valves are in the regulating range and ends when the first valve saturates. That discontinuity establishes a window that permits use of centrifugal pumps. A centrifugal pump whose head gain curve intersects the discontinuity of the loop loss curve will provide the desired volumetric flow.

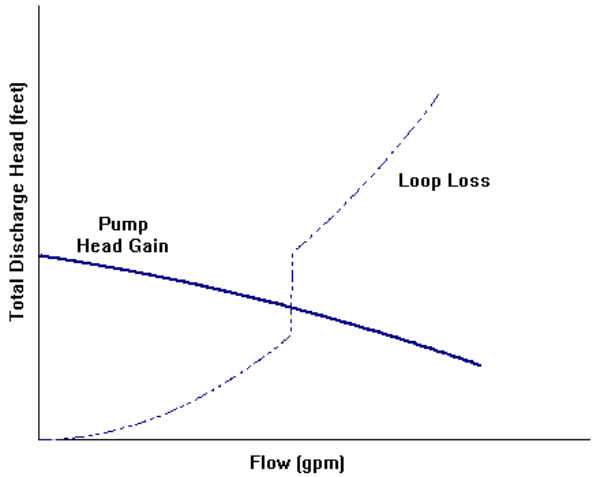

Figure 3: Loop Loss Curve with Regulating Valves

The height of the discontinuity window is dependent on the spring range of the regulating valves and the pressure drops of each of the channel types.

3 RESONANCE FREQUENCY CONTROL

The RFQ RCCS provides continuous and discrete control of the cooling system. Operator interface screens are provided to change setup parameters for continuous control and to initiate discrete controls. Status screens are also provided to display information about the RFQ cooling system.

The RCCS is implemented using Experimental Physics and Control System (EPICS) based hardware and software and is integrated with other networked LEDA EPICS systems. Figure 4 shows the network connections of the RCCS system. The other LEDA systems act in a supervisory role by providing information to the RCCS via EPICS Channel Access to the RCCS Input/Output Controller (IOC) database to initiate actions. Status information from the RCCS is accessible via Channel Access.

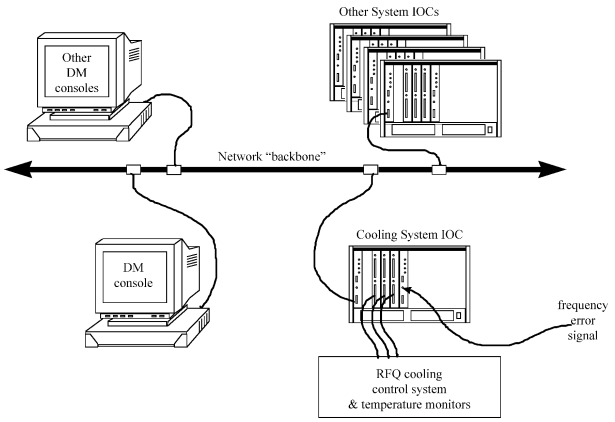

Figure 4: Network Configuration

The RCCS software is constructed using EPICS State Notational Language (SNL) to track the condition of the system and to allow certain control actions to take place. Additional C programs are used to perform the control algorithms and file operations. Figure 5 shows the state diagram that represents the overall conditions of the RCCS. Resonant Frequency Control (RFC) is obtained by going through one of two defined sequences of operations, Startup or Conditioning.

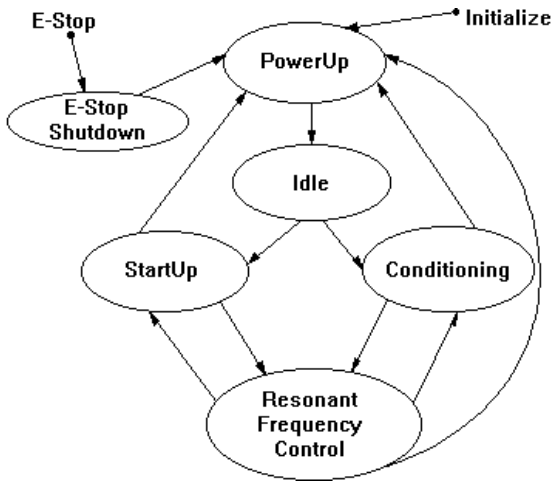

Figure 5: System Level State Diagram

RFC regulates the resonant frequency of the RFQ using a single loop Proportional Integral Derivative (PID) control algorithm that adjusts the setting of the outer loop control valve based on the frequency error provided by the Low Level RF (LLRF) control system. The valve adjustments will alter the temperature of the water flowing in the outer loop, thereby changing the frequency of the RFQ. RFC is the normal operating state of the RCCS.

RFC begins when a valid frequency error from the LLRF system is detected, ending startup or conditioning. The PID algorithm regulates the resonant frequency of the RFQ to +/- 8KHz, which corresponds to a change in water temperature supplied to the inner pumping loops of +/- 0.5°F.

The frequency error, received via an analog signal from the LLRF system, ranges from 0 to 10V DC, where +0.5V represents -50KHz error and +9.5V represents +50KHz error. Any error reading outside the +0.5V to +9.5V range is considered an invalid signal.

If the frequency error signal is lost, RFC is halted and temperature control is started to regulate the Outer Loop Common Supply at the current temperature, until the supervisory system dictates a change to another state or the frequency error returns. The setpoint for temperature control will be the average of sampled temperatures before the error signal was lost. When the frequency error signal returns, temperature control is halted and RFC is restarted.

RFC can only be halted and directed to make a transition to the proper state by the supervisory system or an emergency stop condition.

4 INSTALLATION STATUS

Installation of the RCCS Pump Package and under floor piping was completed in January 1998. Installation of the remainder of the distribution piping is scheduled for completion along with the control system hardware and software in September 1998.

5 ACKNOWLEDGEMENTS

An immense amount of technical insight and installation assistance was provided by Dale Schrage, Lloyd Young, Dave Gurd, Amy Regan, and Frank Spinos, LANL.

FIRST TESTS OF A TRAVELING-WAVE CHOPPER FOR THE ATLAS POSITIVE ION LINAC

R.C. Pardo, J.M. Bogaty, B.E. Clifft
Argonne National Laboratory, Argonne, IL 60439
USA

Abstract

A ten segment traveling-wave chopper has been constructed and successfully tested at 5% of the design 12 MHz repetition rate. The chopper must remove unbunched tails from a partially bunched heavy-ion beam in order to avoid undue emittance growth in the linac and the production of undesirable satellite beam bunches. When poorly bunched beams traverse a chopper, the traditional sine wave chopper produces unacceptable transverse emittance growth and unnecessary beam loss. Emittance growth and unnecessary beam losses are expected to be much reduced in the traveling wave chopper. These first tests have confirmed the validity of these claims, clearly showing much reduced transverse emittance growth as compared to the original sine wave chopper and excellent selectivity for the desired beam. Details of these tests will be presented and compared to calculations. Operation of the new chopper at the full 12 MHz rate is the next goal. Development of a driver power supply capable of full CW operation will also be described.

1 INTRODUCTION

Excellent beam quality is an important feature of heavy-ion beams provided to the research program by the ATLAS superconducting linear accelerator. The measure of beam quality includes relatively low emittance, small spot sizes with little or no halo, small energy spread, and when requested excellent bunch time width (<200 ps FWHM) on target. In order to make use of these properties, a rather larger bunch period of 82.4 ns is provided meaning that only every sixth or eighth RF bucket is filled with beam.

To achieve these beam quality goals, a two stage bunching systems converts the DC beam from the ion source into a beam with a 12.125 MHz bunch structure. The system is able to adequately bunch approximately 70% of the DC beam into acceptable pulses, but the remainder of the DC beam must be removed in order to provide the correct bunch structure and beam quality. This unbunched beam 'tail' is removed with a vertically deflecting electric beam chopper.

The beam chopper which has been used up to now at ATLAS is a resonant 'sine wave' chopper. Bunches are phased so as to arrive at the center of the chopper plates as the sine wave passes through the zero voltage point. The chopper therefore operates at half the frequency of the bunch structure deflecting the unwanted tails both 'up' and 'down'. Since the good beam also sees some voltage due to the finite transit time of the beam bunch through the plate region, portions of the beam pulse are deflected slightly both up and down causing an emittance growth of the transmitted beam. A similar energy gain effect also takes place due to the entrance and exit fringing fields of the chopper. Thus such a device has a significant detrimental effect on beam emittance. The magnitude of the effect depends on the time width of the beam bunch at the chopper. If the chopper can be located in a location with a narrow bunch width these effects can be minimized and acceptable performance is possible. The geometry of a new bunching system in the ion source region of the ATLAS Positive Ion Injector(PII) does not allow the chopper to be located at a location where the beam time width is narrow and the resulting emittance growth from a sine wave chopper will be unacceptable.

Therefore a new non-resonant traveling-wave transmission-line chopping system (TWC) is being developed which can largely eliminate the emittance growth effects described above. The conceptual design and modeled performance has been previously reported [1]. This paper describes the final design and first low duty factor tests of the chopper.

2 CHOPPER DESIGN

The TWC consists of ten shielded plate pair segments arranged transversely to the beam, like rungs on a ladder. The top plates of each section are a portion of one continuous impedance-matched transmission line as are the lower plates. Such a system can propagate a well-formed voltage pulse down the line with a group velocity matched to the velocity of the bunched beam traveling between the plates. The deflector plates have a center-to-center spacing of 4.5 cm which corresponds to a 17.6 ns ion transit time between plates. The deflector plates are isolated from each other by field clamp electrodes which also can be biased with a DC voltage to fine tune any slight beam deflection from incomplete voltage shutoff on the deflector plates. Stripline electrodes are supported by plexiglass plastic strips which provide critical spacing to maintain the proper RF impedance. Three sections of the chopper plate assembly are shown schematically in Figure 1 in relation to the beam direction.

The deflector's characteristic impedance is 125Ω which results from the stripline electrode gap of 3.8 cm and width of 1.5 cm. Each of the stripline electrodes is attached to a pair of 125Ω coaxial connectors. Coaxial cable delay lines are connected in series with the stripline

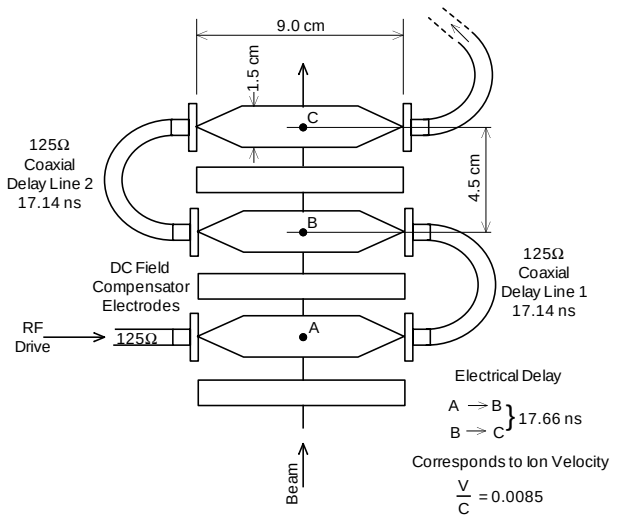

Figure 1: Schematic of TWC deflector plate assembly and its incorporation into the overall transmission line.

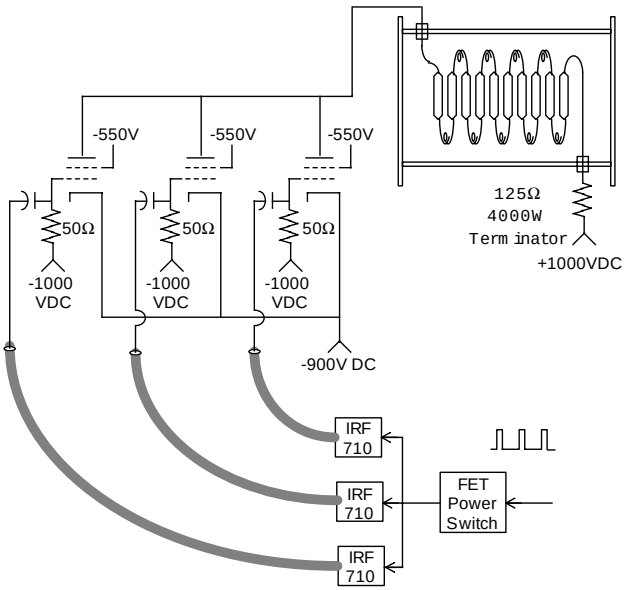

Figure 2: Schematic of the TWC and tetrode final stage with FET grid drivers.

deflectors. The delay lines are used to match the chopper pulse propagation time to the beam velocity. Transition from stripline geometry to coaxial geometry is facilitated by tapering the stripline electrode ends. The tapered ends are paired with a special ground plane electrode assembly (not shown in figure 1) that maintains the 125Ω impedance. The chopper electrodes and water-cooled delay lines are contained in a 0.56 m long by 0.44 m inner diameter cylindrical vacuum chamber.

Each of the nine 3.35m-long delay lines are made from 122.5Ω semirigid coaxial cable[3]. The coax center conductor diameter is approximately 0.0325 cm. The small cross section results in significant ohmic heating which requires direct cooling. A water cooled stainless steel form is used to support the nine delay lines and provide cooling. The delay lines are coiled on the water cooled form and indium soldered for good thermal contact. About 120 watts will be disipated along the delay line during normal chopper operation. The last stripline deflector is terminated in a 125Ω, 4000 watt air-cooled resistor array.

In the quiescent mode, the plates have a vertically deflecting voltage of up to 1000 volts, effectively blocking the transmission of any beam through the device by deflecting all particles vertically onto a set of slits 2 meters downstream. When a bunched beam pulse arrives at the start of the deflecting plates, a zero voltage pulse of 17 ns width or greater is propagated down the chopper, providing a transmission window with no deflecting voltage as seen by the desired beam pulse. At a repetition rate of 12.125 MHz this generates up to 1648 watts of heat into the termination resisitor.

Three Eimac [4] 4CW2000A tetrode vacuum tubes are used in parallel as an electronic switch. The plates of the tubes connect to the chopper transmission-line assembly as shown in figure 2. When the vacuum tubes are cut off, chopper electrode voltage is maintained at the cutoff value of up to 1000V. Pulsing the tubes into conduction causes 8.0 amperes of plate current to flow for about 20 ns. The pulse of current reduces the deflector electrode voltage to zero just as an ion bunch enters the deflector array. The zero volt window propagates through the transmission line array in phase with the desired beam pulse terminating in the 125Ω resistor load. This occurs at a 12.125 MHz CW rate.

Particles in the timing tails will see some deflection. This is minimized by producing as fast a fall and rise time as possible in the voltage pulse. The effect is weighted by the fraction of transmitted particles in the tail regions. Even this effect is lessened compared to the sine wave chopper since the deflection is always in the same direction for the traveling wave chopper, whereas the leading and trailing beam tails are deflected in opposite directions in a sine wave chopper.

3 FIRST TEST RESULTS

The prototype chopper system was mounted in a vacuum chamber on the PII injection beamline. A photo of the prototype assembly is shown in Figure 3. The delay line for this test was made from RG-63 coaxial cable with the outer insulator removed to improve it vacuum properties. Even so the vacuum obtained was barely adequate for these tests and even at 5% duty cycle, noticeable outgassing of the cable occurred.

A beam of 538 keV $^{16}O^{5+}$ with a velocity of 0.0085c was provided by the ATLAS ECR ion source and bunched by a 4-harmonic buncher operating at 12.125 MHz. For this beam, a voltage of 500 V was adequate for complete beam cutoff using only the upper delay line. The lower delay line was used as a DC ground plane. A DC offset voltage of -150 volts was applied to the lower ground

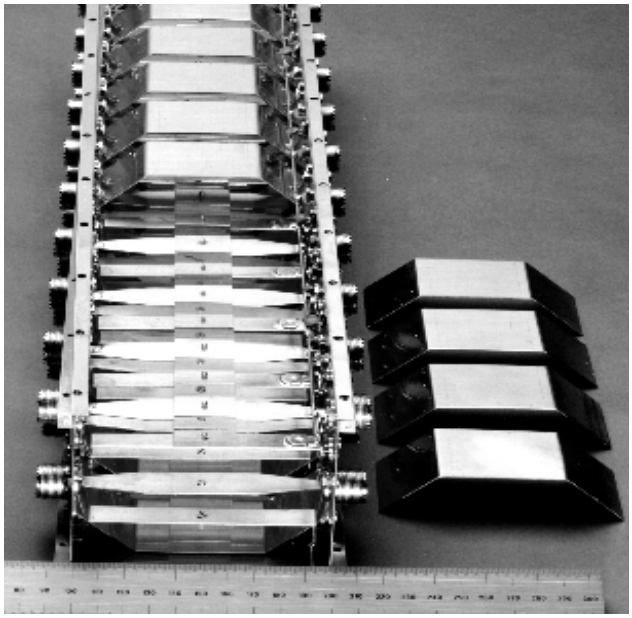

Figure 3: Photo of travelling wave chopper transmission line deflection plate assembly with clamp electrodes in place. A portion of the ground plane electrodes are shown to the side.

plane electrodes to minimize beam steering arising from the inability to completely achieve 0 volts on the transmission-line electrodes. For these tests, a power supply with the required power and rise time was not available and a smaller supply was used, limiting the tests to a 5% duty cycle.

At 500 volts applied deflection, excellent pulse definition was achieved. The achieved voltage pulse waveform is shown in Figure 4. No beam leakage between pulses was observed. 100% cutoff was achieved. These results are in agreement with the calculated voltage and indicated the system was working as expected.

The transverse beam emittance was also measured using the quadrupole method [2]. The original, and still used, sine wave chopper was also immediately upstream of the new chopper and so it was possible to measure the transverse beam emittance with both devices and obtain a direct comparison. Emittance measurements were obtained using both choppers for beam bunch widths of 3 ns and 18 ns FWHM as the beam traversed the chopper plates. Table 1 shows the results of those measurements. The emittance degradation in the chopping plane caused by the sine wave chopper is dramatically demonstrated, especially for the poorly bunched beam. In contrast the TWC shows no emittance growth for narrow pulses and less than a 25% increase in emittance for an 18 ns wide beam. Completion of a full power version of the TWC is expected by the end of the year.

SIMULATION AND MEASUREMENT OF THE ELECTROSTATIC BEAM KICKER IN THE LOW-ENERGY UNDULATOR TEST LINE*

G.J. Waldschmidt, Y.W. Kang
Argonne National Laboratory, Argonne, Illinois 60439 USA

Abstract

An electrostatic kicker has been constructed for use in the Low-Energy Undulator Test Line (LEUTL) at the Advanced Photon Source (APS). The function of the kicker is to limit the amount of beam current to be accelerated by the APS linac. Two electrodes within the kicker create an electric field that adjusts the trajectory of the beam. This paper will explore the static fields that are set up between the offset electrode plates and determine the reaction of the beam to this field. The kicker was numerically simulated using the electromagnetic solver package MAFIA [1].

1 INTRODUCTION

The kicker is positioned just downstream of a 2.856-GHz high-brightness thermionic-cathode rf gun. The rf gun produces peak beam energies of up to 4.5 MeV and peak macropulse current of up to 1.3 A at a repetition rate of 10 Hz. This greatly surpasses the operational limit of the thermionic gun currently in use by the APS. The APS linac then accelerates this beam to energies of approximately 650 MeV before being transported to the LEUTL beamlines. However, this output exceeds the radiation safety restrictions on the linac vault [2,3].

The kicker was designed to dump much of the beam before it reaches the linac and to retain only a fraction of the total beam produced by the rf gun. To achieve this, the kicker is physically surrounded by a constant magnetic field. The field envelopes the kicker, thus deflecting the beam into a dump positioned just past the kicker. The kicker is pulsed by a 150-ns generator, which raises the potential of the electrode plates to 25 kV. When this potential exists, it is sufficient to nullify the effects of the magnetic field, thereby enabling the bunch to pass the kicker and continue along the LEUTL beamline.

Since the bunch length is on the order of picoseconds while the electrodes are pulsed for nanoseconds, the field is considered static. The uniformity of this field, as well as effects due to fringing are discussed in this paper.

2 DESCRIPTION

As shown in Figure 1, the kicker consists of dielectric standoffs, two electrodes, and a feedthrough. The stainless steel electrodes are 10 cm long and separated by 1 cm. They are electropolished with rounded edges in order to improve their reliability under high voltage. An electron beam passing through the kicker can be deflected by nearly 4 mm due to the constant magnetic field. In order to prevent beam scraping, the electrodes are offset from the beamline axis by roughly 2 mm in the direction of the magnetic force. This asymmetry creates a potential perturbation in the electric field that may result in irregularities in the electric field pattern between the electrodes.

The dielectric standoffs serve a dual purpose. They function as a mechanical support for the electrodes and as an alignment device to ensure that the electrodes are positioned within 0.1 mm of specifications. The 35-kV vacuum rated, angled feedthrough supplies the 25-kV potential from the constant current supply through coaxial cables [2].

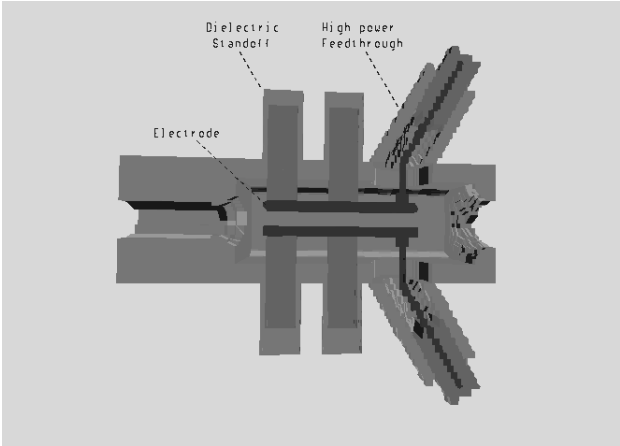

Figure 1: MAFIA rendition of kicker

3 NUMERICAL SIMULATION

Simulations were done with MAFIA 4.01 ECAD software. Two questions were primarily investigated during the simulations. The first question concerns the possible effects of shifting the electrodes off-axis. The second question arises from the actual design criteria, that is, how does the beam behave as is traverses the enclosure. In order to evaluate these issues, the structure was first modeled as accurately as possible within the capabilities of MAFIA. The simulated structure faithfully modeled the important electrical and physical properties

* work supported by U.S. Department of Energy under Contract No. W-31-109-ENG-38

of the kicker. The offset electrodes consisted of rounded edges as did the corners of the interior chamber walls to prevent radiating sources from potentially corrupting the computational domain. The angle of the feedthrough was also considered in order to allow for any slight variation in the field that this produced. The simulation model can be seen in Figure 1.

3.1 Static Solver

The uniformity of the electric field between the electrode plates is of great importance to the reliability and predictability of the kicker. A 25-kV potential was created across the plates be means of the MAFIA static solver module. Using the cgxyz solver, the field strength throughout the volume of the kicker was evaluated. Although the electrodes were offset 20% from the axis, the uniformity of the field strength was verified. An arrowplot showing the constant E-field as well as a visual representation of the fringing fields can be seen in Figure 2. Note that the electrodes are variously colored in order to allow different potentials to exist on each surface.

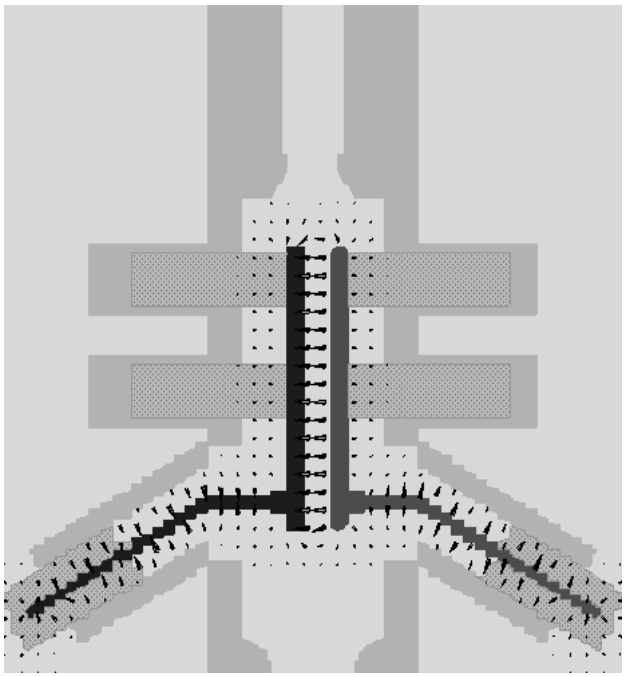

Figure 2: Electric field distribution

Of primary concern is the uniformity of the field along the beam axis, since this is the potential imposed on an intruding beam. Ideally, there exists no field outside the electrodes, while a strong transverse field serving to deflect the beam upward would exist between the plates. The actual field strength along the beam axis is plotted in Figure 3. Since the gap between the electrodes in 1 cm, the maximum electric field between the plates is 2.5 MV/m. In the plot, the electrodes begin at approximately 3.9 cm and extend to 13.9 cm. The virtually constant field strength may be viewed along the entire surface of the electrodes in Figure 4.

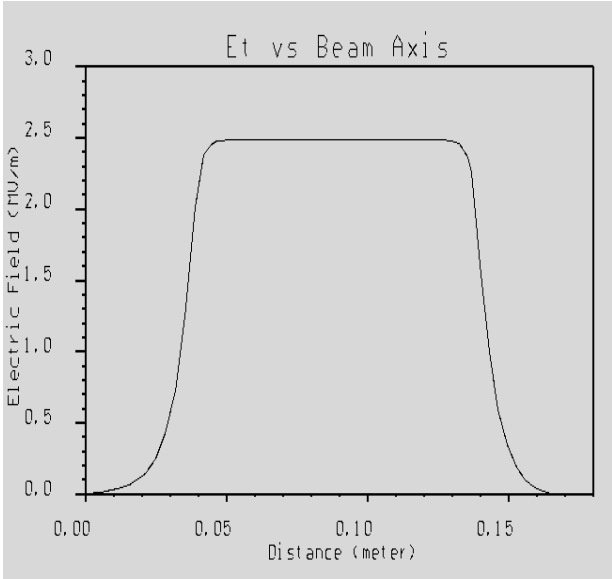

Figure 3: Transverse electric field vs. distance

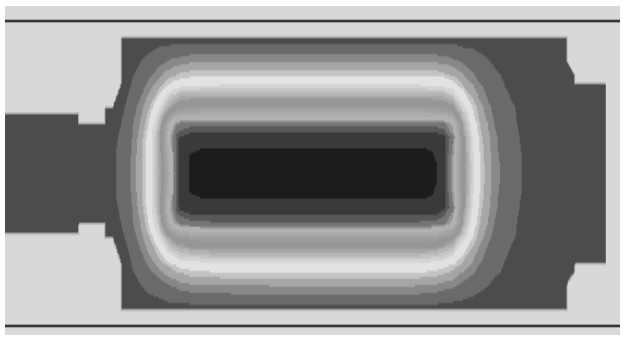

Figure 4: Contour plot of electric field

3.2 Particle-in-Cell Solver

The module TS3 was executed in order to evaluate the overall impact of the kicker with an actual electron bunch passing through the static field. The gaussian beam used in the simulation had a bunch length of 20 ps with an energy of 3.5 MeV and a charge of 350 pC. Given these parameters, a beam deflection of 3.57 mm was calculated analytically. Numerical simulations that account for the effects of fringing fields found the deflection to be approximately 10% greater as the beam traveled the entire length of the kicker chamber.

A plot of the beam can be seen in Figure 5. In this plot, the path of the beam is traced to show the aggregate deflection resulting from the electrodes.

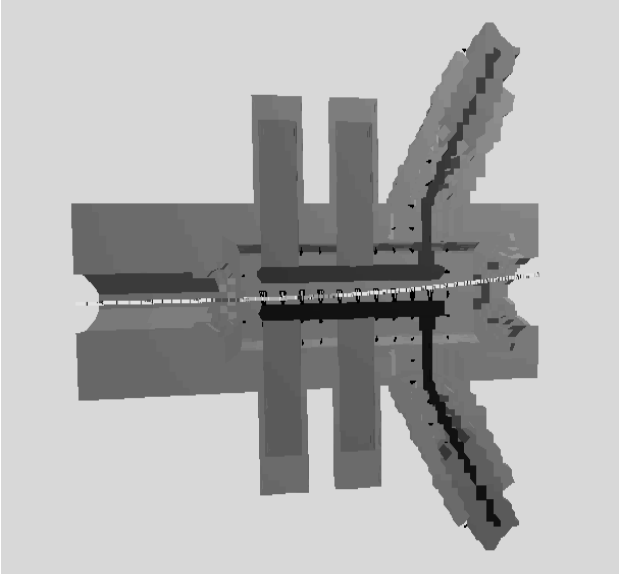

Figure 5: Beam trajectory

4 MEASUREMENT

Preliminary measurement on the relative field distribution in the kicker was made using the HP8753C vector network analyzer. Initially a two-port through calibration was made with a thin plastic line positioned between the electrodes. A small metallic disk, 0.125 inches long with a 0.125 inch diameter, was attached to the line and pulled along the beam axis between the electrode plates. The presence of the disk modified the capacitance of the electrodes. Since the capacitance due to the disk is dependent upon the magnitude of the electric field, the field strength was derived from the power transfer through the plates. This transfer characteristic was then recorded by the network analyzer. The limited distortion of the electric field due to the disk was ignored.

Assuming that the structure is much smaller than a wavelength of the excitation signal, approximate field distributions can be derived. As expected, lower signal frequencies gave noisy results since the coupling was small, whereas higher frequencies gave a distorted field distribution due to transmission line effects. It was found that for 10 cm long electrodes, a few MHz to tens of MHz gave results considered dependable. Figure 6 shows the measured field strength along the beam axis for a 10 MHz signal. The relative electric field distribution can be approximated from this data as:

$$U = \sqrt{|S_{21}|^2 - 1}$$

The above rf technique was used to approximate the static electric field strength. However, there exist reports on the measurement of these fields using a truly static approach [4,5]. At this time, techniques for such measurements are not as well developed as those for magnetic fields.

5 DISCUSSION

The numerical simulation demonstrates the effectiveness of the kicker as a beam chopper. In spite of the offset electrodes, the uniformity of the field was analyzed and found to be satisfactory. The numerical simulation as well as the attempted measurement of the electric field strengths provided results close to those calculated. However, the method used for static field measurements will need to be refined in order to provide more dependable results.

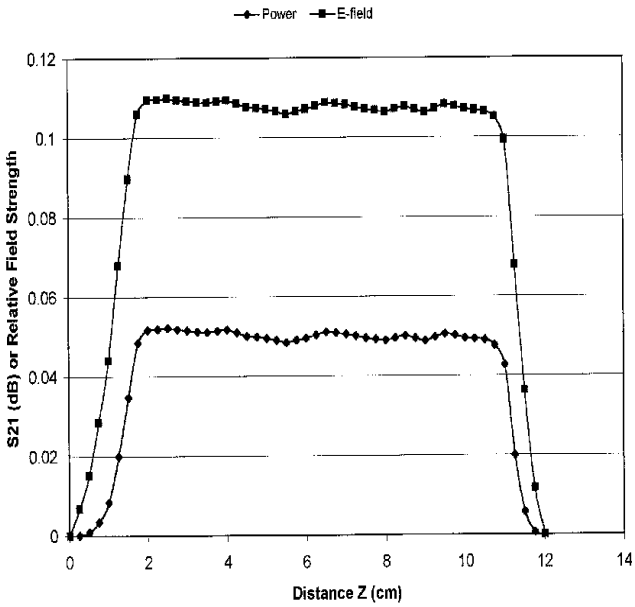

Figure 6: Measured electric field uniformity

6 ACKNOWLEDGEMENT

The authors would like to thank X. Jiang and W. Yoder for their assistance in the setup and measurement of the kicker.

IMPROVED TEMPERATURE REGULATION OF APS LINAC RF COMPONENTS*

R. Dortwegt, S. Pasky, M. White
Argonne National Laboratory, Argonne, Illinois, USA 60439

Abstract

The temperature of the APS S-Band linac's high-power rf components is regulated by water from individual closed-loop deionized (DI) water systems. The rf components are all made of oxygen-free high-conductivity copper and respond quickly to temperature changes. The SLED cavities are especially temperature-sensitive and cause beam energy instabilities when the temperature is not well regulated. Temperature regulation better than ± 0.1 °F is required to achieve good energy stability. Improvements in the closed-loop water systems have enabled us to achieve a regulation of ± 0.05 °F over long periods. Regulation philosophy and equipment are discussed and numerical results are presented.

1 INTRODUCTION

The Advanced Photon Source [1] linear accelerator system [2] consists of a 200-MeV, 2856-MHz S-band electron linac and a 2-radiation-length-thick tungsten target followed by a 450-MeV positron linac. The linac is designed to accelerate 30-ns-long pulses containing 50 nC of electrons to an energy of 200 MeV at 48 pulses per second. The linac rf system includes accelerating structures and SLED cavities that require temperature stability of ± 0.1° F or better. Stability is achieved using closed-loop water systems that provide constant temperature water to the SLEDs, accelerating structures, waveguide, loads, and to the rf reference and drive line.

The optimum temperature of each linac closed loop (LCL) system is found by a standard procedure. Water temperature is varied, and the setpoint is the value that maximizes beam energy. Results from one LCL system are shown in Figure 1. Each LCL has a unique setpoint in the range of 105-116 °F. Absolute knowledge of the temperature is not essential since the setpoint is chosen by direct measurement, but long-term stability is important.

2 GENERAL SYSTEM DESCRIPTION

All linac high-power rf components are temperature conditioned within ± 0.05 °F with DI water from the LCL pumping systems. One LCL is depicted in Figure 2 along with the klystron gallery secondary (DI process water) system (KGSS) that supplies coolant to the heat exchanger (HX) in the closed loop. The APS primary (DI process water) system (APS-PS), from which heat is ultimately rejected, is also shown in the figure. There are five LCLs, all with identical hardware components. Three of the LCLs provide total flows of 80 gpm and the other two provide 25 and 40 gpm.

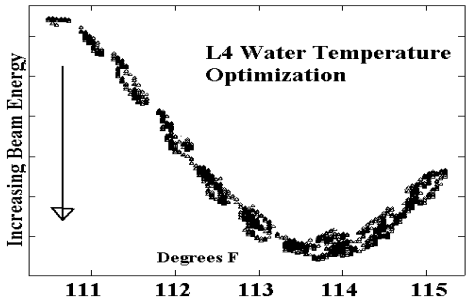

Figure 1: The optimal temperature for L4 is ≈113.7 °F.

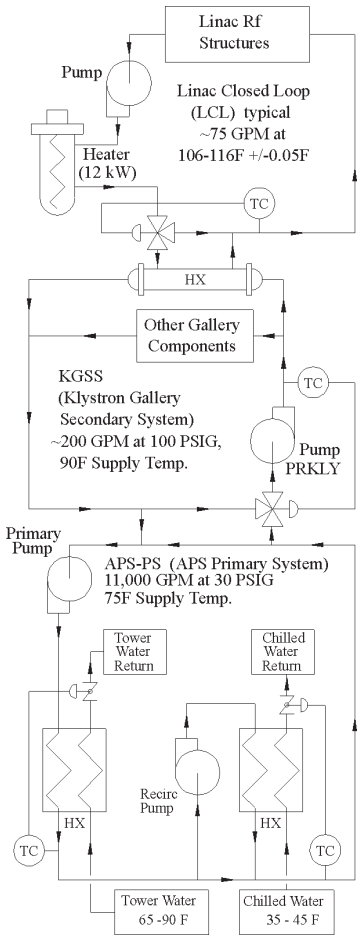

Figure 2: Overview of the linac water system.

* Work supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Contract No. W-31-109-ENG-38.

LCL components include an end-suction centrifugal pump, a 12-kW electric heater, a shell-and-tube heat exchanger, and a 3-way mixing valve to regulate the temperature. The heater serves two functions. It provides energy input to the system on cold startup so the setpoint value is reached in a reasonable time. It also matches steady-state energy input with heat rejection capacity, as the temperature control valve and heat exchanger capacities are more than adequate to remove heat from rf power input and frictional flow losses.

All LCLs are cooled by water circulated by the KGSS pump. KGSS water temperature is controlled at 90 °F by a 3-way mixing valve. Water from the primary system at 75 °F is admitted to the recirculating KGSS.

Whenever possible, cooling of the APS-PS water is done using cooling-tower water. When the cooling tower water is too warm, an additional exchanger cools the primary water using chilled water.

2.1 Brief History of the Linac Water System

The original linac water system provided long-term temperature stability no better than ± 0.5 °F compared to the required ± 0.1°F at steady state. Human intervention was required following significant power transients or equipment upsets. Inadequate performance was primarily due to: 1) poor resolution of the temperature-sensing elements (temperature control instruments only detected changes of the same order as the required steady-state tolerance); 2) installation of thermal sensors in thermowells resulting in very slow response times; 3) variation of KGSS coolant temperature by ≥ ± 1.0 °F.

By the end of 1995 control was improved to ± 0.2 to 0.3 °F. The most notable changes were the installation of direct-immersion RTDs (resistance temperature detectors), and series installation of heater and HX units. Performance periodically became unstable due to a significant derivative term in the control algorithm.

2.2 KGSS and APS-PS Temperature Stability

Efforts to stabilize the temperature of the coolant side of the LCL heat exchangers were initiated in early 1996. A 30-gallon holding tank was installed on the coolant inlet side of the exchanger to average out the fluctuations. A similar tank was installed on the linac side of the heat exchanger to increase capacitance. These modifications reduced temperature fluctuations in the LCL to ± 0.15 °F. Linac mixing valve actuators were also upgraded to the current Worcester models at that time.

In October of 1996, attempts were made to tune the proportional-integral-derivative (PID) loop of the KGSS with partial success. It was possible to tune the system using PI control (P=400, I=1000 s). KGSS stability was ± 0.1 °F, but the system was unable to handle transient heat loads, and equipment trips resulted. Studies indicated that it took ≈60 seconds for output control signal changes to actually be noticed by the sensor due to the long distance between the KGSS RTD and the mixing valve, and because the KGSS RTD was installed in a thermowell.

In order to improve the KGSS's response, its RTD was replaced by a direct-immersion RTD and was relocated immediately downstream of the pump. This permitted improved tuning of the secondary loop with PI control. The control algorithm, executed by the Johnson Metasys system, included a “tune override” feature that imposed “stronger” PID control parameters if the temperature deviated from the setpoint by a preset amount. This feature was removed, and traditional PI tuning was implemented.

These modifications resulted in KGSS stability on the order of ± 0.1 to 0.2 °F and LCL stability of ± 0.1 °F.

2.3 Upgrades to the LCL Control Systems

In early 1997, it became clear that valve tuning was a critical element in system control and that tuning the 3-way mixing valves in the LCLs (controlled by Johnson Controls LCP controllers) was not routine. The Johnson LCP has no specific “tune override” feature, but its response to temperature disturbances did not seem “classical.” As a test, a Watlow 965FDO controller was substituted for one of the Johnson LCP controllers for a short time, during which it was observed that valve tuning in the classic closed loop manner was possible [3]. Based on these results, it was decided to search for a high-resolution, stand-alone temperature controller that could be tuned to the required tolerance.

Valve tuning experience up to this time made it clear that, while a feedback control system functions to correct an error, such a correction can occur only after the error is detected. It was necessary to be able to discern changes in temperature significantly smaller than the acceptable tolerance. The Johnson Controls LCP was able to discern changes only as small as 0.06 °F. Thus, 60% of the available tolerance had already been expended before control action was initiated.

The Honeywell Progeny, whose A/D converter can resolve changes less than 0.01 °F when scaled across the 40 °F range of the applicable transmitter, was chosen as the stand-alone controller. Using this controller, it was demonstrated that steady-state temperature could be controlled to within ± 0.05 °F.

During this time, attempts were made to reduce coolant flow through the LCL heat exchangers so that the control valves would pass 65-75% of the load-side flow through the exchanger. It was felt that more precise temperature regulation would be possible if a larger flow of water were heated or cooled. As the coolant flow was reduced below 2 or 3 gpm, the exchanger demanded 100% of the load flow yet process temperature continued to climb. At such a reduced flow, the coolant flow transitioned from turbulent to laminar resulting in a loss of overall heat transfer coefficient. The surface area of the heat exchanger was reduced by 50% by rotating one end cap

of the 4-pass shell-and-tube unit by 90° so that coolant would pass through only half of the tubes.

Coolant flowrate in each LCL is now regulated at a fixed, heat-load-dependant value of 7-10 gpm by Griswold flow control cartridges. The coolant flowrate for a given station is determined by varying the flowrate until the 3-way control valve on the linac (load) side is ≈65-75% open at 100% load. The output of the electric heaters is set at a constant value to fix the heat load.

In the most recent upgrade, the Johnson Controls LCPs, the original Barber-Coleman control units, and the Honeywell Progeny were replaced by Allen-Bradley PLC-5/20 processors with 1771-N4BS analog I/O modules. Temperature changes on the order of 0.003 °F can be discerned. Previously, the system noise levels were on the order of 0.015 °F above the applicable system resolution.

Other benefits of the Allen-Bradley processors include the ability to tune valves with response characteristics that permit LCL startup from a cold condition to a steady operating temperature without supervision. This was never possible in the past. It has also been found that most rf power transients are handled well within the ± 0.05 °F tolerance range, as shown in Figure 3.

Use of Allen-Bradley PLCs permits communication between the LCL water stations and the APS control room. The LCLs can now be operated remotely in "real time" via the EPICS [4] control system.

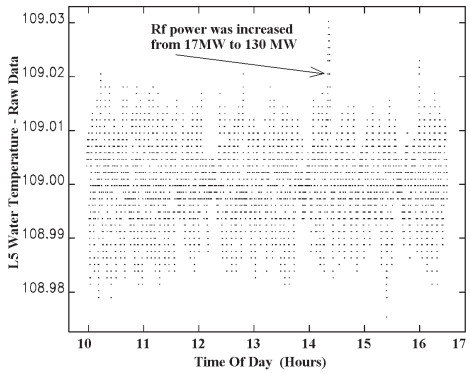

Figure 3: Temperature stability of one LCL over seven hours in April of 1998. The temperature only changed by 0.03 °F in response to an 80-MW increase in the SLED forward power.

2.4 Linac Temperature Control Systems

The LCL temperature control systems now consist of:

1) 3-way Durco ball-type control valves that divert water through or around the heat exchanger as required for stable temperature regulation.
2) Worcester series 75 electric control valve actuators with AF-17 positioners with a resolution of 0.5%.
3) Electric heaters providing fixed heat input rates; rates between 0% and 100% are chosen at setup.
4) 3-wire, direct immersion, 4-s time constant, Minco S603PD8 RTDs.
5) Analog temperature transmitters scaled in the range 85-125 °F (Minco TT676PD1QG).
6) Allen-Bradley PLC-5/20s with P/N 1771-NB4S high-resolution analog I/O cards for PID temperature control (the D feature is not used).

Use of a 3-way diverter valve in the load stream rather than a throttling valve in the coolant stream is especially important. An order of magnitude faster temperature response is obtained with the diverter valve since the final temperature is a result of mixing, and flow ratio changes are immediate upon valve movement. Throttling of the coolant flow results in relatively slower response, since the entire mass of the load stream and the mass of the heat exchanger surfaces must change temperature.

3 CONCLUSIONS

Temperature regulation of high-power rf components to within ± 0.05 °F has been achieved at the APS linac. The system responds quickly to changes in rf power load and maintains long-term temperature stability. The water system and the techniques to optimize the temperature are described more completely in [5]. System studies continue including an effort to find a source for a digital temperature transmitter with suitable resolution to address possible drift issues.

EXPERIMENTAL RESULTS OF THE ACTIVE DEFLECTION OF A BEAM FROM A KICKER SYSTEM*

Y. J. (Judy) Chen, G. Caporaso, J. Weir
Lawrence Livermore National Laboratory, Livermore, CA 94550 USA

Abstract

A high current kicker has been designed and tested on the ETA-II beam line. A bias dipole which surrounds the kicker acts to deflect the beam in the DC mode. High voltage pulsers (10kV) with fast rise times (10ns.) are connected to the internal strip lines of the kicker. They are used to manipulate beams dynamically.

Camera photos which show the switching of the beam from one position to another will be presented. Beam bug measurements of beam-induced as well as active steering will be shown. These will be compared with theoretical predictions.

1 INTRODUCTION

Recently there has been considerable interest in providing advanced flash x-ray radiography capability for stockpile stewardship[1][2]. A multi-axis capability is required in order to produce a tomographic reconstruction of an imploding assembly. It would be economical to produce many lines of sight using a single high current electron accelerator if a kicker could be used to axially section a long beam pulse into pieces which could be directed to different beam lines.

The kicker for this application must be able to handle continuous kilo-ampere beams with great precision and high speed. Switching times of order 10 ns are required in order to make maximum use of the available beam charge. In addition, beam induced fields arise in the kicker and cause additional deflections which must be compensated for by modifying the external pulser voltage waveform.

In order to improve field quality the kicker was fitted with curved strip line electrodes approximating a cylindrical boundary as shown in Fig. 1. The resulting structure strongly resembles a strip line beam position monitor that is in wide use in the high energy accelerator community [4]. These kickers are to be used to handle continuous relativistic electron beams of at least several kilo-amperes so that wake fields in the kicker are significant even for a single passage of the beam. The wake fields for structures of this type are strong enough to significantly steer the beam. The input condition on the beam centroid is amplified as a function of beam current [2] for both a passive and kicked mode of operation. The shaped electrodes improves field quality but residual higher order moments still exist. The strongest field after the dipole moment is the sextupole moment. The nonlinearity of a sextupole field can shape the beam into a triangle and introduce a small amount of emittance growth [5].

2 DESCRIPTION OF EXPERIMENT

The kicker experiment, which comprises high voltage pulsers and the kicker itself with a bias dipole magnet wound around the outside, sits in the transport section of a linear induction accelerator (Fig. 2). A complete system would also include a septum magnet downstream of the kicker. It is the only active component in that section. Experiments to test the system have been and are still being conducted on the Experimental Test Accelerator - II (ETA-II) at the Lawrence Livermore National Laboratory. Two existing pulsers can provide $\pm$10kV into a 50Ω load with a 10-90% risetime of 10 nsecs. The pulser is shown in Fig. 3.

Two different beam line configurations were used. The original layout proved to be inadequate for the set of beam-induced steering experiments. Two resistive wall monitors (known locally as beam bugs) upstream of the kicker were needed to measure input displacement and angle [6]. In fig. 4a, these were labeled BBT08 and BBT09. However, a large focusing magnet, C4A, resided between the two and was necessary to transport the beam to the output of the kicker. It was quickly realized that incorporation of the C4A in the analysis meant the assumption that the magnet was perfectly aligned. A new beam line was designed such that two beam bugs can be placed upstream of the kicker without a magnet between them, as shown in fig. 4b. The spacing between the input bugs must be comparable to the length of the kicker to minimize measurement error in angle.

The first set of results shows that the predicted amplification due to beam-induced steering in a passive kicker matches well with experimental data. These cases were all taken at I_b=1700A where amplification is 1.47 in initial offset and 1.08 and initial angle is 1.15. There is a small background magnetic field that points in both the x and y direc-

Figure 3: Kicker pulser.

tion that is folded into the data analysis. The magnetic field pointed in the $-y$ and $-x$ directions (defined by propagation of the beam in the $+z$ direction) with magnitudes of .3-.6G and .1-.3G respectively. This added an error in beam steering in the $-y$ and $+x$ direction. Fig. 5 shows time-averaged location of the beam at BBT10 for both theoretical projection and actual data for various current values. The error bars on the theory values stems from an assumption that beam bugs have a ± 1.4mm error [6]. For large offsets the error is closer to $\pm .7$mm. This implies that at BBT10, the error should be $\pm(1.4\text{mm} \times 2.41\text{m}/1.33\text{m} + .7\text{mm}) = \pm 3.2$mm. The error bars on the beam bug data include an

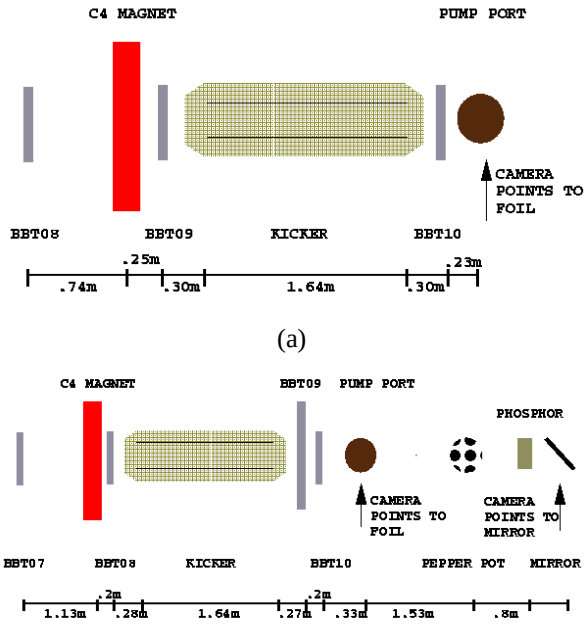

Figure 4: a) Old beam line layout. b) New beam line layout.

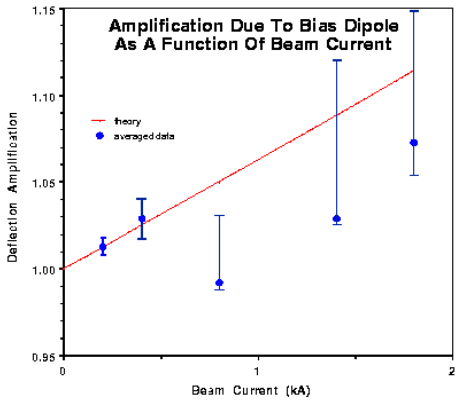

Figure 6: x displacement at BBT09 (old beam line) due to dipole magnet

additional contribution due to the inherent nonlinearity of beam bugs for off-axis measurements. The data are time-averaged over a 40nsec. window.

Case 1 was the zero case where the beam entered the kicker on-axis with little to no angle. Cases 2 to 5 were different combinations of initial offsets in x and y, again with no angle. In cases 6 to 9, the beam is steered into the kicker close to axis but with a large angle. Cases 10-12 is another set similar to cases 2 to 5. These sets of data were taken on three different days.

Fig.6 shows the amplification of bias dipole magnet steering as a function of I_b. This data was collected on the old beam line configuration. Centroid location was derived from finding the geometric center of TV camera images of the beam. The kick due to the magnet is normalized to the predicted steering given no beam-induced effect (setting $I_b = 0$). Here we are trying to trace an amplification factor that at the maximum is only 8% as shown in the last data point in figure 6. Although the error bars are large, the general trend fits well with theory.

A series of tests were conducted using the pulsers to kick the beam. Fig. 7 shows a TV image of a 200nsec. time slice of an electron beam at I_b=1000A hitting a quartz foil (see Fig. 4a). The electron beam on impact produced Cherenkov radiation that a camera can detect. The total beam pulse length is only 70nsec. so the camera captured the electron beam as it was kicked from one position to the other. It shows a beam kicked with V_p=9kV and at an estimated energy of 6.3MeV. The total displacement at the camera foil is 4cm. Fig. 8 shows that if the beam is large entering the kicker it can pick up a sextupole moment created by the applied voltage and consequently have a triangular shape at the output [5].

3 CONCLUSION

The kicker as a viable technology in the advancement of multi-axis multi-pulse radiography has been experimentally demonstrated. The physics characterization of the kicker itself is almost complete.

Beam deflection experiments has shown that the kicker can switch the beam in 21ns (10-90%). The experimental

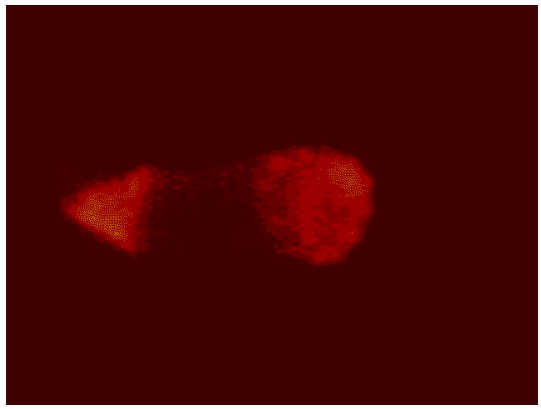

Figure 8: TV camera downstream of kicker which captured a triangularly shaped beam shaped by the sextupole moment inherent in the fields due to the stripline voltages.

characterization of beam-induced effects in the kicker fits well with theory. The predicted sextupole shaping of the beam was also seen.

CHARACTERIZATION OF HIGH POWER CW KLYSTRONS AND ITS APPLICATION TO LOW LEVEL RF CONTROL*

A.S. Rohlev, D.E. Rees
Los Alamos National Laboratory, Los Alamos, NM 87545

Abstract

The power gain, phase delay, and line harmonic spectrum of a 1.3 MW, 350 MHz, CW klystron amplifier have been measured as a function of input power. These measurements of the klystron were taken at several constant perveance and constant impedance operating points. The results are used to enhance the performance of the low level RF control system.

1 INTRODUCTION

Accelerator control systems attempt to maintain a constant cavity field by monitoring the field and modulating the driving RF amplifiers to cancel out any perturbations. The extent to which this can be done depends on the characteristics of the cavity, the strength of the amplifiers, and the quality of the control system. An accurate characterization of the cavity and the amplifiers can be used to improve the performance of the control system. The purpose of this paper is to show results from measurements made on a 350 MHz 1.2 MW klystron amplifier. The measurement technique, while not unique, is relatively simple and can be used on a variety of CW amplifiers.

The 350 MHz klystron tested will be used to drive the RFQ on the Low Energy Demonstration Accelerator (LEDA) for the APT project. The RF architecture of LEDA places several constraints on the low level control system which were quantified by these tests. The LEDA RFQ will be driven by three klystrons operating at 2/3 power or, if one fails, two klystrons operating at full power. In either case the DC bias parameters of the klystrons will be set to allow for an amplitude control margin of about 10%. One control system will be used to drive these klystrons so having the proper phase relationship between the klystrons is critical. Since the klystrons will be operating near saturation it was necessary to get accurate gain curves for a variety of DC bias conditions. Also line harmonic frequencies on the output RF were measured since regulating these could decrease the control margin. Finally, the phase length of the klystron was measured as a function of the DC bias and the input power.

*Work supported by Department of Energy.

2 EXPERIMENTAL SETUP

Figure 1 Shows a block diagram of the experimental setup.

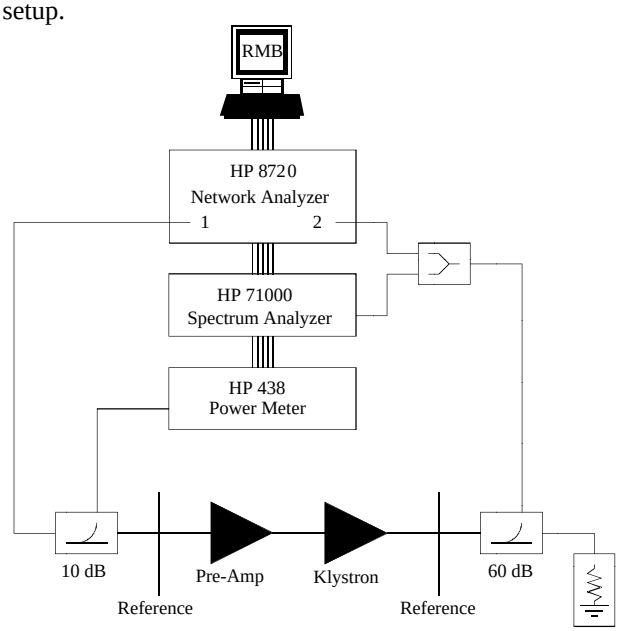

Figure1. Experimental Setup

A HP 8720 network analyzer operating in CW mode at 350 MHz was used to drive the klystron and measure its output power and phase length. A HP 71000 series spectrum analyzer was used to measure line harmonic sidebands (N*60 Hz) on the output RF. Lastly, a HP 438 power meter was used to measure and adjust the RF output power of the network analyzer. The three instruments were controlled, and data was collected, via HPIB by a PC running Rocky Mountain Basic. All measurements were made as a function of input power once the DC bias of the klystron had been established. The line losses from port 1 of the network analyzer to Reference Plane 1 as well as from Reference Plane 2 to port 2 were carefully measured and recorded. The measurements proceeded as follows. First the computer instructed the network analyzer to go to a prescribed output power. The power meter measured the true output power using a well defined 10 dB directional coupler. The true power was relayed back to the computer which used a converging algorithm to adjust the output of the network analyzer until the prescribed RF power was present at Reference Plane 1. The network analyzer then measured the magnitude and angle of S_{21} after which, at the operators request, the input power was incremented and another test point was taken.

From the magnitude of S_{21} the gain between Reference Plane 1 and 2 could be calculated since the line losses were known. Also, since the input power at Plane 1 was known, the output power at Plane 2 could be derived. The angle of S_{21} was the phase length between Planes 1 and 2 plus a fixed angle due to the lines. At several points along a curve the spectrum analyzer was poled to get the output RF spectrum. The spectrum analyzer would measure the main klystron peak as well as any other peaks within 750 Hz of the center. The sidebands occurred exclusively at line harmonic frequencies, and their power relative to the main peak was recorded.

Once the DC bias for the klystron was fixed the input power was initially set at a low level generating less than 50 kW output from the klystrons. The input power was then raised in 1 dB increments, 0.2 dB increments, and finally 0.1 dB increments as the klystron neared saturation. Table 1 shows the different DC bias conditions for which the klystron was tested. The beam current was set to maintain a constant tube perveance in points 1-4 and a constant tube impedance in points 4-7.

Test Point	Beam Current (A)	Cathode Voltage (kV)	Saturated Pout (kW)	Number of Data Points
1	9.85	60.0	279	51
2	15.3	80.0	725	40
3	17.6	88.0	963	42
4	19.4	93.9	1161	50
5	18.3	88.4	1008	30
6	16.4	80.4	806	42
7	12.4	60.2	365	46

Table 1.

3 RESULTS

The test results are summarized in Figures 2, 3, and 4 which respectively show the power, efficiency, and phase characteristics for the klystron.

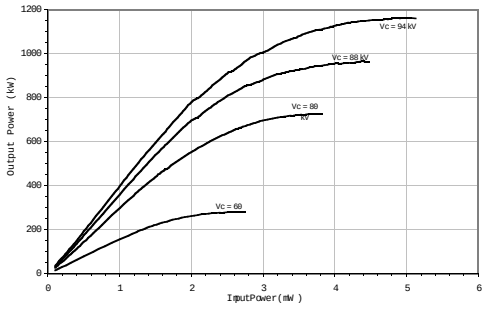

Figure 2. Output power characteristics.

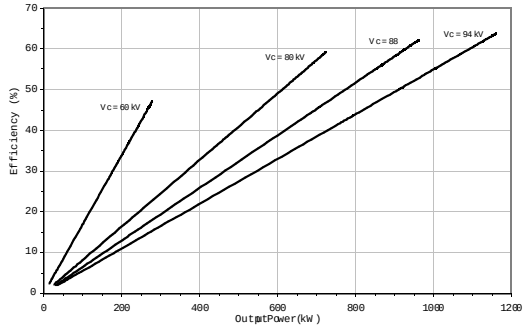

Figure 3. Power efficiency characteristics.

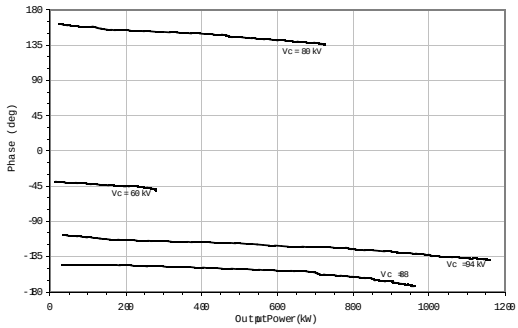

Figure 4. Output phase characteristics.

The figures show the results for bias points 1 through 4. The efficiency is calculated as the ratio of the output RF power to the input DC power. Table 2 show the line harmonic data at several output power levels for bias point 4. There was no appreciable power in the line harmonics above 120 Hz, and only at 1000 kW output was there power in the 60 Hz harmonic.

Pout (kW)	60 Hz Power (dBc)	120 Hz Power (dBc)
117	< -70	-52.8
504	< -70	-53.2
1000	-55.7	-46.9
1159	< -70	-48.3

Table 2. Line harmonic data.

4 CONCLUSION

Several observations about the architecture and performance requirements of the control system can be made from the above data. Measurements of the line harmonic power show that it will introduce about 0.5% error in the cavity voltage and will not seriously reduce the control margin of the system. With respect to the klystron phase data, it is obvious that some sort of individual phase control is necessary for each klystron.

The phase length of the klystron can change by many tens of degrees with cathode voltage and by ten degrees or more for a set DC bias condition. For LEDA three klystrons will drive a single cavity and be controlled by a single system. The cavity phase is the superposition of the three klystron phases and will be maintained at a constant value by the control system. However, without individual control of each klystrons phase, large inefficiencies in transmitted power can occur which will degrade the control margin of the system.

RF SYSTEM DEVELOPMENTS FOR CW AND/OR LONG PULSE LINACS *

Michael Lynch
Los Alamos National Laboratory, Los Alamos, New Mexico 87545 USA

Abstract

High Power Proton Linacs are under development or proposed for development at Los Alamos and elsewhere. By current standards these linacs all require very large amounts of RF power. The Accelerator for Production of Tritium (APT) is a CW accelerator with an output current and energy of 100 mA and 1700 MeV, respectively. The Spallation Neutron Source (SNS), in its ultimate configuration, is a pulsed accelerator with an average output power of 4 MW of beam. Other accelerators such as those that address transmutation and upgrades to LANSCE have similar requirements. For these high average power applications, the RF systems represent approximately half of the total cost of the linac and are thus key elements in the design and configuration of the accelerator. Los Alamos is fortunate to be actively working on both APT and SNS. For these programs we are pursuing a number of component developments which are aimed at one or more of the key issues for large RF systems: technical performance, capital cost, reliability, and operating efficiency. This paper briefly describes some of the linac applications and then provides updates on the key RF developments being pursued.

1 APPLICATIONS OF HIGH POWER PROTON LINACS

APT is by far the highest average power accelerator ever proposed. A table showing pertinent parameters for APT is shown below. 244 klystrons are required for the currently planned 1700 MeV version [1]. A reduced power variation is under consideration due to changing tritium requirements, but even that design is higher in average power than any proposed accelerator. The reduced power version has a final energy of 1300 MeV and requires 160 CW klystrons. In both versions of the linac, a klystron is required about every 4.5 m, so the average power per unit length is very high.

Table 1: Pertinent Parameters of APT Linac

Proton Energy	1700 MeV
Beam Current	100 mA
Beam Power	170 MW
AC Power (for RF)	386 MW
Peak Coupler Power	210 kW
Klystrons (1 MW)	243
Linac Length	1104 m

* Work supported by the US Department of Energy

The RFQ for APT operates at 350 MHz and requires 3 klystrons [2]. The remainder of the accelerator operates at 700 MHz, so the majority of the klystrons are at 700 MHz. Each RF system for APT is generally laid out as shown in Fig. 1. [3]. Each klystron is split 4 ways to drive 4 ports on the accelerator. This splitting arrangement was deemed necessary to ensure reliable operation of the window/coupler assemblies. It was felt that reliable operation could be achieved with up to 250 kW of CW forward power through each window. This allows for situations with high-reflected power in which the RF fields in the window might double.

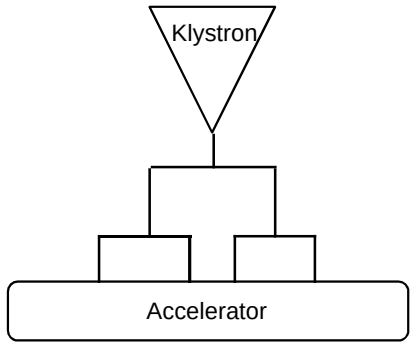

Figure 1: Typical RF System Layout for APT

The Spallation Neutron Source (SNS), in its ultimate configuration, will have an average output current and energy of 4 mA and 1000 MeV, respectively, providing 4 MW of average beam power. In its initial configuration the beam power is 1 MW. A table of the parameters for the 1 MW version is given below. It requires 59 klystrons with most at 805 MHz and 2.5 MW peak power. The remaining 3 are 1.25 MW peak at 402.5 MHz. At the full 4 MW of beam power, the number of klystrons required is 83.

Table 2: Pertinent Parameters of SNS Linac

Proton Energy	1000 MeV
Beam Current	27.7 mA, peak 1.04 mA, average
Beam Power	1.04 MW, average
Pulse Width	1.0 ms
Repetition Rate	60 Hz
Klystrons 805 MHz, 2.5 MW peak 402.5 MHz, 1.25 MW peak	 56 3
Linac Length	486 m

Other accelerators that address transmutation and upgrades to LANSCE have similar requirements. For transmutation, one version uses multiple CW

accelerators, each with a current of 40-mA and output energy of 1 GeV. A table of pertinent parameters for an ATW linac is given below. A significant portion of this linac could be superconducting (from 21 MeV to 1 GeV), but it would still require 56 CW klystrons of 1 MW output power. To achieve complete burn of the nuclear waste, a total of 20 of these machines would be needed. They would be built over about a 25-year period and each would need to operate for 40 years.

Table 3: Pertinent Parameters of ATW Linac

Proton Energy	1000 MeV
Beam Current	40 mA
Beam Power	40 MW
AC Power (for RF)	95 MW
Peak Coupler Power	200 kW
Klystrons (1 MW)	56
Linac Length	355 m

For all of these high average power applications, the RF systems are very key elements of the overall accelerator because they represent approximately half of the total cost of the linac.

2 DEVELOPMENT THRUST AREAS

2.1 System Design Developments

Development is taking place both in system design and in component design to address one or more of the key items: capital cost, operating cost, availability, or technical performance. In terms of system design, APT is planning a supermodule scheme for the normal conducting linac portion (up to 211 MeV). Supermodules allow quick return-to-service in the event of a failure of a component in the RF system. A diagram of a supermodule is given in Fig. 2.

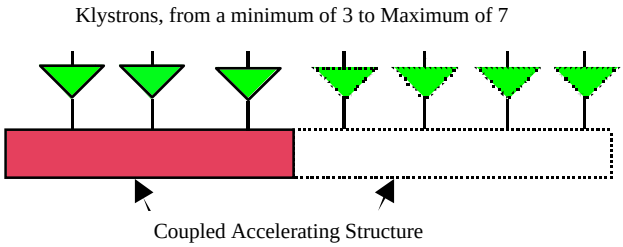

Figure 2: A Block Diagram of a supermodule showing the size variation. Each supermodule has one more klystron than is needed for full-current operation.

In analyzing the availability of the RF system with a large number of generators, we found that the failure and repairs would lead to excessive down time and insufficient production by the machine. The use of supermodules greatly improves the availability of the normal conducting portion of the accelerator. The supermodule is simply a long coupled structure, which requires multiple RF generators to achieve sufficient power. In configuring the RF system an 'extra' RF station is added such that any one RF system can fail, and in a very short time (5 to 10 minutes), the failed unit can be taken off line and operation resumes with the remaining stations. The supermodules vary in size from 3 klystrons (2 required) to 7 klystrons (6 required).

For the superconducting portion of the linac the availability is achieved by installing more modules than are needed to achieve the rated production. If a module fails, it is detuned so the beam will not drive the cavity, and the adjacent modules are adjusted in amplitude and phase to 'make up' the difference. Approximately 5% more cavities are installed than are needed. This adds complication for the control system, but the controls are being developed to handle these complications. An additional feature of the superconducting module is that one klystron drives more than one resonant structure (either 2 or 3) as shown in Fig.3.

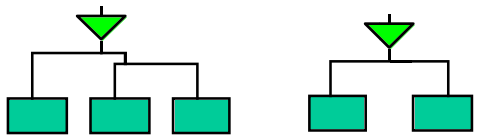

Figure 3: Block diagram of RF system for the superconducting cavities. Each klystron drives either 2 or 3 cavities. The medium and high ß refer to the two types of superconducting structures used in APT. [1]

The overall linac is thus a combination of normal conducting 'supermodules' and a large number of superconducting modules as shown in Table 4.

Table 4: Breakdown of RF Systems for the APT Linac

Accelerator System	Klystrons	Super-modules	Cavities/Klystron
RFQ (350 MHz)	3	1	
CCDTL	22	6	
CCL	29	5	
SC, ß=0.64	36		2 for 6 klystrons, 3 for 30 klystrons
SC, ß=0.82	154		2

2.2 Operating Efficiency

In a simple analysis of the overall efficiency of the accelerator, approximately 44% of the input AC power is converted to beam power. To reach this efficiency, many parts of the RF system are being pushed to their limits. The HVPS must deliver the DC power with 95% efficiency. The RF transport, which includes the circulator, splitters, the RF window, and any phase and amplitude variations in the various drives, must deliver to the cavity at least 94% of the power from the klystron. The beam loading percentage is addressed with the conversion to superconducting cavities for the majority of the accelerator. In the superconducting cavities, the beam loading is 100%. Only in the normal conducting section of the linac (up to 211 MeV) is RF power dissipated in the cavity walls.

Since there is a potential savings of $1M in operating cost for each percentage point improvement in operating efficiency, developments are taking place with the RF generators to develop higher efficiency generators, and generators which have less loss of efficiency when operating below their 'saturated' or 'maximum' output level.

2.3 Low Level RF Controls (LLRF)

We are working to develop LLRF controls for APT which only require 10% excess drive capability in the generator to deal with system disturbances (beam noise, power supply ripple, etc.) In addition we are incorporating DSP technology into the design for advanced capabilities and enhanced flexibility. [4] For SNS, since it is a pulsed application, we will require 20% or more excess drive capability. For both CW and pulsed systems, the LLRF must control fields in the cavities, provide the resonance control signals, provide the RF reference along the entire linac, provide the proper timing signals for the RF system, and provide the proper protection signals. There are, in addition, particular requirements related to the CW or pulsed application.

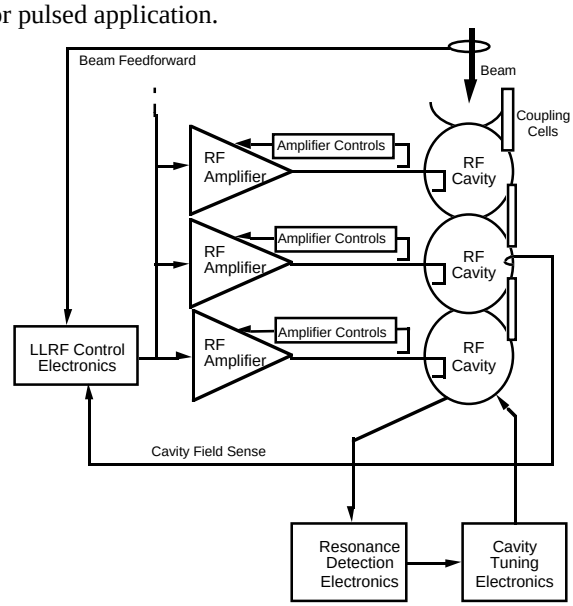

Figure 4: LLRF control diagram for a supermodule. The long coupled accelerator structure is driven by multiple klystrons and controlled with one feedback system. To equalize the klystrons, each one has a control loop.

The Low Level RF (LLRF) controls must be designed differently for the normal conducting and superconducting portions of the accelerator. Figures 4 and 5 show the block diagram for the LLRF controls for these two portions. In the normal conducting portion, the supermodule has multiple drives for one resonant cavity. The implication for the LLRF for this portion is that the separate RF systems must be properly phased and the drives must be 'equalized'. In the superconducting system, one RF drive provides power to multiple cavities (2 or 3). The cavities must be maintained properly relative to each other.

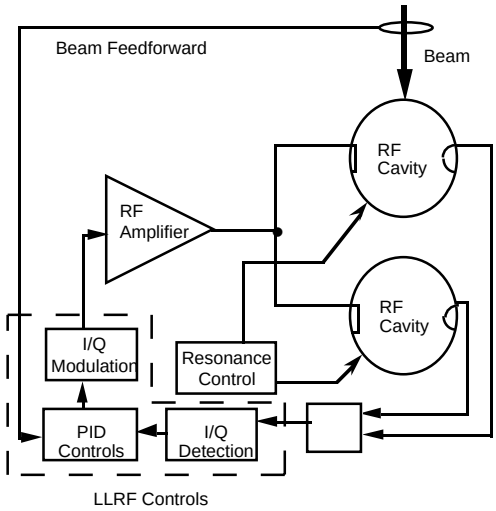

Figure 5: LLRF control diagram for a superconducting module. Each klystron drives more than one cavity.

2.4 Component Design Developments

First and foremost for APT is the 700 MHz RF generator. We are currently pursuing 2 main avenues with an additional pursuit occurring externally. One main avenue is the development of a conventional 'superpower' klystron at 700 MHz [5], which is derived from the CERN 352 MHz CW klystron. The other is a new type of tube, referred to as an HOM-IOT, which promises again the same output characteristics as the conventional klystron, but very high operating efficiency. The external pursuit is an advanced klystron, which is striving for equivalent output characteristics as the conventional klystron, but at higher efficiency.

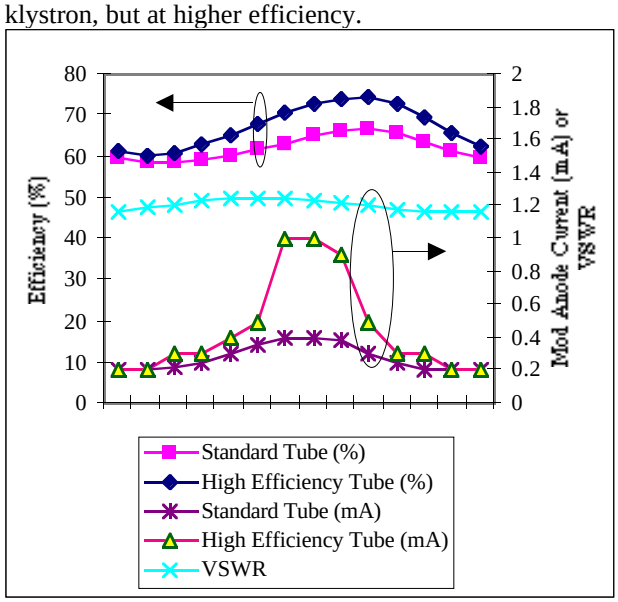

Figure 6: Test results of the standard and 'advanced' 700 MHz klystron from EEV. The advanced tube shows higher overall efficiency, but also shows more sensitivity to the 1.2:1 VSWR test.

The conventional 700 MHz klystron is being developed at CPI and at EEV. The tube has a modulating anode to optimize the efficiency. The tube is expected to operate at

65% efficiency when saturated and should average about 58% in actual operation (due to the need to operate below saturation to enable the feedback control system to work correctly). The advanced klystron is an internally funded venture by EEV. If it is successful, the saturated efficiency will be 70% or greater.

Test results of the standard and high efficiency klystron are shown in Fig. 6. The high efficiency klystron had very good results, although less efficiency than expected. In addition the high mod anode currents indicate that the tube has potential stability problems. Nevertheless, the results are encouraging and further development is taking place.

In both types of klystron, the tube must 'sacrifice' some of its efficiency to allow margin for control [6]. This sacrifice can be recovered with a depressed collector. This was considered but has not been pursued. A new type of tube proposed by CPI has an inherently good efficiency and could eliminate most of the operating penalty. The tube is referred to as a High-Order Mode Inductive-Output Tube (HOM-IOT) and is a density modulated device in which the amount of beam in the tube is determined by the input RF level. The expected efficiency of the HOM-IOT and a conventional klystron, as a function of output power, is shown in Fig. 7. As can be seen, even at half the rated output power, the efficiency is 60% or better compared to less than 50% for the klystron. A diagram of the tube is shown in Fig. 8.

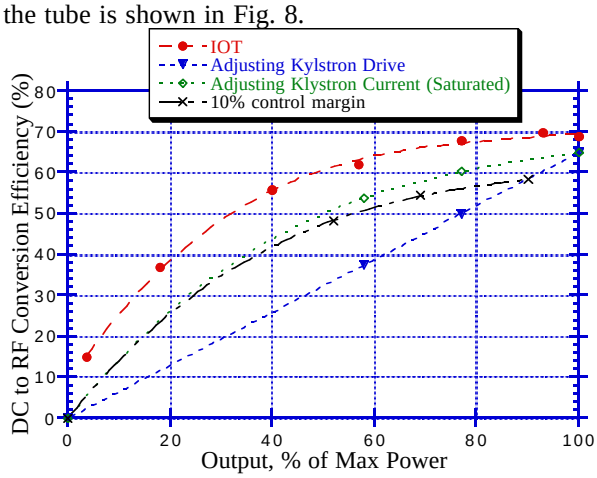

Figure 7: Comparison of the operating efficiency characteristics of the HOM-IOT and a standard klystron.

Other components being developed for APT include High Voltage Power Supplies (HVPS), high power circulators at 700 MHz, and RF windows. The HVPS is the single biggest cost item in the RF system, and there is room for improvement in the operating efficiency and reliability. There are several options being considered for the APT HVPS, from a conventional SCR-controlled supply to various versions based on IGBT technology. [7,8]

The RF windows represent the biggest impact to system reliability. The full APT has approximately 1000 windows, and their reliability is a key issue for APT. In addition there is a complication arising from the mixture

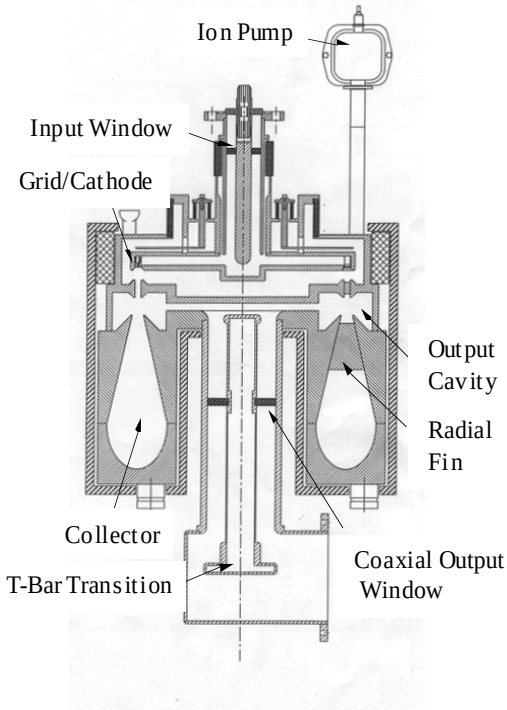

Figure 8: Outline drawing of the HOM-IOT. The tube is rotationally symmetric about the centerline, with the exception of the ion pump and output starting at the t-bar transition.

of normal conducting and superconducting cavities. The normal conducting windows are all based on klystron window technology. [9] For the superconducting cavities, the window design starts with standard klystron window design, but then must accommodate the tough problems of connecting to the power coupler for the superconducting cavity. A sketch of the basic window layout for superconducting cavities is shown in Fig. 9.

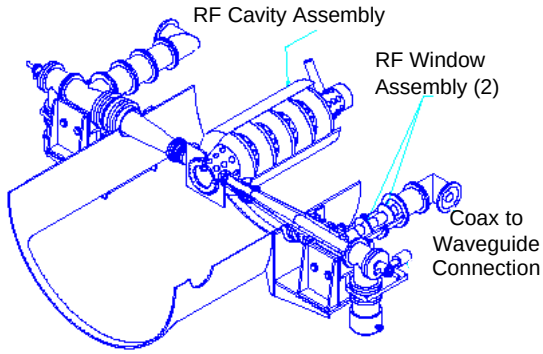

Figure 9: Layout drawing of the RF/vacuum window for a superconducting cavity. Dual windows are used for reliability considerations.

For SNS, a new klystron is being developed to provide 2.5 MW peak at 805 MHz and 7% duty factor with a pulse width of more than 1 ms. [10] Two development contracts have been placed for one klystron, one with CPI

and one with Litton. In addition, options for the High Voltage modulator are being pursued which take advantage of developments in IGBT technology.

In all, IGBT technology is being considered in three different topologies. [7,8] Two different topologies are being pursued for APT. One is an extrapolation of a commercial unit designed for Voice of America installations (Fig. 10). The other is a new design, which has associated risks, but looks to be able to provide cost savings. In both cases, the IGBT technology promises to offer considerable technological advantages over a standard SCR-type of HV power supply. They should eliminate the need for a crowbar, offer significant cost savings, and provide graceful degradation and easy repair. In the case of the commercial unit, the supply utilizes 96 modules wired in series to produce the high voltage. Each module contains a full-wave, 3-phase rectifying bridge, which produces 1.1 kV DC across a small filter capacitor. The module circuitry and controls allows the power supply to continue to operate with approximately 5% failed modules without degradation in performance. The failed modules can then be repaired during a scheduled shutdown.

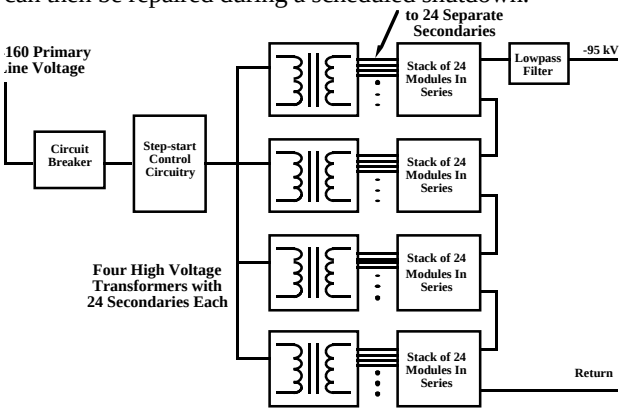

Figure 10: 95 kV advanced HVPS based on IGBT technology features graceful degradation and low stored energy (and thus does not require a crowbar).

The IGBT system being pursued for SNS combines the functions of the HVPS and the HV modulator needed for pulsing of the klystron into a single small unit. The crowbar is eliminated, and significant cost savings are expected.

3 PROJECTED TIMELINE

For the larger version of APT (1700 MeV), the need for the start of Tritium production is 2007. If the smaller version (1030 MeV) is opted for, the need date for start of production moves to 2011 because the existing Tritium can decay further before additional amounts are needed to replenish the decaying amounts. Assuming the smaller version of APT, tube production must begin around 2001 and be complete by 2009. SNS is currently expecting to be completed by 2005. Initial installation of the RF hardware must occur in 2000 and be completed by 2004. Finally, a reasonable assumption at this point is that the first ATW accelerator begins installation in 2007 and is completed by 2012.

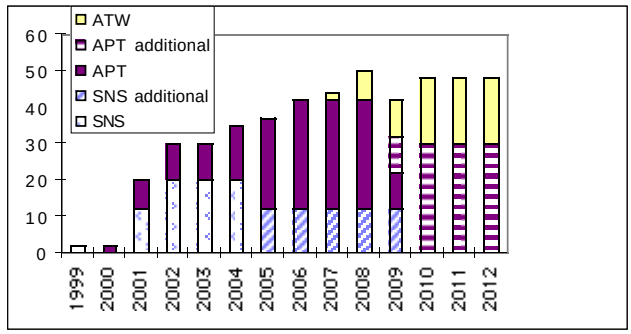

Figure 11: The tube requirements for the APT, SNS, and ATW for the next several years add up to a significant number of high power tubes.

Figure 11 shows all of the needs for these three programs compiled together based on the above dates and assumes that 20% of the initial 'need' for klystrons is produced for 5 years after completion in order to provide spares and replacements for infant failures. As can be seen by the table, the production total reaches a maximum of approximately 50 tubes for one year, and after about 2005 the production maintains a level of 40 or more tubes for over 7 years. There is a similar need for all of the associated RF hardware such as HV power supplies, waveguide, capacitors, circulators, etc.

LINAC R&D IN KOREA*

Won Namkung
Pohang Accelerator Laboratory, POSTECH, Pohang 790-784, Korea

Abstract

A 2-GeV linear accelerator is constructed as an injector to the Pohang Light Source (PLS), the first large-scale accelerator complex in Korea. It is a national synchrotron radiation users' facility for basic and applied science research. The PLS storage ring is a third generation machine with a low-emittance, and it has been serving users since September 1995. With the success of this construction project, there are strong demands on accelerator facilities for various applications, such as a neutron facility for transmutation and energy production called the KOMAC-project, a nuclear data center, a mini-cyclotron for radioisotope production. Most of linac R&D programs are subsystems in the low-energy end/or special components to improve the performance of the existing subsystems of the PLS linac. We present the current accelerator status, R&D activities related to linear accelerators at PAL, and the proposed accelerator programs in Korea.

1 INTRODUCTION

In the early 1960's, there were three particle accelerators in Korea: a 1.5-MeV cyclotron at the Seoul National University (SNU) and two Cockcroft-Walton type accelerators both at the Korea Atomic Energy Research Institute (KAERI) and at the Yonsei University. The cyclotron at SNU was used for accelerator physics studies. While the KAERI machine was used for neutron production via the D-T fusion reaction by 240-keV beams, the 300-keV machine at Yonsei produced proton and Lithium beams for various physics experiments. In the late 1970's, SNU constructed a 1.5-MV Tandem Van de Graaff for materials research.

Recently, there are many imported facilities and equipment related to the particle accelerator technology mainly for medical and industrial applications. In 1980's, the Korea Cancer Center Hospital (KCCH) imported a 50-MeV cyclotron and a 22-MeV microtron for medical treatment. A survey of research and medical accelerators in Korea is listed in Table 1.

The PLS is, therefore, the first large-scale accelerator complex in Korea. It is a national synchrotron radiation users' facility for basic and applied science research consisting of a 2-GeV linear accelerator as a full-energy injector and a low-emittance storage ring.

In 1988, the Pohang University of Science and Technology (POSTECH) initiated the PLS project with financial support from the Pohang Iron and Steel Company (POSCO), and the government joined in the project in 1989. The accelerator construction was officially completed at the end of 1994, and it was open to users in September of 1995 with two beamlines initially. There are now eight beamlines. A commercial company, LG-Semiconductor, built its own beamline for lithography, and the Kwangju Korea Institute of Science and Technology (KJIST) built its own beamline with support from the Kumho Business Group.

With the success of the PLS project, there are strong demands on accelerator facilities for various applications: the KOMAC-project for nuclear transmutation and energy production, a neutron facility for nuclear data production and evaluation, a FEL driver, industrial accelerators, and a 13-MeV cyclotron for medical radioisotope production, and others. We describe briefly recent activities for these accelerators along with R&D activities in the following sections.

Table 1: Survey of accelerators in Korea.

2 POHANG ACCELERATOR LABORATORY

2.1 PLS Status

The 2-GeV injector linac consists of a 100-MeV preinjector and 10 SLAC-type regular modules, with 4 accelerating sections fed by each klystron [2]. Recently, we installed another module with 2 accelerating sections to improve the machine availability. Each module also has a SLAC-type Pulse Compressor with an average energy gain factor of 1.5. Since we use 80-MW-class high-power klystrons, each regular module is able to provide beam energy of 200 MeV with microwave power of 50 MW. The beam injection to the storage ring takes usually 2-5 minutes with 10-Hz and 1.5-ns pulses.

The PLS Storage Ring has a TBA-lattice structure with 12 super-periods with circumference of 280 m. There are two straight sections allocated for the RF-cavities and the injection system. Aluminum vacuum chambers are machined by an outside vendor and welded in-house. The RF system uses 4 RF klystrons of 60-kW to support a beam current of 400 mA at 2.0 GeV and 250 mA at 2.5 GeV. We demonstrated beam energy ramping to 2.5 GeV from 2.0 GeV, and we will provide 2.5 GeV beams from the second half of 1998.

Table 2 shows hours of the total machine operation and user service mode. We operated the linac for 5,480 hours and the storage ring for 4,840 hours in 1997. The user service time is 3,600 hours with the machine availability of 91.4% in 1997 and 92.4% in the first half of 1998. The machine fault statistics are shown in Table 3 for both the injector linac and the storage ring. The most frequent failure was the modulators in the linac and the injection system in the storage ring. We have experienced various beam instabilities, especially the coupled-bunch instability in high-current operations. Therefore, we are developing the longitudinal feedback system in collaboration with SLAC.

Table 2: Statistics for total machine operation and user service mode.

Machine operation (hours)				
	'95[1)]	'96	'97	'98[2)]
Linac	1,870	4,810	5,480	2,848
SR	1,820	4,680	4,840	2,657
User service

Availability	89.6 %	93.8 %	91.4 %	92.6%

[1)] 2nd half year, [2)] 1st half year.

2.2. PAL Test-linac and Nuclear Data Center

Another electron linac, called PAL Test-linac with a beam energy of 100 MeV, was recently constructed in the PLS linac tunnel for R&D activities, such as experiments for development of special electron guns, a free electron laser (FEL), neutron generation, and a slow positron source.

The PAL Test-linac consists of a thermionic RF-gun, an alpha magnet, four quadrupole magnets, two SLAC-type accelerating sections, a quadrupole triplet, and a beam analyzing magnet [3]. With a temporary klystron-modulator, it produces 75 MeV, 30 mA beams at 3 μs and 10 Hz. The machine parameters and achieved values are shown in Table 4.

As applications of the PAL Test-linac, we proposed a pulsed neutron facility for nuclear data production and evaluation. In order to support the nuclear-power development program and the nuclear R&D applications in Korea, KAERI decided to establish the Nuclear Data Center to produce and evaluate nuclear data. Among various kinds of neutron sources (reactors, accelerators, and radio-isotopic neutron emitters), an accelerator-based neutron source is the most efficient one for high-resolution measurements of microscopic neutron cross sections. It produces short bursts of neutrons with a broad continuous energy spectrum by nuclear reactions of energetic photons or charged particles. Especially, an electron linac is a useful tool for the neutron time-of-flight (TOF) measurement as an intense pulsed source. The Test-linac will be jointly utilized for the Nuclear Data Center.

Table 3: Machine fault statistics in 1996-1997.

Storage Ring		Linac	
RF system	65	Modulator	127
MPS system	48	Control system	35
Control system	28	MPS system	30
LCW system	19	Timing system	25
Vacuum system	18	Vacuum system	8
Interlock system	13	Power failure	8
Timing system	12	Microwave system	3
Power failure	6		
Injection system	5	E-gun	1
Total	**214**	Total	**231**

Table 4: Machine parameters of Test-linac.

Beam Energy	100 MeV (75 MeV*)
Beam Current	100 mA (30 mA*)
Pulse Width	6 μs (3 μs*)
Energy Spread	< 1 % (3 %*)
Repetition Rate	60 Hz max. (10 Hz*)
Norm. Emittance	< 30 πmm-mrad

* Achieved values

For the pulsed neutron facility, the machine is to be upgraded with following parameters; The beam energy is at least 100 MeV with beam currents of 0.3 –5.0 A. The

pulse width is in the range of 10-1000 ns, and the repetition rate is 30–300 Hz. The target system uses water-cooled Tantalum. The average neutron yield is approximately 10^{13} n/sec. There will be three time-of-flight beamlines of 10 – 100 meters.

2.3 Linac R&D activities at PAL

There are several R&D programs at PAL to improve the existing machine and to explore possibilities for the future facility expansion and other applications. These are described in the followings.

2.3.1 RF-gun: A one-cell S-band RF-gun is fabricated in-house with a dispenser cathode and installed to the Test-linac. It is capable to produce beams of 1.0 MeV and average 600 mA with 2.0 MW RF-power [4]. It shows the beam energy range of 0.4-1.0 MeV with the peak energy of 0.9 MeV. Therefore, one needs an alpha magnet before injection into the main accelerating section.

2.3.2 Triode RF gun: The triode RF gun is a conventional triode gun with its pulser replaced by a S-band RF power source. A preliminary experiment to investigate the feasibility of this scheme shows that electrons could be bunched at 2.856 GHz, although the extracted bunch current would be relatively low. Presently, a coaxial cavity is being prepared in order to increase the bunch current.

2.3.3 Polarized electron source (PES): The PLS 2-GeV electron linac at PAL is the only facility applicable for nuclear and high-energy experiments in Korea. However, it is very difficult to have meaningful experiments due to the lower duty-factor for nuclear experiments. One of ways to utilize the existing 2-GeV electron beams to nuclear experiments is to use a polarized electron source for studying spin dependencies in the nuclear systems.

The polarized electron source consists of a polarized electron gun with a GaAs-type photo-cathode, a laser system operated at the wavelength near the GaAs band gap, and a polarimeter. In the first stage, we designed and constructed a test stand, which consists of a photo-cathode gun, a light source, a cylindrical condenser and a Mott chamber to develop the polarized electron source.

We used a bulk GaAs as a photo-cathode and supplied a few kV high-voltage. The energy of the emitted laser light is sufficient to photo-excite electrons to just above the photo-threshold for GaAs. Thus, a diode laser with photon energy of 1.56 eV and a maximum power of 20 mW will be used for the light source. The polarized electrons are bent to 90-degrees by a cylindrical condenser and measured the polarization by the Mott polarimeter.

2.3.4 Klystron-Modulator: A new modulator is designed to improve the current PLS 200-MW modulator. It employs an inverter type switching power supply to charge high energy density PFN capacitors, a command charging method to improve the system reliability, and a computerized automatic control system with a microprocessor. This modulator is compact, highly efficient, and reliable with easy remote-control capability. On the other hand, in the electron-positron linear collider program, the modulator efficiency is one of the most important issues in the operating cost. A prototype modulator, called the smart-modulator, is developed in collaboration with the C-band group at KEK. The initial test result shows that the efficiency of the 111-MW modulator system is 47.9% in compare with the design value of 59.3%.

2.3.5 Resonant ring: An S-band traveling-wave resonant ring is constructed for high-power RF tests on microwave components, such as ceramic windows and waveguide valves. This system is capable of delivering traveling microwaves of 4 μsec and 30 Hz with more than 200 MW power level, even though the peak power from the E3712 klystron is limited by 80 MW.

2.3.6 Waveguide valve: There needs a proper waveguide valve for the 80-MW RF system. It is very useful one for easy replacement and quick maintenance of klystrons. We adopted a new concept without limitations on power transmission. The new S-band waveguide valve consists of a U-shaped waveguide section with a pushrod assembly, a vacuum chamber with two H-corner sections and a scaling plate with two viton o-rings. We achieved a power transmission of more than 65 MW at a pulse with of 3.5 μsec and a pulse repetition rate of 30 Hz. It also shows an excellent reliability of the vacuum seal.

2.3.7 Portable cooling-water system; A stand-alone cooling-water system with the precision temperature control for the use of RF tests of microwave components, such as a resonant ring, a energy-doubler, and RF loads. The system consists of a centrifugal circulating pump, electric heater, air-cooled heat exchanger, direct digital temperature controller, and auxiliary components. The capacity of the maximum thermal dissipation is 3 kW with the temperature control range of $24 - 45 \pm 0.2^{o}$C.

3 KOREA ATOMIC ENERGY RESEARCH INSTITUTE: KOMAC-PROJECT

There has been a great demand on electricity along with a rapid economic growth in Korea. The national policy for constructing more nuclear power plants requires spent fuel treatment. As an optional concept, the Korea Atomic Energy Research Institute (KAERI) proposed an accelerator-based transmutation and energy production project called the KOMAC; the Korea Multi-purpose Accelerator Complex [5]. It adopts a 1 GeV and 20 mA CW proton linac for the driver of a 1000 MWth test reactor with electrical power of 300-400 MW. It is

capable to handle spent fuels from 2 units of 1 GW Light Water Reactors (LWR). There are two beam extraction areas, at 100 MeV for fast neutron generation and 260 MeV for medical application. The basic parameters of the KOMAC system are listed in Table 5.

In the first R&D phase of 1997-2001, it is to develop a low-energy end of 20 MeV consisted of an ion-source, RFQ, and CCDTL(I). It requires both positive and negative ion sources for beam extractions at 100 and 260 MeV. The RFQ operates at 350 MHz CW for 3 MeV and 20 mA. The minimum aperture of the vanes is 4.6 mm, and the total length is 2.4 m. The operating frequency of CCDTL is 700 MHz, and the length for 20 MeV is 30 m. The participating institutes in this R&D program are KAIST, PAL, and SNU: KAIST for ion sources, PAL for RFQ, and PAL and SNU for RF sources.

The main linac is suggested to use super-conducting structures for large apertures and reducing operating costs. Since the super-conducting linac technology is now being developed in many places, for example, at TESLA and JAERI, it is desirable for the KOMAC team to participate in collaboration research among interested groups.

Table 5: KOMAC basic parameters

Parameter	Specification
Beam energy	1.0 GeV
Beam current / power	20 mA / 20 MW
Particle	H+ (18 mA) / H- (2 mA)
Operational mode	CW (final), Pulsed (initial)
Accelerator Type	Ion Source / RFQ / CCDTL / Super-conducting Linac
RF system	31 Klystrons (700 MHz)
Beam extractions	100 MeV / 250 MeV
Electricity	68.5 MW
Cooling water capacity	60.0 MW (excluding reactor)
Overall Length	705.4 m

3.1 Ion Sources

A duoplasmatron H^+ ion source has been built at KAERI. It has a peak current of 30 mA with a normalized 90% emittance of 0.5 mm-mrad. While the Korea Advanced Institute of Science and technology (KAIST) is developing an H^- ion source, KAERI is responsible for an injector delivering both H^+ and H^-.

3.2 Radio frequency Quadrupoles (RFQ)

PAL is developing a 350 MHz RFQ which accelerates 50 keV H^+/H^- up to 3 MeV. The total length is to be 3 m with a minimum aperture of 2.4-mm radius. Full beam current will require 68 kW. Because of RF loss on wall surface, we still need total power of 400 kW.

3.3 Phase Matching Section

A phase matching section is required after RFQ for H^- since the frequency of CCDTL becomes 700 MHz. This section will be used as an alignment steer (two beams can be aligned independently). A system of quadrupoles and bunchers for transverse matching is also required in this matching section.

3.4 Coupled-cavity drift-tube linac (CCDTL)

KAERI is developing a CCDTL with the features of conventional DTL and CCL. The CCDTL accelerates both positive and negative ions from 3 to 100 MeV. It is easy to fabricate and install it on the structure without breaking vacuum. The total length is 29.8 m with total RF power of 1.5 MW. As an option, a 5-MeV RFQ is also considered. In the first phase, the first part of CCDTL is to be fabricated to deliver 20-MeV beams. In the second phase, 94.2-m CCDTL is to accelerate beams to 100 MeV.

3.5 Beam Extraction

A partial extraction of H^- beams is planned at both 100 and 260 MeV. A magnetic-stripping study shows that the threshold field for stripping an electron at 100 MeV is 1 T and one for 260 MeV is 0.8 T. Since one expects the emittance degradation in this system, there need more studies on a special magnet with a very sharp peak-field and a laser extraction method.

3.6 Super-conducting linac

A SNU team studies on this subject due mainly to save RF power and to have a large aperture size to reduce beam loss. However, there need more detailed studies on the capital investment cost and availability for the related technologies. In the preliminary investigation, there are three cryomodules: 100-140 MeV, 140-260 MeV, and higher than 260 MeV. The cryostats contain four 4-to 6-cells of 700 MHz niobium cavities. The transverse focus requires doublet quadrupoles in the outside of cryostats.

4 SEOUL NATIONAL UNIVERSITY AND SAMSUNG HEAVY INDUSTRY

4.1 Seoul National University (SNU)

SNU constructed a 1.5 MeV cyclotron in Physics Department in the early 1960's and a 1.5 MV Tandem Van de Graaff in Nuclear Engineering Department in the late 1970's. These are constructed as a graduate program. The 1.5 MV Tandem is being used for Rutherford back scattering (RBS), Photon induced x-ray emission (PIXE) analysis, and various nuclear cross-section measurements.

The Users Support Center at SNU purchased a Tandetron AMS from the High Voltage Engineering Europa. The nominal terminal voltage is 2.5 MV with the maximum of 3.0 MV.

4.2 Samsung Heavy Industry (SHI)

During the last few years, many industrial processes using the electron beam irradiation have been developed. In order to meet the industrial needs for irradiation technology, Samsung Heavy Industry established the accelerator development center and employed an ELV-type industrial electron accelerator developed by the Institute of Nuclear Physics (INP) in Novosibirsk, Russia in the mid-1970s. The ELV accelerator is characterized by the high voltage generation with a cascade coreless transformer.

The main parameters for ELV-type accelerators are as follows; Electron energy is 0.4 - 2.0 MeV, and beam power is no less than 20 kW within the whole energy range. SHI began to commercially manufacture ELV-type accelerators in collaboration with INP for various industrial applications, such as waste-water treatment, flue-gas purification, cross-linking of polyethylene, hardening of coatings and paints, graft polymerization, vulcanization of rubbers, deinsectization of grain, and fabrication of fiber glass plastics.

5 SUMMARY

We believe that we have established technological basis for accelerator related sciences, especially, through experience of the PLS construction. This accelerator community is to contribute the country for advancing basic and applied science research.

REVIEW OF NEGATIVE HYDROGEN ION SOURCES HIGH BRIGHTNESS/HIGH CURRENT

J. Peters
Deutsches Elektronen-Synchrotron, DESY, Notkestraße 85, 22607 Hamburg, Germany

Abstract

Due to the development of reliable H^- ion sources, charge-exchange injection into circular accelerators has become routine. This paper reviews recent developments in negative hydrogen ion sources. The underlying physics, operating parameters and beam characteristics of selected sources will be described and compared.

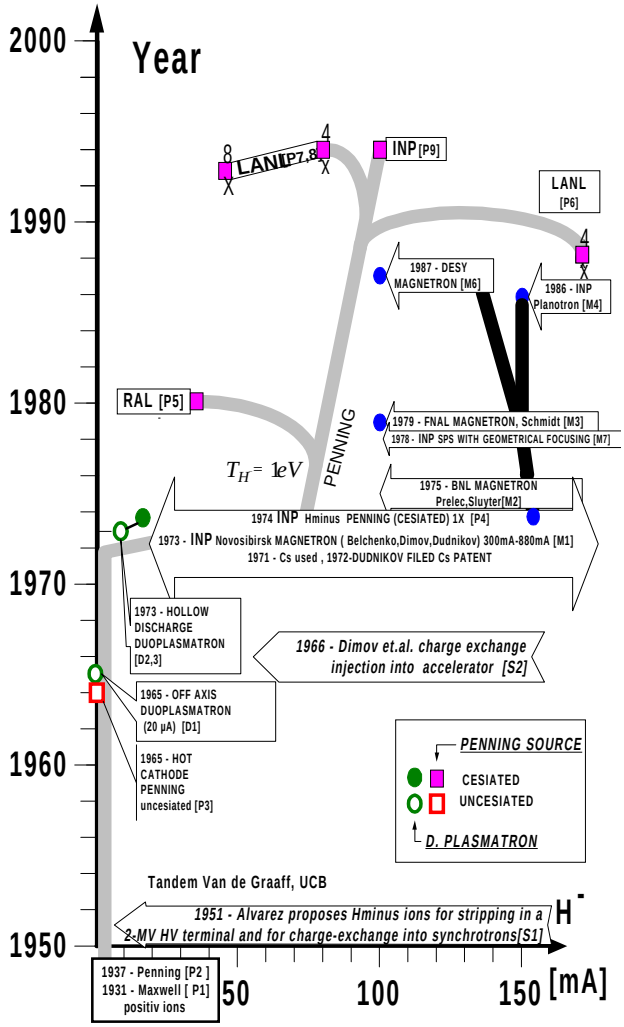

Figure 1: History of duoplasmatron and surface source development.

1 INTRODUCTION

This paper will deal primarily with H^- sources used as injectors for high energy accelerators. Usual (high) H^- currents are 10 to 100 mA dependent on the duty factor. It has taken two decades to reach these currents since Alvarez proposed H^- ions for stripping in a high voltage terminal and for charge-exchange injection into synchrotrons (Fig.1 S1) [1].

Duoplasmatrons (D1,2,3) with their low currents are excluded as well as multi aperture sources which have high currents but low brightness .

1.1 Definition of Brightness and Emittance

Several definitions of brightness are in use. The following relation is adopted here :

$$B = \frac{I}{\varepsilon^N_{x,90\%} \quad \varepsilon^N_{y,90\%}} \quad ,$$

where $\varepsilon^N_{x,90\%}$ is the energy normalized emittance in the (x ,x') plane for the contour containing 90% of the brightest beam and

$$\varepsilon^N = \varepsilon \beta \gamma \quad ,$$

with : $ß = v_{BEAM}/c$ and $\gamma = 1/(1-\beta^2)^{1/2}$.

In the ideal case the contour is an ellipse and ε is the product of the semimajor and semiminor axes times π. Emittances quoted in conventions other than 90% area values can be converted using the following equations :

$\varepsilon_{90\%} = 4.6\ \varepsilon_{rms}$ and $\varepsilon_{90\%} = 1.125\ \varepsilon_{4rms}$ assuming a Gaussian distribution.

1.2 Emittance Scanners and Emittance Errors

Emittance values found in the literature may differ very much even for the same source type and current. For this paper the labs were asked for emittances and the related current, type of emittance scanner, distance from scanner to extractor and other relevant source data. Most labs now use slit-multiwire scanners [DESY, BNL, RAL] or electrostatic sweep scanners (Allison) [LANL, LBL]. These devices are able to measure rms and area emittances. The pepperpot is also still in use. It measures only area emittances. In recently published emittance collections [2] area definitions have been used.

2 SURFACE SOURCES (SPS)

After the discovery of cesiation of surfaces at INP in 1971, the attainable H^- currents increased dramatically. The magnetron was invented (see Fig.1 M1)[3] and the penning source developed to its present standard (P4) [4] in Novosibirsk at INP .

2.1 Magnetron

Magnetron technology was transferred from INP to BNL (M2) [5] and from there to FNAL (M3) [6]. There was a mutual exchange between these two labs. In 1987 magnetron plans were brought from FNAL to DESY.

Figure 2 shows the structure of a magnetron in front and side views. It consists of a central cylindrical cathode surrounded by an anode. The discharge voltage, U_D , is typically ≈150 V and the current 40 A. A magnetic field (≈0.17 T) is parallel to the cathode axis. Hydrogen gas is introduced from the top by a pulsed gas valve.

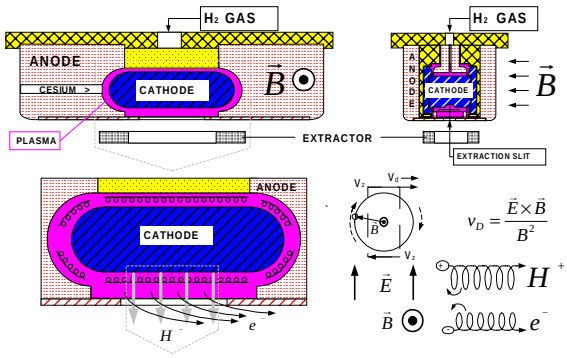

Figure 2: Magnetron source and E×B drift.

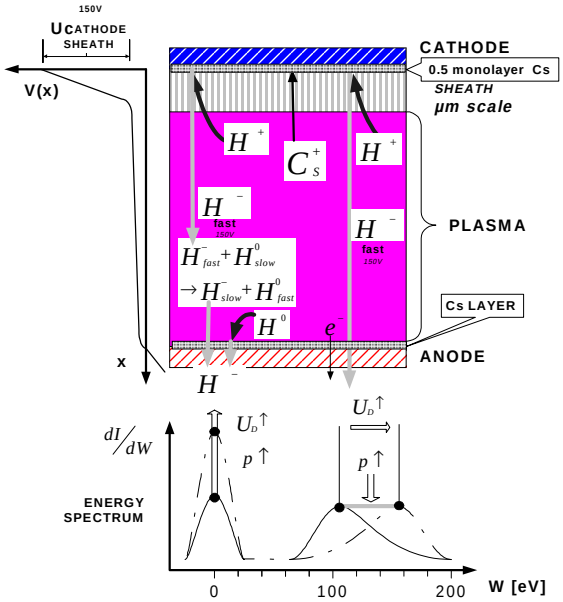

Figure 3: Production of H^- at cathode and anode of the source and their energy spectrum.

Cesium is obtained by heating metallic cesium or a mixture of cesium chromate and titanium. The mixture is available as pellets or powder.

H^- ions are extracted at 18 kV (FNAL, DESY) or 35 kV (BNL) together with electrons. Modern magnetrons have geometric focussing, developed at INP in 1978, with a groove in the cathode and slit extraction followed by a bending magnet [7]. Another possibility is to dimple the cathode and to use a hole as aperture toward the extractor electrode [8].

The electric field between anode and cathode leads to an E×B drift around the cathode, which is shown on a magnified scale Fig.2 (lower part). Positive and negative ions move in the same direction. There is no movement parallel to E as particles gain as much energy as they lose. But parallel to E×B there is a resulting difference v_d (see Fig.2). Charges are not separated due to this effect. A dense plasma is produced.

If one looks with a bigger magnification at the space between anode and cathode (Fig. 3) one notices a transition zone, the so-called sheath, between the plasma and the cathode. Here the potential drops to cathode level. There is only a small potential difference across the plasma. H^+ ions generated in the plasma are accelerated through the sheath. They produce H^- ions at the cathode surface, which is covered in the ideal case with approximately half a mono layer of Cs in order to minimize the surface work function. These H^- particles are then accelerated to U_D passing through the sheath. Some move through the plasma and are extracted. They form a maximum in the energy spectrum (Fig.3 lower part). Others hit slow H^0 particles and exchange speed and charge; this is resonant charge exchange. In this way slow H^- ions are produced. Slow H^- can also be produced by H^0 hitting the cesiated anode surface.

Due to these mechanisms a low and a high energy peak appear in the energy spectrum. To increase the fraction of low temperature ions one can increase the source pressure and discharge voltage U_D, as indicated in the plot. In addition, the position of the high energy peak can be changed by varying U_D and the amplitude lowered by increasing the pressure.

2.2 Semiplanotron

The semiplanotron (see Fig. 4) is an optimized magnetron, with geometric focussing and without a discharge at the back of the cathode. These modifications make it more efficient. Operational experience is, however, limited. Source lifetime may be limited by the accumulation of sputtered particles from the cathode as a result of their drift path being blocked. This might result in a short circuit, consistent with DESY experience.

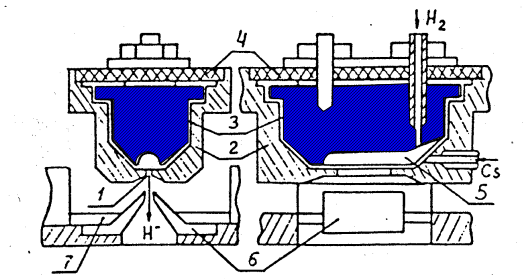

Figure 4: The semiplanotron source. 1. emission slit, 2. anode, 3. cathode, 4. insulator, 5. groove, 6. extractor, 7. steel inserts.

2.3 Penning

In order to avoid the high energy peak of the magnetron spectrum the cathode surface should not face the ion extraction aperture. This is how the penning source is constructed (see Fig. 5).

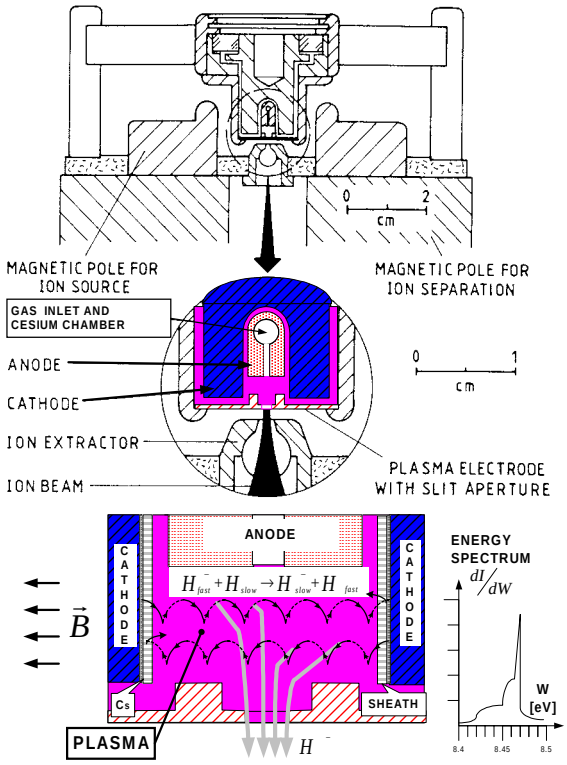

Figure 5: Penning source schematic and its energy spectrum.

A strong magnetic field parallel to the electric field of the sheath guides electrons and ions on cyclotron spirals from cathode to cathode. Fast H^- ions are generated at the cathodes as in the magnetron. They are slowed down due to the charge exchange reaction as they migrate to the plasma aperture. There is only one low energy peak and the H^- temperature has been measured to be less than 1eV [9].

2.4 Multicusp Surface-plasma (converter) Source

Fig. 6 shows a multicusp surface-plasma source. A discharge is produced with filaments. The plasma is confined by a multicusp field. A converter biased at ≈300 V is located in the middle of the source. Secondary emission of negative ions takes place. The H^- ions are produced by H^+, H_2^+ and H_3^+ bombarding the converter. Cesium is injected into the source to increase the H^- yield. Self extraction of H^- takes place with focussing provided by the curvature of the converter. A magnetic filter is used to repel electrons.

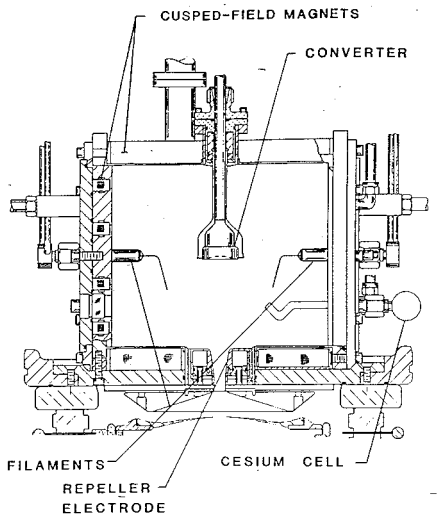

Figure 6: LANL surface production multicusp.

3 VOLUME SOURCES

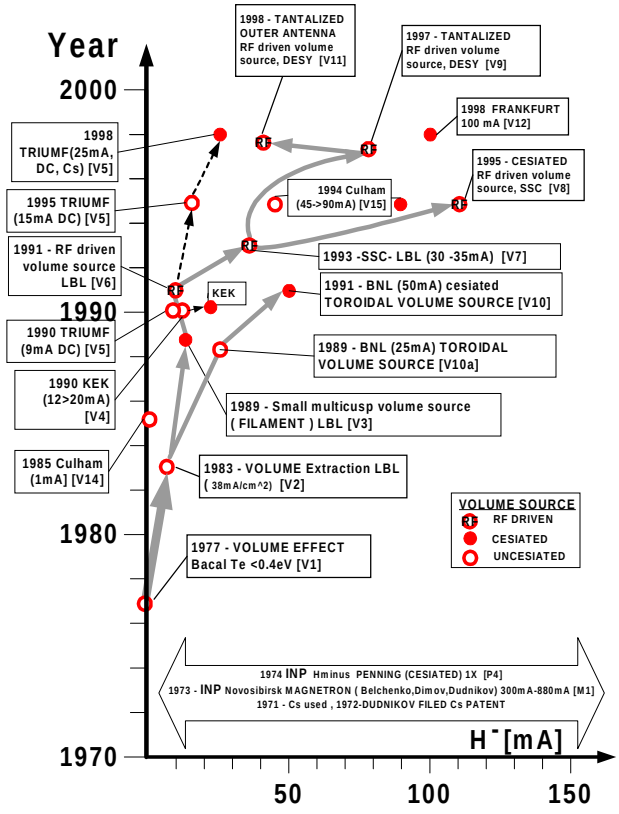

Figure 7: History of volume source development.

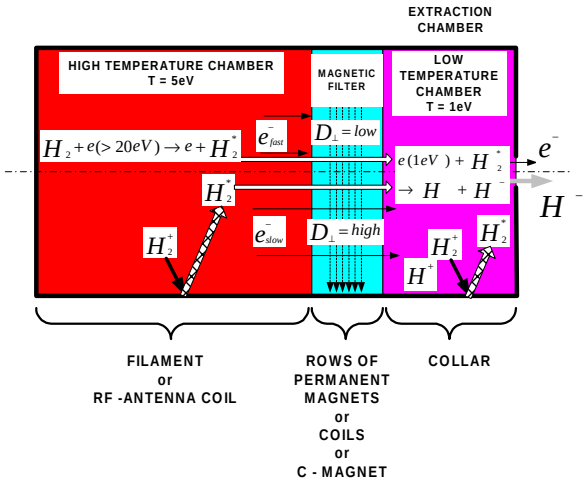

Figure 8: Tandem source for volume production.

In 1977 M. Bacal [10] discovered volume production for H^- generation. This started the development of a new type of sources (Fig. 7). The volume source consists of two chambers, which are connected by a magnetic filter (Fig. 8). In the high temperature chamber energetic electrons hit H_2, which become vibrationally excited. Excited molecule are also produced at the chamber walls out of H_2^+ and H^+. Electrons from the high temperature chamber move by diffusion through a perpendicular magnetic field into a second chamber. Whereas high energy electrons are effectively blocked, slow electrons collect in the second chamber. In this low energy chamber, low temperature 1eV electrons attach to the H_2^* producing H^- ions.

Multi-cusp magnets are used to confine the plasma.

3.1 Filament Volume Source

The first volume sources were uncesiated and had filaments. Currents of up to 20 mA DC [11] were reached with small sources and 45 mA [12] (Fig. 6 V15) with larger ones. Cesiated currents of 25 mA DC [13] and 90-100 mA at 6% duty factor [12,14] V12 have been achieved. The lifetime of these sources is limited by that of the filament.

3.2 RF Volume Source

The filament was first replaced by an rf antenna coil in 1991 [15]. Fig. 9 shows the DESY RF volume source; it is similar to the sources of LBL and SSC. The antenna heats the high temperature chamber and the filter is constructed with two rows of permanent magnets. The low temperature chamber is located inside a collar.

The antennas are coated to reduce plasma modulation by the rf voltage and sputtering. With uncesiated rf volume sources 35 mA were reached. At DESY the collar was biased and tantalum coated, and currents of 80 mA were achieved uncesiated.

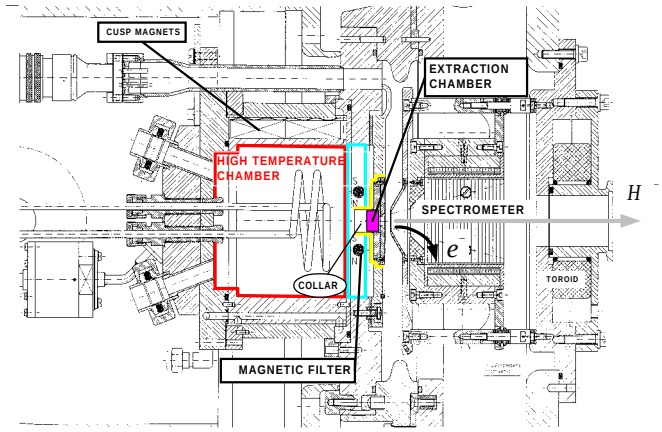

Figure 9: RF driven volume source.

The antennas used by LBL, SSC and DESY were all coated by the same manufacturer. An analysis of the coating found a high percentage of K and Na (Table 1). Different contents of potassium might have contributed to reported differences in source performance.

Table 1: Results of Analyses of the Antenna Coating

ELEMENT	PERCENTAGE
Si	46.9 %
Ti	29.6 %
K	15.2 %
Al	5.7 %
Na	2.6 %

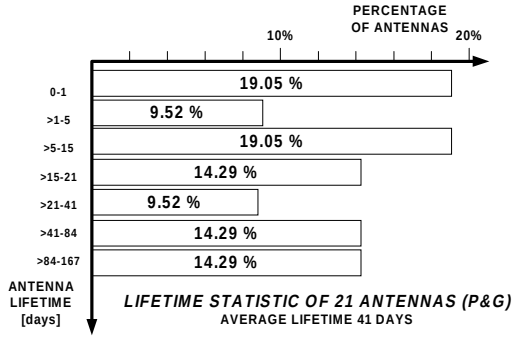

Figure 10: Lifetime statistic of the coated antennae.

DESY has the longest experience in running this type of volume source with the P&G antenna. The performance of the antennae is first limited by spots in the coating. If it survives this period then cracks due to sputtering of the coating material become the lifetime limitation. The average lifetime of only 41 days is higher than that of a filament. However ≈50% of all antennae fail during the first 15 days. This unpredictability is a serious problem for reliability.

In addition it was found that sputtered glass from the coating insulates the chamber walls. After such an event it is necessary to do a careful time consuming cleaning of the whole source. Based on this experience a new rf coupling was developed, which couples through a ceramic of Al_2O_3. This type of ceramic has a sputter rate seven times lower than that of glass and three times lower than Ti.

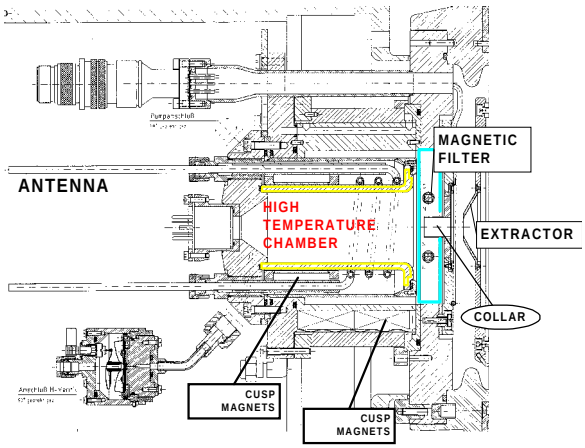

Figure 11: The DESY volume source with an rf coil shielded by Al_2O_3 ceramic.

A source of this type, Fig. 11, was run for 2800 h at 40 mA with a duty factor of 0.05 % and a pulse length of 100 µsec. No degradation in performance was observed.

4 SUMMARY

Table 2: Collection of Source Data

tested uninterrupted run [h]	SOURCE TYP	DUTY FACTOR [%]	$\varepsilon_{n,90\%}$ [π mm mrad]	REF.	BRIGHTNESS [mA/m² mrad²]	C_s CONS [mg/day]	CURRENT I/mA

For high energy accelerators it is important to have a reliable source. Magnetrons have been used for the longest time in accelerators and have tested runs of 7000 h. They have, however a poor brightness. Penning sources provide the highest brightness but run for only about 900 h.

The best tested volume source is a DC 6 - 20 mA source, which runs (limited by the filament) for 500 h.

A new rf volume source with an rf coil shielded by ceramic exhibited no degradation in performance after a run of 2800 h.

According to recent results [11, 14] the future prospects of filament volume sources as high duty factor accelerator sources are very good.

Since the antenna problem was solved [27] rf sources are expected to replace magnetrons. They have a higher brightness, higher reliability and are easier to maintain.

5 ACKNOWLEDGEMENTS

The author is grateful for the contribution of the following colleagues at DESY :

N.Holtkamp, I.Hansen, H.Sahling and R.Subke. I wish to thank the technical groups at DESY for their support, and M. Lomperski of DESY for helpful suggestions to the wording of the report. The support of the source groups of BINP, BNL, FNAL, LANL, LBL, RAL and TRIUMF is gratefully acknowledged.

EMERGING INDUSTRIAL APPLICATIONS OF LINACS

A. M. M. Todd
Northrop Grumman Advanced Energy Systems
9 Jeffrey Lane, Princeton Junction, New Jersey 08550, USA

Abstract

Three emerging linac market areas are discussed: contraband detection using tandem ion accelerators; x-ray sterilization of food using high-power electron linacs; and large volume material surface processing with radiation from superconducting RF accelerator-driven free electron lasers. The opportunities are described and simple economic models are applied to assess the viability of linac technology market penetration. The high cost of ownership is considered a potential problem for accelerator systems in the inelastic contraband detection market. However, the food sterilization and material processing markets appear to have sufficient headroom to permit successful accelerator technology penetration. Of these three areas, food sterilization is likely to be the application that could first experience significant growth early next century.

1 INTRODUCTION

Medical applications, particularly clinical x-ray systems, continue to dominate the industrial market for linear accelerators. However, several developments suggest that significant new markets may soon emerge.

Among these markets is food irradiation which for some time has been pushed within the technical community but has never developed sufficient market pull to secure a commercial foothold. Irradiation should benefit from the recent Food and Drug Administration (FDA) approval of x-rays for the cold pasteurization of red meat, poultry and pork.

Another growth area, driven by Federal Aviation Administration (FAA) and Department of Defense (DoD) funding, is contraband detection. In addition to airport hand baggage, inspection of large cargo volumes and containers at airports, seaports, road and rail border crossings and military bases is a growing market. The current market surge is dominated by advanced x-ray devices and chemical detection "sniffers", but larger linac systems may have a niche in container inspection. Increasing terrorist activity is once again focusing a spotlight on higher performance explosive detection systems (EDS).

Further off in time, ultraviolet (UV) and infrared (IR) micromachining and surface material processing with high-power, linac-driven, Free-Electron Lasers (FEL) has the potential to evolve into a major and varied market. Many applications, principally in polymer and metal processing, are already established and their commercialization is limited only by the economics of available light sources.

The following three sections focus on Contraband Detection Systems (CDS) utilizing tandem ion accelerator-generated gamma-rays for resonance imaging, cold pasteurization of red meat using high-power electron accelerator-generated x-rays, and high-volume surface material processing with UV and IR radiation from a superconducting-RF FEL. The applications, their performance requirements and their economic potential to achieve market penetration are assessed.

We stress the platitudes that successful technology insertion requires market pull and not simply technology push, and that a technology cannot simply be thrown over the wall to thrive without nurturing. Economic considerations are almost always critical, but market infrastructure, operational simplicity, robustness, reliability, availability, maintainability, inspectability (RAMI or the "ilities") and after sale support are all vital.

2 CONTRABAND DETECTION

A principal motivation for contraband detection systems is the increasing number of successful terrorist incidents. Most recently, the Nairobi and Dar es Salaam US Embassy attacks and the despicable incident in Omagh have again heightened awareness of terrorist activities. While we are all aware of the PanAm 103 and TWA 800 incidents, one of which was definitely caused by a bomb, it is not so widely known that there are hundreds of annual attacks at US bases abroad, though few are as severe as the recent al Khobar Towers incident.

Hence, there is a significant opportunity for contraband and explosive detection systems of various kinds: at seaports and airports to inspect hand baggage, cargo and to otherwise detect smuggling; for force protection of bases and embassies; and at border crossings to inspect trains and trucks.

The market characteristics are somewhat fickle with significant peak-to-peak funding oscillations and sales opportunities that often seem to parallel occasional tragedies. The market also remains largely inelastic due to the high cost of ownership (COO) of effective detection systems coupled with the low probability of incidents actually occurring in the first place or being prevented by the system.

InVision Technologies is the market leader with the $1M CTX 5000 x-ray device that is deployed at airports worldwide and is the only presently FAA certified EDS for hand baggage. Lockheed Martin has recently introduced the cheaper L-3 system, while Vivid Technologies and

others market simpler units. Thermedics is a leading supplier of competing chemical "sniffer" systems.

The FAA certification requirement for baggage inspection systems is a throughput of 450 bags per hour. False Alarm Rate (FAR) and detection rates are not public, but simple intuition suggests that values of FAR ≤ 10% and detection probabilities ≥ 90% are probably required to prevent significant transit delay. An interesting economic point is that the cost to install CTX 5000 systems in the 75 busiest airports is estimated at around $2.2B [1]. This figure is greater than the entire 1995 airline industry profit and explains the COO market penetration difficulty of EDS, given the very few US airline bomb incidents to date.

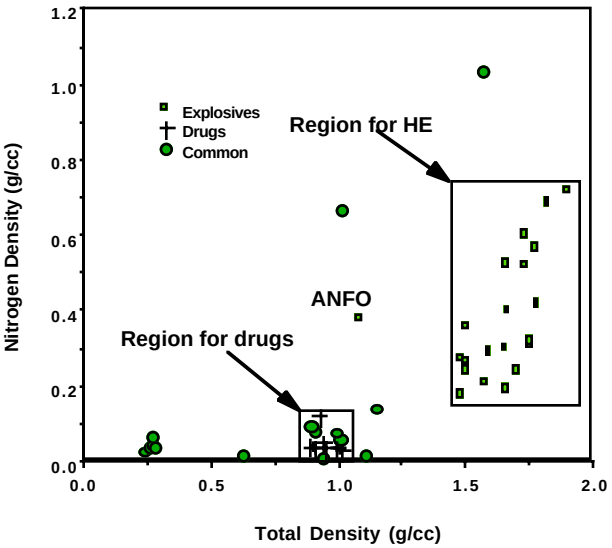

Figure 1: Nitrogen-based High Explosive (HE) identification using the gamma resonance CDS technique [2].

Gamma resonance imaging holds great promise as an EDS technology. Here 1.76 MeV protons impinging on a ^{13}C target produce γ-rays that are arranged to pass through an inspection target. A high-current tandem accelerator is selected for wall-plug efficiency reasons. At a particular detection angle, the γ-rays are resonant with ^{14}N. Hence, measuring the resonant γ-rays determines the sample nitrogen density, while the non-resonant γ-rays yield the total sample density. Figure 1 illustrates that these two simultaneous measurements provide excellent discrimination and the potential for high detection probabilities with corresponding low FAR for nitrogen-based explosives. Tomographic inversion leads to small voxel identification of suspicious material that in principle permits the identification of sheet explosives. Gamma resonance CDS is a relatively immature technology, which is projected to meet FAA throughput and performance targets, but at a higher cost than the competing systems.

In analyzing EDS systems, we have assumed a 15% cost of capital, a 5% of capital cost per annum maintenance expense, $150K annual operating cost comprised of $100K for operating personnel and $50K for other costs and services over a 7 year system lifetime with straight line depreciation. This results in a net present COO of ~$2.0M for a $1M x-ray system and ~$4.0M for a gamma resonance CDS. An interesting figure of merit is that 450 bags/hour, 18 hours a day, 350 days a year for 7 years result in a cost of 5¢/bag per $1M COO. Even if gamma resonance technology matures and can outperform multiple units of other systems as is projected, the high COO will remain a problem in this market unless the driving forces change significantly.

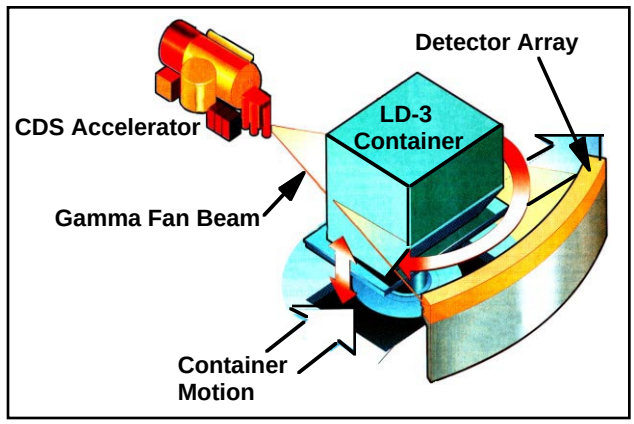

Figure 2: LD-3 airline cargo container CDS interrogation concept [2].

Force protection and airline cargo examination, as indicated in figure 2, have been projected as possible niche markets for the higher potential performance of gamma resonance CDS. Heimann Systems already markets static and transportable x-ray systems, based on conventional electron linac technology, that are used to inspect trucks and other cargo. However, despite strong DoD and Congressional interest, until the recent Embassy bombings, US action on force protection was proceeding conventionally and somewhat slowly, and the need for airline cargo inspection was again being questioned. US Customs interest for train and road border crossings, airframes and sea containers continues to lag DoD, State Department and FAA interest.

Thus, we are forced to conclude that the present outlook for market insertion of accelerator-based gamma-resonance CDS is mixed. However, the rapid swings in attention and funding within this market place suggest that the situation could again quickly reverse in the future.

3 COLD PASTEURIZATION

The motivation for cold food pasteurization is strong and receiving increasing recognition. The US Department of Agriculture (USDA) estimates that $30B in annual hospitalization costs and lost earnings result from contaminated food. The Council for Agricultural Science and Technology (CAST) estimates greater than 33 million annual US cases of food contamination illness and more

than 9000 deaths. Recently, the National Academy of Science, asked by Congress to review the situation, estimated 81 million annual cases of food contamination illness, higher than CAST, and expressed the need for a more centralized and modern Government food safety administration.

In addition to illness, radiation treatment reduces spoilage and adds shelf life of up to a month. This results in additional home market value added and opens new overseas markets because of the economic opportunity for seaborne transportation of US produce.

The FDA has recently approved x-ray cold pasteurization in addition to γ-ray and electron sterilization of red meat, poultry & pork. USDA radiation dose and packaging guidelines are imminent with a 30 to 60 days public review period to follow. We have chosen here to focus on x-rays because they permit significantly more uniform irradiation of thicker product. Within the permitted dose range, direct electron irradiation, while possible at tens rather than hundreds of kilowatts, is limited to boneless product such as ground beef patties.

An important paradigm changes is the recent emergence of a significant fraction of consumers (> 20%) who are willing to pay a premium for safe meat and the impending availability of economic, high-power electron accelerators. This yields the opportunity for near term market insertion shortly after the year 2000 because of the existence of value added headroom through market acceptance of a premium product. This leads to the price elasticity that was missing in the previous EDS market and opens the door for the introduction of a new accelerator product.

We have long been promised that the medical and food sterilization markets have been ready to explode. However, although imported spices have been irradiated for years, only 1B lbs of food is presently irradiated annually worldwide. Of interest is Food Technology Services in Florida, which already produces the premium brand "Nations Pride" poultry with cobalt source irradiation. However, radioactive sources cannot be turned off like accelerator-based sources, have a high environmental disposal cost and issues associated with high throughput.

Similarly, in the more accessible, lower throughput, higher value added medical sterilization market, Impela devices, Titan Scan systems, and most recently the Ion Beam Applications Rhodotron, have been competing for a limited number of orders. The continual drive towards the "greening" of processing technologies suggests that present chemical sterilization will continue to be displaced.

In evaluating the market economics, we assume a service provision business structure for the plant and present year money throughout. A 0.5 MW electron accelerator can generate 40 kW of x-rays that deliver a 1.8 kilogray exposure to 200 metric tons of red meat per 8 hour accelerator shift. At 50 mils/ kW-hour and greater than 50% wall plug efficiency, this leads to a $200K annual cost of electricity and other services. Splitting the mark up that consumers have indicated a willingness to pay for a safe premium product, yields ~ 5¢/lb added cost for irradiation to the service provider, plus a further 10-15¢ for the meat processor and retailer for around 5% of the final product cost. We baseline a $7.5M plant capital cost for the high-power accelerator, conveyor system, shielding and support systems, a 15% cost of capital, 2.5% of capital cost per annum maintenance expense, $100K annual personnel operating cost for a 7 year system lifetime with straight line depreciation.

As shown in figure 3, this leads to a 2.5¢/lb earned value break-even point. Earned value is defined to be the net present value of the free cash flow over the lifetime of the plant. In the vicinity of the nominal 5¢/lb charge, which is removed from the break-even point, there is relative insensitivity to interest rate, plant capital cost and electrical efficiency, which influences the choice of drive accelerator. It is this insensitivity that suggests there is a high probability of successful technology insertion at price levels the market will tolerate. However this also implies that early on in the development of the market, competition for the large available sales volume, which will expand beyond premium brands, will drive the acceptable processing cost for the customer much closer to break-even. Here, sensitivity to efficiency and plant capital cost will become critical discriminators in obtaining adequate margin and the successful accelerator technology will have to be both very affordable and highly efficient.

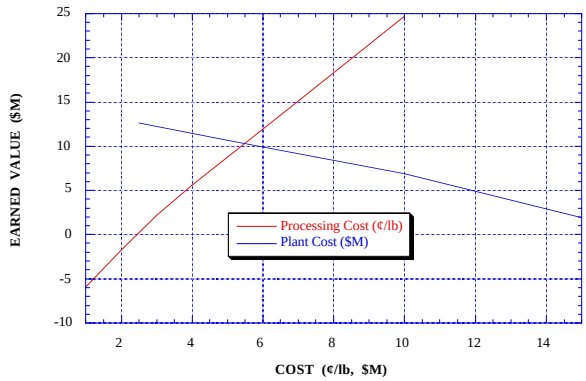

Figure 3: Earned value as a function of plant cost ($M) and unit processing cost (¢/lb).

4 FEL MATERIAL PROCESSING

The third area we consider is large volume material processing with an IR or UV FEL. A superconducting-RF accelerator driver has been assumed because of the high wall-plug efficiency at the very high power level projected. The envisaged system is based on the Jefferson Lab IR FEL that recently set the FEL power record of 311W [3], and is pushing on towards kW power levels to provide market evaluation quantities from some of the processes described below.

The motivation in this case is that future US prosperity is strongly linked to on-shore manufacturing strength. Radiation processing offers the opportunity to widen product value and choice by surface modification, can reduce resource intensity by optimal use of prior investment, may provide near real-time response to consumer demands and leads to reduced environmental impact over competing chemical processing by minimizing waste and improving efficiency.

Many of the metal and polymer applications are proven and patented [4], and the issues for deployment are the available power level and the economics at the desired wavelength. Excitation is vibrational in the IR and electronic in the UV. For instance, many of the processes have already been demonstrated with conventional lasers or lamps, but the cost of these radiation sources is too high and their power levels are too low for practical application. In particular, UV excimer lasers have opened the way to surface modification via transform chemistry, morphology or topography changes dependent on fluence, irradiance and wavelength.

On the other hand, the vacuum lasing medium of the FEL still promises to yield very efficient, high-power lasing, while the wide tunability leads to versatility with respect to processing applications and permits matching to narrow-band absorption. The ultra-short and intense pulse structure gives rise to optimum surface coupling, very high peak powers, as well as the highest heating and cooling rates available for surface modification. In addition, the short pulses minimize collateral damage due to bulk heating and the dry chemistry enables increasingly economic "green" processing.

Polymers are a huge, highly cost sensitive business. 1994 US synthetic fiber production was 9.5 B lbs, while the 1993 World artificial fiber production was 40 B lbs. 1994 US resin production was 5.7 B lbs for food packaging within flexible packaging sales of 14.7 B lbs, but this is dwarfed by the huge food packaging potential in the Third World.

Commercially important polymer applications include improved adhesion for forming multi-component film products or composite structures, more effective fibers for use in filters, and improved feel and appearance of synthetic fiber fabrics. Other applications would yield more easily recyclable food packaging, more durable and attractive carpeting, stronger and more versatile composite materials, and antimicrobial surfaces for shipment or storage of food without the need for refrigeration. As with food sterilization, the latter application has great potential impact in the Third World.

Figure 4 shows an electron micrograph of a polyester fabric surface microroughened with exposure to ultraviolet light from a conventional laser that illustrates the effects of surface texturing. This processing leads to improved look, feel and dye uptake that translates into value added that can be successfully charged to the consumer.

The present hierarchy of polymer processing can be expressed in energy density order as follows. Enhanced adhesion of amorphized PET with UV radiation occurs at 25 mJ/cm^2. Surface roughening of PET leading to enhanced feel, look, mechanical interlock, dye uptake or enhanced filtration via rapid thermal processing with UV and IR radiation occurs at 0.5 J/cm^2. Finally, photochemical anti-microbial surface activation of nylon with 193 nm radiation requires 2.5 J/cm^2. An equivalent suite of high-power metal applications, and micromachining at 2-10 kW, exist but are not described here. In all cases, the true need for FEL-specific properties, as opposed to a tailored, cheaper and smaller conventional laser, must be fully considered.

Figure 4: Excimer-treated polyester fiber showing surface roughening for improved look and feel [5].

We again assume a service provider business structure and present year money. In this case, the FEL power level is 100 kW and 80% annual availability is postulated. A $175K charge is applied for other services plus the annual cost of electricity at 50 mils/ kW-hour and a 20% overall wall plug efficiency. A 3.5 mils/kJ radiation cost, $20M plant capital cost, 15% cost of capital, 2.5% of capital cost per annum maintenance expense, $400K annual personnel operating cost, 10 year system lifetime and 7 year straight line depreciation are also nominally assumed.

This leads to a 2.2 mils/kJ earned value break-even point where plant capital cost is a key parameter in this case. Economics competition considerations similar to sterilization will likely move the system parameter choice from 3.5 mils/kJ towards break-even, thereby determining the accelerator choice and other factors. For this reason we believe that a superconducting-RF-driven linac is the FEL driver of choice. Again, there is clear market opportunity and head room, if accelerator plant cost targets can be met.

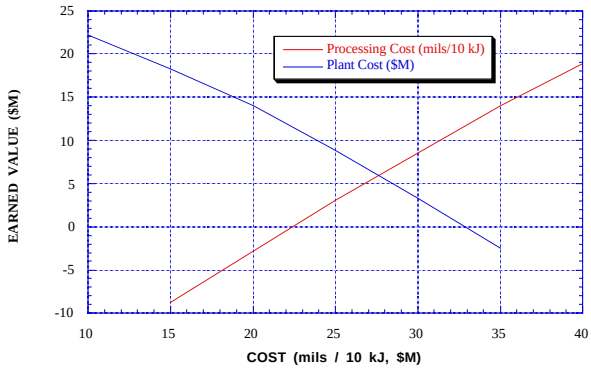

Figure 5: Earned value as a function of plant cost ($M) and unit processing cost (mils/10 kJ).

5 SUMMARY

New linear accelerator product opportunities seem to be immanent. In developing these new products, market and economic forces must always be recognized and observed. Contraband Detection has great potential, but sales are highly politicized and thus the market future is unclear. Sterilization has true and significant market potential and is finally almost here. FEL Material Processing is a potentially huge opportunity worldwide, but is still a few years off

THE CHALLENGE OF INERTIAL FUSION DRIVEN BY HEAVY ION ACCELERATORS

I. Hofmann*
GSI Darmstadt, 64291 Darmstadt, Germany

Abstract

Accelerators have a chance to participate in the enormously growing energy market of the 21st century if inertial confinement fusion can be shown to be competitive with fossil and fission alternatives. While it is expected that ignition and gain of fusion pellets will be demonstrated by the National Ignition Facility after 2005, the development of a suitable driver with high efficiency and rep-rate capability remains the next challenging issue. We review the status of the European HIDIF study group which has set itself the goal of demonstrating the feasibility of the RF linac based heavy ion driver. Related experimental investigations (beam halo) are briefly discussed.

1 INTRODUCTION

Thermonuclear fusion promises a long-term supply of energy under all presently discussed scenarios of population development and environmental constraints (CO_2). It can be assumed that the expected expansion of the energy market in non-OECD countries within the next fifty years will dramatically increase the need for new, affordable energy sources other than fossil. It is estimated that the non-OECD energy market doubles every 25 years; on the other hand stabilization of the CO_2-level at 550 ppm (parts per million, with presently 350 ppm and a pre-industrial value of 270 ppm) would require 15 TW of additional carbon-free primary energy by the year 2050 [1]. Note that the present total energy consumption is 13 TW. This perspective describes the tremendous potential of fusion energy.

Although enormous progress has been achieved in both approaches to fusion energy, magnetic confinement (MFE) and inertial fusion energy (IFE), the gap between scientific understanding and attractive commercial realization is still big. One of the crucial questions is the complexity of a thermonuclear energy plant, which seems to exceed significantly that of fission reactors. The presently most advanced study exists for the tokamak based ITER (International Thermonuclear Experimental Reactor), which is designed for 1 GW fusion power and has a volume exceeding that of the Westinghouse AP-600 light water reactor by two orders of magnitude. We expect that inertial fusion reactors are significantly more compact and offer a number of conceptual advantages, for the following reasons :

- decoupling of driver and reactor chamber, which reduces the complexity of the overall system and allows to use several chambers for one driver; this could also shorten substantially the development path of a commercial system.
- liquid blanket protection, which offers the potential for lifetime reactor chambers, instead of solid walls (as in MFE) that would be exposed to serious radiation damage requiring frequent replacement [2].
- while the standard fuel is an equimolar D-T mix, it is not excluded for IFE to consider (at a more advanced stage) fuels with significantly less or no T inventory, for instance D-^{3}He; in MFE the only option is D-T due to excessive bremsstrahlung losses at the higher temperatures required for all other reactions.

The next milestone in inertial fusion is the expected low-gain target ignition with the laser driven "National Ignition Facility" at Livermore (NIF) and "Megajoule" in Bordeaux, France. These facilities are designed to demonstrate (beyond the year 2006) for the first time propagating fusion burn in D-T fuel on a single-shot basis, which would clearly set inertial fusion to the forefront of fusion development.

In parallel to this the development of a suitable driver with a rep-rate capability of the order of 10 Hz is the next most important requirement for advancing inertial fusion energy. For heavy ion accelerators the necessary rep-rates are common standard, but the required intensities and phase space densities have yet to be demonstrated. Heavy ion accelerators can satisfy the efficiency requirement of 20-30% which follows from the relationship $\eta G \geq 7-10$ needed for a reasonably small re-circulating energy. Here G is the target gain and η the driver efficiency. An η of 20% is consistent with a low-risk gain $G \approx 40$ and achievable with the RF driver. This perspective of heavy ion drivers applies equally to the RF linac/storage ring concept as to the induction linear accelerator, a concept pursued by the US community [3].

Other presently discussed options are high rep-rate diode pumped glass lasers developed at Livermore and expected to get from the presently 1 J per unit to the 100 J level

* this paper summarizes the work of the HIDIF study group with the following members: S. Atzeni[1], R. Bär[2], M. Basko[3], R. Bock[2], K. Bongardt[4], J. D'Avanzo[2], H. Deitinghoff[5], C. at 10 Hz in 2-3 years [4]. Electron beam pumped KrF laser concepts have been proposed at NRL/USA [5] and in Japan [6], which are expected to deliver up to 200 J at a few Hz. For the long–term future of GSI a 100 T-m synchrotron is presently explored, which would deliver up to 10^{13} U^{4+} ions and 40-50 kJ total energy in a single bunch. The SIS heavy ion synchrotron at GSI can in principle operate at 1 Hz, but public grid load restrictions limit the present rep-rate to 0.5 Hz. Using an Ar^{10+} beam at 300 MeV/u and the highest presently achieved intensities (5×10^{10} particles) it is able to produce bunches with 100 J energy at this rate. The next step will be in 1999 the possibility of accelerating highest currents of U^{28+} after completion of the new IH-structure high-current injector for UNILAC. With the expected 10^{11} U ions in the SIS the bunch energy can be raised to close to 1 kJ.

2 THE HIDIF-STUDY

The scope of the HIDIF study has been to demonstrate the feasibility of an RF linac and storage ring based scheme for high repetition rate ignition consistent with an indirectly driven low-gain target. It has been carried out within the framework of a European Study Group in the years 1994-98. Collaborators in the field of the accelerator have been individuals from GSI, CERN, Rutherford, Frankfurt University (IAP) and FZ Juelich. The most challenging issue is the requirement of small beam loss and minimum dilution in all of the six-dimensional phase space in order to match the requirements of short pulse lengths (6 ns) and small focal spots (1.7 mm radius) at the target. The study succeeded to show that the designed driver satisfies the requirements of producing the necessary beam power. The concept of indirectly driven targets has been chosen since it appears difficult with heavy ion beams to achieve a 1% symmetry of implosion as required by direct drive (see Fig. 1 and Ref. [7]).

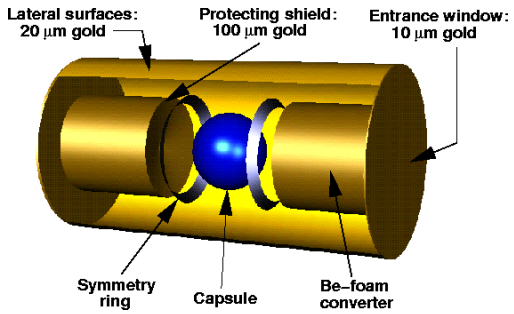

Figure 1: Indirectly driven reference target proposed for HIDIF. The heavy ion beams are converted into x-rays by two Be converters. The fusion capsule implosion is driven by the symmetrized radiation (courtesy of R. Ramis).

The HIDIF driver has a number of characteristic features, which are summarized in the following:

- charge state 1+ to reduce space charge effects,
- 3 ion species (for telescoping, see below) accelerated in the same linac but stored in different rings,
- 16 ion sources of each species,
- four funneling stages for RFQ's and DTL's and one main high-current DTL linac up to 10 GeV and a total pulse current of 400 mA,
- simultaneous two-plane multi-turn injection into storage rings to minimize injection losses,
- multi-turn injection into RF barrier buckets and, after filling of all rings, adiabatic prebunching,
- final bunch compression (fast) in induction bunchers with multiple beam lines to obtain the required 6 ns pulse length,
- conventional focusing using super-conducting quadrupoles in matrix array.

The funneled linac tree is shown schematically in Fig. 2 (see also Ref. [8]) assuming ion sources for Bi^{1+} with a current of 25 mA (for a prototype ion soutce see section 3).

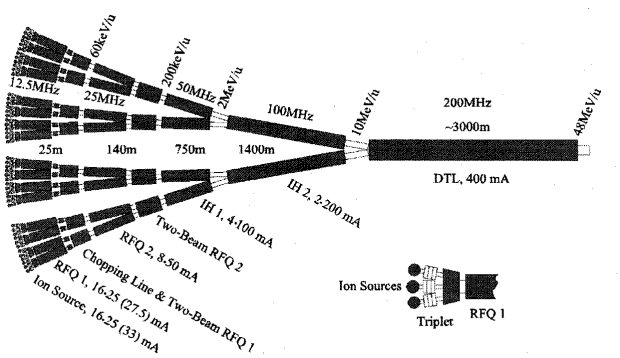

Figure 2: Scheme of a linac funnel tree for HIDIF (courtesy of A. Schempp).

The envisaged linac peak current of 400 mA and the gaps between different barrier buckets as well as the switching of the linac beam to different storage rings and to different ion species lead to a total pulse duration of 1.5 ms, which is also the duration of the RF power cycle (see Fig. 3).

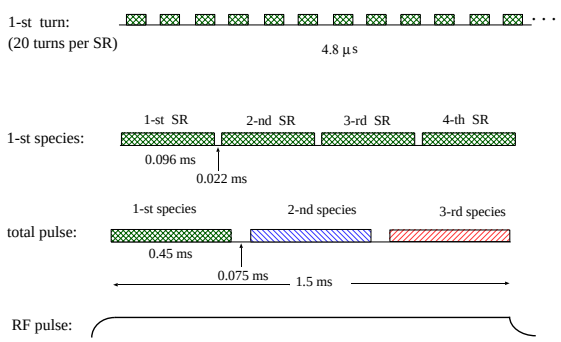

Figure 3: Linac pulse structure.

As a result the average linac current in this period is 192 mA. The scenario assumes 12 bunches per storage ring, which is equivalent to a stored energy of 250 kJ per ring.

The full scenario is shown in Fig. 4 for the reference case with 3 MJ requiring a total of 12 storage rings. Single-charged ions of three atomic species are accelerated in the same linear accelerator to identical momenta and stored and bunched in a set of 4 storage rings per species. The bunches are synchronized by delaying them in sets of delay lines (one set per storage ring) so that they coincide per species in time at the entry into the induction bunchers. Each bunch will at this stage travel on a separate trajectory, each induction buncher carrying 36 beam lines in parallel. In the final transport towards the target, bunches of each of the three species are merged together in a common beam line. This "telescoping" goes back to an idea originally discussed by Burke [11]. Bunches of different ion species (here masses varied by 10%) but identical momenta can be superimposed in the longitudinal phase space in the final beam lines, which saves beam lines and final optics by the number of species (here three). The number of beam lines converging on the reaction vessel is now 48, which is reduced by a factor of three with respect to a single ion species (non-telescoping) scenario.

It is generally desirable to have the average linac current as high as possible as this determines the driver efficiency and helps to minimize beam loss in the storage rings due to ion-ion charge exchange. The linac efficiency is estimated to 30%, the total driver efficiency to close to 20% for the maximum rep-rate of 50 Hz.

2.1 Computer Modeling

The issue of space charge makes it necessary to model key issues by means of computer simulation. The following sub-sections of the driver have been studied with 2d or 3d codes:

- drift tube linac above 10 MeV/u (3d),
- debunching and capture in barrier buckets of rings,
- two-plane multi-turn stacking (2d with preliminary 3d), showing that the beam losses can be kept at the level of 1-2% [12]
- prebunching and final bunch compression,
- final focusing system to target.

The drift tube linac simulation shows that the required output results for current, emittance and momentum spread ($\epsilon_N = 1.2$mm mrad and $\Delta p/p \leq 0.1\%$) can be satisfied [13]. A full linac simulation starting from injection into the first RFQ throughout the main linac remains a goal for future work. This includes the issue of beam loss throughout the linac and storage rings and the resulting activation, which must be considered carefully.

Driver parameters (for Bi^+ and similar mass ions) for this standard target are summarized in Table 1. The scheme is modular in the sense that doubling of the energy requires doubling of the number of storage rings and bunches. For future work it is planned to study in more detail the option of a DTL based on H-mode cavities, which promises significantly higher linac current than the above considered 400 mA [14]. Such structures have been successfully taken into operation for the CERN Pb-Linac and the GSI U^{4+} high-current injector [15], which operates at 36 MHz and assumes a space charge limited current of I(emA)$= 0.25A/q$. It accelerates U^{4+} at 16 mA current from a MEVVA ion source which has recently shown to exceed the required current on the test bench [16]. The main advantage of this structure for fusion applications is the high acceleration efficiency at relatively low values of β. The possibility is discussed of using multiple beam cavities for an IH-RFQ as well as an IH-DTL at relatively low frequencies (10 rsp. 20 MHz). The design is eased by the fact that quadrupoles are not used internal to the RF tanks (see Fig. 5). This concept requires a special funneling technique, which is possibly easier than the funneling of separate accelerator lines as in the usual approach. The maximum gradient that can be expected is about 7 MV/m using cavities in an H_{211} mode, which is another attractive feature of this scheme.

ion energy (GeV)	10
total driver energy (MJ)	3
linac current (mA)	400
storage rings	12
number of stored bunches	144
stored bunch length (ns)	250
ion species (telescoping)	3
final pulse length (ns) (base line of main pulse)	6

3 EXPERIMENTS

A prototype Bi ion source at Frankfurt (IAP) has recently been shown to deliver 21 mA [9] (Fig. 6). The source has a seven hole extraction system with a maximum extraction voltage of 27 kV. The fraction of Bi^{1+} in the ex-

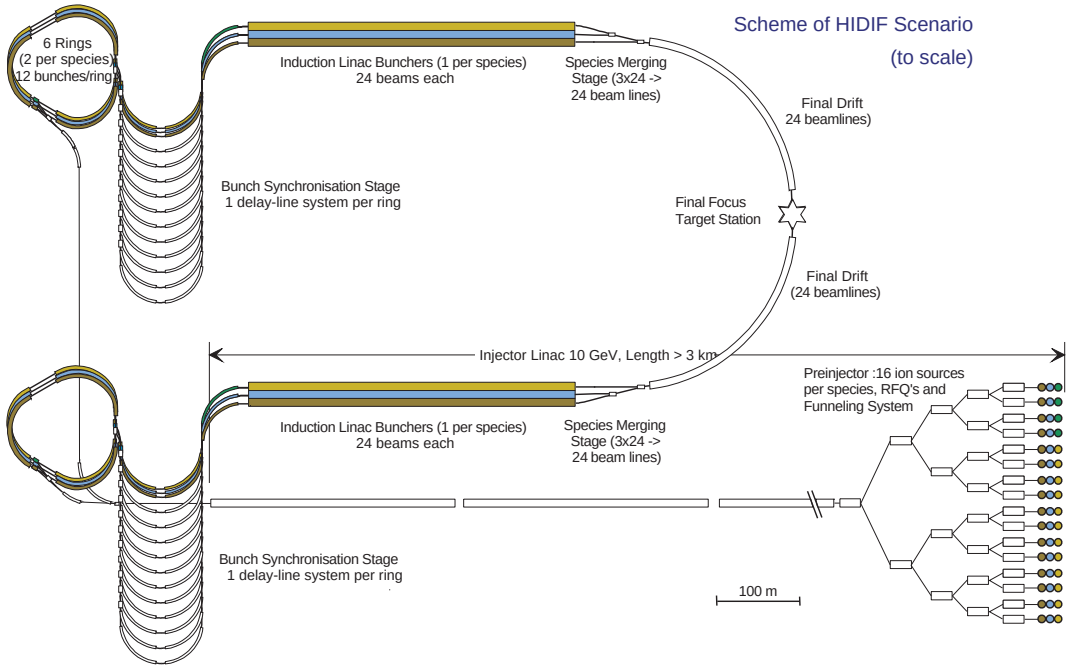

Figure 4: HIDIF layout for reference energy of 3 MJ.

tracted current was measured as 93%. The RFQ funneling concept is studied in another experiment at Frankfurt in a scaled version using two He^{+} beams from 2 identical ion sources [10].

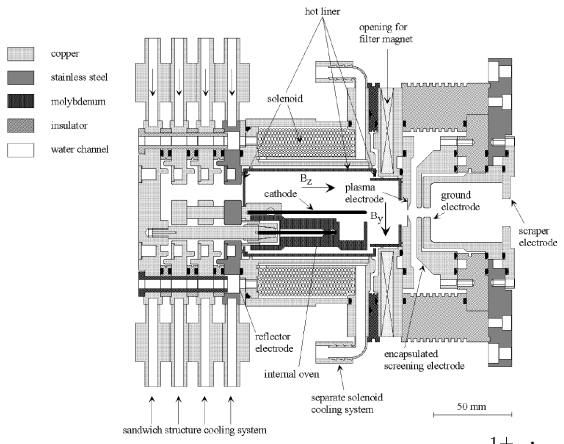

Figure 6: Schematic drawing of prototype of Bi^{1+} ion source and extraction (courtesy of M. Weber).

Beam loss plays an important role for high average beam power. The total activation of 10 GeV Bi ions is reduced by approximately two orders of magnitude compared with that of 1 GeV protons due to the substantially shorter Coulomb range of the heavy ion [17]. For a fusion driver at 10 Hz and 50 MW beam power the average linac current is ≈5 mA, and a loss of 10^{-3} seems acceptable. This is less stringent than the requirements of future high-current proton linacs discussed for various applications. A critical area appears to be the injection into the storage rings (operated at 2-5 MW beam power), where the presently studied two-plane injection with 1-2% loss would require a further reduction of the losses by an order of magnitude.

This leads to the conclusion that the study of halos in linacs and rings requires more attention than previously assumed. One of the first steps is experimental verification of the standard picture of halo formation driven by mismatch (envelope) modes [18, 19]. Such experiments are difficult to carry out in any existing linac. Since it is commonly accepted that the strength of space charge is less important, we are lead to the conclusion that such basic studies can be carried out in a synchrotron or storage ring as well. We have made some preliminary computer simulation studies of the effect of mismatch for a beam injected into the synchrotron SIS. Using a Ne^{10+} beam at the injection energy of 11 MeV/u and a current of 2.5 mA we have found that a mismatch of 1.5 leads to more than doubling of the rms emittance after 20 turns (corresponding to 200 cells). The phase advance per period is $\sigma_{0,h} = 130^{o}$ in horizontal and $\sigma_{0,v} = 99^{o}$ in vertical direction. The tune depression is only as small as 0.98. The initial distribution in the simulation is assumed as waterbag (see Fig. 7).

Comparing different values of mismatch and of current we have found that higher beam current primarily accelerates the emittance growth, whereas the mismatch is responsible for the size of the emittance growth as is shown in Fig. 8. It should be noted that the effect is unexpectedly large and presumably related to a resonance phenomenon with the FODO lattice, since a corresponding calculation for constant focusing gave only 1/4-th of the emittance growth.

As a next step we plan to realize this in an experiment at the SIS by extracting the beam after a variable number of turns and transport it to a plastic scintillator to observe its transverse density distribution with a gated CCD camera.

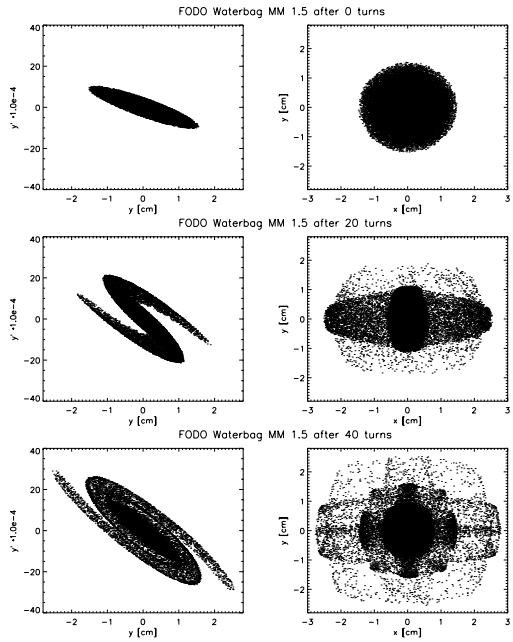

Figure 7: 2d-simulation (particle-in-cell) of halo development for a coasting beam in a FODO synchrotron lattice with weak space charge and 50% mismatch (shown are y-y' and x-y projections after 0,20,40 turns).

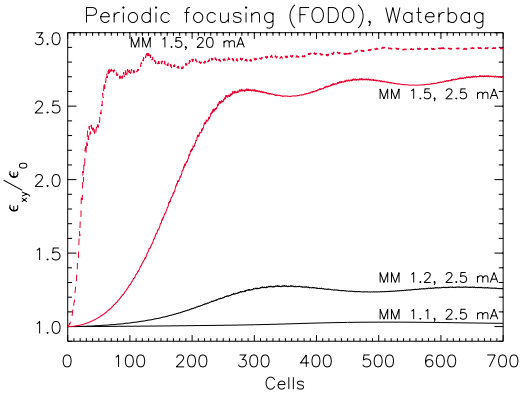

Figure 8: RMS emittance growth of simulated mismatched coasting beam in a FODO synchrotron lattice.

An important ingredient to the halo formation is the frequency of the mismatch oscillations, which is shifted by space charge. In this context it is also worth mentioning that we have recently measured in the SIS the frequency shift of these mismatch oscillations, both the "breathing" and the "quadrupolar" mode. The beam was excited by a quadrupolar exciter in the frequency band considered and the response signal on a quadrupolar pickup was evaluated [20].

4 CONCLUSIONS

The HIDIF accelerator study has for the first time considered detailed computer simulation studies of key areas in the RF linac/storage ring approach to inertial fusion. Future work will have to concentrate on the low-energy part of the linac (in particular funneling) and include new developments like the H-mode structure. Developments on the side of the target play an important role, in particular if novel concepts like the "fast igniter" [21] are better understood and their relevance for energy producing targets is consolidated. The expected reduction in Megajoules could result in significant reduction of the complexity of the driver. Accelerator experiments on key issues, including beam halo, are needed to verify the increasingly demanding computer simulation.

ACKNOWLEDGMENTS

The author wishes to acknowledge the help of O. Boine-Frankenheim in performing the beam halo simulations.

TOWARD A FOURTH-GENERATION X-RAY SOURCE *

David E. Moncton
Argonne National Laboratory, Argonne, IL 60439 U.S.A.

Abstract

The field of synchrotron radiation research has grown rapidly over the last 25 years due to both the push of the accelerator and magnet technology that produces the x-ray beams and the pull of the extraordinary scientific research that is possible with them. Three successive generations of synchrotron radiation facilities have resulted in beam brilliances 11 to 12 orders of magnitude greater than the standard laboratory x-ray tube. However, greater advances can be easily imagined given the fact that x-ray beams from present-day facilities do not exhibit the coherence or time structure so familiar with the optical laser. Theoretical work over the last ten years or so has pointed to the possibility of generating hard x-ray beams with laser-like characteristics. The concept is based on self-amplified spontaneous emission (SASE) in free-electron lasers. A major facility of this type based upon a superconducting linac could produce a cost-effective facility that spans wavelengths from the ultraviolet to the hard x-ray regime, simultaneously servicing large numbers experimenters from a wide range of disciplines. As with each past generation of synchrotron facilities, immense new scientific opportunities would result from fourth-generation sources.

1 INTRODUCTION

The rapid growth in the field of synchrotron radiation research over the last 25 years has been the most exciting period in the history of x-rays since the period immediately after they were discovered by Röntgen over 100 years ago. The brilliance of x-ray beams versus time since their discovery in 1895 (Fig. 1) shows that the technology was unchanged for more than six decades. Remarkably, however, x-rays had unprecedented scientific impact. X-rays garnered the first Nobel Prize and some 20 more, all based on x-rays provided by only minor improvements of tubes that Röntgen used for his first experiments. From the first generation of parasitic synchrotron facilities that appeared in the 1970s through the second-generation facilities that were designed explicitly to produce synchrotron radiation, to the third generation that use an optimized magnet lattice and insertion devices, synchrotron x-ray research has enjoyed gains in beam brilliance that are 11 to 12 orders of magnitude greater than the standard laboratory x-ray tube. Given that this rate of improvement exceeds Moore's Law for semiconductors by approximately a factor of two, it is reasonable to ask, What could be a better source of x-rays than the insertion device (ID) upon which the Advanced Photon Source (APS) and other third-generation sources are based?

* Work supported by the U.S. Department of Energy under contract W-31-109-Eng-38.

2 SOURCE CHARACTERISTICS

An ID x-ray beam from a third-generation x-ray synchrotron radiation facility, while highly directional and monochromatic, does not have the full coherence of an optical laser. The transverse coherence length of radiation from an ID at the APS is ~10 μm, which is useful to condensed-matter physicists and others in understanding the dynamics of solids. However, the coherence length is small compared to the size of the source itself (170 mm), which means the source is only very weakly coherent. Making up for that shortfall represents an enormous opportunity. If the technology can be developed to make a source fully coherent, it would be orders of magnitude better than those existing today.

Another major opportunity to exceed the limits of existing x-ray sources lies with the time structure of the beam. Current machines produce bunch lengths in the 100-psec regime. This structure enables science well beyond the reach of steady-state x-ray tubes, and many experiments exploit this time dependence.

However, 100 psecs is longer than the time associated with many interesting physical phenomena. In the optical

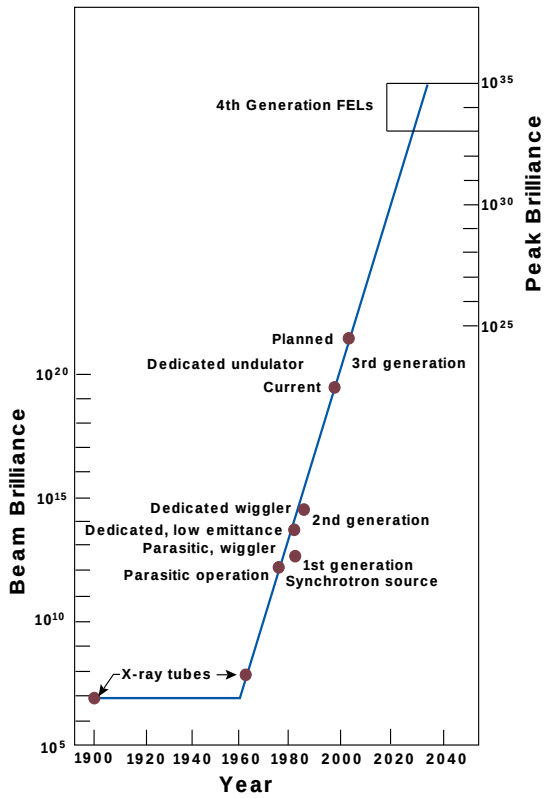

Fig. 1: History of (8-keV) x-ray sources, beam brilliance vs. time.

regime, femtosecond lasers have existed for quite some time and have made the first forays into this time domain. The ability to bring x-ray time scales down into the sub-picosecond regime is very compelling, since many of the most interesting physical phenomena cannot be studied with long-wavelength optical radiation.

3 TECHNOLOGICAL CHALLENGES

It now appears that substantial improvements in source characteristics can be achieved with the development of x-ray free-electron lasers (FELs). The technologies to produce FEL-based radiation for ultraviolet and shorter wavelengths have been under consideration for some time using different accelerator-FEL configurations. At this time, neither the optical cavity approach[1] nor the seeded amplifier concept[2] appears to be workable in the hard x-ray range, although future developments could change this situation. Recently, the concept[3,4,5,6] of self-amplified spontaneous emission (SASE) has captured the imagination of the synchrotron radiation community. The SASE concept eliminates the need for optical cavities or input seed radiation. The very stringent electron beam qualities required for SASE operation in the hard x-ray region can be met with the recently developed laser driven radio-frequency (rf) photocathode gun[7] and in the beam compression and linear acceleration technology in connection with the high-energy linear collider program.[8] Recent measurements by the University of California, Los Angeles group at Los Alamos National Laboratory[9] have shown the first convincing evidence of SASE gain at 16-μm wavelengths.

The Stanford Synchrotron Radiation Laboratory has developed a SASE-based concept[10] called the Linac Coherent Light Source, which would use the Stanford linac and theoretically produce a gain of 8 or 9 orders of magnitude over third-generation undulator beams in the hard x-ray range. This would be an excellent R&D project to supply the necessary experience for a new fourth-generation user facility. And it would be reasonably cost-effective since the linac already exists. However, it would not be sufficient to meet the needs of the synchrotron community at large, because the facility would only support a few experimental stations, at most. This limitation is due to the pulse rates associated with conventional linear accelerators.

A newer alternative, the superconducting linac, is in principle capable of supplying the pulse rate needed to support a farm of x-ray undulators, as shown in Fig. 2. This approach is based upon the anticipated maturity of the superconducting rf technology for the high-energy linear collider program. A group at the Deutsches Elektronen-Synchrotron[11] is pursuing the concept of a superconducting linac that can support the very high pulse rates necessary to feed a large number of SASE undulators for x-rays. Such a facility would also be able to produce ultraviolet beams either at lower energy points on the linac or by using spent electron beams after they have produced the SASE x-rays. Research and development is expected to go forward internationally over the next few years, yielding a decision on whether to proceed with such a facility in conjunction with a new high-energy physics linear collider.

At Argonne National Laboratory, we are installing a low-energy (750 MeV) undulator test line (LEUTL) (Fig. 3) on the APS linac.[12] The LEUTL is located in a 50-m-long extension of the linac tunnel that is configured to enable study of SASE in the 100-nm-wavelength range.

4 SCIENTIFIC RESEARCH

A fourth-generation light source will support a wide range of disciplines and a large number of individual experiments. It is therefore difficult to be specific about the scientific opportunities in a short article. To provide summary information, Figs. 4 and 5 attempt to simply characterize the advances from one generation of light source to the next in terms of our ability to extract spatial and temporal information from material systems, which is the essence of virtually all x-ray research. Focusing on spatial information to begin with in Fig. 4, we can see the

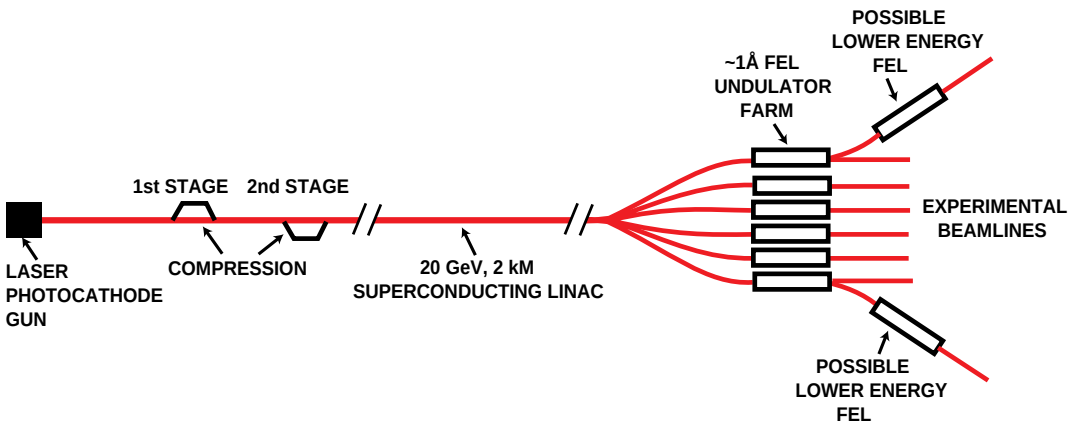

Fig. 2: Diagram of a possible fourth-generation synchrotron facility using self-amplified spontaneous emission free-electron lasers.

general evolution of imaging methods in direct space or diffraction methods in momentum or reciprocal space. Generally, information on the structure of materials is extracted over a length scale from 1 mm to atomic dimensions. As the brilliance of x-ray beams has improved, higher fluxes, coupled with much higher degrees of collimation, have expanded the boundaries of various diffraction and imaging techniques.

This progress is very tangible now at the APS, where imaging and diffraction methods overlap to cover the entire range of spatial length scales, from the atomic up to the macroscopic, particularly in the 1-μm regime. That is the very important length scale on which information is stored in the human gene, as well as in integrated circuits. For example, protein crystallography is arguably the most challenging area of x-ray diffraction today. Two years ago, the first protein crystal structure solved with the APS was a complex, 100,000-atom molecule.[13] Data sets for proteins of this complexity can now be obtained at the APS in less than an hour, and in some cases less than 15 minutes. With the APS operating 5000 hrs/yr, the possibility of achieving within a decade a storehouse of comprehensive data on all proteins that are important to life seems realistic.

As one looks at the region of Fig. 4 that pertains to fourth-generation sources, there is growing overlap between imaging and diffraction methods. In practice, this overlap actually represents the emergence of integrated imaging and diffraction approaches, which are only possible with highly coherent sources. As an example of what may be possible with the enormous increase in coherence from x-ray FELs, consider how we now obtain information on the structure of complex molecules. The major prerequisite to an x-ray diffraction experiment of the type mentioned above is a crystal in which some 10^{18} copies of the molecule are arranged in a nearly perfect crystalline array. The need for this form of the sample is a consequence, in principle, of the relative weakness of the source of x-rays and the associated scattering cross-section. Furthermore, it is a tremendous burden to the researcher interested in the structure to be required to have such a sample of the molecule of interest. It is now the

most significant limitation in the rate of protein structure determination. One of the most compelling aspects of the x-ray FEL source is the possibility to eliminate the need for this form of the sample and to be able to extract molecular structure, using new x-ray holographic methods,[14] from a single molecule or a relatively small number of identical molecules in solution. One cannot underestimate the impact of this evolution on biology and chemistry. It is beyond the scope of this paper to discuss this method further, but this will be the subject of upcoming fourth-generation scientific workshops in the next few years.

The other complementary aspect of x-rays is the ability to extract information on the dynamic structure of materials. Figure 5 shows how information is extracted using direct time-resolved x-ray studies and the reciprocal method known as inelastic x-ray scattering. On early storage-ring sources, these two techniques were separated by many orders of magnitude and their ability to extract information in the very important intermediate regime (millivolts or picoseconds) was essentially non-existent. With better beam sources, this gap has narrowed. On third-generation sources, phonon dispersion curves[15] are studied in order to conduct inelastic experiments that have millivolt energy resolution. Time-resolved experiments are moving into the sub-nanosecond region. Investigations of complex materials, such as proteins, are benefiting from third-generation sources, which allow imaging a high-quality diffraction pattern in the time of a single intense pulse—about 100 psecs.

We now proceed to the area of the Fig. 5 that relates to the fourth-generation sources. Here it is anticipated that the improvements in source characteristics made possible by x-ray FELs will finally lead to the closure of the "dynamics gap" shown in the figure. While this appears to be only a quantitative improvement in the range of the two principal methods, it is actually much more than that because it allows access to the energy range in which most phenomena of interest in chemistry, biology, and the physics of technologically-relevant materials occur. It is not yet clear specifically how experimental methods will evolve to permit the anticipated extensions of resolution. Like x-ray holographic methods discussed briefly above, which are a blend of imaging and diffraction methods, we expect that new approaches will be devised to take advantage of the extraordinary time-structure and peak brilliance of the source. The objective will be to provide movie-like representations of molecular motion at the sub-picosecond level. It is critically important that these new methods provide information in direct space where motion is more naturally related to function, as in catalytic reactions or biological processes. In traditional crystalline solid-state systems where crystal momentum is a good quantum number, inelastic methods are very powerful. But in complex aperiodic systems, real-space methods for elucidating dynamics will be much more readily interpreted. If this challenge can be met, fourth-generation sources will have immense impact.

5 CONCLUSION

One can easily imagine that extraordinary science would result from the use of x-ray sources based on FELs. The higher coherence and greater spatial resolution afforded by FELs, together with a two- or three-order-of-magnitude improvement in time resolution to the 100-fsec range would prove invaluable for determining molecular structures and watching atomic and molecular processes. Furthermore, beyond the examples mentioned above, the high intensities in these short pulses would provide intriguing opportunities for non-linear physics, and perhaps offer powerful new opportunities for applications in microscopy.
